Physical examination may reveal decreased breath sounds and dullness to percussion over the left side of chest if a significant amount of abdominal viscera has migrated into the chest. Rarely, herniation of colon or small bowel may result in bowel sounds heard over the left side of the lower chest. Upright chest radiographs may show an air- and fluid-filled mass in the left side of the lower chest, which should be particularly evident on the lateral view. Respiratory distress should be appropriately addressed and the patient should be fluid resuscitated. Attempts should be made to place a nasogastric tube to decompress the stomach in the patient with associated respiratory compromise or abdominal pain but may be difficult or impossible because of angulation of the gastroesophageal junction (Fig. 128.18). Surgical consultation should be sought because urgent operative intervention may be necessary if the patient has signs of obstruction or strangulation.

CHEST WALL TUMORS

Tumors of the chest wall may occur at any age, from infancy to late adolescence, and may be benign or malignant. Benign tumors include lipoblastoma, mesenchymoma, mesenchymal hamartoma, aneurysmal bone cysts, chondroma, lipoid histiocytosis, osteochondroma, osteoid chondroma, lymphangioma, or hemangioma, as well as infectious processes such as tuberculosis and actinomycosis. If the clinical and radiologic picture clearly indicates a benign, self-limited process, observation may be appropriate. However, if there is concern that the lesion is not benign, even a small chest mass in a child should be considered malignant and biopsy is appropriate. Malignant tumors are composed of a variety of histologic types and may be either primary or secondary. Many malignant tumors may be present at birth and have been identified early in the first year of life.

Clinical Findings

Benign tumors of the chest wall are usually asymptomatic until trauma or fracture brings them to attention. Malignancy may be signaled by a rapid increase in size, pain, tenderness, or local inflammation. Pleural or pericardial effusions may be present, causing dyspnea and tamponade, respectively, if sufficiently large. Physical examination may reveal chest wall fullness or a mass, and large lesions or effusions may cause diminished breath sounds on the affected side. Chest radiographs may show pleural effusion and a peripheral mass, the depth and extent of which are better demonstrated by a CT scan.

The site of the lesion may suggest certain diagnoses (Fig. 128.19). Ewing's tumor typically involves the lateral aspects of the ribs. Chondrosarcoma typically involves the costal cartilages between the sternum and the distal rib end. The sternum is a favored site for anaplastic sarcomas. These last two tumors may extend intrathoracically and outside the bony thorax.

Management

Initial management of patients presenting with respiratory distress includes supplemental oxygen administration, evaluation for pleural and pericardial effusions with aspiration or tube thoracostomy drainage if present, and pain management if clinically indicated. Radiographic evaluation should include a CT scan of the pertinent area, bone scans of the entire body, and a metastatic bone survey. Multimodal, coordinated treatment involving surgery, chemotherapy, and radiotherapy is frequently required. Initial biopsy should be performed by a

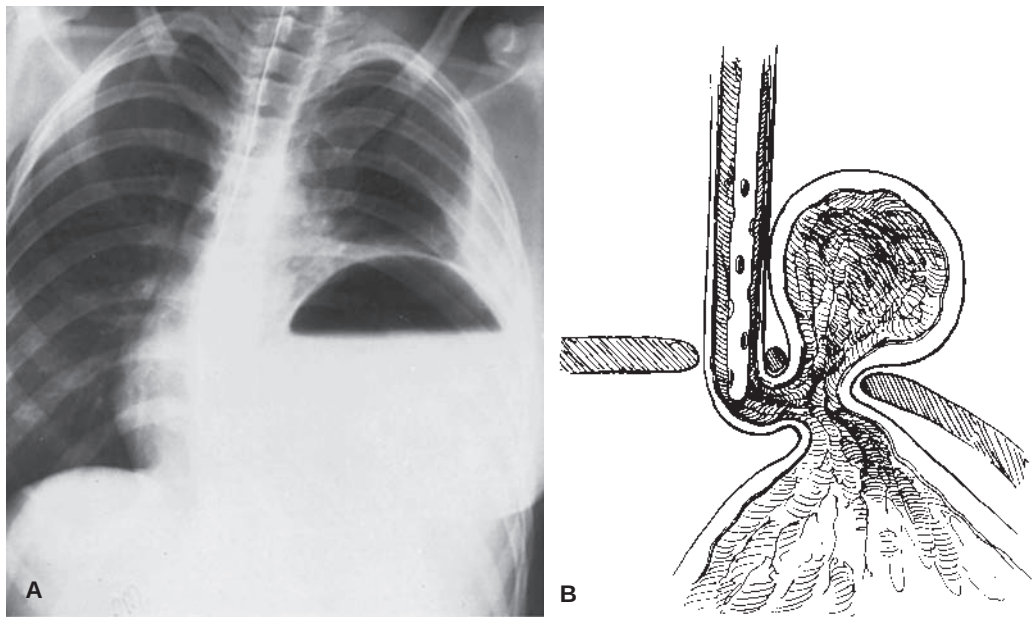

FIGURE 128.18 **A:** A 13-year-old girl developed first right-sided and then left-sided epigastric pain with retching but little or no vomitus. She had grunting respirations. A radiograph revealed a large air- and fluid-filled mass in the left side of the lower chest. **B:** As shown in the diagram, a nasogastric tube would not pass into the stomach.

core needle technique or a limited open approach, with care to place and orient the incision so as not to compromise the subsequent resection and chest wall reconstruction. Preoperative chemotherapy and radiotherapy may be useful to shrink selected lesions. Resection of the tumor and even subsequent recurrences have resulted in disease-free survivals of 15 years or more. Extensive chest wall resections may result in thoracic instability and paradoxical chest wall motion. Technical advances have included the use of rigid materials such as mesh and methylmethacrylate, and together with improvements in surgical technique and postoperative care, significant resections including sternectomy or vertebrectomy can be done safely with excellent preservation of chest contour and respiratory function.

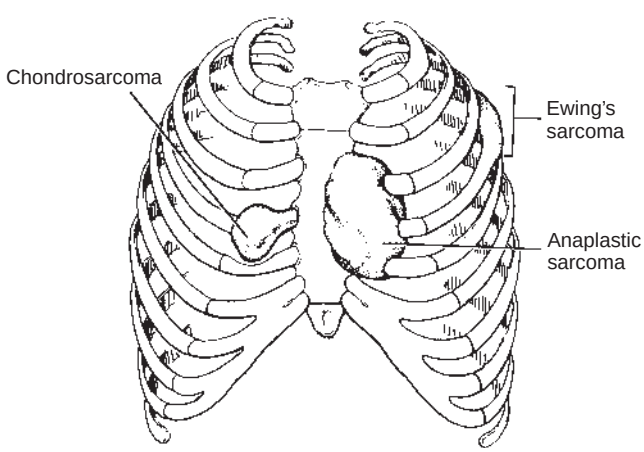

FIGURE 128.19 Malignant chest wall tumors in children. Most common lesions and their usual sites of origin are shown.

CHAPTER 129 ■ TRANSPLANTATION EMERGENCIES

HEIDI C. WERNER, MD, KARAN McBRIDE EMERICK, MD, MARYANNE R.K. CHRISANT, MD, AND ELIZABETH B. RAND, MD

Although attempts at therapeutic solid organ transplantation began in children and adults in the 1960s, it was not until calcineurin inhibitors were introduced for immunosuppression in the late 1970s that transplantation became established as a useful therapy. The successful management of graft rejection led to astonishing improvements in graft and patient survival, followed by further refinements in surgical techniques, medical management, and prevention of long-term complications. The area of pediatric solid organ transplantation has grown rapidly over the intervening years as a result of continued improvements in surgical and medical management and widening acceptance of and indications for transplantation. Indications for solid organ transplantation in children now include uncorrectable congenital structural defects; organ failure from a myriad of acute and chronic, intrinsic, and extrinsic causes; and a host of genetic/metabolic diseases.

This chapter provides a brief history of pediatric transplantation, highlighting the development of the major advances in the field. Discussion of clinical topics begins with an overview of the general principles of organ transplantation, immunosuppressive therapy, and prophylaxis for infections in the solid organ transplant recipient.

The chapter continues with discussion of common outpatient complications that prompt emergency department (ED) evaluation in these patients, including surgical complications, fever/infections, hypertension, lymphoproliferative disease, and miscellaneous complaints.

HISTORY OF TRANSPLANTATION

The first attempts at liver transplantation in humans were made at three separate institutions in 1963, each resulting in the death of the recipient. In 1967, a pediatric patient with hepatoma survived orthotopic liver transplant; however, the complexity of the operation and the inadequacy of the immunosuppressive agents of the period resulted in dismal 1-year survival rates. Similarly, early successful kidney transplantation occurred in 1959 in several centers as the result of live twin or other sibling donation. The first successful human cardiac transplant was performed by Christiaan Barnard in 1967; the recipient lived a total of 18 days, dying of overwhelming infection. The second human heart transplant was performed 3 days after the first, on December 6, 1967, by Adrian Kantrowitz in Brooklyn, New York. Dr. Kantrowitz's infant recipient died of a bleeding complication within the first 24 hours. By the end of 1968, 99 heart transplants had been performed worldwide; however, most centers had abandoned cardiac transplantation because of the high mortality attributed to rejection. In the early days of solid organ transplantation, the only available maintenance immunosuppression was azathioprine and steroids. In 1978, the introduction of cyclosporine transformed the field of solid organ transplantation; survival rates for kidney and liver recipients rapidly improved. Cyclosporine was first used to treat thoracic organ transplant recipients in 1981, and its application similarly enhanced survival rates. Improved survival for recipients led to appreciation of medium- and longer-term surgical complications, including vascular thromboses, ischemic graft injury, and technical problems with anastamoses, in turn prompting improvements in organ selection, procurement and storage techniques, and surgical refinements in the recipient. Medical complications resulting from too much or too little immunosuppression also led to improvements in care, including the development of a still-growing armamentarium of immunosuppressive agents, adjuvant therapies, and infection prophylaxis. Pediatric cardiac transplantation was first successful in the early 1980s in the wake of the introduction of cyclosporine. Problems specific to infants and children with complex structural heart disease required innovative surgical techniques. Advances in donor options, surgical techniques, and medical management have transformed pediatric solid organ transplantation from a heroic experimental therapy to an established successful treatment for solid organ failure. In addition to the treatment of primary and structural diseases resulting in organ failure, the application of transplantation has been extended to become a useful therapy for genetic/metabolic disorders with life-threatening manifestations that are cured by organ replacement. In short, the current state of pediatric transplantation is impressive in the increasing number and complexity of recipients and in the improvement of overall survival for every solid organ. Many of the major hurdles facing early transplant recipients have been overcome; however, continued refinement of immunosuppression is expected to further reduce long-term morbidity and mortality. Solid organ transplantation is still limited largely by organ scarcity, and the ever-broadening categories of successful indications for the procedure compound this problem.

Given the growth in pediatric transplantation overall, ED physicians can expect to see increasing numbers of recipients with all manner of complaints, ranging from common pediatric illnesses to surgical complications and effects of medications. This chapter focuses primarily on those complications that occur following initial discharge from the hospital, rather than on the perioperative surgical and medical emergencies that occur during initial operative hospitalization.

TABLE 129.1

ADVERSE EFFECTS OF IMMUNOSUPPRESSIVE AGENTS[a]

Adverse effect	Cyclosporine	Tacrolimus	Azathioprine	Mycophenolate	Steroids	Sirolimus
Systemic increased risk of infection	+	+	+	+	+	+
Increased risk of malignancy	+	+	+	+	−	−
Hyperglycemia/posttransplant diabetes mellitus	+	+	−	−	+	−
Bone marrow suppression	−	−	+	+	−	+
Nephrotoxicity	+	+	−	−	−	−

GENERAL PRINCIPLES OF TRANSPLANT MEDICINE

Solid organ transplantation is a complex undertaking considered only for children with life-threatening primary or secondary disease of vital organs. The evaluation of a candidate for pediatric transplantation is a complex process, with wide and variable indications for each organ type. Despite the variation and complexity of the different types of organ transplants, there are many similarities in the postoperative monitoring and management of graft recipients. The ultimate goal of any organ transplantation is to restore normal quality of life, and to that end, various general principles hold across all organ transplant fields.

The general principles of management include (i) monitoring of graft function; (ii) surveillance for infectious complications; (iii) monitoring for long-term adverse effects of immunosuppression; and (iv) maintenance of standard well child care (including modified immunization schedule, growth and nutrition, and psychosocial issues). ED evaluations are directed by the acute problems that may arise from surgical or medical complications and that may manifest as fever, graft dysfunction, pain, or drug toxicity. To evaluate the common complaints of the transplant recipient, it is helpful to review the immunosuppression medications that both sustain the graft and health of the recipient and precipitate many of the complications of transplantation. Table 129.1 summarizes typical adverse effects of the most commonly used medications. Table 129.2 indicates drug interactions that frequently precipitate toxicities. Each medication is discussed in further detail in the next section.

IMMUNOSUPPRESSIVE MEDICATIONS

Corticosteroid

Corticosteroid therapy is used for induction of immunosuppression, with dosing often beginning in the operating room. Steroid therapy is effective for both treatment and prevention of acute rejection. Although for many years, long-term, low-dose steroid dosing was believed to be necessary for most transplant recipients, there is growing evidence that this therapy is not required for many heart and liver recipients. Corticosteroid therapy decreases inflammatory response by preventing the chemotaxis and recruitment of mediating lymphocytes, and it can also be lympholytic at higher doses. Intravenous methylprednisolone (Solumedrol®) is used in the immediate perioperative period with a transition to oral prednisone. It is also used for treatment of acute rejection and is extremely effective. Reasonably common acute adverse effects include hypertension, hyperglycemia (sometimes requiring insulin), psychosis, and joint pain (Table 129.1). Chronic adverse effects include those listed in this section, plus the Cushing's syndrome, bone demineralization, linear growth delay/arrest, adrenal suppression, and cataracts, as well as others.

TABLE 129.2

MEDICATIONS THAT ALTER IMMUNOSUPPRESSANT MEDICATION METABOLISM

Drug	Agents that increase blood concentrations (decrease metabolism)	Agents that decrease blood concentrations (increase metabolism)
Calcineurin inhibitors (cyclosporine and tacrolimus)	Diltiazem Nicardipine Nifedipine Verapamil Fluconazole/ketoconazole Voriconazole Clotrimazole Clarithromycin/erythromycin Azithromycin Metoclopramide Amiodarone Methylprednisolone Omeprazole Nefazodone	Carbamazepine Phenobarbital Phenytoin/fosphenytoin Rifabutin Rifampin Rifapentine St. John's Wort Probucol Terbinafine
Azathioprine	Allopurinol Methotrexate Angiotensin converting enzyme inhibitors	Antacids Cholestyramine Iron preparations
Mycophenolate	Probenecid Tacrolimus	Antacids Cholestyramine Iron preparations
Sirolimus	Diltiazem Nicardipine Nifedipine Verapamil Fluconazole/ketoconazole Voriconazole Clotrimazole Clarithromycin/erythromycin Azithromycin Metoclopramide Amiodarone Methylprednisolone Omeprazole Cyclosporine	Carbamazepine Phenobarbital Phenytoin/Fosphenytoin Fosphenytoin Rifabutin Rifampin Rifapentine St. John's Wort

Tacrolimus (Prograf®, FK506)

Tacrolimus is a macrolide immunosuppressant in the category of calcineurin inhibitors produced by the fungus *Streptomyces tsukubaensis*. A potent immunosuppressive, tacrolimus is effective as treatment for acute and chronic rejection, as well as for maintenance prophylactic immunosuppression, either alone or in combination with adjuvant drugs. Tacrolimus is dosed orally every 12 hours, with monitoring of trough levels to adjust dosing daily in the perioperative period. Once the therapeutic dose is established, levels may be checked as infrequently as every 3 months for a stable liver recipient (or thoracic transplant recipient) for as long as 2 years posttransplantation. Common side effects include hyperglycemia (sometimes requiring insulin), hypertension, headache, increased creatinine, and renal electrolyte wasting (particularly magnesium and potassium). Less common adverse effects include dermatologic diseases, such as eczema, common warts (the severity of which can range from mild to disfiguring), and neurotoxicity (seizures) (Table 129.1).

All immunosuppression leaves the recipient more prone to infections and posttransplant lymphoproliferative disease (PTLD). PTLD is a special problem in infant recipients who are more commonly Epstein-Barr virus (EBV) naive. Tacrolimus is erratically absorbed orally; food and various other medications, particularly anticonvulsants, macrolide antibiotics, fluconazole, and related drugs, will alter absorption (Table 129.2). Target levels for tacrolimus will vary depending on the organ received, the time elapsed from transplant, history of rejection, current infections, and renal function. It is important to note that immunosuppression and toxicities (particularly nephrotoxicity) are synergistic with cyclosporine and ibuprofen, among others (Table 129.2).

Cyclosporine (Neoral®, SangCya®, Sandimmune®)

Cyclosporine is a cyclic, 11 amino acid polypeptide produced by fungi. Cyclosporine is quite effective for prophylaxis for rejec-

tion but is less effective as treatment for acute or chronic rejection. This agent was essentially the only immunosuppressive drug available for many years, and it is still widely used as a primary agent or in combination with other medications. Oral dosing is every 8 hours for infants and toddlers, and twice daily for older children and adults. Morning trough levels or area-under-the-curve levels are monitored to optimize dosing. The original form of cyclosporine required bile micelle formation for absorption, which may be a problem for liver recipients with acute or chronic rejection or other causes of cholestasis, but the Neoral/SangCya® brands form do not. In fact, these are better absorbed in the face of the cholestasis of rejection. Regardless of the brand chosen, it is important not to interchange one for another. Adverse effects are similar to those of tacrolimus, with hypertension, renal injury, infection, skin problems, PTLD, and seizures (Table 129.1). In addition, there is frequent hirsutism and gingival hyperplasia. As with tacrolimus, target levels vary depending on the organ, time from transplant, and status of the patient.

Azathioprine (Imuran®)

Azathioprine is used as an adjuvant immunosuppressive therapy in combination with a calcineurin inhibitor and/or corticosteroid therapy. Azathioprine is rapidly converted to 6-mercaptopurine, the active form of the drug, which acts as a lymphocytic antiproliferative by inhibition of purine synthesis. The most common adverse effect is myelosuppression. Indeed, the level of myelosuppression can be used to monitor dosing and compliance; however, active metabolite levels can now be measured directly. Dosing should be adjusted in renal failure due to renal metabolism and clearance. Idiosyncratic reactions include drug fever, hepatotoxicity, and pancreatitis. Increased risk of infection and late neoplasm have been attributed to long-term use of azathioprine.

Mycophenolate Mofetil (CellCept®, MMF)

Mycophenolate mofetil (MMF) is an ester of mycophenolic acid (MPA), which is the active metabolite, and has lymphocytic antiproliferative properties. The drug is administered orally on a bid or tid basis, and levels are generally not monitored. The drug is rapidly metabolized to MPA, which is a potent selective competitive inhibitor of inosine monophosphate dehydrogenase and, therefore, inhibits synthesis of the purine nucleotide guanosine. T and B lymphocytes are dependent for proliferation on de novo purine synthesis, whereas other cell types can use alternate salvage pathways. The drug, therefore, selectively inhibits proliferation of B and T lymphocytes and also inhibits antibody formation by B cells. Mycophenolate is effective as treatment for acute rejection and is used mainly as a short-term adjuvant immunosuppressive therapy. Common adverse effects are primarily gastrointestinal (GI) symptoms, including diarrhea and cramping. Other effects include vomiting, anorexia, leukopenia, infection, and PTLD (Table 129.1).

Sirolimus (Rapamune®)

Sirolimus is a newer immunosuppressive medication used primarily in adults but with growing indications in children. Sirolimus inhibits T-lymphocyte activation and proliferation in response to antigenic and cytokine stimulation. Its mechanism differs from the calcineurin inhibitors, and its toxicity profile is different. Sirolimus can be used as a single agent or in combination with calcineurin inhibitors. Reports of serious complications with sirolimus as a primary agent in liver (hepatic vascular thrombosis) and lung (bronchial anastomotic breakdown) recipients have limited its use in the perioperative period. However, it has been very effective for long-term maintenance, especially in children with renal injury from calcineurin inhibitors. Sirolimus is dosed once daily and has excellent absorption and biliary excretion. Common adverse effects (primarily reported in adults) include edema, hypertension, hyperlipidemia, and hypercholesterolemia, with many other effects reported. Side effects seen in the pediatric population include nephrotoxicity (typically dose-related and short-lived) and marrow suppression.

Lympholytic Agents: OKT3 and Antithymocyte Globulin (ATG)

OKT3 is a mouse antibody against the CD3 antigen of human T cells. It is available only for IV use. Levels of OKT3, human anti-OKT3 antibodies, and T-cell subtype counts are monitored. OKT3 is used for treatment of acute rejection that is steroid resistant or for induction of immunosuppression for patients with hepatorenal syndrome who cannot tolerate tacrolimus or cyclosporine in the perioperative period. Common side effects are attributable to a cytokine release syndrome (CRS) associated with the first few doses of OKT3; hyperpyrexia is most common. The first dose is typically administered in the intensive care unit for monitoring and rapid response to the CRS should it occur. OKT3 is administered after appropriately timed premedication with steroids, acetaminophen, and antihistamine. CRS can be severe and can progress rapidly to life-threatening shock, with cardiovascular collapse and pulmonary edema. Resuscitation equipment and medications should be available, and fluid overload and/or pulmonary edema should be treated prior to administration. Cerebral edema (and herniation) may occur. Use of OKT3 is associated with increased risk for bacterial and viral sepsis and development of PTLD. Aseptic meningitis is also associated with OKT3 use, with typical manifestations and cerebrospinal fluid findings; seizure risk is also increased. Treatment with OKT3 imparts increased risk for viral infections and PTLD, even after the treatment course is completed.

Other antilymphocyte antibodies, such as antithymocyte globulin (ATG), are available with various modifications designed to reduce CRS and improve efficiency of induction, particularly useful in renal transplantation. Monoclonal preparations arising from nonhuman hosts (e.g., rabbit ATG, horse ATG) carry with them a risk of serum sickness, which can occur 2 or 3 weeks after treatment. Symptoms of malaise, fever, skin rash, and joint pain may implicate this diagnosis.

COMPLICATIONS RELATED TO IMMUNOSUPPRESSION

Although immunosuppression puts patients at greater risk for infectious complications and this likely accounts for the majority of ED visits in transplant recipients, there are certain drug-related side effects that may commonly be encountered in

TABLE 129.3

OVERVIEW OF COMPLICATIONS OF SOLID ORGAN TRANSPLANTATION

Organ	Vascular	Surgical	Immunosuppression	Graft function and rejection	Common presentation of rejection
Kidney	Bleeding Renal artery stenosis Vascular thrombosis	Urinary leak Ureteral obstruction	Infection Cosmetic changes Hypertension Nephrotoxicity PTLD noncompliance	Hyper acute rejection Rejection Drug toxicity Recurrent disease	Nonspecific: fever, abdominal pain Specific: uremia
Liver	Bleeding Hepatic artery thrombosis Portal vein thrombosis	Biliary leak Biliary obstruction/ stricture	Infection Cosmetic changes Hypertension Nephrotoxicity Hepatotoxicity PTLD Noncompliance	Primary nonfunction Rejection Recurrent disease	Nonspecific: fever, itching, abdominal pain, anorexia Specific: cholestasis, pleural effusion
Heart	Bleeding Pulmonary artery hypertension[a] Pulmonary venous obstruction[a]	Pulmonary artery hypertension Pulmonary venous obstruction	Infection Cosmetic changes Hypertension Nephrotoxicity Hepatotoxicity PTLD Noncompliance	Primary graft failure Acute rejection Chronic (vascular) rejection Arrhythmia Hypotension	Nonspecific: fever, malaise, abdominal pain, cough, weakness Specific: ventricular failure/CHF, low cardiac output, arrhythmia, pericardial effusion
Lung	Bleeding	Dehiscense, tracheal obstruction, diaphragmatic paralysis	Infection Cosmetic changes Hypertension Nephrotoxicity Hepatotoxicity PTLD Noncompliance	Graft failure Obliterative Bronchiolitis (rejection)	Nonspecific: fever, cough, malaise Specific: hypoxia, chest radiograph findings, pulmonary function test deterioration

PTLD, posttransplant lymphoproliferative disease; CHF, congestive heart failure.
[a]Typically as a result of pretransplant diagnosis and/or prior surgeries.

an urgent care setting (Table 129.3). Patients receiving calcineurin inhibitors are at risk for nephrotoxicity. Patients who have had low cardiac output for long periods prior to transplantation may also be at increased risk. Renal dysfunction may be manifest by edema and decreased urine output and may follow a course of antibiotics, use of nonsteroidal antiinflammatory drugs (NSAIDs), or a diarrheal illness resulting in dehydration. Patients should be closely evaluated and immediate drug levels obtained and followed. Calcineurin inhibitors should not be subsequently administered until drug levels are determined and the etiology of renal insufficiency is explained. Renal failure is a possible temporary or permanent outcome of an acute insult on an overlay of chronic calcineurin inhibitor exposure. Although relatively few patients progress to requiring chronic dialysis, this is a potential end point for these patients.

Patients receiving calcineurin inhibitors, especially in conjunction with steroids, are at risk for systemic hypertension. It is notable that about two-thirds of postcardiac transplantation patients have hypertension, and most require some antihypertensive therapy. Typical medications used to control hypertension are calcium channel blockers (especially amlodipine) and angiotensin-converting enzyme inhibitors. The latter class of drugs may also contribute to renal toxicity; therefore, renal function must be closely monitored.

INFECTION PROPHYLAXIS

One important complication related to immunosuppression in transplant patients is that it places the patient at increased risk for developing infections, both conventional and opportunistic (Table 129.3). The child's susceptibility to infection will vary, depending on the level of immunosuppression used, his or her overall health at the time of transplant, and exposures and immunities prior to transplant. Young children and infants who have had little infectious exposure and have few immunizations are at particular risk for early viral infections posttransplant. The most common viral infections posttransplant include cytomegalovirus (CMV), EBV, herpes simplex virus (HSV), and varicella-zoster virus. Patients who have complicated postoperative courses in which there are bile leaks or collections, or complications that necessitate multiple abdominal surgeries and long-term antibiotic use, are at high risk for fungal infections. Most viral and fungal infections begin to appear approximately 1 month posttransplant,

whereas the risk of bacterial infection is highest in the first few postoperative days. Most transplant programs employ protocol use of perioperative prophylactic antibiotics, as well as antifungal and antiviral therapy. The regimen varies slightly with the age and exposure history of the patients.

Given that both primary and reactivated CMV infections can be serious threats to transplant recipients, antiviral therapy is an important part of the posttransplant regimen. Prophylactic therapy for CMV infections may include CMV hyperimmunoglobulin (CMV-IG), oral acyclovir, and IV or oral ganciclovir or valganciclovir for the first 3 to 6 months after the transplant and during treatment with monoclonal or polyclonal antibodies. The risk is particularly high in CMV-negative recipients who have received CMV-positive allografts. CMV infections may be asymptomatic or may present with symptoms such as fever, leukopenia, pulmonary disease, hepatic dysfunction, intestinal bleeding, or diarrhea. Some programs monitor the presence of CMV antigen in the blood and treat intermittently with IV ganciclovir.

Pneumocystis jiroveci can also be an important pathogen posttransplant. Prophylactic regimens may include sulfamethoxazole–trimethoprim as a single dose (at half the therapeutic dose) daily or as a full dose (10 mg per kg per day trimethoprim), in two divided doses three times per week. Other regimens include monthly IV pentamidine and monthly aerosolized pentamidine. Sulfamethoxazole–trimethoprim may also serve as a urinary tract infection suppressant in renal transplant recipients. These patients are also at increased risk for oral and esophageal candidiasis because of steroid and antibiotic treatment. Therefore, oral nystatin is given for 6 to 12 months after the transplant.

IMMUNIZATIONS IN THE SOLID ORGAN TRANSPLANT RECIPIENT

Ideally, every solid organ transplant recipient would receive all standard childhood immunizations prior to transplantation. In reality, many young infants undergo transplantation before completing childhood immunizations and, more distressingly, immunizations are often withheld from children with chronic diseases on the basis of misunderstanding the necessity to continue immunizations by parents and primary care providers. Although infants and children with chronic disease may have reduced efficacy from immunization, failure to provide immunization has still lower protection. When evaluating a febrile transplant patient, careful consideration should be given to immunization status.

Following initial recovery from the transplantation procedure and any perioperative complications, a standard immunization schedule (with catch up as necessary) should be implemented as per the Advisory Committee on Immunization Practices (ACIP) and American Academy of Pediatrics (AAP) recommendations, with modifications only for live virus immunizations. It is generally accepted that inactivated virus immunizations are safe in the immunocompromised patient, although reduced rates of seroconversion may be expected, especially for children with higher degrees of immunosuppression. Patients often receive relatively more immunosuppression during the first year after transplant and, from a practical perspective, routine immunizations may be more effective if resumed thereafter. Attenuated live virus immunizations have been the subject of greater controversy; the standard recommendation is that immunocompromised individuals should not receive live virus immunization. Retrospective studies from centers administering live virus immunizations (MMR and Varivax®, in particular) to selected liver transplant recipients on maintenance immunosuppression have shown no evidence of infectious complications and a reduced but still significant rate of serologic protection.

GENERAL PRINCIPLES OF MANAGEMENT

Hospitalizations in the first 6 months after transplant are common. For example, 60% of recipients of cadaver donor renal allografts and 50% of living donor recipients are hospitalized in the first 6 months after transplant. The most common causes for hospitalization include treatment of acute rejection, viral and bacterial infections, and treatment of hypertension (Table 129.3). These are also the most likely reasons for presentation to the ED. The encounter in the ED with the renal, liver, or heart transplant recipient need not provoke a sense of uneasiness in the physician if the following pertinent principles of evaluation and treatment are applied:

1. If the transplant patient is critically ill or hemodynamically unstable, the patient should be stabilized by using the same lifesaving interventions used for any critically ill individual with attention to the ABCs of resuscitation. The primary focus should be on the patient and not on graft survival. A critically ill transplant patient should be stabilized and then transported to a transplant center.
2. The transplant center should be regarded as a valuable source of information and assistance. The transplant center should be contacted early in the ED evaluation. No changes in immunosuppressive medication should be undertaken independent of input from the transplant center unless the medication is determined to be the cause of the life-threatening event (i.e. anaphylaxis).
3. All symptoms require thorough evaluation because a patient receiving immunosuppressive medications may have blunted or atypical presentations of severe disease, particularly when infection is involved. Abdominal pain may represent a surgical emergency even when mild in nature. Steroid therapy may blunt the inflammatory response in a transplant patient such that visceral perforation, urine or bile leak, or infectious peritonitis may not be accompanied by classic peritoneal signs. Therefore, all complaints warrant full investigation.
4. Conditions that impair the patient's ability to take or absorb medications (e.g., vomiting, diarrhea) necessitate hospital admission for parenteral administration of the immunosuppressive medications and careful monitoring. Simple conditions, such as gastritis with vomiting or gastroenteritis with diarrhea, may lead to significantly diminished cyclosporine levels and the potential for rejection and graft loss.
5. Fever in the immunocompromised patient requires aggressive investigation because it could be a manifestation of a wide spectrum of disease from severe opportunistic infection to acute graft rejection. If the patient is obviously septic or meningitic, blood cultures should be drawn and broad-spectrum antibiotics administered expeditiously. Headache, seizures, or neurologic changes in the setting of

a fever are indications for a lumbar puncture with cerebrospinal fluid cell count, as well as comprehensive stains and culture for bacteria, viruses, fungi, and acid-fast organisms, to be performed as part of the primary evaluation.

6. Renal or liver allograft dysfunction may be secondary to causes other than rejection. Problems such as bile duct or ureter obstruction, infection, drug toxicity, and rejection may mimic each other but require different therapy. In addition, volume depletion can significantly increase the serum creatinine level in renal transplant recipients. Therefore, these patients must be fully evaluated in a transplant center where they may have prompt immunosuppressive drug levels, graft-specific imaging studies, and possibly graft biopsy before antirejection therapy is initiated.
7. Cyclosporine and tacrolimus have several drug interactions (Table 129.2) that alter patients' metabolism and may lead to dangerously high or low levels. Numerous medications, such as NSAIDs, can also act synergistically with these agents to increase their nephrotoxic effects. Careful attention should be paid to potential drug interactions and to the levels of cyclosporine or tacrolimus in all transplant patients.

APPROACH TO FEVER

Fever is the most common reason for the pediatric transplant recipient to seek evaluation in an ED. A fever in a transplant patient may be a manifestation of any number of infections or processes from acute graft rejection to systemic sepsis. Assessing these patients is challenging because their immunosuppression may mask many of the typical physical findings associated with their disease process (e.g., peritoneal signs).

Patient assessment should include (i) a careful physical examination that includes examination of all wounds; (ii) pulse oximetry and chest radiograph if the patient has cough, dyspnea, tachypnea, or other signs of hypoxia; (iii) a screen of graft function (liver function tests and creatinine level analysis), in addition to other routine laboratory tests such as complete blood cell count, differential prothrombin time/partial thromboplastin time, and possibly disseminated intravascular coagulation panel, if the patient appears septic; and (iv) a blood culture for bacterial and viral pathogens, blood buffy coat CMV antigen assay by rapid assay technique, urine for urinalysis, rapid CMV assay, and viral culture of the urine and a standard urine culture if the child has a fever or appears ill. Because some patients may have a central venous catheter, line sepsis should always be considered in the differential diagnosis.

If the patient appears well, has normal laboratory evaluation and chest radiograph (if presenting with respiratory symptoms), and has an obvious minor source of infection, such as otitis media or an upper respiratory tract infection, the patient may be sent home with appropriate therapy. As previously mentioned, the transplant center should always be notified at the time of the visit that the patient had been evaluated and what the diagnosis was. Close outpatient follow-up is mandatory within 48 hours.

In the liver transplant patient, elevated levels of liver aminotransferases may be a sign of rejection, arterial or venous thrombosis of the graft, or even biliary stricture and obstruction with resultant cholangitis. The initial study required in this case is an ultrasound examination with Doppler flow study to view arterial and venous blood flow to the graft and to assess the biliary tree for evidence of dilation, which suggests obstruction. If obstruction is suspected from the ultrasound evaluation, percutaneous transhepatic cholangiography (PTC) is usually necessary to image the biliary tree and biliary–enteric anastomosis. Prior to the PTC, the patient is given broad-spectrum antibiotic coverage for the common biliary pathogens (e.g., gram-negative enteric organisms). Ampicillin (200 mg per kg per day) and cefotaxime (100 mg per kg per day) are usually adequate. If the ultrasound evaluation is otherwise abnormal (i.e., demonstrating a fluid collection), the situation could require surgical revision of the biliary anastomosis or biliary stent placement either by the interventional radiologists or by open procedure by the transplant surgeons.

If the ultrasound evaluation is normal and no source for the fever or increased liver function tests is found, the patient requires admission and liver biopsy to rule out rejection or viral infection. In the renal transplant recipient, particular attention should be paid to the graft site because fever, tenderness over the transplanted kidney, poorly controlled hypertension, diminished urinary output, and recent weight gain may all be signs of rejection. A rise in the blood urea nitrogen and creatinine levels also suggests rejection. However, ascending urinary tract infection, infected perinephric collections (lymphocele, seroma, and urinoma), ureteral stenosis or obstruction, and renal vascular thrombosis may also present with similar findings. These emergencies require in-hospital workup, beginning with urine culture, blood culture, Doppler and conventional ultrasound, nuclear renal scan, antegrade or retrograde pyelogram when indicated, and possible renal biopsy.

INFECTION

In general, the onset and type of infection and the responsible agent is related to the intensity and type of immunosuppression, as well as the time since the transplant procedure. In the first few weeks after transplant, the most common infections are urinary tract infection and wound infection with bacterial pathogens. After this period, the incidence of opportunistic infections increases.

Pneumocystis jiroveci Pneumonia

P. jiroveci pneumonia (PCP) is most common within the second to sixth month after transplant. In most cases, a patient with PCP presents with dry cough, dyspnea, diffuse interstitial infiltrates, and hypoxemia. Suspicion of infection with this pathogen necessitates a diagnostic intervention such as bronchoscopy with a bronchoalveolar lavage as soon as possible. The isolation of pneumocysts on the silver stain of the lavage fluid confirms the diagnosis. Infection is treated with IV sulfamethoxazole–trimethoprim (20 mg per kg per day of trimethoprim given IV in four divided doses) or pentamidine (4 mg per kg given IV in a single daily dose).

CMV Infection

CMV infection is the single most important infection in the transplant recipient. CMV infection in an immunocompetent host is usually asymptomatic, whereas in a transplant patient, it

may be devastating. CMV causes a syndrome characterized by anorexia, malaise, myalgias, and arthralgias, usually heralded by the initial presentation of fever. These symptoms may be accompanied by an atypical leukocytosis and usually occur within 2 to 3 months of transplant but may occur at any time. In approximately one-third of febrile patients with CMV infection, pulmonary disease develops and may rapidly progress to adult respiratory distress syndrome and death. The risk of succumbing from disseminated CMV disease, prior to the availability of ganciclovir, is 4%, 14%, and 19% in patients after kidney, heart, and heart-lung transplantation, respectively. CMV may also cause localized disease, which in transplant patients may localize to the renal or hepatic graft (causing a picture of hepatitis) and mimic rejection. Another specific site of CMV involvement is the mucosal lining of the GI tract where the virus may cause ulceration and massive GI tract hemorrhage. The effects of the organ-specific infection are amplified by several of the systemic effects of the virus, including thrombocytopenia and leukopenia caused by bone marrow suppression, and impairment in alveolar macrophage function and cell-mediated immunity, which predispose the patient to further opportunistic infections by other viral agents or *Pneumocystis*. Diagnosis of CMV is made by culture, serology, or antigen detection, and therefore, cannot be determined in the ED. However, blood samples can be sent for early antigen detection and culture if CMV is suspected. The transplant physicians can determine by weighing the patient's presentation and risk factors whether preemptive treatment is indicated in any particular patient in the ED. Treatment of active CMV includes lowering of the immunosuppression and administering IV ganciclovir (5 to 10 mg per kg per 24 hours in two divided doses). CMV disease may represent (i) a primary infection in a CMV-nonimmune recipient who acquires the infection from the allograft or transfusion of CMV-positive blood products, (ii) reactivation of latent virus as a consequence of immunosuppression (most recipients in this situation show some evidence of CMV infection, although only 20% become symptomatic), and (iii) superinfection of a CMV-immune patient with a strain of CMV of donor or environmental origin. The course of CMV infection is influenced by the type and intensity of immunosuppression the patient has received. Azathioprine and particularly OKT3 and Antithymocyte globulin (ATG) have the highest risk of reactivating CMV disease.

Epstein-Barr Virus and Posttransplant Lymphoproliferative Disease

EBV is a ubiquitous virus and, similar to CMV, is associated with hepatitis as well as a more systemic illness. Acute EBV infection presents as a mononucleosis-like syndrome with diffuse B-cell hyperplasia. However, of particular concern with EBV infection is the risk of PTLD. PTLD refers to a range of lymphoproliferative disorders—resulting from EBV activation of lymphocytes—that are under the influence of immunosuppression. This can present anytime from 1 month after transplant to many years after transplantation. The clinical presentation of PTLD is highly variable and may include fever, lymphadenopathy, sinusitis, upper airway obstruction from tonsillar enlargement, splenomegaly, GI bleeding from necrotic intestinal lymph nodes, or intestinal obstruction or perforation. This disorder is most common in children who are not immune to EBV at the time of transplant and thus develop EBV infection. The overall incidence in pediatric renal transplant recipients is less than 1%, but the risk increases with increasing exposure to immunosuppressive medications such as OKT3 and tacrolimus-based immunosuppression.

The diagnosis of PTLD is rarely made in the ED. It usually requires a combination of analysis of tissues (lymph node, tonsil, liver) for evidence of EBV-transformed B cells and quantitative EBV polymerase chain reaction (PCR) from blood confirming viral replication. However, blood can be sent from the ED for EBV PCR if this condition is suspected. Specific T-cell studies are used to determine the clonality of the lymphoproliferation and thereby to determine the appropriate therapy, which can range from reduction of immunosuppression and antiviral therapy to cytotoxic chemotherapeutic agents, such as cyclophosphamide and anti-CD20 antibody therapy. In many cases, the PTLD responds to discontinuation of immunosuppressive medications without ensuing allograft rejection.

Herpes Simplex Virus

Reactivation of latent HSV infection is common in transplant recipients. Patients presenting with an oral or genital lesion resembling herpes should have a scraping for immunofluorescence performed on the lesion. If HBV is present, oral acyclovir is used for minor lesions without systemic symptoms. Extensive lesions, fever, or other systemic symptoms require IV acyclovir treatment (750 to 1,500 mg per square meter per 24 hours given IV in three divided doses) to prevent disseminated herpes infection.

Varicella

Varicella is a highly contagious pathogen that is common among school children. In a transplant patient who is immunocompromised, it may become a disseminated disease spreading to the liver, lungs, and central nervous system (CNS). If a patient has been exposed only to varicella (household contact or played in the same room with an infected individual), the patient should receive varicella-zoster immunoglobulin (VariZIG). VariZIG (125 units or one vial per 10 mg) should be given within 96 hours of exposure, but the sooner it is administered, the more efficacious it will be. VariZIG has been on a patient specific allocation for approximately 3 years in the United States, requiring registration of the patient and a drop shipment to the institution that arrives within 24 hours. Thus it is imperative to request the drug as soon as the diagnosis is made. If the transplant patient is diagnosed with varicella, he or she should be admitted to the hospital for IV acyclovir therapy (1,500 mg per square meter per 24 hours in three divided doses) and a sharp reduction in steroid dosage. Herpes zoster may occur in as many as 5% to 10% of adult transplant patients, representing reactivation of old varicella infection, although it rarely disseminates. Acyclovir may hasten resolution of lesions, but no change in immunosuppressive regimen is usually needed.

Adenovirus

This viral infection occurs in up to 7% of pediatric transplant patients and should be considered when the patient presents with high fever and liver and/or pulmonary dysfunction with

or without diarrhea. A nasopharyngeal swab and stool for viral culture should be sent to screen for the virus in the febrile posttransplant patient.

Other Viral Pathogens

Recently, other viruses have been identified as pathogens in transplant patients. Human herpesvirus-6 (HHV-6) and human herpesvirus-7 (HHV-7) are causative agents of severe disease in stem cell transplantation. In solid organ recipients, the most common clinical manifestation is a nonspecific febrile syndrome. Other symptomatic infections are rare and may include hepatitis, colitis and nonspecific neurologic sequelae. In adult liver transplant patients, active infection with HHV-6 or HHV-7 may increase the risk of developing severe CMV disease and invasive fungal infections. Risk factors for infection with HHV-6 include antirejection therapy with OKT-3 or antithymocyte globulin. The role of HHV-6 or HHV-7 in solid organ rejection is still unclear.

Fungal and Nocardial Infections

Fungal infections in the posttransplant patient can have various clinical presentations. They may present as a subacute respiratory illness with local or disseminated findings on chest radiograph. Alternatively, the patient may have a systemic illness with nonspecific symptoms of malaise and fever that may be acute or chronic. Fungal infections may also present with metastatic disease. Examples are the 20% to 30% of patients with cryptococcal infection who demonstrate skin lesions weeks or months before the development of CNS lesions and the 10% to 15% of patients with disseminated *Candida* infection who have skin lesions early on in its course. Similarly, *Nocardia* and *Mucor* species may show early skin lesions before evidence of more serious deep-seated infection presents itself. Another common fungal infection is candidal esophagitis, which may present with dysphagia or odynophagia. CMV and HSV infection of the esophagus may also occur with similar symptoms.

Fungal infections generally do not occur in the first month after transplant but rather in the subsequent months. Between the first and sixth months, *Candida* species are the major fungal pathogens. Infections with *Aspergillus* are less common but are associated with high mortality. Fungal infection of the CNS may be difficult to assess because the classic signs of CNS infection, such as meningismus, are often absent in immunosuppressed patients. The common presentation of headache, often without fever, may be the only indication that a CNS infection exists and warrants thorough neurological evaluation, lumbar puncture with fungal stains and cultures, and possibly an imaging study of the brain, preferably magnetic resonance imaging. Acute or subacute meningitis is most commonly caused by *Listeria monocytogenes,* whereas chronic meningitis is most often caused by *Cryptococcus neoformans* and focal brain abscess is often indicative of *Aspergillus* infection.

GASTROINTESTINAL EMERGENCIES

Transplanted patients may develop GI complications that are secondary to many different causes, ranging from infection to postsurgical complications to dehydration of any cause. Perforation and bleeding may occur secondary to necrotic lymph nodes from PTLD or because of small bowel ulcerations from CMV infection. Intussusception or luminal obstruction may occur secondary to enlarged lymph nodes from PTLD, and peritonitis may be caused by any of the aforementioned conditions, including bile leak from an anastomotic breakdown or bile duct ischemia, particularly in the early posttransplant period. Severe variceal bleeding is also seen in the liver transplant patient with portal venous thrombosis and consequent prehepatic portal hypertension. Dehydration should be promptly addressed as it may lead to renal toxicity of immunosuppressive medications. In such instances, the medication should be held and a medication level checked, if possible. Interpretation will depend on the timing of the last dose given. Pancreatitis may be seen as a complication of taking azathioprine. Tacrolimus toxicity can produce complaints of severe epigastric pain or diffuse abdominal pain. Mycophenolate can cause gastritis, esophagitis, and diarrhea. In addition to viral involvement of the GI tract, infectious processes that are most common in transplant recipients include *Clostridium difficile* colitis and candidal esophagitis.

The approach to these patients in the ED is the same as for the nonimmunocompromised patient: (i) stabilize with fluid resuscitation or blood products if necessary, (ii) nasogastric intubation if evidence of upper GI bleeding or obstruction, and (iii) frequent monitoring of vital signs while transfer to the transplant center is arranged.

MISCELLANEOUS EMERGENCIES

Transplant recipients may also experience many of the usual childhood emergencies, including hydroceles and herniae. Scrotal edema on the side of the renal transplant is a common finding; it is generally self-limiting and not a problem. Other possible complications include deep venous thrombosis on the side of the transplanted kidney, which is confirmed by noninvasive venous imaging and managed with anticoagulant therapy. Less common complications are suture-line disruption with subsequent "blow out" or aneurysmal rupture at the anastomotic site in both liver and renal transplants.

Careful attention should be paid to a transplant recipient with a headache. In addition to usual causes of headaches, meningitis, pseudotumor cerebri, malignancy, and malignant hypertension must be considered. In a patient with papilledema, the most likely cause is pseudotumor cerebri, which is a complication of steroid treatment and may be related to changes in steroid dose.

CONCLUSION

Emergencies in the pediatric transplant patient are common, consequent to the complex nature of the procedures and the depressed state of the immune system. With the ever-increasing number of organ transplants being performed each year in children, more of these patients are likely to be seen in the ED. Therefore, a working knowledge of the nature of these procedures and the common emergency situations that may arise in this patient group is essential to proper assessment and management of these patients' problems.

CHAPTER 130 ■ ADOLESCENT EMERGENCIES

MONIKA GOYAL, MD, CYNTHIA J. MOLLEN, MD, MSCE, AND JANE M. LAVELLE, MD

OVERVIEW

Adolescence is a cultural construct that can be defined as the transition from the dependent state of childhood to the independence of adulthood. This process usually begins with the changes in physical growth caused by activation of the hypothalamic-pituitary-gonadal axis, termed puberty, which commonly occurs between the ages of 8 and 11 years in girls and 9 to 12 years in boys. As discussed in more detail in this chapter, many physiologic, psychological, and environmental factors can delay the onset of puberty; therefore, adolescence may begin with changes in cognitive processes or relationships with peers and family members. At the other end of this transition process, an individual may not achieve true independence until well into the third or fourth decade of life. Because an end point is difficult to define, individuals are usually categorized as adolescents through age 21 years, although some pediatric facilities only care for adolescents without chronic illnesses until their 19th birthday. For many reasons, it is not unusual for individuals with special health and emotional needs to seek health care in pediatric settings well after they have achieved independent adult status.

Although the physical, psychological, and social changes associated with adolescence are well defined, the process is extraordinarily unique for each individual. There are many pathways by which biological, emotional, and environmental conditions can affect the rapidly changing adolescent. Surprisingly, although many adolescents struggle with the transition to independence from parents and childhood caregivers, for most adolescents these transitions occur smoothly with relatively little emotional distress or physical ailment. This may not be true for their parents or caregivers. Because optimal emergency care of adolescents is based on an understanding of the patient's developmental processes, a brief overview of the principles of adolescent development is presented, followed by a summary of health problems and patterns of emergency department (ED) use by adolescents.

The developmental tasks of early adolescence include establishing autonomy from parents or caregivers, moving from concrete to abstract thought and decision-making processes, and adopting a peer group identity. During the middle phase of adolescence, the struggle toward establishing an individual identity occurs, as one becomes aware of him- or herself as a sexual being and progressively longer-lasting intimate relationships evolve. Relationships with peers and adults change rapidly during middle adolescence. Family and social roles may become strained, and frameworks for moral decision making may develop at what may seem in opposition to traditional value systems. In the third phase of adolescent psychosocial development, individuals may strive to accept a sexual identity, establish meaningful interpersonal relationships, and work toward long-term life goals. It is not surprising that with so many somatic, psychological, and social changes occurring simultaneously, presentation for emergency medical attention is likely. Although the vast majority of adolescents cope well with their development and have only occasional episodic need for emergency medical services, up to one-fifth of teenagers have serious behavioral or medical problems, including conditions that can cause serious injury and threaten their lives. It is of paramount importance to approach each teenager and young adult on an individual basis. A standard approach based on chronologic age or physical appearance is never indicated or prudent. It is important to note that as teenagers develop a growing sense of self-awareness, the ways that their physical development differs from their peers can have significant impact on their identity and behavior. In particular, the physical development of individuals with chronic physical or emotional health conditions provides little insight into their psychosocial development.

The health care needs of adolescents are reflected by the chief causes of their mortality and morbidity. Since the 1980s, although there has been a gradual decrease in the adolescent death rate, it still remains high. The death rate for adolescents is 80 per 100,000 with a male:female ratio of 2:1. The root cause of the majority of adolescent deaths can be attributed to the "social morbidities" (substance abuse, sexually transmitted diseases, accidents, homicides, suicides, mental health disorders, and eating disorders).

Of all deaths of individuals between 15 and 24 years of age in the United States, three-fourths are the result of motor vehicle crashes, other unintentional injuries, homicide, and suicide. The leading causes of these unintentional injuries include motor vehicles, drowning, poisoning, firearms, fires, and falls. Homicide, the second leading cause of death, accounts for almost 15% of all deaths in the adolescent age group, the majority of which are caused by firearms; suicide accounts for more than 10%. Surveys of teens have revealed some insight about the extent they are at risk for some of these health problems. Results from the 2007 National Youth Risk Behavior Survey, which surveys a nationally representative sample of high school students, indicates that more than 10% of teens reported never or rarely wearing a seat belt and almost 30% reported traveling in a car driven by someone who had been drinking. Moreover, 18% reported carrying a weapon. Substance abuse is also a major contributor as 75% reported drinking alcohol, 20% smoked cigarettes, almost 40% smoked marijuana, and 7% had tried cocaine at least once.

More recent trends and changes in American family life, including increased incidence of unwed teenage pregnancy, high divorce rate, the deterioration of public education in some segments of our society, and unemployment, undoubtedly contribute to the health care problems of adolescents. These findings indicate that adolescent death and injury are not random events but have an epidemic cause that may be altered by timely, appropriate interventions.

Another important influence on the overall health of adolescents is their lack of access to the health care system. The National Health Interview Survey revealed that one in seven adolescents has no health insurance; overall, 16- to 24-year olds comprise the highest portion of uninsured individuals. Adolescents from poor, nonwhite families that are headed by one adult are most likely to be uninsured, contributing to ethnic disparities in health care access and overall health status. Other populations that may have limited access to coordinated health care for other reasons include youth who develop a minority sexual identity or those who have been displaced or abused. As a whole, 10% of adolescents have no regular source of health care, and 18% identify local EDs, outpatient clinics, and city clinics as their only source of health care. When adolescents do have a regular physician, it is usually a family practitioner; the remaining are cared for by internists or pediatricians. Unfortunately, studies indicate that most of these primary care physicians perceive themselves to be deficient in experience, knowledge, and training in the care of adolescents.

Adolescents account for approximately 10% to 15% of all ED visits; of these, 13% require acute hospitalization. In one report, 78% of these visits were triaged to the acute and urgent categories. A more recent survey of hospital discharges revealed that more than one-half of all discharges in patients 15 to 24 years of age were a result of pregnancy and its complications, poisoning (substance abuse and suicide gestures/attempts), and trauma (including physical and sexual abuse). Other reasons for ED visits include minor trauma, sexually transmitted infections (STIs), mental health disorders not associated with suicide, and routine visits for acute and chronic illness. There are multiple reasons contributing to an adolescent's choice to seek care in an ED setting. Inexperience, denial, and fear may delay the recognition of disease symptoms and the timely seeking of medical care. The anonymous setting of the ED is often preferred because they can be treated in certain instances without parental consent and are rarely, if ever, refused. Although the adolescent's acute health care needs may be well served this way, proper follow-up, patient education, and recognition of chronic problems may be less than adequate.

Just as children are not just small adults, adolescents are not just large children. Adolescents are prone to a distinct group of diseases and have special medical needs that are much different from those confronted by younger children or adults. Tolmas eloquently listed some important considerations for medical professionals preparing to care for this group of patients: "a knowledge of the growth and developmental tasks that young people address, a personal interest, respect for confidentiality, honesty and pragmatism in all aspects of behavior and conversation, and a genuine attempt to keep from projecting one's own moral code." This chapter addresses these considerations by first briefly reviewing some special considerations in the history and physical examination of adolescents, then, in following sections, focusing on legal rights of adolescents in obtaining health care, adolescents with special health care needs, pregnancy, rape and sexual abuse, and interpersonal violence.

GENERAL CONSIDERATIONS FOR THE HISTORY AND PHYSICAL EXAMINATION

While evaluating the history, it is important to assess the developmental age of the adolescent and not to simply treat the adolescent with a standard approach or strictly on the basis of his or her physical appearance. As for all patients, listening to the adolescent's fears and concerns is extremely important. Taking a moment to establish rapport and eye contact, while demonstrating patience and a caring demeanor, aids in conducting a successful interview. Medical staff may grossly underestimate an adolescent patient's concerns regarding health, because more than 50% of adolescents worry about their health. Teens may avoid seeking appropriate care for social or psychiatric concerns, and psychosocial strain occurring within this period of immense change is often translated into somatic complaints. The reason for the visit is thus often intentionally or unintentionally disguised and presented in conventional or acceptable, nonspecific medical complaints because of the adolescent's fears, embarrassment, or lack of insight. The clinician must always be alert to the possibility of a "hidden agenda," of which the adolescent and his or her family may not be completely aware.

Because nonspecific somatic complaints can be related to pregnancy; sexual, emotional, or physical abuse; mental health disorders; or substance abuse, at some point during the patient evaluation the adolescent should be interviewed without the presence of the parent or other caregiver. The physician must always ensure the patient that confidentiality will be maintained and that openness and honesty between patient and physician is a prerequisite for good medical care.

General questions about the adolescent's home and school life are helpful in assessing overall "wellness" of the teen. Table 130.1 lists the components of the psychosocial interview—Home, Education/Employment, Activities, Drugs, Sexuality, and Suicide (HEADSS)—providing a framework to identify health risk behaviors. Reviewing components of this list may well be pertinent to the chief complaint that brings the teen to the ED. It is important for the adolescent patient to understand the relevance of personal questions to foster both respect and trust. Adolescents who believe that they must keep behaviors, thoughts, or personal identity concerns secret from adult caregivers may be more willing to disclose to an acute care provider who they may see only once. In some EDs, a computer-based survey may be a more comfortable way for adolescents to express their concerns. Once information pertinent to the adolescent's physical and emotional health has been disclosed, it is imperative that a plan for disclosure to the appropriate supportive adults be discussed.

A brief sexual history must be taken for almost every complaint (see Chapters 90 and 93). Interviewers obtain more reliable information if questions are asked in a matter-of-fact but nonleading and open-ended fashion. Adolescents give the "proper" or perceived "desired" answer to such questions to

TABLE 130.1

THE PSYCHOSOCIAL INTERVIEW

Home	Activities	Sexuality
Where and with whom do you live?	What do you do for fun?	Have you ever had sex with someone?
Who is your legal guardian?	Do you have a best friend?	Do you have sex with men or women?
How do you get along with everyone at home?	Group of friends?	How many partners have you had?
Do you feel safe at home?	Who do you talk to about problems?	Are you using birth control?
Education/employment	Have you ever been in trouble with the police?	Have you ever been pregnant?
What school do you attend?	**Drugs**	Do you use condoms every time?
What grade are you in?	Do your friends smoke, drink, or use drugs?	Did anyone ever hurt/scare you?
How are you doing?	Did you ever smoke?	**Suicide**
Did you ever repeat a grade?	Do you drink? How often? How much?	Do you ever feel down?
Are you in a special class/program?		What do you do to feel better?
Do you have a job?		Did you ever feel like hurting yourself?

From Ehrman WG, Matson SC. Approach to assessing adolescents on serious or sensitive issues. *Pediatr Clin North Am* 1998;45:189–204.

gain the provider's acceptance and sympathy; alternatively, they could withhold information for fear of judgment or stigmatization. It is relevant here to note that there are reliable and unreliable personal historians, and it is extraordinarily difficult for the acute care provider to distinguish between the two. Therefore, it is prudent to obtain noninvasive (urine-based) testing for prevalent bacterial sexually transmitted infections (STIs), regardless of personal history. The decision to pursue more invasive examinations, such as speculum or bimanual examinations, should be made after careful consideration of the history, physical examination, and potential sequelae of suspected infections and procedures. Just as a delay in treatment of pelvic inflammatory disease can lead to infertility and chronic pain, a rushed judgment to perform a full pelvic examination on a virginal adolescent can have equally as devastating emotional, and possibly social, sequelae, not the least of which may be a lifelong mistrust of health care providers.

Phenotypic changes associated with puberty were defined and standardized by Tanner in the mid-20th century, using largely Caucasian subjects. In the last two decades, there has been a growing recognition that the timing and progression of physical development can be dramatically affected by genetic, cultural, social, and psychological factors. Thus, the staging of pubertal development is now referred to as sexual maturity rating (SMR), reflective of a broader basis and range of what is accepted as normal. Figures 130.1, 130.2, and 130.3 illustrate the progression of breast and pubic hair development, and Figs. 130.4 and 130.5 are the currently accepted SMR growth charts that reflect growth curves for "early" and "late" bloomers, as well as "normal." Abnormal progression is a sign of underlying pathology, which may be the product of organic disease, social distress, emotional problems, or any combination of these. Abnormal progression almost always requires a thorough evaluation and close follow-up. Therefore, maturity rating becomes important in the evaluation of many adolescent complaints.

LEGAL ISSUES

When caring for a minor patient, it is important for the health care provider to have a basic understanding of the legal and ethical issues that may arise. Each state has individual provisions; however, the following general discussion applies to most situations.

Consent

There are many exceptions to the requirement that a parent or legal guardian must consent to medical care for a minor before care can be provided. In the emergency setting, it is often

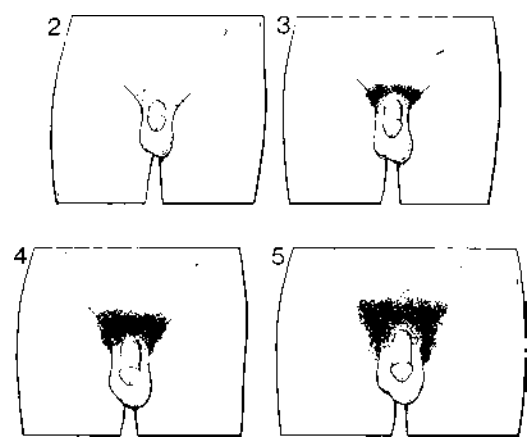

FIGURE 130.1 Stages of pubic hair growth and development of the external genitalia in boys. Numbers in left-hand corner refer to staging according to Tanner. Description of stages of pubic hair: 1, no pubic hair (not shown); 2, long, downy pigmented hair at and lateral to the base of the penis; 3, dark, coarse, curled hair at and lateral to the base of the penis; 4, abundant adult-type sexual hair limited to the pubic region with no extension to the thighs; 5, sexual hair is adult type in quantity and distribution with spread to the medial aspects of the thighs. Description of genitalia stages: 1, prepubertal; 2, enlargement of the testes and scrotum, with pigmentation and thinning of the scrotum; 3, lengthening of the penis, further enlargement of the testes and scrotum; 4, increase in width and length of the penis, further enlargement of the testes and scrotum, increased pigmentation of the scrotum; 5, adult size and shape of genitals. (Modified from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303; and Root AW. Endocrinology of puberty. I. Normal sexual maturation. *J Pediatr* 1973;83:1–19.)

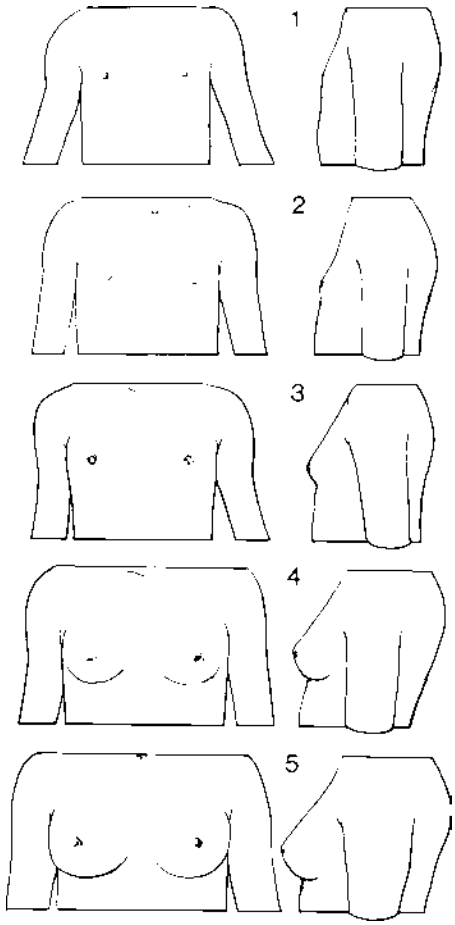

FIGURE 130.2 Stages of breast development in girls. Numbers refer to staging according to Marshall and Tanner. Description of stages: 1, no breast development; 2, breast budding widening of areola and elevation on mound of subareolar tissue, erect papilla; 3, continued enlargement of breast and widening of areola without separation of their contours; 4, areola and papilla project above the plane of enlarging breast; 5, mature breast, areola and breast in same plane, erect papilla. (Modified from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303; and Root AW. Endocrinology of puberty. I. Normal sexual maturation. *J Pediatr* 1973;83:1–19.)

appropriate to initiate care prior to the arrival of the parent. In addition, there are situations where the minor may be legally able to provide informed consent. Such provisions vary by state, but services covered generally include contraceptive services, pregnancy-related care, diagnosis and treatment of STIs or other reportable diseases, including HIV (human immunodeficiency virus), examination and treatment related to sexual assault, and counseling for alcohol and drug problems. In addition, some mental health services may be included. Finally, minors who have achieved a certain status can consent for care; although the specifics vary by state, they usually include having graduated from high school or having served in the armed services, as well as married minors, minors who have been pregnant or given birth, and minors living independently from their parents.

In addition to specific legal statutes, over the years the "Mature Minor Doctrine" has developed under the common law and has been written into statute in some states. This doctrine states that a minor may consent to medical care if (i) he or she understands the nature of the proposed treatment and its risks, (ii) the physician believes the patient can give the same informed consent as an adult patient, and (iii) the treatment proposed does not involve very serious risks. It is generally applied to adolescents who are at least 14 years old. There have been no cases in over 30 years in which a parent has successfully sued a treating physician for nonnegligent care of an adolescent without the parent's knowledge. This doctrine must be applied carefully, however, taking each case on an individual basis. As discussed previously, some 14-year olds will be very mature and able to understand the risks and benefits of treatment, whereas some older adolescents may not have the maturity to consent. When obtaining consent from a minor patient, the physician should document the information that led to the judgment that the patient is "mature" in the medical record.

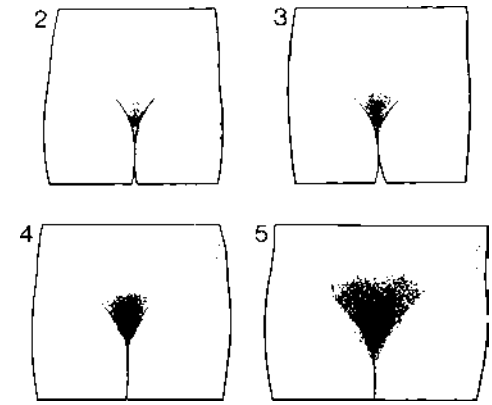

FIGURE 130.3 Stages of pubic hair growth in girls. Numbers in left-hand corner refer to staging according to Marshall and Tanner. Description of stages: 1, no pubic hair (not shown); 2, long, pigmented hair over mons veneris or labia majora; 3, dark, coarse, curled hair spread sparsely over the mons veneris; 4, abundant, adult-type sexual hair limited to the mons veneris; 5, sexual hair is adult type in quantity and distribution with spread to the medial aspect of the thighs. (Modified from Marshall WA, Tanner JM. Variations in patterns of pubertal changes in girls. *Arch Dis Child* 1969;44:291–303; and Root AW. Endocrinology of puberty. I. Normal sexual maturation. *J Pediatr* 1973;83:1–19.)

Confidentiality

The practice of confidentiality encourages the adolescent patient to provide an honest history and to begin to take control of his or her own health care. Furthermore, some amount of confidentiality is required by law. In 1996, the Health Insurance Portability and Accountability Act (HIPAA) was passed, which delineates strict guidelines protecting the disclosure of patient information. In general, if a minor is able to legally consent to medical care, then that minor also controls disclosure of information related to that service. Importantly, HIPAA regulations do not overrule state laws that authorize a health care provider to disclose a minor's health information to a parent or guardian. As of this writing, the U.S. Department of Health and Human Services has not issued a final rule related to proposed changes in HIPAA that may affect health care provision to minors.

A private interview with the adolescent patient should be a routine part of the health care provider's approach to all

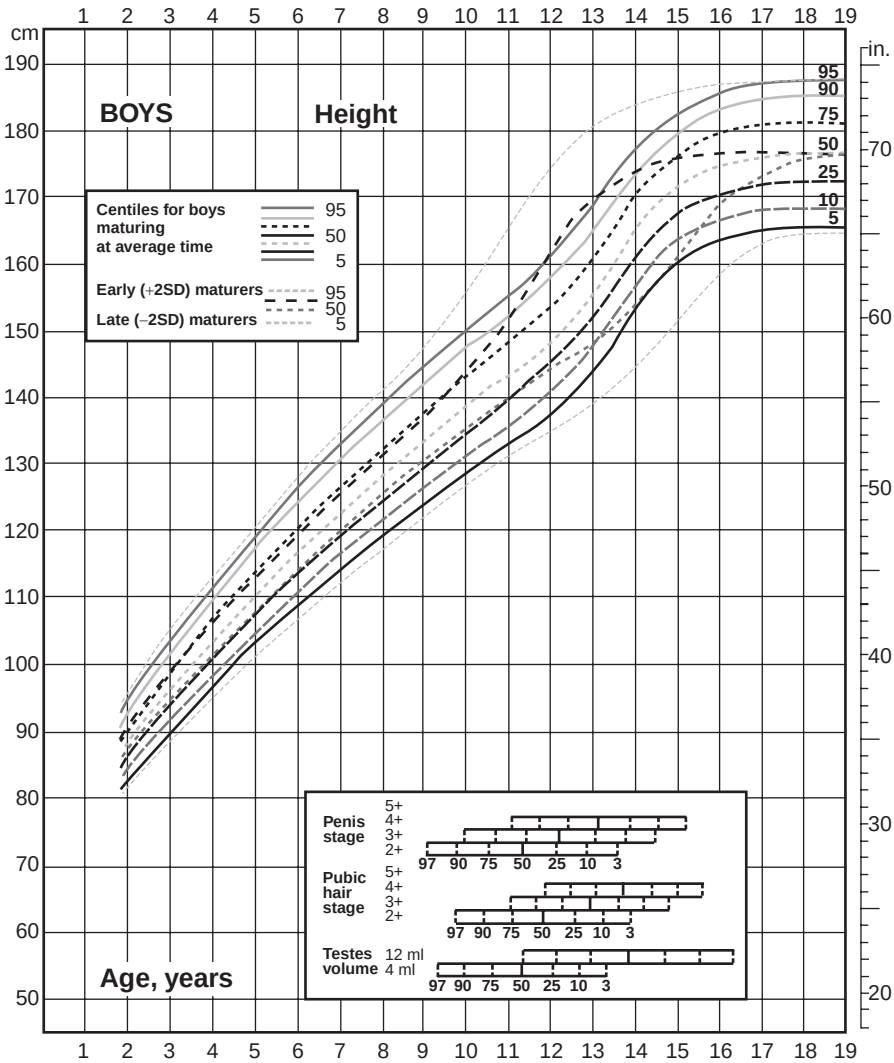

FIGURE 130.4 The currently accepted sexual maturity rating growth chart for boys that reflects growth curves for "early" and "late" bloomers, as well as "normal."

adolescent patients. Confidentiality is best defined at the start of the interview in front of the patient and parent/guardian. The limits of confidentiality, based on local mandated reporter statute, should also be defined at the outset. These limits may include clinical evidence or suspicion of physical abuse, suicidal ideation or intent, and homicidal intent; some states may include the diagnosis of pregnancy or sexually transmitted infections under their definition of "abuse." Thus, confidentiality is not unqualified, and it is critical to maintain up-to-date knowledge of the laws of the state in which one practices. If a teen is in imminent danger, he or she should be informed of the need to disclose this important information to a responsible, caring adult either alone or with the clinician's assistance. The primary physician, social work counselor if available, and appropriate child protective or mental health agency should always be involved to ensure necessary follow-up and community-based services.

Documentation and Payment

Both the release of medical records to a parent or guardian and a bill for services sent to the guardian can effectively breach the adolescent's confidentiality. It may not be necessary to document everything that is learned during an interview with a patient, particularly if it does not directly relate to the patient's chief complaint. In addition, it is advisable to be familiar with the billing procedures and codes of your particular environment so that you can discuss with the patient the likelihood of a parent learning about a health care visit when a bill arrives.

SPECIFIC ISSUES

Patients With Special Health Care Needs

The prevalence of chronic health conditions in adolescents and adults has dramatically increased over the last several decades. The adolescent with special health care needs may face problems as he or she struggles to establish a personal identity and cope with the rigors of chronic illness in family and health care settings that stress compliance and may overemphasize short-term physical health. As individuals with chronic health conditions age to adulthood, they and their families often find that different systems and supports exist once they cross the threshold of their 21st birthday. The new systems may be seen in a

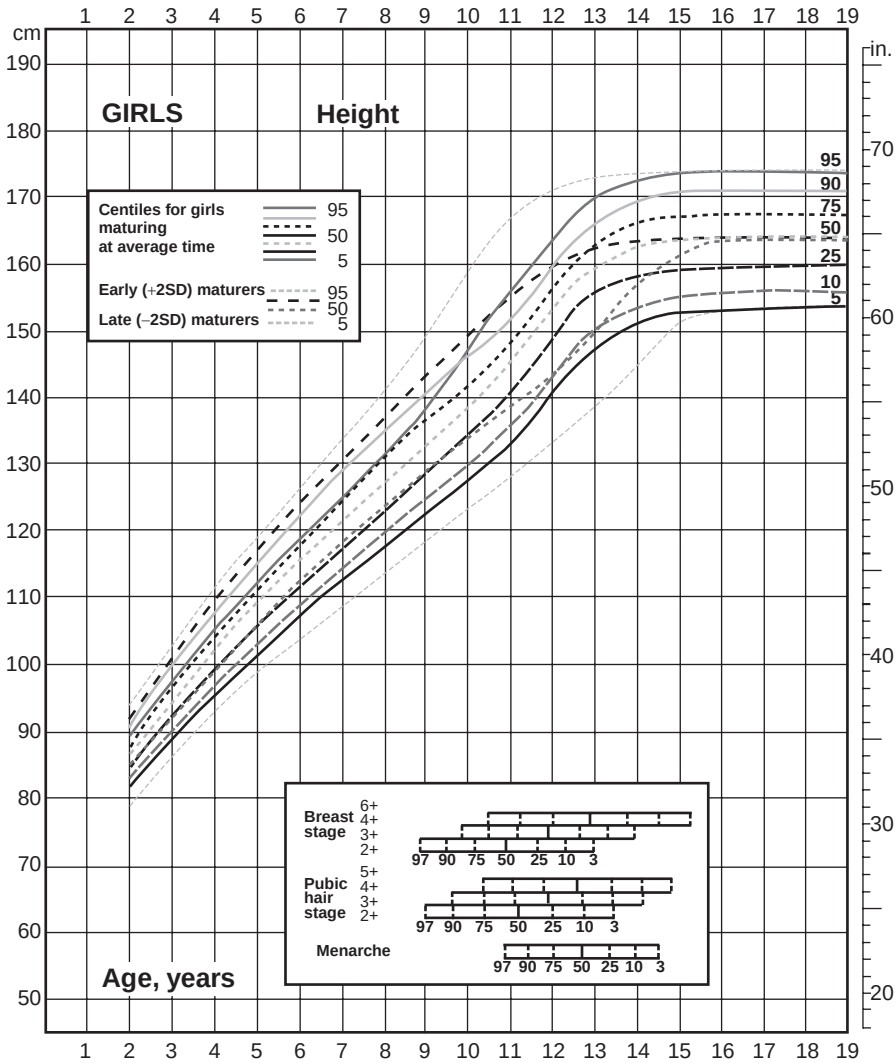

FIGURE 130.5 The currently accepted sexual maturity rating growth chart for girls that reflects growth curves for "early" and "late" bloomers, as well as "normal."

negative light by the patient and the family, due in part to increasing expectations of personal responsibility, facilities that seem less attractive and receptive, and the grief experienced by young adults and their families as they face the loss of lifelong child-oriented care providers and support systems. Interest and research toward understanding how to provide effective and compassionate care to adolescents with chronic health conditions, as well as to promote safe and continuous health care transition, has been a growing focal point in the health literature for the last 20 years. This section focuses on the role of emergency care providers in meeting these goals by first describing the nature of the problem. This is followed by a discussion of developmental and behavioral needs of affected adolescents and of the necessity of coordinated transition planning as it relates to emergency care.

Stein and Silver estimated that 14.8% (10.3 million) of all children in the United States have chronic health conditions. Children with special health care needs are typically defined as those who have, or are at increased risk for, a chronic physical, developmental, behavioral, or emotional condition and who also require health or related services of a type or amount beyond that required by children generally. Adolescents with special health care needs can exhibit a number of developmental and behavioral sequelae of their functional limitations and increased dependence on family members and health care systems. Because physical growth and pubertal development are often affected, they must struggle with developing a healthy body image at a time when biological, psychological, and societal forces emphasize the importance of being "normal." Furthermore, increased health risks of pregnancy or STI, and limitations of reproductive function and capacity, often interfere with normal risk taking and developing age-appropriate gender roles. Frequent time spent in hospitals or recuperating from acute exacerbations at home limits peer group activities and further curtail opportunities to learn expectations of social behavior. The struggle for autonomy and transition from dependence to independence is almost always affected by special health care needs. Although the duration and intensity of parental and professional supervision may be significantly increased, there is often little else to prevent affected youth from developing behaviors that are counterproductive to health, but may foster a short-term sense of independence or temporarily soothe discordant emotions. There are numerous reports in the adolescent health literature reporting rates of substance abuse and sexually transmitted infections in populations with special health care needs that approach and surpass

rates in their nonaffected counterparts. Other common coping behaviors that can contribute to poor overall health include poor adherence with treatment regimens, social withdrawal, and developmental regression. This lists just a few of the barriers faced by this population that demand increased attention to ensuring adequate time and opportunities for exploration and personal growth.

There is no doubt that most young adults successfully navigate adolescence and achieve some level of independent adulthood in spite of the additional burdens imposed by their special health care needs. Emergency care providers can foster success by supporting continuous and coordinated transition to adult roles and health care systems. Health care transition is defined as the purposeful and planned move from child- to adult-oriented care. It has long been recognized that transition is a complex and dynamic lifelong process that has the goal of maximizing lifelong functioning and potential. In the 2002 Consensus Statement on Health Care Transitions for Young Adults with Special Health Care Needs, leaders from the American Academy of Pediatrics, American Academy of Family Physicians, the American College of Physicians and American Society of Internal Medicine emphasized that the core components of effective transition to be flexibility, responsiveness, continuity, comprehensiveness, and coordination. This statement summarized decades of research and indicates that transition is necessary to maintain quality health care, and therefore, must be a priority for all pediatric health care providers. Although not specifically dependent on emergency care providers, any provider can contribute in the process of successful transition by fostering positive attitudes about adult-oriented health care and promoting independence in the young adult patient and coordinating care.

Based on the medical home model created and promulgated by the American Academy of Pediatrics, the following recommendations are made to emergency care providers who treat youth with special care needs. First and foremost, emergency care professionals should maintain a future orientation by proactively asking adolescents about transition plans in regard to work, school, and goals for independence. Asking in this way is usually perceived as supportive. A future-oriented approach can also be emphasized by clearly establishing decision-making roles of the patient and supportive family members. This also fosters a sense that personal independence is a reasonable and desirable objective. Every adolescent and young adult with special care needs should have a primary care provider (PCP) who takes responsibility for coordinating subspecialty care and supports a comprehensive transition plan. Once the patient has been medically stabilized, a member of the emergency care team should attempt to communicate with the PCP. In addition, the patient may possess a portable medical summary and transition plan that can be relied on in determining optimal treatment options and dispositional planning. Researchers from the Centers for Disease Control and Prevention (CDC) reported in 2001 that 1 in 11 (9.3%) children with special health care needs relied on the emergency room as their usual source of care. This proportion surpasses 1 in 10 in many regions of the country, including the upper midwest, west, and southeastern United States. In the absence of an identifiable PCP, there is an opportunity to emphasize the necessity of establishing a medical home and transition plan. Often, emergency care providers establish relationships and get to know the needs of the affected individual and family. Thus, a directed and facilitated referral to a primary care colleague can be personally fulfilling, as well as much more effective and cost-efficient than sporadic problem-based care. When a transition plan exists, care must be tailored to maintain consistency with that plan. This may involve additional time spent in the ED as home care or alternative care settings are arranged.

In conclusion, emergency care professionals are key to advocating for systems change that facilitates safe and continuous health care transitions. This entails the development of uniform health and social benefit packages that foster transition as opposed to arbitrarily defined cutoffs based on chronologic age or short-term governmental budget priorities. Findings from the CDC's National Survey of Children with Special Health Care Needs (2001) indicate that more than one-third of participants who had insurance reported that the insurance plan was not sufficient to meet their or their family member's health care needs. Because emergency care providers are often sought after for policy recommendations, coordination with adolescent and internal medicine subspecialist's efforts to enhance the public's awareness of the cost to society of inadequate and discontinuous health care coverage is necessary. Likewise, pediatric care providers can work together to foster interagency and interinstitutional collaborative efforts and performance evaluations that support the vital role of transition planning. Finally, policy makers and community can be educated on the burden to communities of inadequate and sporadic health care services, as well as the need for resource allocation that supports the receiving end of the child- to adult-oriented health care continuum.

Pregnancy

Pediatric emergency medicine subspecialists who routinely care for adolescents will frequently evaluate patients for the diagnosis of potential pregnancy and for complications of early pregnancy. Therefore, it is important to possess the necessary knowledge and skills to care for sexually active teenagers and to identify and access appropriate resources to ensure adequate treatment and follow-up. Twenty percent of sexually active teenagers become pregnant yearly, accounting for approximately 750,000 pregnancies. Although many pregnant teenage women may not have intended to become pregnant, several qualitative and quantitative studies report that many of these young women may have desired pregnancy for various reasons. More than one-half (56%) of teenage pregnancies result in a live birth, whereas 30% end in therapeutic abortion, and 14% end in spontaneous abortion.

Clinical Manifestations

The symptoms of pregnancy in teenagers are variable. It should be considered in the differential diagnosis for almost every chief complaint of the postpubertal adolescent girl. In a retrospective review of adolescents found to be pregnant during a visit to a pediatric emergency department (PED), only 8% mentioned pregnancy as part of their chief complaint in triage. Physicians elicited concern for possible pregnancy in only 36% of cases, and 10% of the patients denied sexual activity. Silber and Sadaat noted that the diagnosis of pregnancy was

missed in 14% of these teens on their initial visit. Causey and colleagues retrospectively compared adolescents presenting to a general emergency department (GED) who were diagnosed with pregnancy with those in whom the diagnosis was not made during an ED visit but subsequently went on to have a child. They found that 43% presented during the first trimester, 25% in the second trimester, and 33% in the third trimester. Of the 100 patients in whom the diagnosis was not made, one-third of these patients had complaints that were suspicious for pregnancy.

The most common presenting complaint associated with early pregnancy is a missed or abnormal menstrual period. However, the menstrual history is particularly unreliable in teenage women secondary to anovulatory cycles. As many as two-thirds of pregnant teens report a missed period. Other symptoms commonly associated with pregnancy include fatigue, dizziness, breast tenderness, weight gain, nausea, syncope, and morning sickness. Many adolescents report nonspecific complaints related to the gastrointestinal or genitourinary tracts. In the previously described PED study, 77% of pregnant patients complained of gastrointestinal symptoms. Similarly, in the GED study, 91% of patients diagnosed with pregnancy had abdominal or genitourinary complaints. Less commonly, the presenting symptom is associated with complications of early pregnancy, including vaginal bleeding, hyperemesis, hypertension, headache, hyperglycemia, vaginal discharge, or dysuria.

Thus, it is important to consider performing a pregnancy test in peri- and postmenarcheal teenage women. Even if a positive pregnancy test is unrelated to the presenting symptoms, there are several advantages to the patient in identifying pregnancy as early as possible. These include earlier initiation of pregnancy precautions and prenatal care if childbirth is desired, earlier detection of life-threatening complications such as ectopic pregnancy, opportunity for consideration of options such as therapeutic abortion or adoption, and increased time for counseling, regardless of the patient's ultimate choice.

Pregnancy Testing

Urine pregnancy tests use the enzyme-linked immunosorbent assay (ELISA) technique, using a highly specific monoclonal antibody directed against the β-subunit of human chorionic gonadotropin (β-hCG). Following implantation, the trophoblast begins to secrete β-hCG 9 to 11 days following ovulation. Concentration of this hormone doubles approximately every 1 to 3 days, reaching about 100 mIU per mL at the time of the first missed menses. Levels rise rapidly during the early stages of pregnancy, roughly doubling every 2 to 3 days until 6 to 8 weeks' gestation, and then fall gradually and level off by 20 weeks' gestation. Available urine pregnancy kits are qualitative and detect levels of 5 to 50 mIU per mL, which allows the diagnosis of pregnancy to be made 7 days after implantation (10 to 14 days following conception), with a sensitivity of 98%; this timing usually coincides with a missed menses. These tests can be performed in less than 5 minutes and have a false-negative rate of less than 1%. The most common cause of a false-negative test is very early pregnancy, with a β-hCG level below the test's detectable range. Therefore, if pregnancy is suspected, repeat testing should be done in 1 week. Urine pregnancy tests using ELISA are specific to the β-subunit of β-hCG, and generally do not cross-react with structurally similar proteins such as Follicle Stimulating Hormone (FSH) and Leutenizing Hormone (LH). Conditions other than pregnancy that can lead to β-hCG production and a false-positive pregnancy test include choriocarcinoma, embryonal cell carcinoma of the ovary, and neuroendocrine tumors of the lung, adrenal, and liver, and a recent pregnancy loss usually within the last month.

An alternative test is the quantitative β-hCG level, measured on serum samples, employing radioimmunoassay. Quantitative β-hCG testing is expensive and time-consuming and offers no advantage over urine tests in making the diagnosis of uncomplicated pregnancy. However, this test is helpful when complications of pregnancy are suspected. Levels of β-hCG that are abnormally elevated for gestational age may indicate multiple gestation or molar pregnancy. Abnormally low levels, or levels that fail to increase appropriately in the first 8 weeks, may indicate spontaneous abortion or ectopic pregnancy. After delivery or fetal loss beyond the first trimester, the β-hCG level decreases rapidly over 2 weeks, and may be undetectable by urine or serum test by 3 to 4 weeks. Following first trimester loss when the serum concentrations are much higher, β-hCG may be detected for 8 weeks.

Evaluation

Once the diagnosis of pregnancy has been determined, goals of the ED evaluation include (i) dating the pregnancy, (ii) recognizing symptoms that require immediate referral for obstetric or gynecologic evaluation, (iii) identifying and treating presenting and potential nonsurgical complications, (iv) assessing chronic medical conditions, (v) providing appropriate counseling, and (vi) securing appropriate and timely follow-up.

The Nagele rule can be used to establish the estimated date of confinement if the date of the last menstrual period is known and the teen has regular periods. To use this rule, add 7 days to the first day of the last menstrual period, subtract 3 months, and add 1 year. A bimanual examination is indicated to determine uterine size and to assess the integrity of the cervical os. The uterus is enlarged to the size of an orange at 8 weeks' gestation, and at 12 weeks is palpable just above the pelvic brim. The fundus reaches the umbilicus by 20 weeks.

Key components of the history, physical examination, and laboratory examination for all teenagers diagnosed with pregnancy are reviewed in Table 130.2. In the ED, it is imperative to recognize those patients who are immediately at risk for life-threatening complications and require acute resuscitation and emergent evaluation by a surgical subspecialist. Figure 130.6 describes an overall approach to teens with possible pregnancy. It is imperative that both the medical and psychosocial aspects of the diagnosis be addressed.

Pregnant patients who present with vaginal bleeding, with or without abdominal pain, represent a high-risk group. First-trimester vaginal bleeding occurs in 20% to 25% of patients. Common etiologies include ectopic pregnancy, spontaneous and incomplete abortion, missed or threatened abortion, STI, and trauma. The initial laboratory workup should always include a complete blood count, both to assess the amount of blood loss and to provide a baseline if bleeding continues. A urinalysis can detect the presence of white blood cells, bacteria, glucose, or protein. Other laboratory screening tests that are rarely indicated during an ED evaluation include Papanicolaou smear, syphilis serology, HIV testing, rubella

TABLE 130.2

EVALUATION OF THE TEEN WITH SUSPECTED PREGNANCY

History
Date of last menstrual period (date of conception)
Contraceptive use
Previous sexually transmitted disease
Previous upper genital tract infection or surgery
Gravity, parity, previous abortion
History of previous ectopic pregnancy
Lower abdominal pain
Vaginal bleeding, discharge, dysuria
Vomiting, diarrhea
Past medical history
Medications
Allergy

Physical examination
Vital signs
Abdominal examination/fundal height
Pelvic examination/uterine size (first trimester)

Laboratory tests
Urine β-hCG
Baseline serum quantitative β-hCG (if uterine size discordant with dates)
Urinalysis
CBC, RPR
Testing for *Neisseria gonorrheae* and *Chlamydia trachomatis*
Wet mount (*Trichomonas vaginalis*, presence of WBCs)
Pelvic/transvaginal ultrasound

hCG, human chorionic gonadotropin; CBC, complete blood count; RPR, rapid plasma reagent, WBCs, white blood cells.

serology, and hepatitis B serology. If unknown, Rh determination is indicated if there is uterine bleeding. It is important to note that Rh-negative teens with pregnancies greater than 8 weeks' gestation should receive Rh immunoglobulin if there is risk of fetal or placental blood loss.

Ectopic pregnancy is the leading cause of maternal mortality in the United States during the first half of pregnancy; therefore, timely recognition and treatment is imperative. The prevalence of ectopic pregnancy among women presenting to an ED with first trimester bleeding and/or pain ranges from 6% to 16%. The CDC has reported that the overall mortality from ectopic pregnancy fell from 35.5 to 5.4 deaths per 10,000 ectopic pregnancies from 1970 to 1988, attributed to improvements in earlier diagnosis and treatment. Although the overall incidence of ectopic pregnancy in teenagers is low, this group has the highest mortality rate, largely due to a tendency to delay seeking care. Risk factors for ectopic pregnancy include prior ectopic pregnancy, tubal abnormalities, prior upper genital tract infection, and assisted reproduction. The use of intrauterine devices does not increase the risk of ectopic pregnancies. Their use has been associated with ectopic pregnancies because they are effective in preventing intrauterine pregnancies. In the rare occasion that implantation does occur, it is more likely to be in an ectopic location.

The diagnosis of ectopic pregnancy must be considered in any patient with vaginal bleeding and/or abdominal pain. Patients can present with a wide spectrum of symptoms, including abnormal vaginal bleeding; intermittent crampy, lower abdominal pain; or acute abdominal pain associated with shock (with or without vaginal blood loss). Fortunately, with the development of sensitive urine pregnancy tests, most patients with ectopic pregnancy present before rupture has occurred. The approach to these more stable patients includes subspecialty consultation, quantitative serum β-hCG levels, serum progesterone levels, abdominal and/or transvaginal ultrasound, and close follow-up. In a normal singleton pregnancy, serial serum β-hCG levels should increase by 67% every 48 hours during the first month of pregnancy. Levels that do not rise or rise more slowly than expected are indicative of an abnormal pregnancy (usually an ectopic pregnancy or a pregnancy that is destined to spontaneously abort). Serum progesterone levels may play some role in the diagnosis of normal versus abnormal pregnancy. A progesterone level greater than 25 ng per dL is seen in 95% of normal pregnancies; a level less than 5 ng per dL suggests an abnormal pregnancy. Ultrasound is used to visualize the uterine cavity to assess for the presence of a gestational sac. When the β-hCG level reaches the discriminatory zone (a level that varies based on local transvaginal ultrasound expertise), a gestational sac should be visible within the uterus. If no sac is seen, the pregnancy is presumed to be ectopic.

Therapeutic options at this point include curettage or medical termination with methotrexate or etoposide therapy, both chemotherapeutic agents. For patients undergoing curettage, the diagnosis of ectopic pregnancy can be confirmed by a lack of villi on pathologic specimens or by a fall in β-hCG levels 12 to 24 hours after the procedure. Emergency laparoscopy is indicated for patients in whom there is concern about hemodynamic stability or correct diagnosis, or in those with gestational sacs greater than 4 cm or hCG levels greater than 10,000 mIU per ng. Conservative medical management may be appropriate in adolescents who are stable; have no evidence of any bleeding; and have a hemoglobin of greater than 8 g per dL and a gestational sac less than 4 cm, without immunocompromise, bleeding diathesis, liver, or renal disease, providing that close follow-up can be secured. As many as 83% of patients meeting these criteria may experience spontaneous abortion and resorption. Methotrexate given as a single 50 mg per m^2 intramuscular shot results in successful involution of the pregnancy in 95% of cases. Slaughter and Grimes demonstrated a 92% cure rate in outpatient candidates using methotrexate therapy, with only 5% to 16% requiring a second dose. Lipscomb demonstrated a success rate of 94% when hCG levels were less than 10,000 mIU per ng. The side effects of this therapy are generally mild and self-limited. However, tubal rupture has been reported in 3% to 4% of cases. Thus, thorough discharge instructions along with close follow-up are very important.

Although less common, those presenting with an acutely ruptured ectopic pregnancy have an immediate life-threatening condition. These patients usually have a history of abnormal vaginal bleeding and intermittent pelvic pain. On physical examination, vital signs may reflect compensated or uncompensated shock, the abdomen is tender, the uterus is tender and may be slightly enlarged, and an adnexal mass may or may not be palpated after rupture has occurred. These patients require immediate subspecialty consultation with either gynecology or pediatric surgery, depending on the care setting. They should have continuous vital sign monitoring, fluid resuscitation with normal saline, and packed red blood cells as needed. Serial

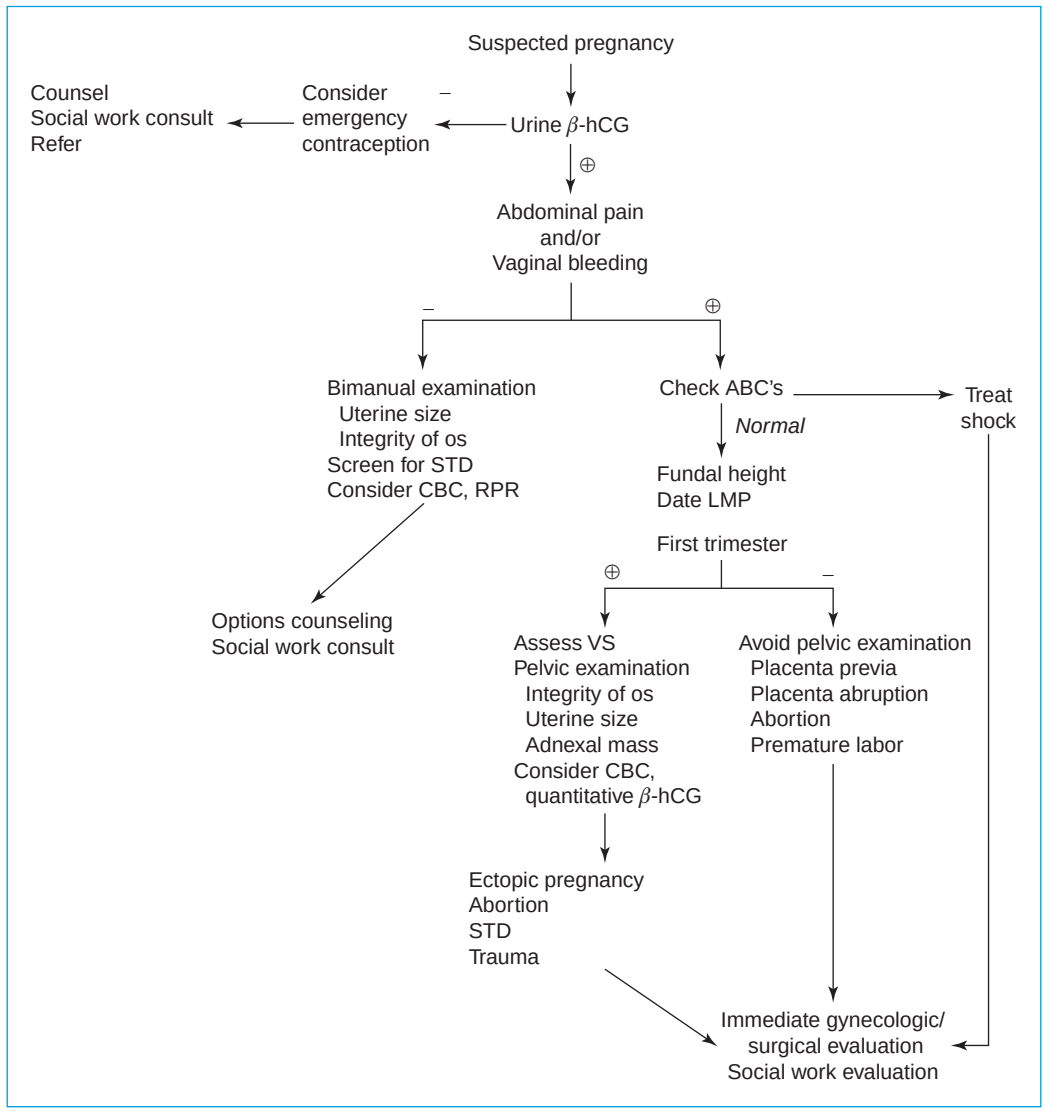

FIGURE 130.6 General approach to the pregnant teen. (From Mollen CJ, Pletcher J, Lavelle J. Emergency department management of teen pregnancy. *Clin Pediatr Emerg Med* 2002;4:61.). hCG, human chorionic gonadotropin; ABCs, airway breathing circulation: LMP, last menstrual period; VS, vital sign; STD, sexually transmitted disease; CBC, complete blood count; RPR, rapid plasma reagent.

hemoglobin determination, coagulation profile, Rh screening, and type and cross are important components of the laboratory evaluation. Emergency surgical evaluation is the treatment of choice. Ultrasound is contraindicated in the unstable patient and may delay surgical intervention.

Spontaneous abortion is another cause of vaginal bleeding in the pregnant teenager, which can be septic, threatened (or missed), inevitable, or complete. Spontaneous miscarriage is very common in early pregnancy, up to one-half of all fertilized ova that implant into the endometrium are lost. Most spontaneous abortions occur during the first trimester, although a small number occur after 20 weeks' gestation. Vaginal bleeding can indicate threatened abortion, when the patient's external cervical os is closed, or an inevitable abortion, when the external os is open. If products of conception are found in the vaginal vault of a patient with an inevitable abortion, the abortion is incomplete. Uterine curettage or vacuum aspiration may be indicated if bleeding is heavy and life-threatening, or if the patient desires to discontinue the pregnancy. The diagnosis of a complete abortion is made if an intact gestational sac is present following uterine curettage, or if there is reversion to a negative β-hCG.

Sexually transmitted infections should be considered in all pregnant teens. Screening for *Chlamydia trachomatis* and *Neisseria gonorrhoeae* can be accomplished using polymerase chain reaction (PCR) or ligase chain reaction (LCR) technology on a dirty urine specimen. A blind high vaginal swab for wet mount and Gram stain can be used to identify the presence of trichomonads and white blood cells. Trichomoniasis also is best detected by performing rapid antigen or PCR testing on a vaginal swab. When vaginal blood is present, a speculum examination is necessary to identify the site of bleeding. A bimanual examination detects the presence of upper genital tenderness, uterine size and presence of abnormal mass or fullness.

Physical and sexual abuse can be both a predictor and correlate of pregnancy in teenagers. In the evaluation of more than 1,000 primiparous teenagers by Fiscella et al., childhood sexual abuse was associated with younger age of first coitus and of first pregnancy. Furthermore, rapid repeat adolescent pregnancy has been associated with interpersonal violence in low-income teenagers. Finally, sexual abuse is a common precipitating event for pregnancy. Boyer et al. reported that of 295 adolescents with a history of sexual abuse, 12% did not consent to sex that led to their pregnancy. Similarly, Gershenson et al. reported that 60% of teen mothers had coercive sex and 23% became pregnant by perpetrators who were most often boyfriends, dates, or friends. The majority of pregnancies were associated with large gaps in partner age. For example, teen girls 11 to 12 years of age became pregnant by boys who were on average 10 years older. In response to some of this data, several states have begun to more aggressively enforce statutory rape laws. The possibility that sexual abuse may exist in teens concerned about pregnancy and/or diagnosed with pregnancy in the ED needs to be considered and explored. Health care providers are mandated to report significant concern for sexual abuse in all patients younger than 18 years of age. It is also important to assess safety issues and screen these teens for depression, substance abuse, and suicide risk. Usually, a multidisciplinary approach is required to ensure the patient is safe, as well as able to obtain appropriate counseling and medical follow-up.

Pregnancy in Teens With Chronic Illness

Physicians should also remember to include the possibility of pregnancy in teens with chronic illness. This is a group that may be experiencing the most rapid increase in pregnancy rates. In addition, in teens with certain chronic conditions, the pregnancy may be considered high risk. One study of sexual behaviors in adolescents with chronic illness or disability indicates that teenagers with chronic conditions are as sexually active as their otherwise healthy counterparts, regardless of the visibility of the chronic condition. Furthermore, contraception may be less effective in teenagers with chronic illness for multiple reasons.

Counseling and Legal Issues

Counseling the teen regarding the options for pregnancy may be the most important part of the visit. In the changing, demanding environment of the ED, it is important to secure a quiet, focused time. This is best done using a multidisciplinary team comprised of physicians, nurses, and social workers. The social worker plays a crucial role in providing continuous support, identifying important social and mental health concerns and important outpatient resources, and providing ongoing dialog throughout the ED visit.

Confidentiality should be maintained throughout the visit to encourage autonomy, protect privacy, promote necessary medical follow-up, and guard the teen from any physical harm or humiliation that may result from disclosing pregnancy status to family member. The results of the test are best initially shared with the adolescent alone. At this time, the practitioner has the opportunity to encourage the teen to share the information with a trusted adult friend who can offer support and assistance to the teen in necessary follow-up. The teen may choose to share this information with those that have accompanied her to the ED or her partner, or may want to contact another adult. A nonjudgmental and compassionate approach will assist the teen in choosing the option that suits her life situation best because she is the one who will be most affected by that choice. There are certain situations in which disclosure is required, regardless of the teen's wishes. Every state has enacted mandated reporter statutes that include suspected physical or sexual abuse and suicidal or homicidal ideation; some states include pregnancy in young women younger than 13 years old in the definition of child sexual abuse.

Options with regard to pregnancy outcome include parenting the child, adoption, and termination. By far, the most common outcome is the choice to parent the child. Adolescents are twice as likely as older women to have no or only third-trimester prenatal care. Those choosing this option will fare best if they have scheduled follow-up in a comprehensive, teen-based prenatal program. It is important to include the option of adoption when counseling, even though few teenagers choose this option. For those choosing termination, it is essential to provide information regarding the procedure and where it can be done, as well as assistance in overcoming any financial and social barriers. This option is easier physically, psychologically, and financially if done in the early stages of pregnancy. Although many states have enacted parental notification or consent requirements prior to a minor undergoing abortion, these statutes do not apply to options counseling, which should remain confidential. A current list of state provisions regarding specific requirements is available at the website of the Alan Guttmacher Institute (www.agi-usa.org). Fortunately, the majority of teens that have abortions involve a parent/guardian in this process.

In the ED setting, it is optimal to ensure scheduled follow-up in 2 to 3 days with the teen's primary care provider or an adolescent medicine specialist. It is also important to review the patient's medical insurance and link him or her to eligible coverage/resources. This allows the teen to consider all options and make the best choice. The ED social worker also plays an important role by contacting the teen to answer questions and aid in identification of resources, as well as ensuring follow-up. Forman et al. prospectively followed 96 diagnosed teen pregnancies and found that the time to referral appointment was significantly shorter for patients who planned to terminate their pregnancy, compared with those who planned to continue it. The need to arrange close follow-up and to facilitate connection to care following the ED visit should not be underestimated.

Adolescents With Negative Pregnancy Tests

Those teens that present with concern for possible pregnancy, but whose pregnancy tests are negative, represent a group at higher risk for future pregnancy and STI acquisition. Intervention in the ED should include evaluation for STIs, as well as counseling regarding effective birth control and emergency contraception (EC). These patients benefit from a social work evaluation with focus on the teen's home environment, need for mental health services, medical insurance, and access to health care. Approximately, one-third of adolescents presenting to a clinic setting requesting a pregnancy test are pregnant. Almost three in every five teens had a negative pregnancy test result at a clinic before ever becoming pregnant. Further, at least one-half of these teens are not using effective birth control. The majority feel positive or ambivalent with regard to becoming pregnant, 15% may actively try to conceive, and 50% believe

their partner wants them to become pregnant. Overall, 56% of teens who initially test negative will become pregnant over the following 18 months. Obviously, pregnancy prevention requires a comprehensive, longitudinal program; however, education can begin during the ED visit and an effort can be made to link the teen with an effective health care program.

Emergency Contraception

More recently, the U.S. Food and Drug Administration (FDA) declared that using a combination of ethinyl estradiol and levonorgestrel, or levonorgestrel alone, to be safe and effective forms of emergency contraceptive. In 1998, Preven was approved by the FDA and includes a pregnancy test, four Ovral® tablets (each containing 0.05 mg ethinyl estradiol and 0.5 mg norgestrel), two tablets to be taken 12 hours apart, along with instructions. In 1999, a dedicated progestin-only product (Plan B®) was approved, which includes two tablets of 1.5 mg norgestrel. Initial labeling indicated the tablets to be taken 12 hours apart, but recently that was changed to give both tablets at once and now has been updated to give one 1.5 mg tablet × 1 dose. Both regimens should be given within 120 hours of unprotected intercourse. Two years ago, the FDA approved the nonprescription sale of Plan B to anyone older than 17 years.

There are very few side effects to the use of emergency contraception. Nausea, less commonly seen in patients using the progestin-only method, can be relieved by prescribing an antiemetic 1 hour prior to each dose. Ninety-eight percent of women will have withdrawal bleeding by 3 weeks; if this does not occur, a follow-up pregnancy test is required. Contraindications for the combined method are the same as those for combined oral contraceptive use. Contraindications for the progestin-only method include pregnancy, undiagnosed vaginal bleeding, and allergy. Pregnancy is considered a contraindication simply because if pregnant, the medication will not work, not because its use will impose any risk to the fetus. Use of the combined regimen results in approximately 75% reduction of pregnancy. The use of the progestin-only method results in an 89% reduction. The mechanism of action is presumed to be delay or inhibition in ovulation, or decrease in tubal motility.

Employing a telephone survey, Delbanco et al. found that only 23% of teens were aware that anything could be done to prevent pregnancy after unprotected sex. Of those teens who did have some knowledge of it, 32% did not know that a prescription was required and 78% underestimated the length of time after unprotected sex that this method would be effective. However, after hearing about this option, two-thirds of the teens stated they would likely use them. Todd and colleagues found that almost one-third of women younger than 18 years of age, presenting to an urban ED, had an unintended pregnancy risk, thus the option of EC may be underutilized. Providers should document the date of the last menstrual period, the time/times of intercourse, use of other methods of contraception, symptoms of pregnancy, any contraindications that the patient may have for this therapy, and the results of a urine pregnancy test. Knowledge regarding this safe and effective method of pregnancy prevention is important to health providers routinely caring for adolescents.

Delivery

Patients presenting to the ED in active labor should be transferred to the obstetrical unit as soon as possible. However, even in a PED, patients have presented when the newborn is crowning, making transfer impossible. Fortunately, the majority of deliveries occur spontaneously, and the primary role of the clinician is to control the process. However, a subspecialist should be called to the ED to deliver the newborn whenever possible.

All EDs should have the necessary equipment for this procedure, which includes surgical scissors, three hemostats, a cord clamp, a bulb syringe, sterile sponges, sterile towels, a basin, and povidine–iodine solution. Warm blankets, a warmed isolette, and neonatal resuscitation equipment are also needed. If possible, document date of the last menstrual period, the estimated date of conception, prenatal care, significant health problems, current medications, the time the contractions began and the interval between them, and whether membranes have ruptured. Examine the perineum for bleeding, prolapsed cord, crowning, or fetal parts. If there is significant vaginal bleeding, avoid cervical examination so as not to precipitate bleeding if the patient has a placenta previa. If there is no significant bleeding, cleanse the vaginal area, and using a sterile gloved hand, assess degree of cervical dilation and effacement. When there is complete cervical dilation (10 cm) and effacement (thin, flat cervix), and the head is at the perineum, delivery is imminent. As the head advances place one hand on the suboccipital area of the infant's head to control the speed of delivery, with the other hand apply moderate upward pressure to the fetal chin to decrease perineal injury. Gently suction the nose and mouth of the infant. Check for the presence of a nuchal cord, and gently slip it over the infant's head. If this is not possible, the cord should be clamped in two places and cut in between these clamps to avoid anoxia. Gentle downward traction of the head assists delivery of the anterior shoulder followed by upward traction to deliver the posterior shoulder. Control the remainder of the delivery, then hold the infant with the head down at a 15-degree angle for approximately 1 minute, allowing for secretion drainage and a small blood transfusion from the placenta. The umbilical cord is then clamped and cut, and the infant can be handed off to another clinician. The placenta usually spontaneously delivers within 5 to 30 minutes; palpate the uterus afterward to stimulate contractions and reduce blood loss. The mother should be transferred to an obstetrical unit as soon as possible.

Rape/Sexual Assault

Rape is defined as genital contact without consent, through use or threat of use of force or fraud, or when the victim is unable to give consent because of physical or mental disability. Statutory rape is intercourse with a female younger than the age of consent, which is considered to be 16 years in most states. The term *incest* applies to the situation in which the assailant and victim are related, and therefore, could not legally marry or have a functional situation simulating this relationship. *Sexual abuse* or *molestation,* a broader term, is involvement of the adolescent in activities that he or she does not fully comprehend. These include exhibitionism, fondling, oral–genital contact, and rectal or vaginal penetration. Incest is probably the most common form of adolescent abuse, and is the most underreported and difficult to prove.

Females of ages 12 to 24 years are at the greatest risk for experiencing a rape or sexual assault. More than one-half of

all rapes of women occur before age 18 years; 22% occur before age 12 years. Fewer than one-half (48%) of all rapes and sexual assaults are reported to the police; these represent the tip of the iceberg. According to the 2007 Youth Risk Behavior Surveillance System (YRBSS), 7.8% of students had been forced to have sexual intercourse. Female students (11.3%) were significantly more likely than male students (4.5%) to have been forced to have sexual intercourse. Black students (10.5%) were more likely than white students (7.0%) to have been forced to have sexual intercourse. According to the 2000 National Crime Victimization Survey, 62% of rape and sexual assault victims knew the perpetrator. More than 40% of rapes and sexual assaults came at the hands of a person the female victim called a friend or acquaintance.

Due to the magnitude of this problem in the pediatric age group, the pediatric emergency physician should develop skills in treating these patients. In many cities, Sexual Assault Response Teams have been developed to provide comprehensive and consistent care to these patients. Physicians practicing in a particular area must be knowledgeable of the state laws regarding the care of adolescents.

Clinical Manifestations

Adolescent victims present in one of the following two ways: (i) following an acute event with an unknown perpetrator, or (ii) after acute stress when an incestuous relationship is revealed. All patients who have been assaulted within the previous 72 hours or those with symptoms should be evaluated on an emergency basis. Asymptomatic patients with ongoing chronic abuse (not occurring in the preceding 72 hours) can be scheduled in special outpatient clinics designed to care for this particular group. These patients benefit from a multidisciplinary approach, including physicians, social workers, nurses, and psychologists, to provide optimal care. SANE (sexual assault nurse examiner) programs have been very successful in providing standardized evaluation and evidence collection in these patients. The aim of the acute intervention is to obtain the details of the incident, perform a complete medical evaluation, collect medicolegal evidence, and provide appropriate medical and psychological follow-up. The acute intervention is not intended to ascertain whether a crime was committed. All suspected cases of abuse/rape must be reported to the police.

Evaluation and Management

Consent for interview, examination, and collection of evidence should be obtained from the victim. Accurate and thorough records are of the utmost importance. The victim should be given control of the situation and has the right to terminate the process at any point. A supportive female or male, or ideally an experienced rape counselor/nurse, should be present throughout the interview and examination. The patient should be placed in a secluded, quiet room as soon as possible after arrival.

The history should include the details of the event, including time and place; the details of the sexual acts (including whether oral, rectal, or vaginal penetration occurred); whether ejaculation occurred; the force or threat that was used by the assailant; the name and relationship of the perpetrator; and the associated use of alcohol, drugs, or weapons. Hygiene, including bathing, douche, or change of clothes after the event, should be recorded. Medical history, including menstrual history, sexual activity, previous history of STIs, birth control use, last intercourse, previous obstetric and gynecologic history, and history of health problems, should be documented.

As many as 46% of victims have nongenital injuries, with as many as 15% of them requiring therapy and follow-up. Up to 80% of victims have minor genital injuries, most of which are external and involve the posterior fourchette. These observations emphasize the need for a complete, careful examination. However, the presence of a normal examination does not imply that assault did not occur. Photographs should be taken with the victim's consent, whenever possible. However, the taking of photographs does not preclude careful, descriptive documentation of existing injuries on the patient's chart.

The physician should explain the parts of the examination before performing them to allow the patient to assume control and to alleviate as much anxiety as possible. A chaperone should always be present. A complete physical examination to assess for bruises, scratches, and SMR is needed. To prevent cross-contamination, the examiner should wear gloves and change them as often as needed.

There are a few general rules to consider when collecting forensic evidence. When in doubt, always collect the specimen for evaluation. Always air-dry the swabs used to collect the evidence. Place specimens in glass or paper containers for transfer. Do not lick the envelopes, and be careful when touching items that may have fingerprints. Core evidence includes cotton Q-tip swabs from the oral cavity, the vaginal vault, and the anus.

A description of the patient's general appearance and emotional status, as well as a description of clothing condition, begins the physical examination. The patient should undress while standing on a clean sheet. Each article of clothing is then placed in a separate, labeled, paper bag. The sheet that the patient stood on is also submitted as evidence. Describe all injuries, noting size, location, and color.

Comb the patient's hair over a clean sheet of paper to collect any debris/assailant hair, fold the paper, and place it in a labeled envelope. If there is history or evidence of oral trauma, a swab from the gum line and buccal mucosa can also be evaluated for the presence of sperm. Next, the victim should be asked to chew on a piece of filter paper or a cotton ball to obtain a sample of saliva. Eighty percent of people secrete blood group antigens in their saliva, sweat, and other body fluids.

Stains on the skin should be swabbed with saline-moistened swabs and stored in dry, labeled test tubes. These should be air-dried and placed in labeled glass tubes. The use of a blue light source may aid in identifying areas that should be swabbed and sent for forensic analysis. Debris under the fingernails should be removed with a wooden curette and placed in a labeled envelope. A careful external examination is paramount, and then the hymen and the posterior fourchette should be carefully inspected for areas of laceration. Matted pubic hair should be removed, and the remaining pubic hair gently combed into a labeled envelope.

The decision to perform and how to perform a speculum examination should be given careful thought. Although speculum examinations are almost never indicated on prepubertal females after assault, they are more commonly conducted in adolescents. However, the examination should always be preceded by clear and precise instructions about what the process will entail, as this may be the first time an adolescent female

has an internal examination. Moreover, the decision to perform a speculum examination becomes even more difficult if the patient is developmentally delayed. Given that the patient has already experienced significant trauma by virtue of being a victim of sexual assault, it may be necessary to perform the examination with the patient sedated to avoid any additional emotional or psychological trauma.

A speculum examination is indicated to assess for the presence of vaginal and cervical trauma. Avoid lubricants because they affect both sperm motility and culture results. If secretions are present in the posterior fornix, aspirate it and place it in a sterile container for sperm and acid phosphatase detection. Cotton swabbings taken from the posterior fornix should be used to make slides for detection of motile sperm, acid phosphatase, and blood group antigens. Vaginal swabs for wet mount and Gram stain should also be obtained. The remainder of the pelvic examination is completed in the usual manner. The rectum should be carefully examined. Some centers use colposcopy to identify and photograph genital injury.

Between 4% and 30% of rape victims contract STIs as a result of the victimization. Studies have shown that 2% to 12% of adolescents at the initial visit have gonorrhea, and 1.5% to 10% have chlamydia. On follow-up visit, 1% to 3% have positive cultures. The risk of *Trichomonas* and bacterial vaginosis range from 5% to 25%. Therefore, evaluation for STIs and prophylactic treatment is indicated (Table 130.3). The risk of human papillomavirus is unknown; however, the proportion of patients having abnormal Papanicolaou smears ranges from 3% to 27%. The risk of herpes simplex virus, syphilis, and HIV is low. Laboratory evaluation includes culture/LCR for chlamydia and gonorrhea, and vaginal specimens for trichomoniasis. Serum is sent for blood type, DNA identification, drug testing, syphilis, hepatitis B if the patient is not fully immunized, and HIV testing. Urine and serum for drug evaluation should be considered.

Follow-up of the patient 7 days after the initial examination is recommended by the CDC for repeat urine or vaginal specimens for gonorrhea, chlamydia, and *Trichomonas*. A test for syphilis should be repeated at 6 to 8 weeks. Testing for HIV is done again at 3 to 6 months after the incident, and if negative, again at 1 year. The risk of transmission after a single sexual assault is very low. Prophylaxis may be considered for patients presenting within 48 hours of the assault.

All patients should have a pregnancy test performed. Pregnancy occurs as a result of rape in 1% of victims. If the patient is not at risk for early pregnancy, a protocol for pregnancy prevention may be followed. This treatment should be given within 120 hours of the event.

A list of the comprehensive list of the evidence collected should be included in the patient's medical record. All specimens should be labeled carefully with the patient's name, medical record number, date and time of evidence collection, the location from which the evidence was collected, and the examiner's name and signature. Transfer of custody must be documented with the name of the person receiving the evidence and the date and the time of transfer.

Finally, all patients should have scheduled medical and psychological follow-up before discharge from the ED.

TABLE 130.3

PROPHYLAXIS OF ADOLESCENTS FOLLOWING SEXUAL ASSAULT

Chlamydia trachomatis	Azithromycin 1 g po once Doxycycline 100 mg po bid for 7 days
Neisseria gonorrhoeae	Ceftriaxone 125 mg IM/IV once
Trichomonas	Metronidazole 2 g po once Cefixime 400 mg po once Metronidazole 500 mg po for 7 days
Hepatitis B	Give vaccine if patient not fully immunized
HIV	Consider prophylaxis
Emergency contraception	

bid, twice a day; HIV, human immunodeficiency virus; IM, intramuscular; IV, intravenous; po, orally.

Interpersonal Violence: Detection and Intervention

Interpersonal violence has reached epidemic proportions in the United States, and adolescents are at particularly high risk for violence-related injuries. Homicide is the second leading cause of death for 15- to 19-year olds, and the CDC estimates the ratio of nonfatal injuries from physical assaults to homicides as 90:1. According to the 2007 YRBSS, 35% reported being in a fight in the last year and 18% reported carrying a weapon. Violence is not limited to the inner city; one study reported that 89% of students in a suburban middle school knew someone who had been robbed, beaten, stabbed, shot, or murdered, and 57% had witnessed such an event. In addition to physical injuries, youth involved in interpersonal violence are at risk for posttraumatic stress disorder, major depression, and substance abuse.

Multiple studies have helped refine the risk factors for violent injury; knowledge of these risk factors can assist the clinician in obtaining an appropriate screening history. Several key risk factors include a prior history of fighting, failing in school or having dropped out of school, and substance use. Other risk factors include weapon carrying, witnessing violence (in the home, in the community, through the media), lack of school "connectedness," depression, and quick temper. Although few studies have described effective screening tools for interpersonal violence, the emergency medicine physician can roughly gauge a youth's risk for future violent injury by inquiring about the risk factors described previously. Any adolescent being treated for a violent injury should be screened for future risk, with social work and community referrals available as needed. In the hectic environment of the ED, it is not always feasible to provide appropriate counseling for risk reduction; instead, knowledge of available community resources and linking the patient back to the PCP are key interventions.

More specifically, the American Academy of Pediatrics Task Force on Adolescent Assault Victim Needs outlines

appropriate care for the victims of interpersonal violence. After stabilizing and treating the patient's injuries, the guidelines recommend providing a thorough social work evaluation and determining appropriate follow-up, notifying the police when appropriate, and providing support for the patient's family and friends. In addition, the emergency physician should assess the risk of retaliation, both for the safety of the patient and the safety of the others involved in the incident, and be prepared to intervene if retaliation seems imminent (through the police or community resources).

CONCLUSION

The care of adolescents is both challenging and rewarding. They present to the ED with a wide spectrum of diseases and often require gynecologic evaluation and referral, crisis intervention, and medical or psychological follow-up. Thus, the ED should design an organized approach to the care of the adolescent patient.

CHAPTER 131 ■ BEHAVIORAL EMERGENCIES

MIRNA M. FARAH, MD, AND JOSEPH ZORC, MD, MSCE

This chapter reviews a number of conditions with prominent behavioral and somatic symptoms that may cause an infant or child to be brought to the emergency department (ED) (Table 131.1). Although these conditions rarely require emergency intervention, the associated symptoms, such as stereotyped movements or cyanosis, may mimic other disorders with important physiologic consequences. The conditions reviewed in this chapter are heterogeneous; age of onset, symptoms, and prognosis vary widely. Some are part of normal childhood development, and others likely have an organic or genetic basis. All these conditions, however, have prominent behavioral features as part of the history that are the key to diagnosis. Familiarity with these disorders aids the emergency practitioner in an appropriate evaluation followed by reassurance of the family and referral, if necessary, to a source for ongoing care that is the basis for treatment.

GENERAL APPROACH

Diagnosis of these disorders depends on obtaining a history of symptoms associated with the child's other activity at the time. Organic conditions such as seizures (see Chapter 69) or syncope (see Chapter 73) are involuntary and usually unrelated to other behaviors. Gathering the necessary information requires a careful history because the child's caregiver may not recognize the behavioral nature of the event and emotional response may cloud recall. The clinician should review the episode chronologically in detail; key data include any precipitating events (e.g., breath-holding attacks, hyperventilation); the child's level of consciousness before, during, and after the episode (sleep disturbances); and any history of similar symptoms in the child or family members (tics). Having the caregiver act out the episode to demonstrate it and allow for measurement of duration may be useful. Social history and assessment of family dynamics (see Chapter 133) may further strengthen the diagnosis of some of these disorders.

Further evaluation beyond a careful history and physical examination is generally unnecessary for these conditions. The clinical picture may be specific enough to lead to the correct diagnosis. Laboratory values are generally normal or merely document the degree of symptoms (e.g., cyanosis) that has occurred. If the history is unclear or ambiguous, further investigation or referral may be warranted to rule out an important diagnosis, as discussed in the appropriate chapter of this text. As in all uncertain clinical scenarios, the degree of evaluation should reflect the seriousness of potential diagnoses, in accordance with the maxim primum non nocere (above all, do no harm).

Management of these disorders generally requires referral to a physician with an ongoing relationship with the patient, the child's medical home. For some of the conditions that are part of normal development (e.g., night terrors), reassurance may be all that is necessary. Nevertheless, the emergency practitioner may play an important role in this process because he or she may have the best opportunity to obtain important historical information that may be forgotten by the time of a later evaluation. The effect that a correct initial diagnosis may have on preventing unnecessary tests and reducing further anxiety should not be underestimated.

BREATH-HOLDING SPELLS

Background

Breath-holding spells in young children have been described since antiquity; accounts of this condition can be found in the works of Hippocrates, Rousseau, and Dickens, among others. In the modern medical literature, Lombroso and Lerman characterized the clinical syndrome in a group of 225 children with breath-holding spells. These patients were identified in a prospective study of almost 5,000 children, suggesting an incidence of 4.6%. The physicians described episodes of apnea and color change followed by loss of consciousness and postural tone that appeared to be triggered by an inciting event such as pain, fright, or agitation. Breath-holding children were categorized as cyanotic (62%), pallid (19%), or indeterminate (19%), on the basis of the type of color change. These subgroups appeared to have distinctly different clinical features. Cyanotic breath-holding spells were usually preceded by vigorous crying; pallid spells were sudden and more likely to be followed by convulsive activity.

Pathophysiology

Although the cause of breath-holding spells remains unclear, research has refined the understanding of this condition. The diagnostic term itself is a misnomer. *Breath-holding* would suggest voluntarily "waiting to exhale"; however, most episodes appear to be involuntary and to occur at the end of expiration. Studies of breath-holding children have reported associations with autonomic dysfunction and anemia, as well as an apparent familial predisposition. The clinical difference observed between pallid and cyanotic spells may have a basis in pathophysiology; pallid breath-holding spells can be reproduced by a vagal stimulus and are associated with subtle differences in autonomic function. These findings suggest a similarity to vasovagal syncope or neurally mediated hypotension

TABLE 131.1

BEHAVIOR-RELATED PROBLEMS PRESENTING WITH SOMATIC SYMPTOMS

Cyanosis
Cyanotic breath-holding spells

Syncope
Cyanotic or pallid breath-holding spells

Motor Activity
Tic disorders and Tourette's syndrome
Paroxysmal choreoathetosis
Benign paroxysmal torticollis
Opsoclonus and myoclonus
Spasmus nutans
Gratification disorder (infantile masturbation)

Hyperventilation Syndrome

Sleep-Related Disorders

as described in adults, although further confirmatory research is needed.

Diagnosis

The diagnosis of breath-holding spells is based on the clinical history. Initial presentation usually occurs within the first 2 years of life and is not associated with other physical, developmental, or behavioral disorders. The typical episode begins with an inciting stimulus such as anger, frustration, fear, or pain. The child begins to cry, either briefly or for a prolonged period, and then suddenly stops in full expiration with mouth wide open. The spell may resolve at this point or proceed to color change followed by loss of consciousness. The child then becomes limp but soon may progress to an opisthotonic posture. Return to consciousness usually occurs within 1 minute. Severe breath-holding episodes may be associated with body jerks or incontinence and a transient recovery period of several minutes.

When a child is evaluated after a breath-holding spell, the clinician should expect to find normal findings in physical examination. Laboratory test results are also usually normal and add little to the evaluation. Some physicians suggest measuring hemoglobin level because anemia has been associated with breath-holding spells. Electroencephalogram (EEG) performed during a spell reflects hypoxemia but returns to normal afterward. Thus EEG is not recommended as a diagnostic test.

The differential diagnosis of breath-holding spells includes seizure disorders (see Chapter 69), structural cardiac disease (e.g., tetralogy of Fallot), arrhythmia (e.g., long QT syndrome; see Chapter 84), syncope (see Chapter 73), and apnea (see Chapter 9) secondary to infection, brain tumor, injury, or congenital causes. A characteristic history in a healthy child with normal physical examination findings should be sufficient to make the diagnosis. The key elements of the history are identifying the precipitating event (which may include minor trauma) and determining that the color change preceded any motor activity (unlike most seizures). In uncertain cases involving syncope, an electrocardiogram (EKG) is advisable to measure the QT interval corrected for heart rate.

Management

Once the diagnosis has been made, parents should be reassured that there is no evidence of long-term sequelae from typical childhood breath-holding spells. The relationship between the inciting event and the spell should be explained, as well as the possibility of recurrence. Frequency of recurrence varies from daily to yearly, but most breath-holding children stop having spells by school age. Inciting events such as pain and frustration are to be expected in healthy children, and overzealous attempts at prevention may impair the exploratory behavior and appropriate limit setting that is part of normal development. If a spell recurs, parents should be instructed to clear the airway and place the child in a lateral, supine position away from other objects. In severe cases, referral to a specialist is indicated because treatment with atropine, scopolamine, other medications, or a cardiac pacemaker has been helpful in selected cases. A randomized trial found a reduced frequency of spells in children treated with iron, although the efficacy of this treatment in nonanemic children remains unclear.

TICS AND MOVEMENT DISORDERS

Tics are involuntary, rapid, repetitive movements or vocalizations that may present throughout childhood and be confused with seizures or other disorders. Tic disorders affect 2% to 5% of school-aged children and range from mild, self-limited symptoms to the chronic Gilles de la Tourette's syndrome, which can be severe and debilitating. Boys are affected with tics three times as commonly as girls, and familial predisposition has been well documented. Attention deficit/hyperactivity disorder (ADHD) and obsessive-compulsive disorder are more common in children with tics. A recent area of research interest has been a hypothesized increase in tics and obsessive-compulsive symptoms following group A streptococcal infections known as *PANDAS* (pediatric autoimmune neuropsychiatric disorders associated with streptococcal infections). A recent large cohort study suggests that this association, if present, accounts for a small subset of these symptoms among selected children.

Diagnosis of tic disorders relies on obtaining a history of stereotypical, involuntary motor activity that most often involves the muscles of the head and neck. Eye movements, head twitches, and shoulder shrugs are common, although complex movements and vocalizations may also occur. Unlike partial seizures, tics are nonrhythmic and partially suppressible, which may result in their being absent at the time of an evaluation. Tics tend to increase at times of anxiety, stress, and fatigue and decrease during sleep or relaxation. Tics may be precipitated by medications, especially stimulants such as methylphenidate. The differential diagnosis of tic disorders includes chronic diseases affecting the central nervous system, such as Wilson's disease, Sydenham's chorea, and metabolic disorders. A toxic cause should be considered because adverse reactions to many medications, including neuroleptics, metoclopramide, and antihistamines, can present with dystonic symptoms simulating tics.

ED evaluation and management of tics should be limited to establishing the diagnosis by history and ruling out other conditions. Physical examination finding is usually normal.

Laboratory tests, imaging studies, and EEG results are also usually normal and generally unnecessary. The emergency practitioner should reassure the family that tics are not harmful and should encourage further discussion with a continuing care provider. Mild tics in young children often resolve spontaneously; more severe tics may require referral to a neurologist or psychiatrist for consideration of pharmacologic treatment.

Other movement disorders of childhood are listed in Table 131.1. Disorders of paroxysmal choreoathetosis are usually chronic and familial. Opsoclonus–myoclonus is a syndrome of chaotic, irregular eye movements that is associated with neuroblastoma in more than 50% of affected patients. *Spasmus nutans* is a condition involving head tilt, nodding, and nystagmus that presents in infancy and is associated with optic glioma in some cases. Benign paroxysmal torticollis presents in infancy with recurring episodes lasting minutes to days and must be differentiated from posterior fossa tumors and other conditions. Gratification disorder is a condition of stereotyped self-stimulatory movements in young children that may resemble epilepsy but can be interrupted with distraction.

HYPERVENTILATION SYNDROME

Background

Hyperventilation is defined as ventilation in excess of that required to maintain normal arterial blood partial pressure of oxygen (Pa_{O_2}) and partial pressure of carbon dioxide (Pa_{CO_2}). This causes the elimination of more carbon dioxide than is produced, resulting in respiratory alkalosis and an elevated blood pH. Hyperventilation may be produced by an increase in either frequency or depth of respiration. The pathophysiology of the hyperventilation syndrome contains two components: (i) physiologic derangement produced by hyperventilation and (ii) underlying psychiatric disturbance most often including anxiety and panic.

Clinical Manifestations

Onset is typically around 13 to 14 years of age. Girls are affected twice as often as boys. Patients almost always report that their symptoms occur in "spells" or "attacks" lasting a few minutes to several hours each. In the ED, patients can present with various combinations of symptoms, including dyspnea, tachypnea, breathlessness, chest tightness and pain, palpitations, anxiety, panic and a feeling of impending doom, paresthesias, coldness of the extremities, tetany, trembling, blurred vision, light headedness, syncope, or seizure. Physical examination may reveal obvious hyperventilation, or more commonly, periodic deep-sighing respirations.

EKG changes, such as ST-segment depression and flattening and inversion of T waves, both in the resting and exercise EKG, have been reported in adults who hyperventilate. However, unlike in ischemia, these changes occur early in exercise and disappear as exercise continues.

Differential Diagnosis

The manifestations of hyperventilation syndrome are variable and can initially seem worrisome. Organic disorders that require serious consideration in the differential diagnosis include asthma, metabolic acidosis (e.g., diabetic ketoacidosis), hyperammonemia, hypocalcemia, drug intoxication (including salicylism), hypercapnia, cirrhosis, organic central nervous system disorders, fever, and the response to severe pain. A few paroxysmal disorders, such as hypotensive syncope, Stokes–Adams attacks, epilepsy, and migraine, should be ruled out. However, many of the previous organic disorders can be excluded on the basis of careful history and physical examination. A clinical problem is that hyperventilation syndrome and asthma often coincide, leading to a vicious circle—that is, asthma symptoms increase anxiety, which may induce hyperventilation.

Elements of history that suggest the diagnosis of hyperventilation syndrome include lack of nocturnal symptoms; sudden occurrence, sometimes at rest without typical trigger factors; chronicity or variable duration of symptoms; lack of response to adequate pharmacotherapy (e.g., for asthma); reference to breathlessness; expression of anxiety; and finally, normal results of a diagnostic workup. Intensive efforts should be made to diagnose functional symptoms at an early stage because this will prevent stigmatization and fixation of symptoms and disease and will also prevent children from undergoing unnecessary and potentially harmful therapies. Assessing whether voluntary hyperventilation reproduces the patient's symptoms is also helpful. This provocation test is currently the best diagnostic method and is accomplished by asking the patient to hyperventilate for at least 3 minutes, enough to bring the Pa_{CO_2} to less than 50% of baseline. Termination of symptoms on rebreathing into a paper bag is another suggestive finding. When the syndrome is recognized, extensive laboratory evaluation is rarely required in the pediatric population and may add to the child's anxiety. However, as in many clinical situations that result in a diagnosis with psychological or psychiatric implications, the emergency physician may rarely elect to order laboratory data to support the diagnosis. The specific tests obtained should be determined by the patient's symptoms but will usually be selected from among chest radiograph, EKG, serum calcium and electrolytes, and blood gas determinations.

Treatment

The therapeutic approach to hyperventilation syndrome has several stages and/or degrees of intervention:

1. Psychological counseling: "Reassurance" by physicians, family, and professionals is the most prominent instrument to reduce or diminish observed respiratory symptoms in the absence of significant organic abnormality. Reassurance measures may include the demonstration of normal diagnostic results to patients and parents. Children and adolescents need to be reassured in specific terms relevant to their fears. Child life specialists or social workers are most helpful in this treatment. Counseling and supportive therapy are necessary to discover the sources of the psychological disturbance experienced by the child. These efforts should start in the ED, but psychiatric consultation and/or referral is often required.
2. Physiotherapy: The classic remedy for hyperventilation is relaxation and breathing into a paper bag. The patient rebreathes his or her own expired air and thus inhales air

enriched with CO_2. Most experts recommend that the patient understand the mechanism by which the symptoms are produced. For adolescents, in particular, emphasizing that the patient has control over the production of symptoms is important. This understanding is often accomplished by voluntary overbreathing and attribution of cause of symptoms to hyperventilation. Relaxation techniques such as self-hypnosis may positively influence the pathological breathing pattern and slow down the respiratory rate. Relaxation may also diminish the underlying anxiety. Parents and others should also avoid reinforcing the patient's symptoms through attention.

3. Pharmacotherapy: A major goal is to avoid or reduce the use of pharmacotherapy, limiting it to patients who fail to respond to education and counseling. Propranolol and anxiolytics have been used successfully in children to interrupt these spells. The prognosis of hyperventilation syndrome in children and adolescents is worrisome, with 40% of patients showing persistent symptoms into adulthood.

SLEEP DISTURBANCES

Background

Childhood sleep disturbances are common, occurring in 20% to 30% of children between the ages of 1 and 8 years. They are often a clue to underlying emotional or family stresses during certain childhood developmental stages. The predominant sleep disturbances include resistance to being put down for the night, frequent nighttime awakenings in infancy, and parasomnias in school-aged children. Anticipatory guidance on the part of the primary care physician can minimize the impact of these disturbances.

Clinical Manifestations and Management

Parasomnias

Parasomnias are physical phenomena during sleep that do not usually result in excessive daytime sleepiness. They can be subdivided into four groups: arousal disorders, sleep–wake disorders, rapid eye movement (REM) sleep disorders, and other parasomnias, such as sleep enuresis and sleep bruxism.

Arousal Disorders. Arousal disorders tend to occur during the first third of the night, in the transition from deep non-REM to light non-REM sleep. A positive family history is often present. The disorders are paroxysmal, often associated with activation of the autonomic nervous system and skeletal muscles, unresponsiveness to the environment, and amnesia for events. Most of these episodes last 2 to 10 minutes, followed by a rapid return to sleep. Intercurrent illnesses, medications, physical or mental fatigue, sleep deprivation, and emotional distress can trigger these parasomnias in susceptible individuals.

Confusional arousals are brief episodes of confused state seen most commonly in children younger than 5 years. The brain is only partially awakened during these episodes. They consist of disorientation in time and space, slow speech and mentation, and bizarre behavior, such as placing a piece of cloth in the refrigerator. Children do not express fear or panic and spontaneously return to sleep with no recollection of the event the following morning. These episodes are benign and gradually decrease in frequency with age.

Pavor nocturnus (night terrors) are dramatic events which may occur at any age and seen in as many as 20% of children between 5 and 7 years of age. The child abruptly awakens 15 to 90 minutes after sleep onset, with a piercing scream or cry, sits up in bed with wide-open eyes, extreme anxiety, and autonomic phenomena (sweating, flushing, and rapid heartbeat and breathing). The child appears confused, is not able to recognize the parents, and is inconsolable for 10 to 15 minutes. Then he or she relaxes and falls back to a quiet sleep with no recollection of the event in the morning. Night terrors usually occur so rarely that treatment is not necessary. Their frequency decreases with age.

Somnambulism (sleepwalking) appears in children 4 to 6 years of age. The child sits up suddenly with eyes glassy and staring and may then arise and walk around clumsily toward a light or a noise. During sleepwalking, children often appear confused, and many attempt to vocalize inappropriate answers to questions. Other bizarre behaviors include urinating in closets, ambulating outside, or climbing out of a window. The episodes usually last less than 15 minutes, and when the child is returned to bed, he or she will fall asleep uneventfully. Temporal lobe epilepsy may be difficult to distinguish from somnambulism but can be differentiated by adequate sleep EEG studies. Unlike in adults, somnambulism in children is benign and self-limited, but there is a high potential for harm. Management consists of "sleep-proofing" the home: windows and doors should be locked, and gates placed across stairs. A bell could be placed on the child's door to alert the caregivers of these events. Parents can be reassured that most children outgrow sleepwalking over several years.

Sleep–Wake Transition Disorders. Sleep–wake transition disorders occur in the transition from wakefulness to sleep, from sleep to wakefulness, or in sleep-stage transitions.

Rhythmic movement disorder starts at around 8 months of age and generally stops by age 4. Boys outnumber girls 3:1. The usual pattern is body rocking followed by head rolling or banging against the crib sides immediately before sleep onset and throughout light sleep, lasting several minutes to an hour. Head banging is typically not associated with crying. No significant injuries are incurred, although callus formation and contusions may be observed. Management consists of reassurance and advice to pad the crib.

Somniloquy (sleep talking) appears in school-aged children. The speech can be spontaneous or induced by conversation from another person. Sleep talking may be vivid and revealing but is also usually outgrown with time.

Nocturnal leg cramps and *restless leg syndrome* may prevent children from initiating or returning to sleep. Patients feel the need to frequently toss, turn, and kick to relieve their leg discomfort. Children with restless leg syndrome may be misdiagnosed with growing pains or ADHD. Restless leg syndrome may be associated with sleep apnea. Symptoms can improve with dopaminergic agents and benzodiazepines.

REM Sleep Disorders. REM sleep disorders often occur during the last part of the night when REM sleep predominates.

Nightmares are unpleasant dreams from which the child is usually awake and responsive by the time the parents arrive, and for which substantial recall can occur. Approximately 10% to 50% of children between the ages of 3 and 6 years experience nightmares, but this frequency decreases over time. The child who just had a nightmare should be reassured with embraces and soothing words, and the parent should stay until the child is calm. Parents of children with occasional nightmares should be reassured about the benign nature of these episodes. Frequent nightmares may be a sign of distress that merits a psychological evaluation. Certain medications can trigger nightmares, such as L-DOPA, β-blockers, and withdrawal from REM-suppressing drugs.

Other Parasomnias. *Bruxism* (clenching and grinding of teeth during sleep) occurs in 50% of healthy infants at the time of tooth eruption, but it also occurs in children 10 to 20 years of age due to stress. Bruxism can also be caused by dental malocclusion and neurologic conditions. For persistent nightly bruxism, tooth guards can protect the teeth and reduce potential damage to the temporomandibular joint. Relaxation exercises such as self-hypnosis to relax the body at bedtime can be helpful for older children.

Primary nocturnal enuresis is defined as enuresis occurring in a child older than 3 years, who is otherwise well and has never been dry at night, although he or she can stay dry all day. This condition is the most common non-REM disorder, with an incidence ranging from 5% to 17% of all children between 3 and 15 years of age. The enuretic episode typically occurs during the first cycle of the night. It is characterized by tachycardia, tachypnea, penile erection in boys, increased intravesical pressure, and spontaneous bladder contraction. The differential diagnosis includes organic problems such as diabetes mellitus, diabetes insipidus, and urinary tract infection, although these symptoms would be rare if the definition just given is adhered to. The sleep quality of children with nocturnal enuresis is poor due in part to the fear or anxiety of bedwetting during sleep. So, active treatment should be started as soon as the enuretic child is ready and wants to be dry during sleep. Treatment starts with conditioning modalities. Medications, such as imipramine, that have both anticholinergic effects on the bladder and stimulant effects on sleep-stage patterns, or antidiuretic hormones are considered a last resort and should be prescribed only in severe cases, under the supervision of the primary care physician.

Dyssomnias

Dyssomnias are primary disorders of sleep excess or insomnia.

Narcolepsy is a rare syndrome characterized by excessive daytime sleepiness. Onset is gradual, often between 15 and 35 years of age with a strong genetic predisposition. The two most important symptoms of narcolepsy are daytime sleepiness (that is irresistible and that cannot be fully relieved by any amount of sleep) and cataplexy (sudden loss of muscle tone with preservation of consciousness, triggered by strong emotions such as laughter, crying, anger, or fear). Other complaints include attacks of daytime sleep (short, 10- to 20-minute naps after which children feel refreshed, then feel sleepy again within 2 to 3 hours), sleep paralysis (inability to move during the onset of sleep or on awakening), hypnagogic hallucinations (vivid imagery at the onset of sleep or awakening), and disturbed nighttime sleep. The occurrence of REM sleep at the onset of sleep is the most characteristic and striking abnormality observed in narcolepsy. Management includes a regular schedule of naps and adherence to a consistent sleep schedule. Short-acting stimulant drugs, such as a low dosage of dextroamphetamine or methylphenidate for daytime sleepiness, and sodium oxybate, tricyclic antidepressants, or serotonin reuptake inhibitors are recommended for cataplexy, sleep paralysis, and hypnagogic hallucinations. Issues to be addressed with adolescents are driving, poor school performance, and difficult peer interactions. The degree of sleepiness rarely lessens, but cataplexy, sleep paralysis, and hypnagogic hallucinations improve or disappear with age in one-third of patients.

Obstructive sleep apnea syndrome affects 1% to 3% of all children and peaks between 2 and 6 years of age. It is caused by upper airway obstruction, resulting in frequent apneic spells during sleep, hypoxia, hypercarbia, frequent arousals, and sleep fragmentation. This leads to neurocognitive disruption and decreased stages 3 and 4 of non-REM sleep. Children may present with loud snoring, excess daytime somnolence, morning headaches, hypertension, cardiac arrhythmias, cor pulmonale, failure to thrive, enuresis, anoxic seizures, aggressiveness, decreased attention span, and poor school performance. Predisposing risk factors to obstructive sleep apnea include obesity, craniofacial abnormalities, and hypotonia. An overnight polysomnogram is the gold standard for confirming the presence and severity of obstructive sleep apnea. Management involves otolaryngologic or pediatric sleep medicine consultation for thorough airway evaluation and appropriate measures to relieve obstruction, maintenance of continuous positive airway pressure, and initiation of weight loss in obese children. However, the most common and effective treatment for obstructive sleep apnea is tonsillectomy and adenoidectomy, after which symptoms resolve in 70% to 80% of the cases.

CHAPTER 132 ■ CHILD ABUSE

JOANNE N. WOOD, MD, MSHP, AND STEPHEN LUDWIG, MD

Child abuse is the single diagnostic term used to describe a range of behaviors, from somewhat harsh discipline to intentional repetitive torture. This phenomenon is complex and results from a combination of individual, familial, and societal factors. The common final pathway for these factors is parental behavior destructive to the process of normal growth, development, and well-being of the child. Abuse may be subdivided into four broad categories: (i) physical abuse, (ii) sexual abuse, (iii) neglect, and (iv) emotional abuse. Each form of abuse has individual characteristics of family dynamics and clinical manifestations and requires skillful physician management.

The task of the emergency physician is difficult. The physician must first maintain an open mind to the possibility that abuse not just occurs but also occurs commonly. Thus, abuse should be included in the differential diagnosis of any injury or any physical or psychological complaint that does not have an obvious etiology. Second, the physician must identify signs and symptoms of suspected abuse. Next, the potential family crisis must be managed to protect the child, yet maintain the abusive parents' motivation for help. Finally, the legal requirements for reporting abuse to the proper social service or police authority should be thoroughly understood.

The demands of managing a case of child abuse may be lessened by sharing the responsibility with other health care professionals. The skills of physician colleagues, as well as nursing and social work staff, are invaluable. The child abuse field has been a model for multidisciplinary collaboration, which is most productive if begun in the initial phases of case management in the emergency department (ED). Establishing an institutional or departmental protocol for the management of abuse cases is also essential. This protocol relieves the emergency physician from having to reconstruct a complete management plan for each new case. Having a standard protocol to follow allows the physician more time to concentrate on the individual needs of the patient and parents.

To the unfamiliar observer, the easy solution to all abuse cases is to "take away the child and put the parents in jail." This commonly held treatment philosophy would be practiced more if it were truly a panacea. However, the alternative forms of child care (i.e., institutional care, foster care, extended family care) are each fraught with their own hazard. With the use of well-organized community services, abusive behavior can be controlled while the child and family receive therapy. In some cases, however, removal of the child and establishing data on which to effect the removal will be the main focus of the ED visit.

There may be support for the notion that parents who bring their abused child to the ED are motivated to seek help for their child and for themselves. Most parents feel remorse about their abusive behavior. The severity of injuries inflicted is often overestimated as a result of parental guilt. The emergency physician must neither overlook nor mismanage the opportunity to identify abuse early and help control the parents' behavior. Sharp focus must be maintained on the dual goals of case management—protect the child and use the crisis to strengthen and preserve family life. When these dual goals are in conflict, it is the former that must take priority.

PHYSICAL ABUSE

Background

Physical abuse is the most often reported form of child abuse. Definitions of physical abuse vary from state to state. Operationally, the definitions vary from institution to institution and indeed from person to person. Even the definition of physical abuse is a definition in transition. Over the past century, many advances in the "rights of the children" have been made. For example, the enactment of child labor and compulsory education laws has been an important step forward. As the history of abuse is traced through the centuries, the forms and definitions of abuse have changed. Definitions currently used are likely to continue to change with time. The present widespread medical interest in abuse was stimulated by C. Henry Kempe with the introduction of the term *battered child syndrome* in 1962. It was only as recently as 1968 that the last of the 50 states enacted child abuse legislation. Many states are now using their second or third generation of child abuse laws.

The Child Abuse Prevention and Treatment Act (CAPTA), as amended and reauthorized in June 2003 by the Keeping Children and Families Safe Act of 2003 (Pub L No. 108-36), defines child abuse and neglect as, at a minimum, any recent act or failure to act.

- Resulting in imminent risk of serious harm, death, serious physical or emotional harm, sexual abuse, or exploitation
- Of a child (a person younger than age 18, unless the child protection law of the state in which the child resides specifies a younger age for cases not involving sexual abuse)
- By a parent or caregiver (including any employee of a residential facility or any staff person providing out-of-home care) who is responsible for the child's welfare.

There are four major types of child maltreatment: (i) physical abuse, (ii) child neglect, (iii) sexual abuse, and (iv) emotional abuse. Physical abuse is the infliction of physical injury as a result of punching, beating, kicking, biting, burning, shaking, or otherwise harming a child. The parent or caregiver may not have intended to hurt the child but rather the injury may have resulted from overdiscipline or physical punishment.

The true incidence of abuse is elusive. Many cases of abuse occur in the privacy of the home and are never recognized or reported. The federal government has collected three national incidence studies in 1979–1980, 1986–1987, and 1993–1995. A fourth cycle of data is being collected and a report is pending. These data are shown in Fig. 132.1. The National Center for Child Abuse and Neglect (NCANDS) also collects data through voluntary reporting by state child protective services (CPA) agencies. These data sources all underestimate the incidence of abuse. There are about 3 million reports and 1 million substantiated cases per year or an incidence of 42 per 1,000 children. The breakdown in the forms of abuse is shown by type and age in Fig. 132.2.

Homicide is now the fifth leading cause of death in children aged 1 to 4 years and the fourth leading cause of death in

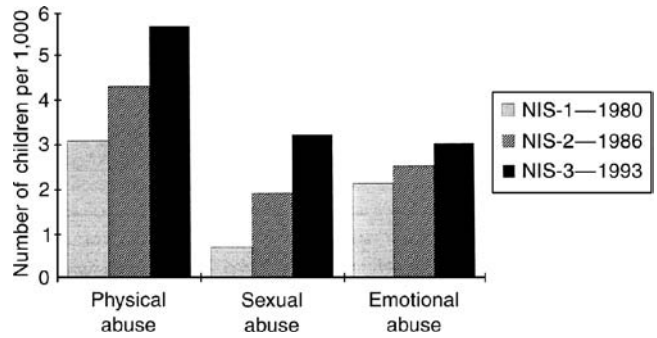

FIGURE 132.1 Incidence of child abuse per 1,000 children by abuse type determined by three national incidence studies. (From the U.S. Department of Human Services. Reprinted with permission.)

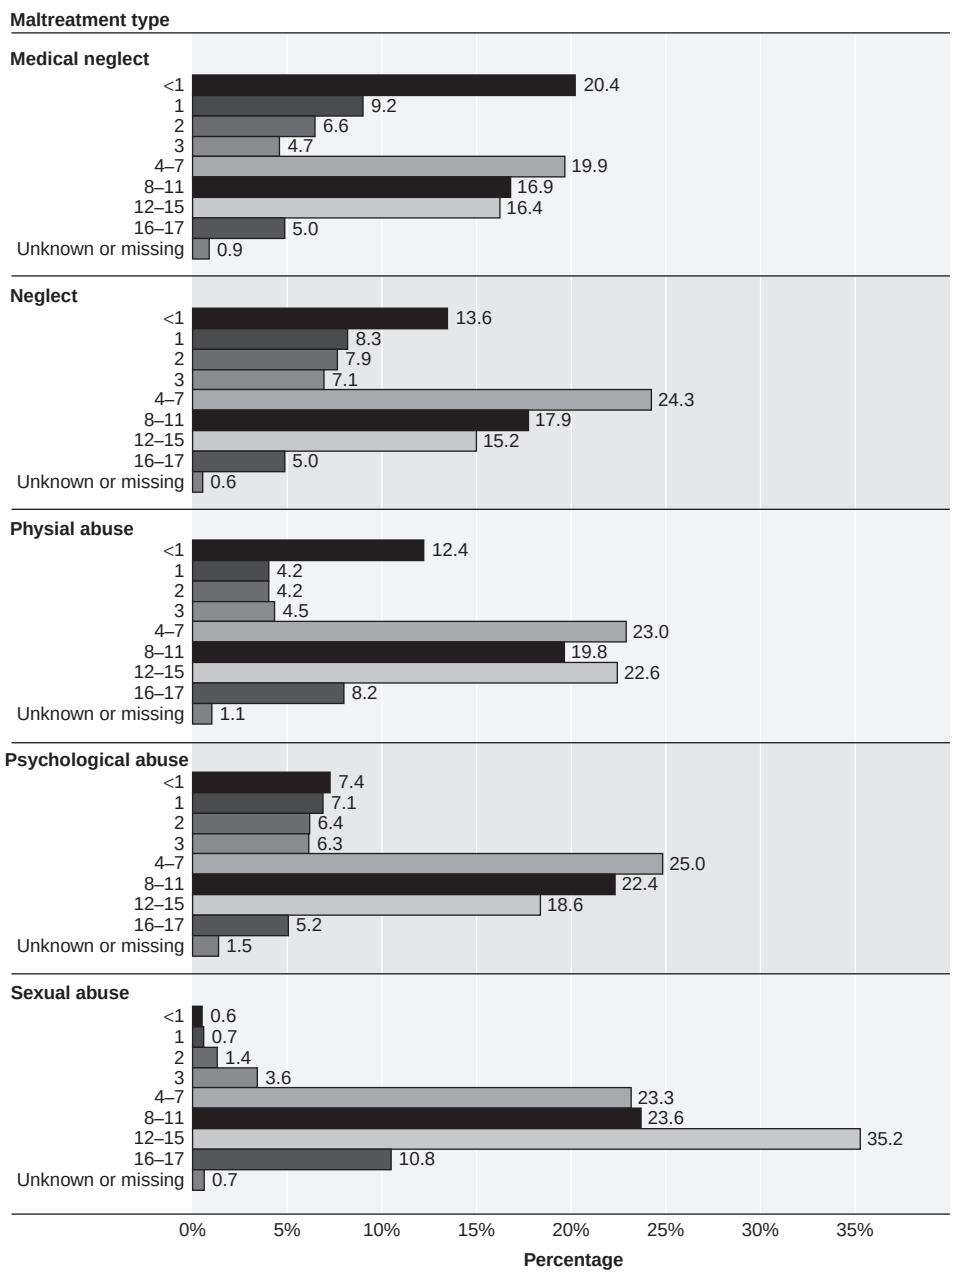

FIGURE 132.2 This bar chart displays the medical neglect, neglect, physical abuse, psychological abuse, and sexual abuse maltreatment types by age within each maltreatment type. The percentage of victims for each age group within each maltreatment type is shown. (From U.S. Department of Health and Human Services, Administration for Children & Families, Administration on Children, Youth & Families, Children's Bureau. *Statistics & research, child maltreatment 2007*.)

(From U.S. Department of Health and Human Services, Administration for Children & Families, Child Welfare Information Gateway. *Child abuse and neglect fatalities: statistics and intervention*.)

children aged 5 to 14 years. There are 2,000 to 5,000 deaths annually or an incidence of 5.4 per 100,000 children 4 years and younger. The incidence of child homicide has steadily increased. According to a review by the Centers for Disease Control and Prevention (CDC), the rate of homicide in the 1- to 4-year-old age group has increased sixfold since 1925. The NCANDS reported 1,760 child fatalities in 2007. Seventy-eight percent of deaths occurred in children younger than 3 years. The perpetrators in these cases of child homicide are most often adults who are known by their child victims (Fig. 132.3).

Dynamics

Many factors contribute to the reasons a parent abuses a child. Helfer's formulation of the necessary elements is shown in Fig. 132.4. The factors include a parent who is capable of abuse, a child who actively or passively becomes the target, and a crisis that triggers the angry response. Green has added to this triad the concept that the process must exist in a society that unknowingly condones or even encourages violence—in particular, violence against children. Some of the factors that contribute to the parents' abusive potential are listed in Fig. 132.5.

Stress and lack of specific child-rearing information and experience play dominant roles. The combination of these factors causes many parents to misread normal childhood behavior as defiant or provocative and to react with a violent, destructive response. The typical example is the parent who is angered by the 1-year-old child's refusal to become toilet trained. The child's contribution to abuse may be real, as in the case of negative behavior, disparate temperament, or behavior imagined by the parent (e.g., "He's just like his father"). Children with prolonged neonatal hospitalization, disabilities, or developmental delays are at increased risk. Living situations in which nonbiological parents are present are also high risk. For example, the adopted child or the child living with a parent's significant other may be the target of abusive behavior. The crisis that initiates abuse varies tremendously. It may be unrelated to the child, such as the stress of a family member's death or economic disappointment. However, crisis often occurs because the child's behavior does not meet parental expectations. The crisis is identifiable as the spark that ignites the existing potential for abuse.

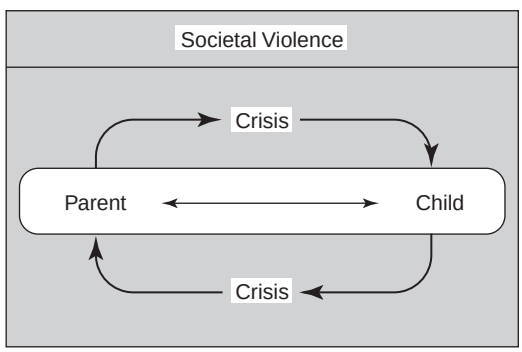

FIGURE 132.4 Essential elements of child abuse. (Adapted from Helfer RE. Why most physicians don't get involved in child abuse cases and what to do about it. *Child Today* 1975;4:28.)

Manifestations

The manifestations of physical abuse may affect any body/organ system. Thus, the emergency physician must be prepared to recognize various signs and symptoms. Abuse may also be seen by any specialist physician.

Integument. The skin is the most commonly injured body organ. Cutaneous injuries may be divided into nonspecific and specific traumatic lesions, burns, and hair loss. Of the nonspecific traumatic injuries, the bruise or contusion is most commonly seen. Although bruises are also common in ambulatory children who are not abused, accidental bruises usually have a different distribution and appearance. Accidental injuries occur most commonly on the extremities and forehead. As bruising moves centrally and becomes extensive, the likelihood of abuse rises. Also, bruising in a young non-ambulatory infant is uncommon and should raise concern for abuse. Contusions undergo recognizable stages of healing. In the first 24 hours, the size of the bruise increases slightly if careful measurements are made. The process of resolution is variable. The approximate age of the bruise should be determined and compared with the history provided but exact dating of bruises is not accurate. Prothrombin time, partial thromboplastin time, bleeding time, platelet count and medication history (including OTC drugs) should be obtained if the issue of "easy bruisability" has been offered as a possible explanation.

Other nonspecific cutaneous injuries include lacerations, punctures, and abrasions. The following criteria are important for the evaluation of any nonspecific injury: (i) the history of injury, (ii) the child's age and developmental level, (iii) the presence of other old or new injuries, (iv) the interaction between the parents and the child, and (v) the interaction between the parents and the ED staff.

Specific skin injuries are those that clearly reflect the method or object used to inflict the trauma. Loop-shaped marks are readily seen after a beating with an electric cord or wire. Linear marks may result from a belt or paddle injury.

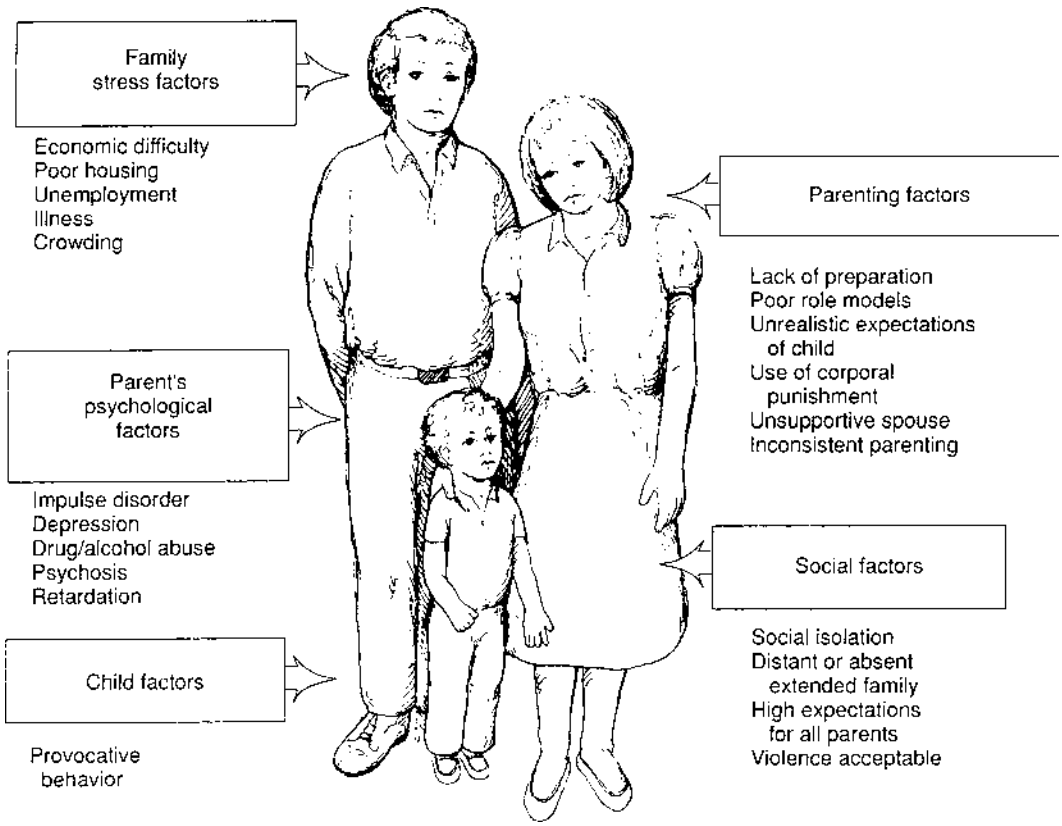

FIGURE 132.5 Risk factors that contribute to abuse and neglect.

Rope burns result in circumferential marks on the wrists, ankles, or around the neck when a child has been bound. Another common specific integument lesion is a handprint on the side of the face or symmetrically on the upper arms. The lesion produced by a slap leaves ecchymotic areas in the location of the interphalangeal spaces. Human bites appear as circular lesions 1 to 2 in. in diameter. Forensic dentistry can match the skin lesion with the dentition of the alleged perpetrator. Some specific skin lesions are shown in Fig. 132.6.

Burns of the skin may be caused by abuse or neglect. Burns account for 5% of cases of physical abuse. In particular, tap water scald burns that occur in an immersion pattern (Fig. 132.7A) are often the result of intentional trauma. Immersion burns are likely to be inflicted by an abusive parent when they occur on a child who is being toilet trained. Other indications of abuse are (i) a delay in seeking treatment, (ii) a history of the child being unsupervised, and (iii) the child being brought to the hospital by the parent who was not present at the time the burn occurred.

In attempting to match the physical findings of the burn with the available history, several factors must be appreciated. The extent of the burn depends on the temperature of the water, duration of exposure, thickness of the skin involved, and presence or absence of clothing. Water temperature 54°C (130°F) or greater causes a full-thickness burn with less than a 30-second exposure. Because palms and soles are thick, they are often spared. Clothing tends to keep the hot water in contact with the skin and causes more severe burns. Burns presumably caused by falling or thrown fluids should produce a droplet or splash pattern. When the child has several small bullous lesions, the main differential diagnosis is a second-degree burn versus bullous impetigo caused by bacterial infection. This differentiation is easily made by Gram stain and culture of a bulla.

Other burns may occur through contact with a hot solid rather than a hot fluid. Cigarette burns are the most common. If the history given is of a child brushing against a cigarette or of hot ashes falling on the child, the resulting injury should be a nonspecific first- or second-degree burn. When a cigarette is extinguished on the child's skin, the injury is a burn that is 8 to 10 mm in diameter and indurated at its margin. A healed cigarette burn is indistinguishable from any other circular skin lesion such as impetigo, abscess, or vesicles. Burns from radiators, hot plates, cigarette lighters (Fig. 132.7B), curling irons, or standard irons imprint the shape of the hot object. More recently, there have been reports of children burned by microwave ovens.

The final category of integumental injury is injury to the hair. Traction alopecia is seen when a parent pulls the child by the hair. The scalp is usually clear, differentiating this lesion from tinea capitis, seborrhea, and scalp eczema. Alopecia areata produces a lesion in which the hair is uniformly absent. In the case of traction or traumatic alopecia, patches of broken hair remain.

Skeletal System. The skeletal system is also commonly traumatized when children are physically abused. As previously

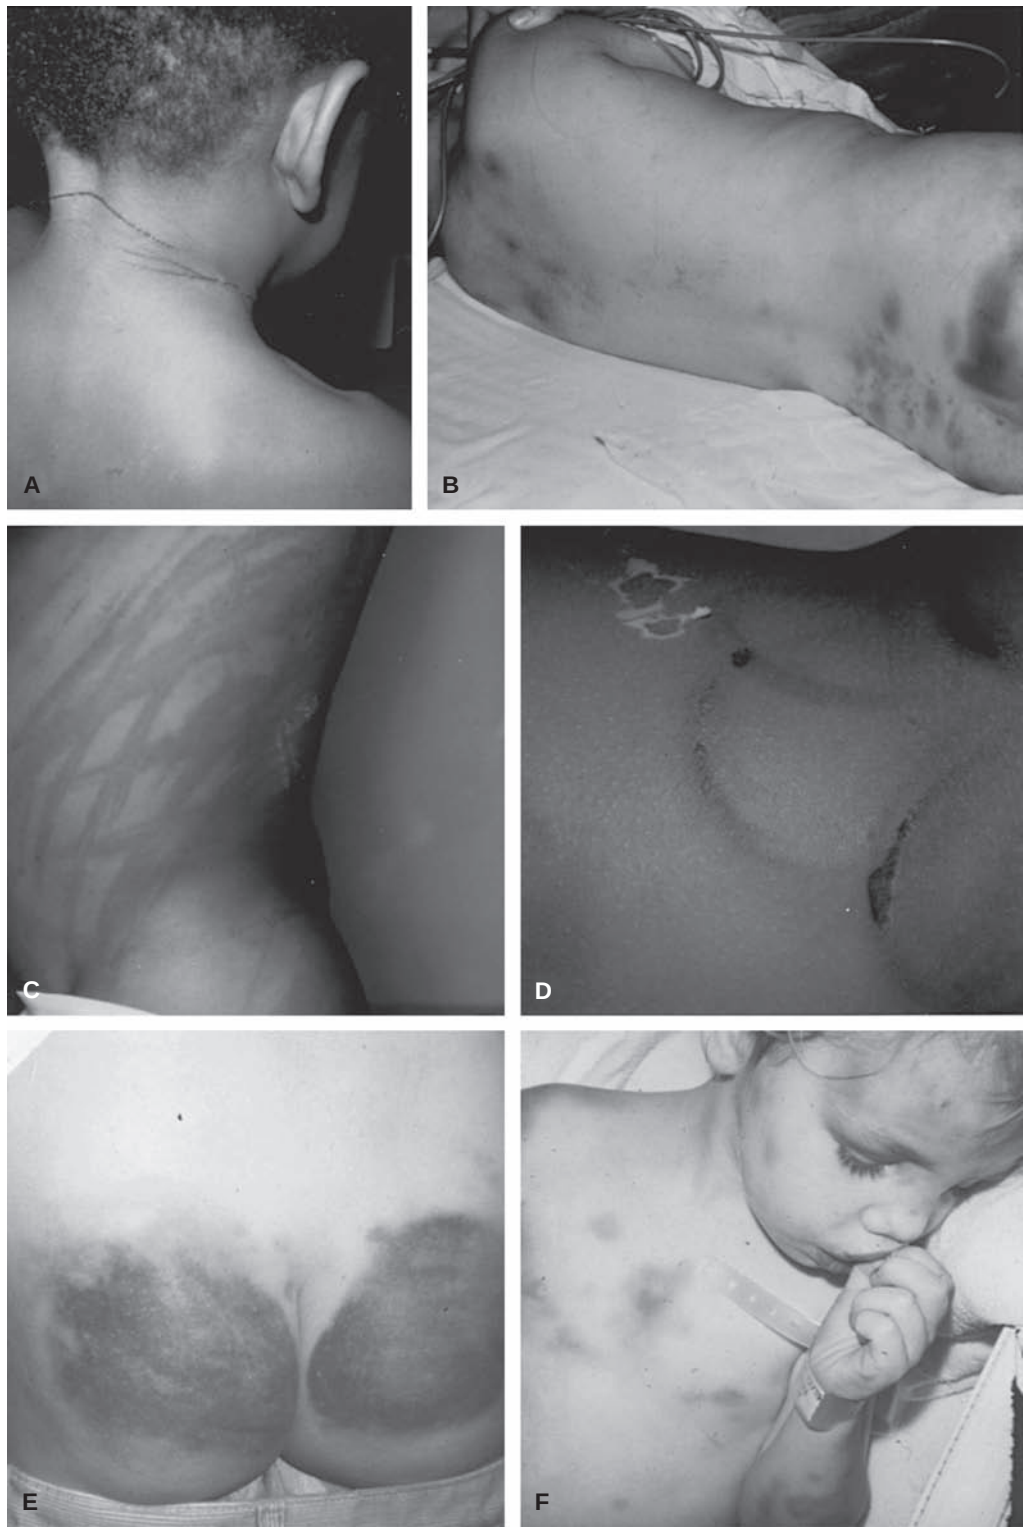

FIGURE 132.6 Cutaneous manifestations of child abuse. **A:** Strangulation mark. **B:** Bruises at various stages of healing. **C:** Linear loop-shaped marks. **D:** Multiple loop-shaped marks. **E:** Buttocks bruises as a cause of myoglobinuria. **F:** Multiple bruises in a central pattern.

FIGURE 132.7 **A:** Hot water burn in an immersion pattern. **B:** Pattern burn from cigarette lighter.

mentioned, matching the history of injury with the physical findings is important. Considering the mobility and strength of the child is also important in identifying suspicious injuries. The radiologist needs to review the patient's past radiographs to identify the child with multiple visits to the hospital for the treatment of fractures. When suspicion of abuse is high, a radiographic skeletal survey should be obtained to ascertain the condition of the entire skeletal system. It may be helpful to repeat a skeletal survey 2 weeks after a suspected injury, as healing may make the injuries more apparent.

Support for the use of radioisotope scans and magnetic resonance imaging (MRI) as a more sensitive and immediate way of demonstrating bone injury is increasing. However, radionuclide scans and MRIs are still second-line studies. Some of the indications for a radiographic skeletal survey or bone scans are listed in the "Management" section of this chapter. A skeletal survey is often performed on a young child with one obvious fracture and then reveals multiple healing old fractures. The skeletal survey is the preferred radiographic study because it provides information on the type, location, and age of fractures, as well as presence or absence of bone diseases.

Bone injuries may be of several types, including simple transverse fractures, impacted fractures, spiral fractures, metaphyseal fractures, or subperiosteal hematomas. Radiographs of some of these injuries are shown in Fig. 132.8. To explain a transverse fracture, the history should be that of direct force applied to the bone. Differentiating the true cause of this type of fracture is often difficult. The impacted fracture should have an accompanying history of force along the long axis of the bone, such as the child's falling on his or her outstretched hand. In the case of a spiral fracture, a history of twisting or torque during the traumatic event should be present. Metaphyseal chip fractures

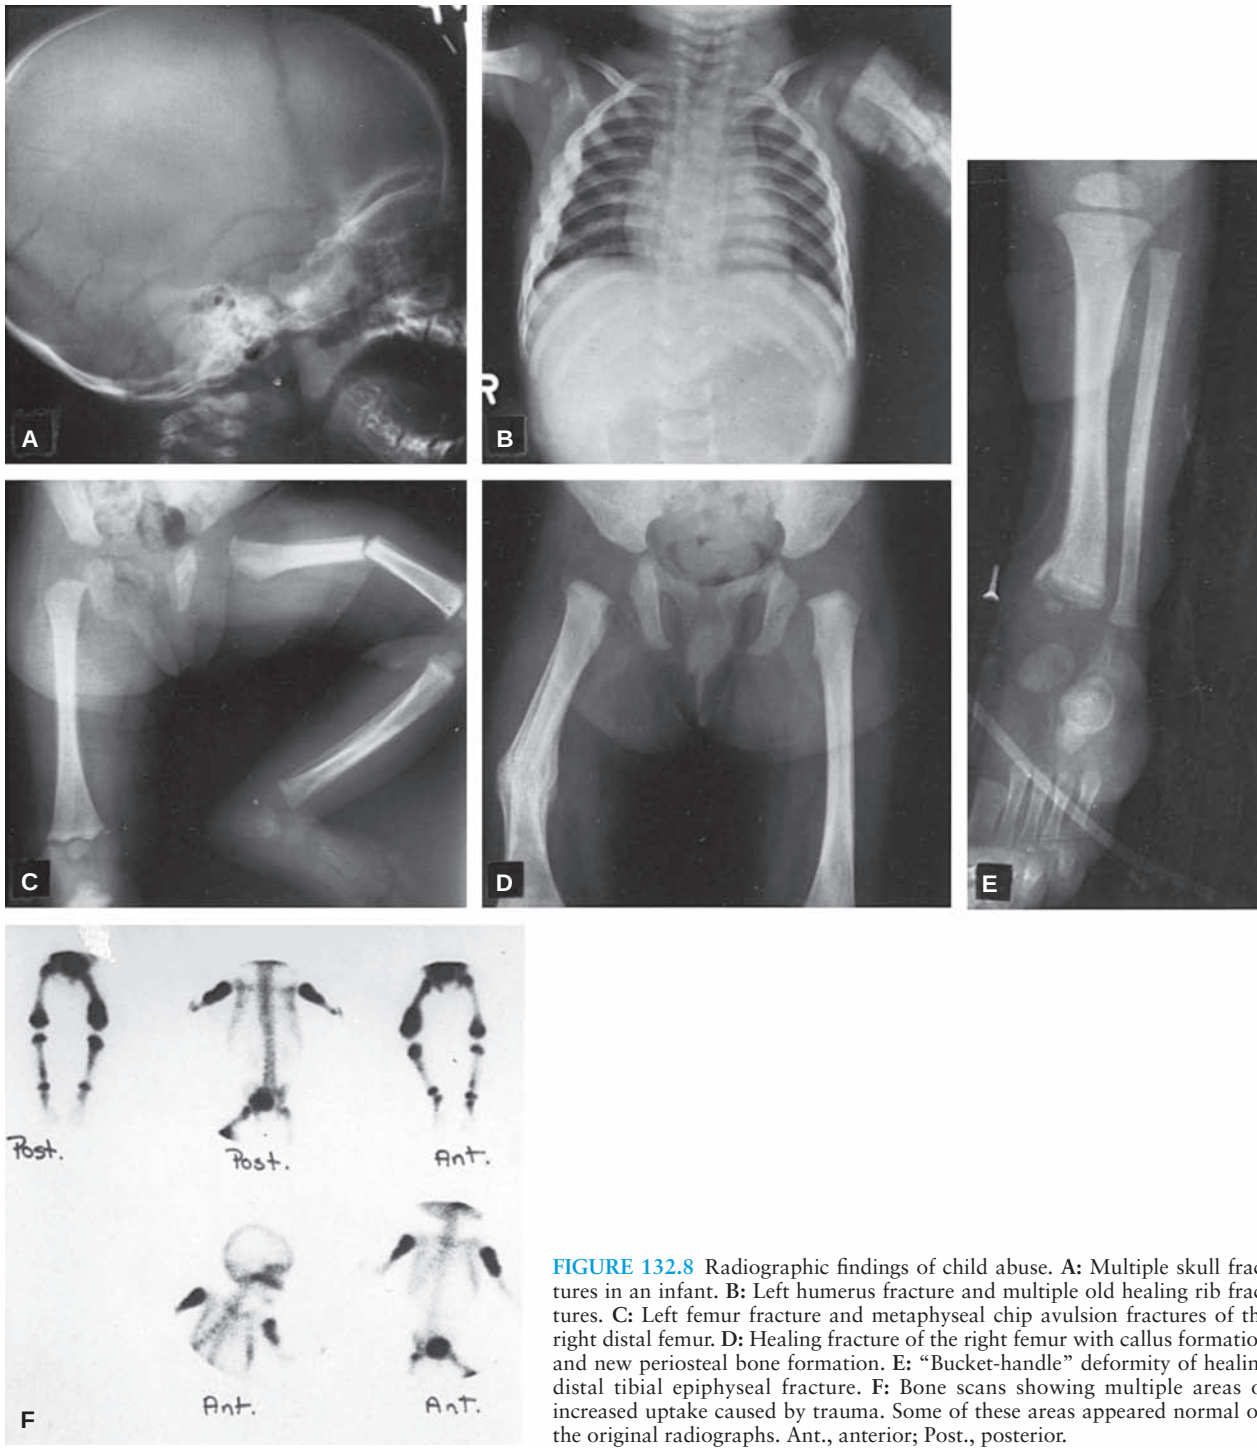

FIGURE 132.8 Radiographic findings of child abuse. **A:** Multiple skull fractures in an infant. **B:** Left humerus fracture and multiple old healing rib fractures. **C:** Left femur fracture and metaphyseal chip avulsion fractures of the right distal femur. **D:** Healing fracture of the right femur with callus formation and new periosteal bone formation. **E:** "Bucket-handle" deformity of healing distal tibial epiphyseal fracture. **F:** Bone scans showing multiple areas of increased uptake caused by trauma. Some of these areas appeared normal on the original radiographs. Ant., anterior; Post., posterior.

occur when the extremity is pulled or yanked. It is hypothesized that the periosteum is most tightly adhered at the metaphysis, causing small bone fragments to avulse. Metaphyseal chip fractures are almost exclusively caused by abuse. Subperiosteal hematomas produce a characteristic radiograph. The elevation of the periosteum is seen as a linear opacification running parallel to the bone surface. Subperiosteal hematomas are produced by direct trauma to the bone.

However, in up to 10% of small and premature infants, symmetric periosteal elevation that is not caused by abuse may occur along the tibia or humerus. The reason for this finding is unknown, but it should not be confused with abuse.

The location of the fracture is important in the identification of abuse. The fracture of a clavicle or the dislocation of a radial head is a common noninflicted injury. However, when the femur and/or ribs of a young child are fractured, the suspicion of abuse increases. Anderson reported on a series of children with femur fractures. Of 24 children who were younger than 2 years, abuse was proved in 19 cases. In two-thirds of these children, the fracture was the only sign of abuse.

Feldman and Brewer reported on a series of children with rib fractures and noted an obvious history of trauma—for example, motor vehicle accident, an obvious bone disease such as osteogenesis imperfecta, or child abuse.

Feldman and Brewer also report examining several children who received external cardiac compression and finding that none of them had sustained rib fractures as a result of their cardiopulmonary resuscitation. In a confirmatory report, Schweich and Fleisher found that when the parents could not provide a history for rib fractures, the cause was abuse. The mean age of the group of children who had inflicted trauma was 3 months, whereas the group having accidental rib fractures had a mean age of 8.5 years. Abusive rib fractures are frequently posterior in location and are thought to result from anterior-posterior compression of the thorax rather than blunt trauma in most cases. The history of injury must be matched with the physical finding.

Other uncommon and therefore suspicious fractures are located in the vertebrae, sternum, pelvis, or scapulae. Uncommon fractures need to be carefully evaluated unless a clear history of significant trauma, such as an automobile injury, is reported.

The age of a fracture may be estimated from the amount of callus formation and bone remodeling seen on the radiograph. Table 132.1 lists fracture landmarks by date. Dating of fractures is not an exact science because many confounding variables, such as the child's age, location of the fracture, and nutritional status, must be considered. Nonetheless, the child who presents with an acute fracture and has a second fracture with a callus stands out as having sustained more than one episode of trauma. The usual long-bone fracture may take 8 to 10 days to form callus and several months to heal completely. In the acute stages of injury, soft-tissue swelling should be seen for 2 to 5 days. Soft-tissue swelling may be clearly seen on standard radiographs. Skull fractures or fractures of other flat bones cannot be dated in the same way. Caution should also be exercised in dating metaphyseal fractures as some metaphyseal fractures will not develop much callus or exhibit the classic stages of healing.

TABLE 132.1

DATING FRACTURES

0–10 days
Soft-tissue edema
Joint fluid
Visible fracture fragments
Visible fracture lines

10 days–8 wk
Periosteal new bone (layered)
Callus (first subtle and then heavy)
Bone resorption along fracture line makes fracture line more visible
Metaphyseal fragments often more visible

≥8 wk
Periosteal new bone matures, becomes thicker
Callus formation becomes more dense and smoother
Metaphyseal fragments are incorporated into metaphyseal callus and become smoother
Fracture line less visible and then invisible
Deformities and cortical bumps persist

When a young child sustains multiple fractures, the differential diagnosis must be widened beyond accidental trauma and abuse to include osteogenesis imperfecta, infantile cortical hyperostosis, scurvy, syphilis, osteoid osteoma, neoplasms, rickets, hypophosphatasia, and osteomyelitis. Table 132.2 details the distinction between child abuse and osteogenesis imperfecta. The other conditions are much more rare than abuse and can be ruled out both by the appearance of the bone on the radiograph and by the levels of calcium, phosphorus, and alkaline phosphatase in the serum.

Central Nervous System. Injuries to the central nervous system (CNS) are the main cause of child abuse deaths. These injuries may be subdivided into two categories: direct trauma

TABLE 132.2

OSTEOGENESIS IMPERFECTA VERSUS CHILD ABUSE

Finding	Osteogenesis imperfecta	Child abuse
Incidence	Rare	Common
Positive family history	Common	Common
Blue sclerae	Common	Rare*
Abnormal teeth	Common	Rare
Hearing impairment	Common	Uncommon
Osteoporosis	Common	Rare
Abnormal fracture healing	Common	Rare
Wormian bones	Common	Rare
Joint laxity	Common	Rare
Short stature	Common	Occasional
Fracture recurrence in protected environment	Common	Rare
In utero fracture	Occasional	Rare
Biochemical studies	Abnormal	Normal

*Light blue sclera can be a normal finding in young infants.

and shaking injuries. Direct trauma is inflicted either by striking the child with an object or by dropping or throwing the child against a wall or onto the floor. The extent of the resulting trauma depends on the amount of force used, the surface contacted, and the child's age. The child may be brought to the ED with a small subgaleal hematoma or in coma. Injuries may vary from scalp contusions to intracerebral hematomas.

A history of a young infant falling off a bed or dressing table is often presented. The precise extent of injury from this type of fall is unknown, but several reports suggest that even uncomplicated skull fractures are as uncommon as 1% to 2% of cases. If the injury is more severe and the only history is of a fall from less than 8 to 10 feet, abuse should be suspected. Another scenario is that of a child who sustained trauma 1 week before the ED visit. The visit is prompted by the parent's noticing a soft spot on the child's cranium. This sequence may occur when the initial scalp hematoma so rapidly expanded that it had a bony consistency. Only with degradation and softening of the mass does the parent now perceive the hematoma. Although a delay in seeking treatment is a well-recognized red flag for child abuse injuries, this case provides a plausible exception. In all children younger than 1 year who have a history of head trauma, skull radiographs are recommended. Infants tend to sustain skull fracture more easily and are more vulnerable to serious sequelae. If a fracture does exist and abuse is suspected, a skeletal survey and further head imaging with a CT and/or MRI should also be obtained. For the diagnostic methods to be used for more serious head injuries, refer to Chapter 116.

Shaking injuries characteristically cause serious CNS damage without evidence of external trauma. The infant's relatively large head size and weak neck muscles are predisposing factors for whiplash injury. Whether the injury is caused by shaking alone or shaking followed by an impact is controversial (Fig. 132.9). There are some parent defense experts who have attempted to discredit this form of injury, but it remains one of the most important and lethal forms of abuse. In most fatal cases, minor bruising to the scalp is apparent, although such scalp injuries may not be apparent until the scalp is reflected during the autopsy.

The shearing and contusive forces that result from shaking the infant produce this type of injury. Specific lesions that occur include hematomas, subarachnoid hemorrhages, or brain contusions, particularly in the frontal and occipital lobes. The child may present with lethargy and a "septic" appearance, with seizures, or in a coma. The physical examination is often otherwise unremarkable except for retinal hemorrhages (Fig. 132.10A). Occasionally, bruises on the upper arms or shoulders indicate the sites where the child has been grasped. Lumbar puncture may produce grossly bloody, xanthochromic or normal spinal fluid. If computed tomography is available, it shows the characteristic findings of occipital contusion and intrahemispheric blood (Fig. 132.10B). This form of abusive behavior by the parent is usually triggered by the infant's persistent crying. Excessively rough forms of play and misguided resuscitative efforts have been cited as alternative explanations for head injuries by caregivers but there is not any data to support the claims that these activities can result in the types of injuries seen in abusive head trauma. Imaging the CNS has been advocated for all children under 2 years of age who have signs of physical abuse, as there may be occult or old injury independent of neurologic signs and symptoms.

Gastrointestinal System. Gastrointestinal (GI) injuries are relatively uncommon abuse manifestations but, similar to CNS injuries, account for a significant percentage of fatal injuries. Of all GI injuries, mouth trauma is perhaps the most common.

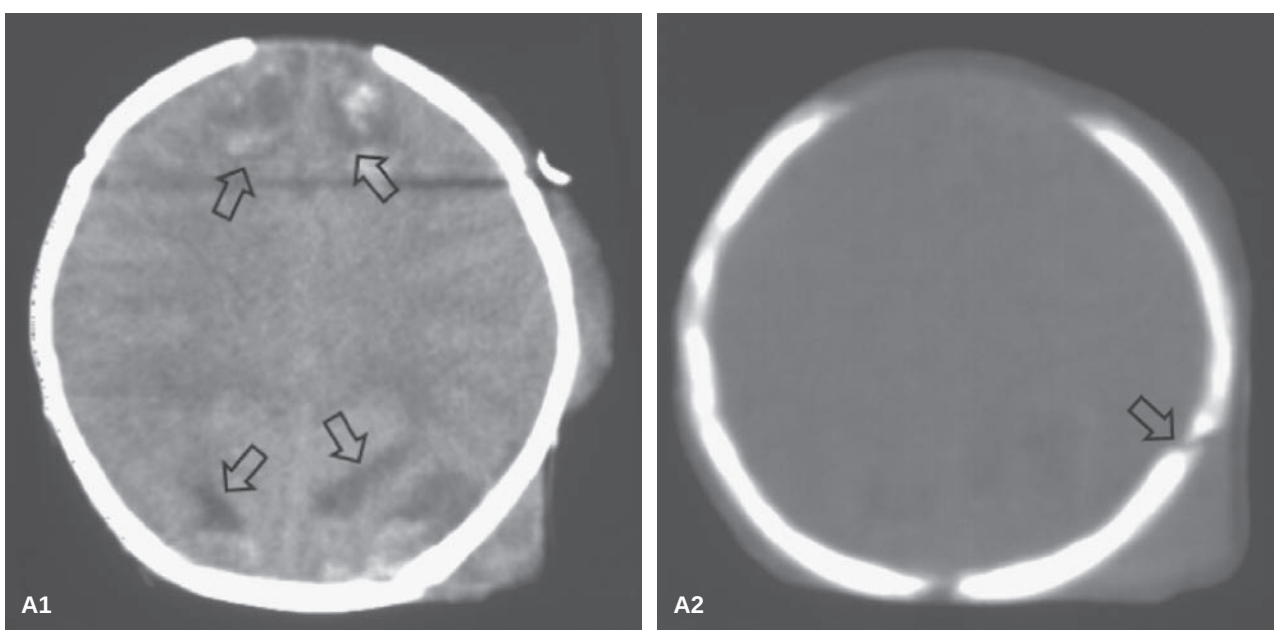

FIGURE 132.9 **A:** Six-week-old infant examined by computed tomography (CT) without contrast. **A1:** Axial CT shows focal areas of increased and decreased density in the anterior and posterior parasagittal regions *(arrows)*. Scalp swelling is present on the left. **A2:** Axial bone window shows fracture of the right parietal bone *(arrow)*. (*continued*)

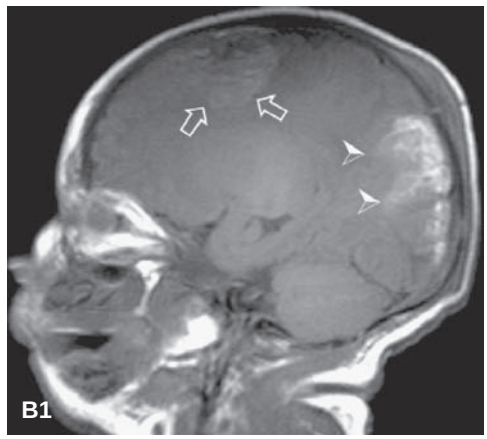

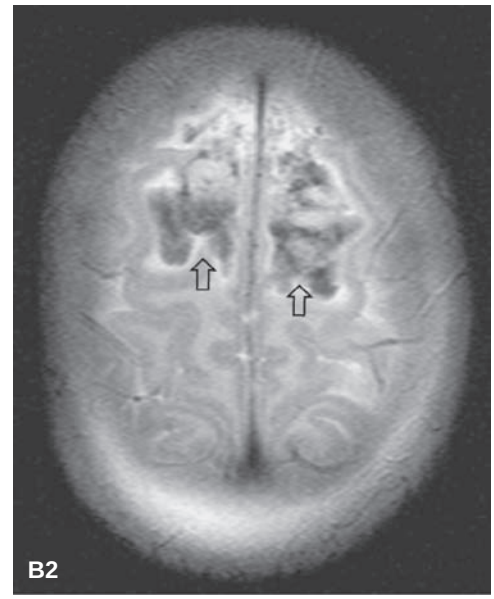

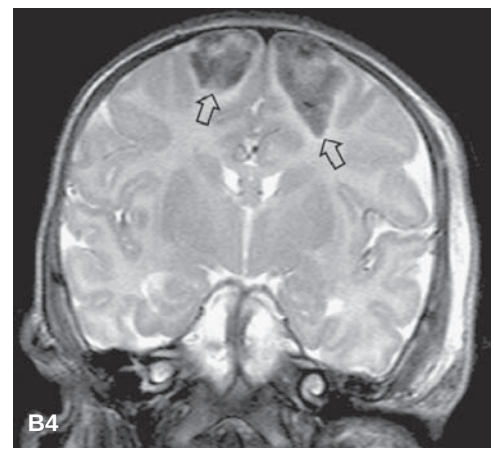

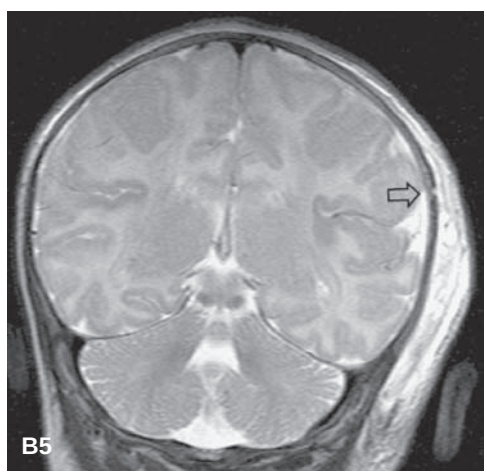

FIGURE 132.9 (*Continued*) **B:** Six-week-old infant examined by magnetic resonance imaging (MRI) studies. Same patient as **A1**. **B1:** Sagittal T1WI shows both an older clot with methemoglobin as high signal intensity in the parietooccipital region *(arrowheads)* and a more recent clot as deoxyhemoglobin in the frontal region *(arrows)*. **B2:** Axial T2WI shows the frontal parasagittal hemorrhagic areas of injury *(arrows)*. **B3:** Axial T2WI shows the posterior, parietooccipital older areas of injury as areas of bleeding with blood fluid levels *(arrowheads)*. **B4:** Coronal T2WI through the frontal region shows bilateral parasagittal hemorrhagic changes *(arrows)*. **B5:** Coronal T2WI at the site of fracture *(arrow)* shows overlying scalp swelling and bleeding. (Courtesy of Robert A. Zimmerman, MD.) (*continued*)

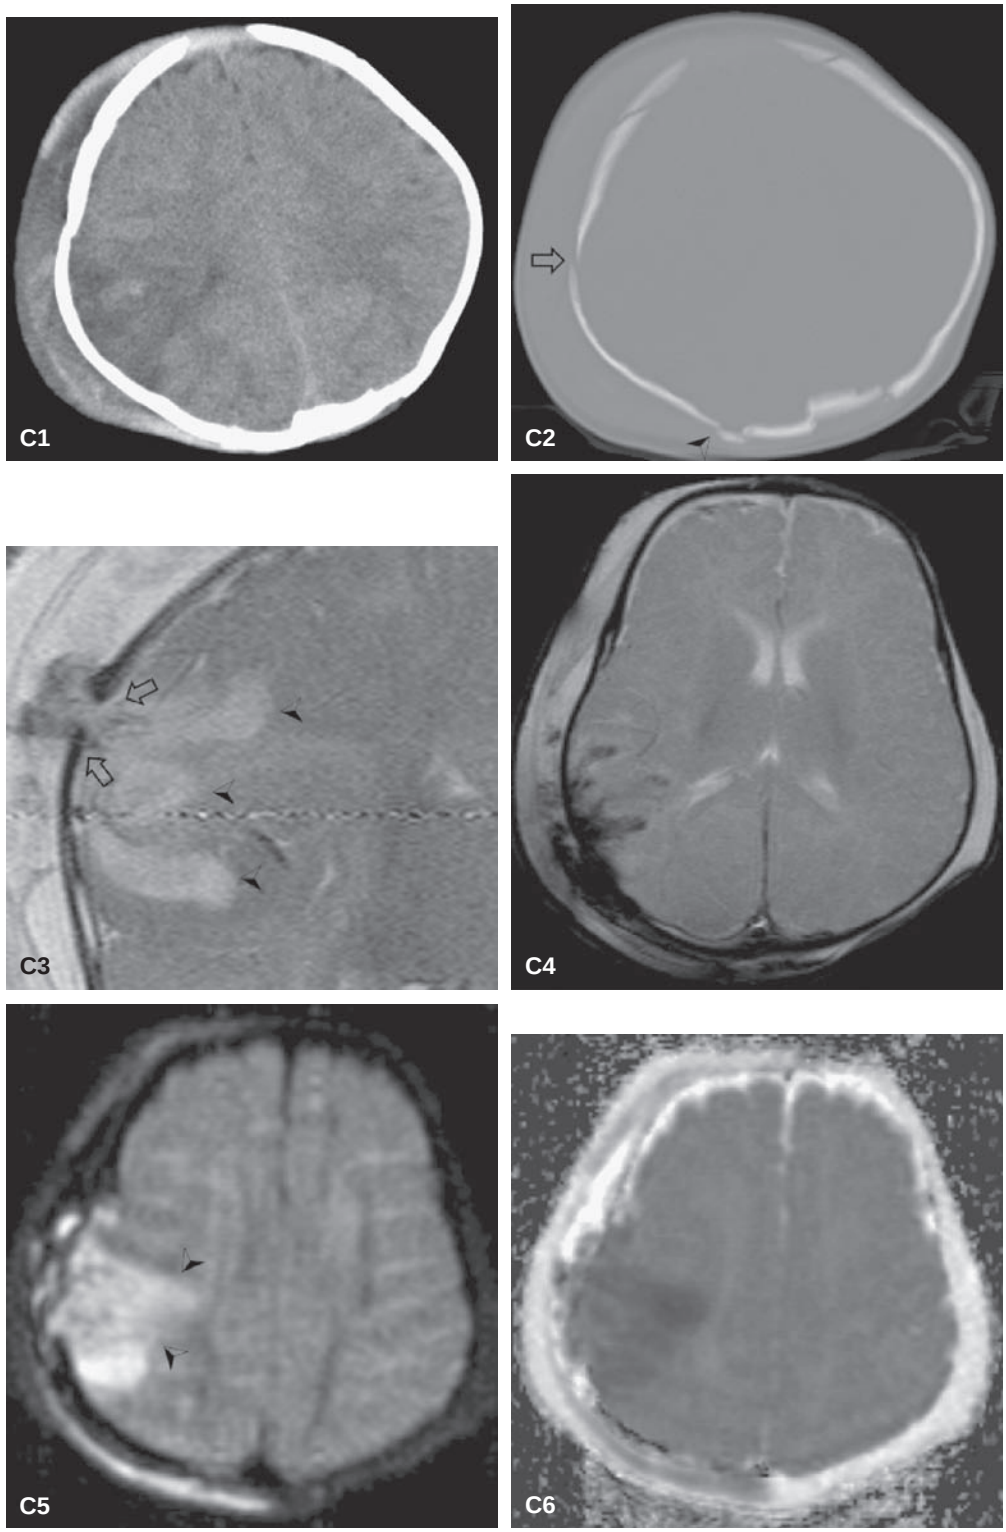

FIGURE 132.9 (*Continued*) **C:** Five-month-old male infant examined by CT and MRI on the day of admission. Parts **C1** and **C2**, axial CTs without contrast; parts **C3–C6**, MRI images. **C1:** Axial CT, brain windows, shows hemorrhage within the soft tissues of the scalp; underlying hypodensity and hyperdensity within the brain in the right parietal region consistent with contusional change. **C2:** Axial bone window at the same level as **C1** shows a fracture of the right parietal bone *(arrow)* and an additional area of fracture posteriorly at the lambdoid suture *(arrowhead)*. **C3:** Coronal T2WI demonstrates separation of the bone at the site of fracture *(arrow)* and underlying brain swelling involving the cortex, consistent with contusion *(arrowheads)*. Abnormality is present at the site of the fracture in the extracalvarial soft tissues, consistent with hemorrhage and/or herniation of brain tissue through the fracture. **C4:** Axial two-dimensional FLASH susceptibility gradient echo scan demonstrates extensive intraparenchymal and soft-tissue scalp areas of signal loss consistent with bleeding. **C5:** Axial diffusion imaging through the site of contusion shows restricted motion of water consistent with cytotoxic edema *(arrowheads)*. **C6:** Axial apparent diffusion coefficient (ADC) map at the site of the restricted motion of water shows hypointensity consistent with cytotoxic edema. (Courtesy of Robert A. Zimmerman, MD.) (*continued*)

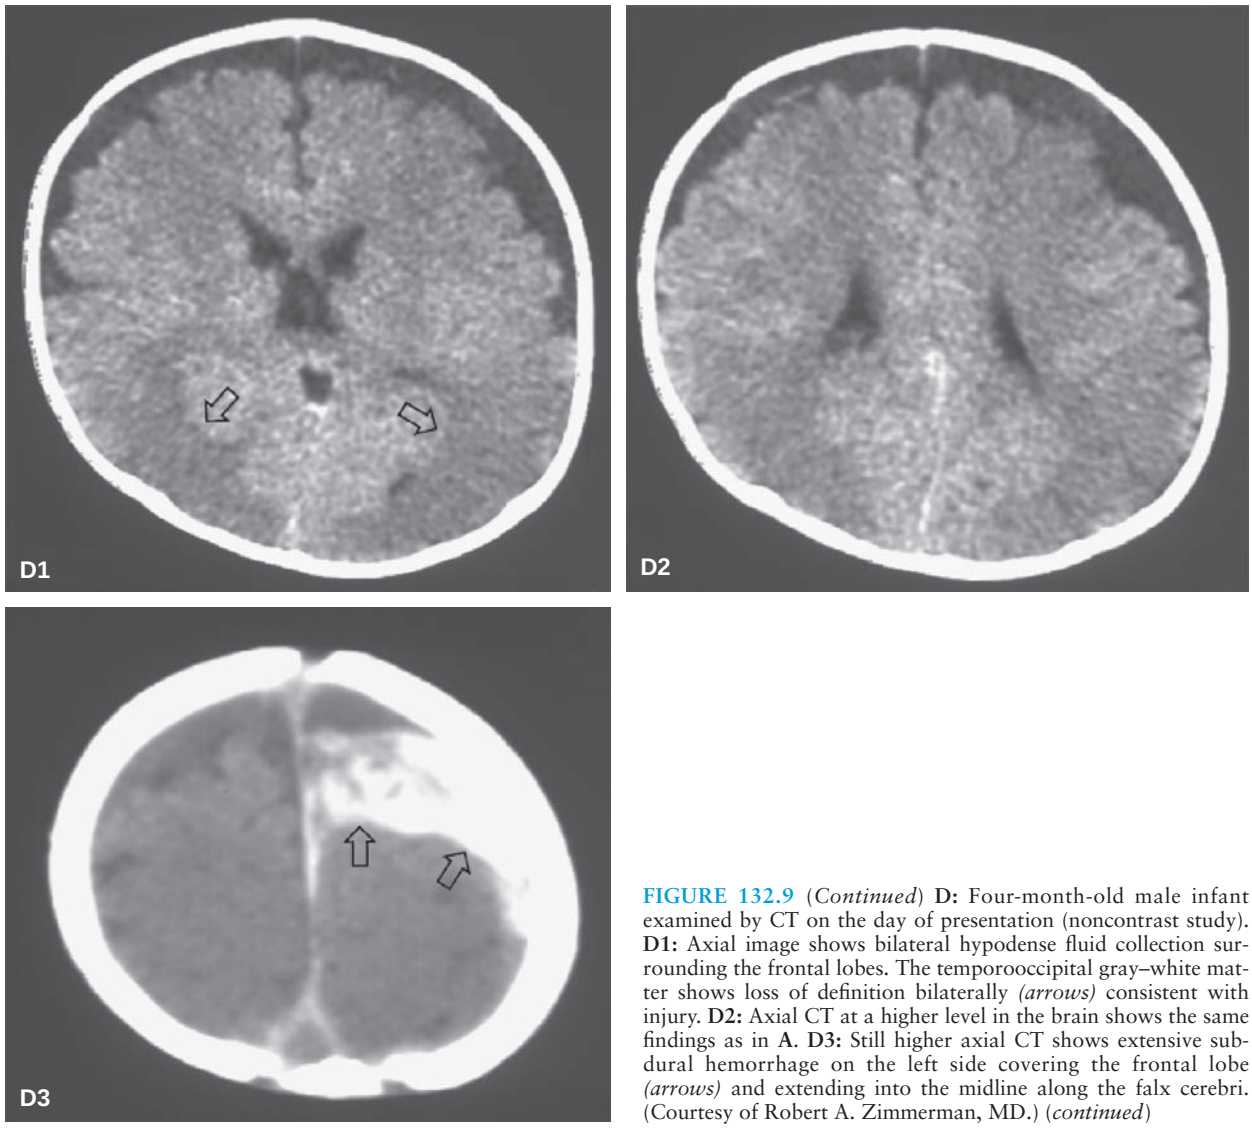

FIGURE 132.9 (*Continued*) **D:** Four-month-old male infant examined by CT on the day of presentation (noncontrast study). **D1:** Axial image shows bilateral hypodense fluid collection surrounding the frontal lobes. The temporooccipital gray–white matter shows loss of definition bilaterally *(arrows)* consistent with injury. **D2:** Axial CT at a higher level in the brain shows the same findings as in **A**. **D3:** Still higher axial CT shows extensive subdural hemorrhage on the left side covering the frontal lobe *(arrows)* and extending into the midline along the falx cerebri. (Courtesy of Robert A. Zimmerman, MD.) (*continued*)

Small infants may sustain a tear of the frenulum resulting from "bottle jamming." In older children, dental trauma may be a sign of abuse.

Other GI system manifestations are more medically serious and generally result from blunt trauma to the abdominal contents. Rupture of the spleen or laceration of the liver causes the child to present with elevated levels of liver enzymes, with an acute abdomen, or in shock, with no external source of bleeding and with absent or only minor bruising of the abdominal wall as shown in figure 132.11. The identification and management of these emergencies are covered in Section IV. A less acute presentation is the afebrile child with persistent bilious vomiting from a duodenal hematoma with small-bowel obstruction. Documenting an elevated serum amylase or lipase level or increased liver enzyme levels is important in providing tangible evidence of abdominal trauma in cases that lack any radiographic finding or abdominal wall bruising. Due to the recognition that abusive abdominal injuries may be occult at the time of presentation for medical care, some experts advocate screening all victims of suspected child abuse for occult abdominal trauma. Recommended screening tests include liver enzyme tests, amylase and lipase and urine analysis. Elevation of the serum amylase level may also identify those cases that should be followed for possible development of a pancreatic pseudocyst. See Chapter 107 for more detailed information on abdominal trauma.

Cardiopulmonary System. Abuse may be manifested in cardiac or pulmonary trauma, with no injuries that are characteristically induced by abuse. Pulmonary contusion, pneumothorax, hemothorax, cardiac tamponade, and myocardial contusion may all occur occasionally. Specifics of identification and management of these problems are covered in Chapter 118. Measurement of cardiac enzymes may help identify cardiac trauma.

Genitourinary Systems. Common genitourinary complaints, such as hematuria, dysuria, urgency, frequency, and enuresis, may be the initial signs of abuse. These problems may result

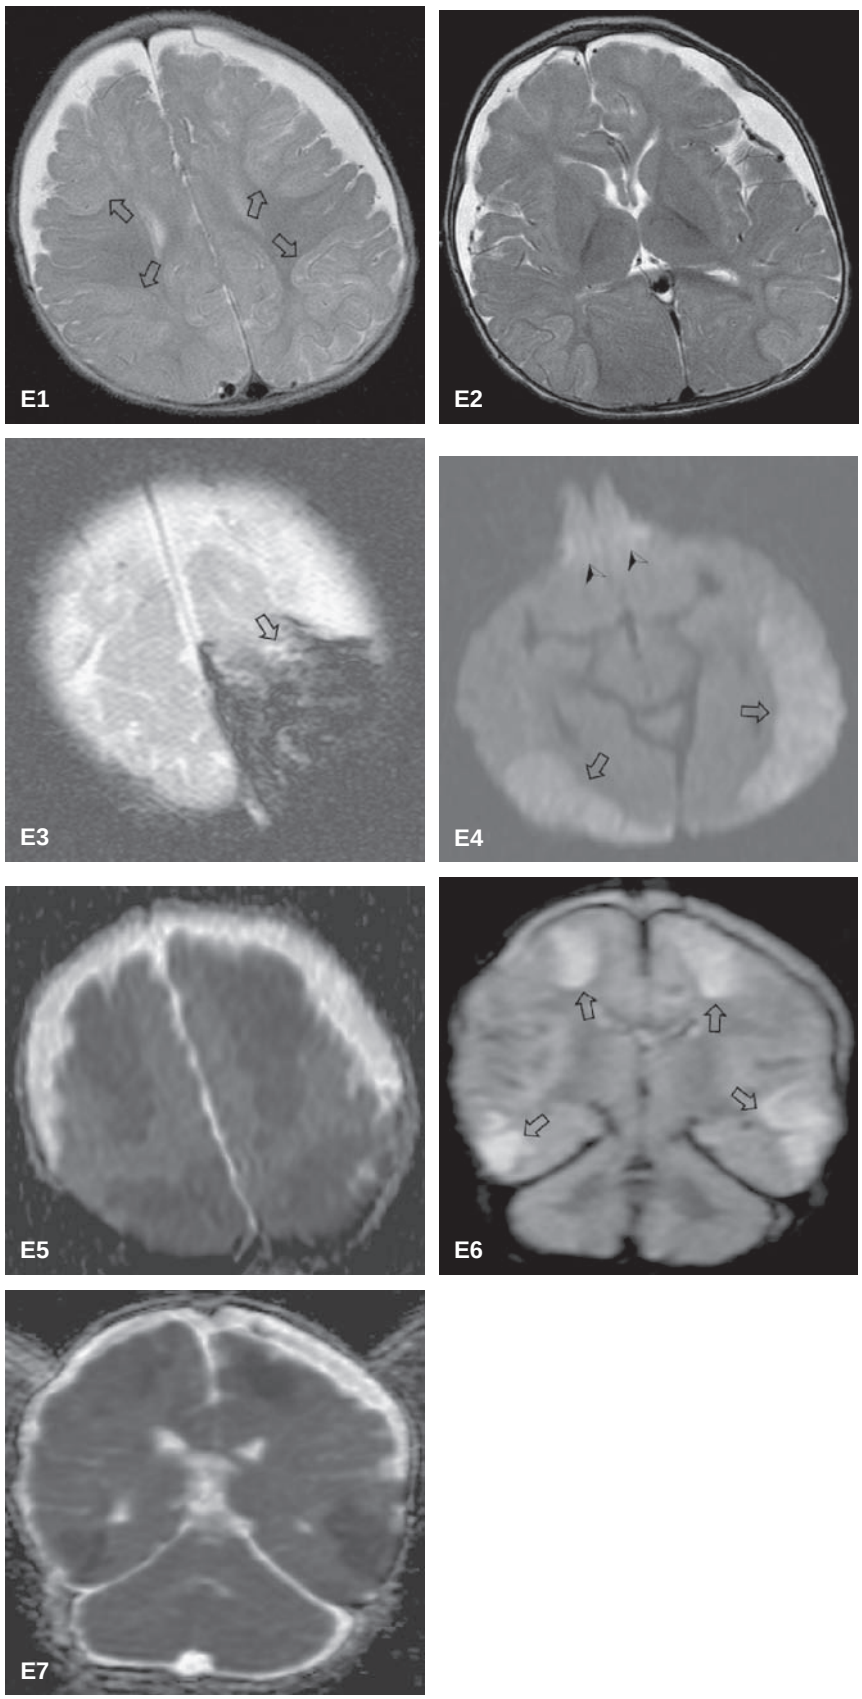

FIGURE 132.9 (*Continued*) **E:** Four-month-old male infant (same as **D**) examined on the day of presentation. **E1:** Axial T2WI shows bilateral subdural fluid collection surrounding the frontal lobes. There is abnormal subtle increased T2 signal intensity in the cortex both anteriorly and posteriorly within the brain *(arrows)*. There is sparing of the rolandic region. **E2:** Axial T2WI at a lower level shows the same findings. **E3:** Axial T2WI gradient echo susceptibility scan shows extensive area of hemorrhage in the subdural space overlying the left parietal region *(arrow)*. **E4:** Axial diffusion weighted image shows bilateral temporooccipital areas of restricted diffusion consistent with cytotoxic edema *(arrows)*. Note anteriorly in the region of the gyrus rectus that there is also bilateral cytotoxic edema *(arrowheads)*. **E5:** Axial ADC map at a higher level in the brain shows the hypointense signal in the bilateral parasagittal watershed region frontally, consistent with cytotoxic edema, as well as posteriorly in the bilateral parietal region. **E6:** Coronal diffusion weighted image shows bilateral parasagittal posterior frontal areas of cytotoxic edema and bilateral temporal watershed areas *(arrows)*. **E7:** Coronal ADC map of these injuries shows hypointense signal at the site of cytotoxic edema. (Courtesy of Robert A. Zimmerman, MD.)

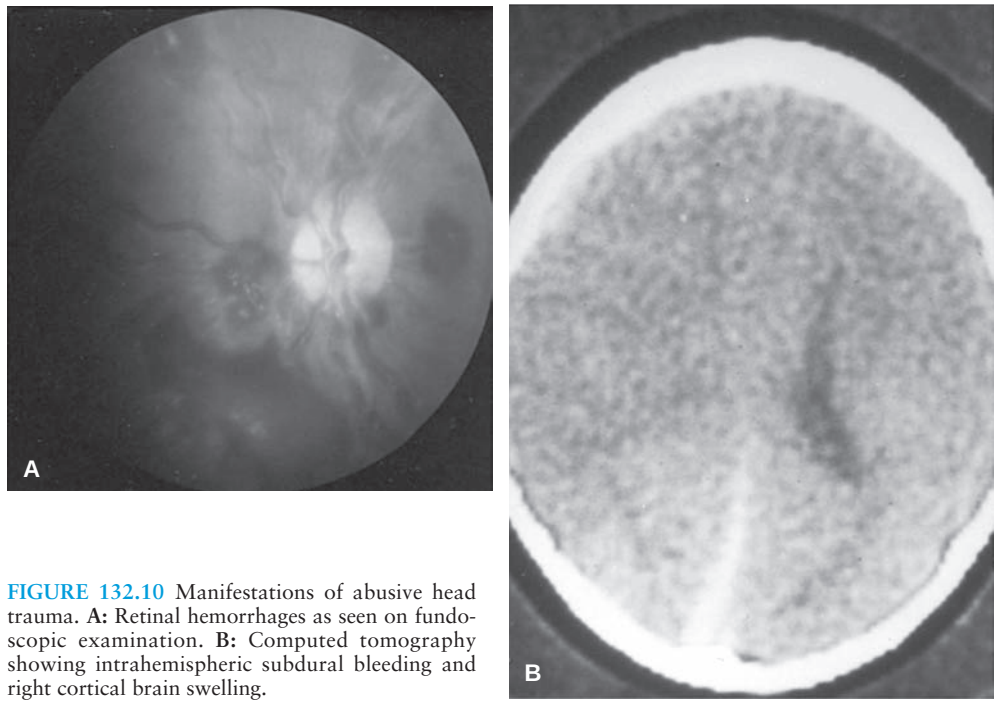

FIGURE 132.10 Manifestations of abusive head trauma. **A:** Retinal hemorrhages as seen on fundoscopic examination. **B:** Computed tomography showing intrahemispheric subdural bleeding and right cortical brain swelling.

from direct trauma, sexually transmitted infections (SITs), or emotional abuse. Some aspects of genitourinary manifestation are covered subsequently in the "Sexual Abuse" section. As for direct trauma, any part of the genitourinary system may be involved, from the renal parenchyma to the urethral meatus. Penile trauma that does not have an adequate explanation may be an alerting sign of abuse. Traumatic hematuria is managed as described in Chapter 112.

A life-threatening renal manifestation may be the occurrence of rhabdomyolysis and myoglobinuria. With extensive deep soft-tissue and muscle trauma, myoglobin may be liberated in quantities sufficient to cause acute renal failure. Such children have dark or tea-colored urine that tests positive for blood with urine dipstick but has no visible red blood cells on microscopic examination. Serum myoglobin levels confirm the diagnosis, and the serum creatine phosphokinase

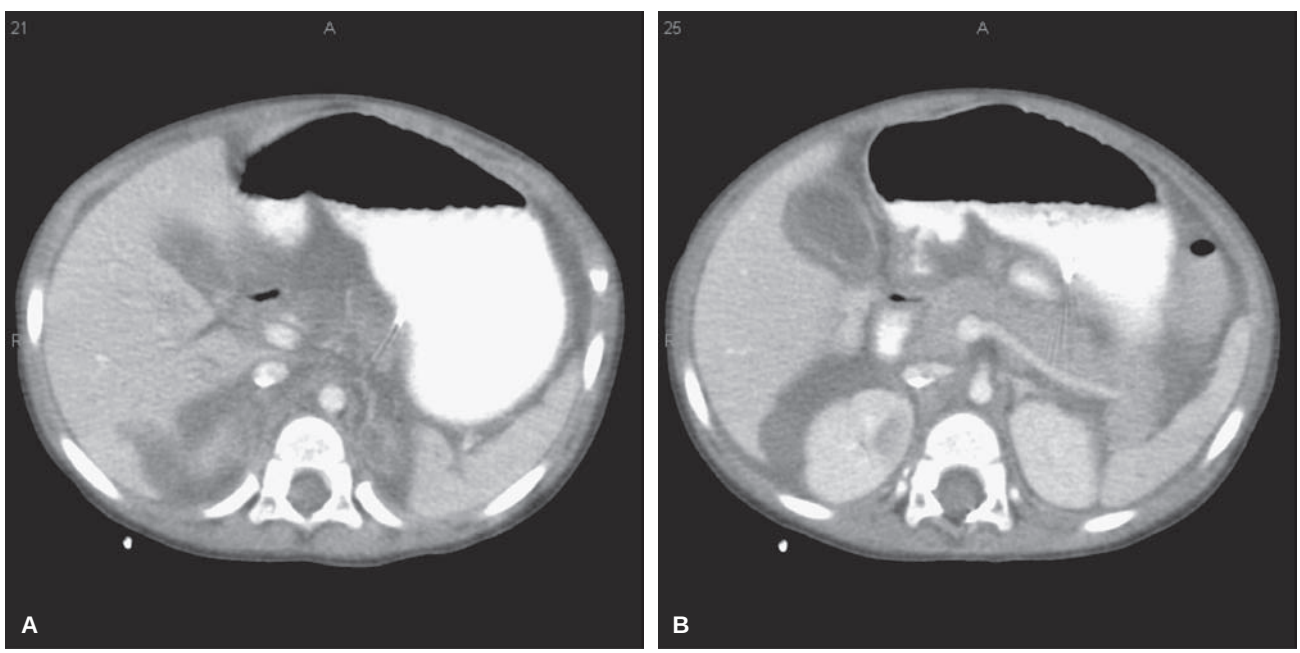

FIGURE 132.11 **A:** Abuse victim with computed tomographic (CT) scan evidence of injury to the liver and spleen. **B:** CT scan showing injury to the kidney and pancreas.

can reach extremely high values. Before using hypertonic intravenous contrast materials in the child with heme-positive urine, myoglobinuria should be considered and ruled out. The patient with possible myoglobinuria and acute renal failure must not be given potassium-containing intravenous solutions.

Sensory. The sensory organs are vulnerable to physical abuse, including ocular, nasal, and otic injuries. The eye may sustain several different forms of injury, including periorbital ecchymosis, corneal abrasion, subconjunctival hemorrhage, hyphema, dislocated lens, retinal hemorrhages, or detached retina. Each lesion is discussed in Chapters 110, 111 and 117. A careful history of injury is important when treating any of these conditions. Injury to the nose may result in simple hemorrhage or fracture and dislocation.

A direct blow to the ear may also cause ecchymosis, hemotympanum and perforation of the tympanic membrane (Fig. 132.12). In such cases, hemotympanum following basilar skull fracture should also be considered. The presence of discoloration behind the ear (Battle's sign) may be a further indication of a basilar skull fracture. Refer to Chapter 116, which deals specifically with these aspects of emergency care.

Unusual Manifestations. Rarely, the emergency physician is confronted by one of the unusual abuse manifestations. Cases of toxic and nontoxic ingestions, electrolyte disorders such as hyponatremia and hypernatremia, foreign bodies, bathtub drowning, strangulation, and multiple serious infections may be the result of abuse. In these situations, the parent actively abuses the child by feeding, instilling, or injecting harmful substances or objects into the child's body. Some children with a toxic ingestion reveal that their parents forced them to ingest the substance. The most common toxic ingestants of this type are alcoholic beverages that are given to or forced on the child to either quiet the child or demonstrate "manly" qualities. Other drugs may be used to poison the child. Most recent reports are of cocaine ingestions and passive inhalation of "crack" cocaine that has been vaporized (see Chapter 102).

Several cases have been reported in which parents have placed their children on high-salt, water-only, or pepper diets as a form of punishment. Such children may present with signs of hypernatremia or hyponatremia, possibly with seizures. Foreign bodies have been found in every orifice, as well as under the skin and in fingernail beds. There have been case reports of children who were smothered and present to the ED with florid pulmonary edema. Several cases of Munchausen syndrome by proxy (also referred to as pediatric condition falsification and child abuse in a medical setting) have been reported in which a parent has inflicted illness on the child rather than feigning or inducing illness (Table 132.3). Cases of fictitious fever, hematuria, and even sepsis have resulted from this form of abuse. Although rare, the unusual manifestations of abuse should be considered when more common causes of these problems could not be identified.

FIGURE 132.12 Ecchymosis on the internal surface of the pinna may result from "boxing" the ear, crushing it against the skull.

Management

The management of a child abuse case is difficult unless the emergency physician has a previously prepared, well-structured protocol. If reports of abuse are not a daily occurrence, an institutional policy serves as an important guide to the mechanics of management. Consultants from different disciplines, such as nursing and social work, provide invaluable assistance. A multidisciplinary approach simplifies the initial decision making and subsequent case management. The steps in the protocol are shown in Fig. 132.13.

Suspect Abuse. The first step is to decide whether a reasonable likelihood of abuse exists. Many shades of suspicion make the term *abuse* imprecise. Although every traumatic

TABLE 132.3

CHARACTERISTICS OF MUNCHAUSEN SYNDROME BY PROXY

Difficult to understand medical situation, often with recurrent episodes
Failure of other centers to arrive at diagnosis—"doctor shopping"
Unsupportive or "absent" marital relationship
Compliant, cooperative, overinvolved mother
Medical knowledge in parent's background
Findings abort with surveillance of child
Findings correlate to the presence of parent
Extensive medical care in parent's medical history

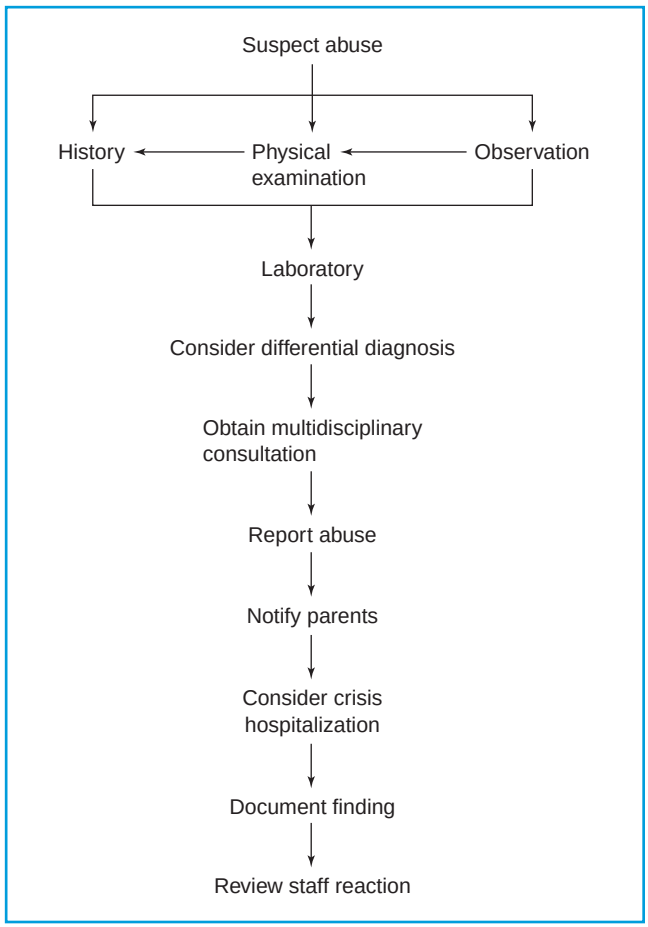

FIGURE 132.13 Procedure for emergency department management of suspected physical abuse.

injury should be suspected as abuse, the physician has the onerous task of deciding how much suspicion is necessary to take some action (i.e., report). To establish the level of suspicion, data are gathered by obtaining a complete history, performing a thorough physical examination, comparing the history and physical examination, observing interactions, and obtaining laboratory studies and/or radiographs. Then, the physician can formulate a differential diagnosis and assign a rank to abuse. Indications of abuse in the history and physical examination and observational data must be used as building blocks that are added until they achieve a certain threshold of suspicion. As demonstrated in Fig. 132.14, when the threshold is reached, a report of suspected abuse must follow. In the example of case 1, the building blocks must be used to build a level of suspicion; in case 2, the physical injury is sufficient to make the diagnosis.

A highly detailed history is always important. As in many other medical situations, this process is initiated by asking some general, open-ended questions about "what happened." If the child has sufficient verbal skills, the first questions are directed at him or her. General inquiries must then be followed with specific requests for information; however, a harsh interrogation only alienates the family. Some specific historical indications are listed in Table 132.4.

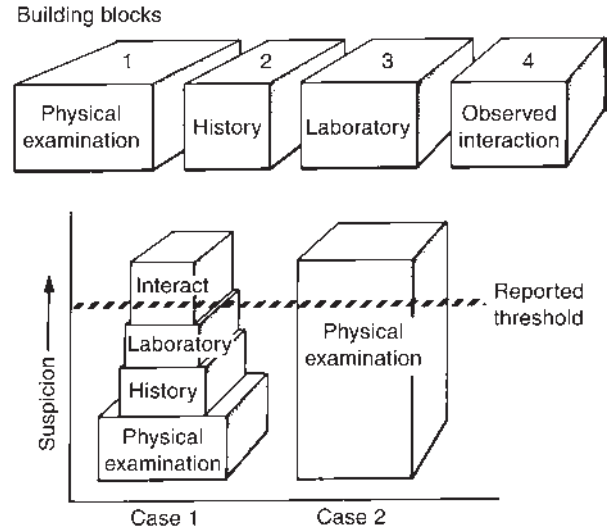

FIGURE 132.14 Building a level of suspicion.

As with the history, the physical examination must be thorough. The signs of physical abuse are detailed in the "Clinical Manifestations" section. A thorough examination serves as a means to uncover these findings. Although the clinician may be tempted to merely glance at a small contusion on a child's face, such a cursory examination fails to reveal possible linear and loop-shaped marks on the upper thighs and buttocks. Table 132.5 lists some of the important physical examination features that are indicators of abuse.

After completion of the history and physical examination, the next step is to compare them. Does the stated history match the physical findings? Does the history make sense? Does the history correlate with the developmental level of the child? Answers to these important questions may add further elements of suspicion.

This step of comparing history and physical examination is completed subconsciously by most practitioners. Physicians often attempt to match the patient's degree of symptoms with the presence or absence of physical findings, particularly in patients with psychosomatic complaints. In

TABLE 132.4

HISTORICAL INDICATORS OF ABUSE

- Is the history one of inflicted injury?
- Is there an absence of history, a "magical" injury?
- Could the injury have been avoided by better care and supervision?
- Are there inconsistencies or changes in the history?
- Is there a history of repeated injury or hospitalization?
- Was there a delay in seeking medical care?
- Does the history over- or underestimate the injury?
- Is there a medical history of prematurity, failure to thrive, and/or failure to receive adequate medical care, such as immunization?
- Is this a high-risk history (e.g., fall down stairs, dropped baby)?

TABLE 132.5

PHYSICAL INDICATORS OF ABUSE

- Does the injury match the history of injury?
- Are there pathognomonic injuries such as looped wire marks, cigarette burns, and/or bottle jamming?
- Are there multiple injuries?
- Are the injuries at various stages of healing?
- Are injuries in unusual locations?
- Are there different injury forms (e.g., burns, fractures)?
- Is there evidence of overall poor care?
- Has poisoning been documented in a young child?
- Is there evidence of failure to thrive without a history of symptoms or physical findings?
- Are there any unexplained physical findings?

child abuse cases, this step should be a conscious and well-defined step because it is vital to establishing suspicion. In some cases, a lack of consistency is obvious, such as a parent's claim that burns on the child's buttocks occurred when the child inserted his or her finger into an electric socket. Other situations may be less clear, such as the injury being attributed to hot plastic seat covers on an automobile. Although the latter explanation has in fact been reported as a case of accidental injury, it rarely explains burns on the buttocks.

Laboratory data and radiographs are another source of indicators of abuse. The laboratory studies used are few and, for the most part, document the obvious or rule out other disease states. Biochemical, hematologic, and urinary studies that are used appear in Table 132.6, along with their indications. Radiographs document a specific bony or soft-tissue injury. They may provide a comprehensive and longitudinal record of osseous injury at any site in the skeletal system. Indications for performing a skeletal survey include (i) any child younger than 2 years presenting for an injury suspicious for abuse (ii) any child with severe or extensive fractures, (iii) any child who has a history of more than one fracture, (iv) a history in the child or the family of "soft" or easily broken bones, and (v) anytime there is suspicion. Due to the high risk of occult head injury, head imaging with CT and/or MRI is also recommended in children younger than 1 to 2 years presenting with abusive injuries.

During the time occupied by the history, physical examination, and performance of laboratory studies, the physician should be cognizant of the interactions among family members and among the parents, the child, and the ED staff. Such awareness often uncovers subtle indicators of abuse. The observation of parents arguing vehemently on the way to the radiology department may be a clue. The parent who appears to be distant from both the child and the physician is also a suspect. Although the parent who is intoxicated or incoherent never fails to gain staff attention, such individuals are in the minority of abusive parents. Observation of the child is also important. All abused children are not withdrawn, passive, and depressed. On the contrary, some are competent, outgoing, or "pseudomature."

The observed state of the child depends on several factors: (i) the length, frequency, and severity of abuse; (ii) the child's developmental level and age; and (iii) the amount of positive

TABLE 132.6

LABORATORY/DIAGNOSTIC EVALUATION OF THE PHYSICALLY ABUSED CHILD

Radiographic skeletal survey
Method of choice for screening abused children for bony injury
For all children <2 yr old with suspected physical abuse
Of limited use in children >5 yr
For children 2–5 yr old, maybe useful in some cases
Repeat skeletal survey performed in 2 weeks may identify fractures missed on initial survey and clarify indeterminate findings.
Radionuclide bone scan
Adjunct to skeletal survey
Most useful if there is high suspicion of bony injury and skeletal survey is negative
CT scan
Provides sliced views through internal organs, such as brain and abdominal organs
Essential part of the evaluation of seriously injured children
Initial test used for children with suspected abusive head injury
Magnetic resonance imaging
More sensitive than CT for many injuries
Can provide images in multiple planes
Generally used as an adjunct to CT in the acute care setting
Blood tests for easy bruising/bleeding
Complete blood cell count
Prothrombin time
Partial thromboplastin time
von Willabrand's panel
± Bleeding time
Clotting factors
Screening tests for evidence of abdominal trauma
Liver
Alanine aminotransferase
Aspartate aminotransferase
Pancreas
Amylase
Lipase
Kidney
Urinalysis
Toxicology screens
For children with unexplained neurologic symptoms or symptoms compatible with ingestion
Variance among laboratories in drugs tested in "tox screen"
Screening of urine *and* blood and/or gastric contents
Consideration of blood alcohol levels for children with altered mental status

CT, computed tomography.
Adapted from U.S. Department of Health and Human Services. *A nation's shame: fatal child abuse and neglect in the United States: a report of the U.S. Advisory Board on Child Abuse and Neglect: fifth report.* Washington, DC: U.S. Department of Health and Human Services, April 1995.

interaction the child's parents and extended family have had between abusive episodes. Physicians are often surprised that the child does not immediately state the nature and extent of the abuse and ask for asylum. Such statements by children are actually rare and occur mainly in adolescent patients. Children are loyal to their parents. Abusive parents may be only episodically abusive and at other times nurturing and loving. Young children may have no framework for comparison and may

accept the abuse as the norm. Somewhat older children may understand and dislike the abuse but may fear the consequence of reporting it even more. In the child's mind, it may be better to live with the pain of abuse than to face the unknown of institutional or foster placement.

The final step in establishing a threshold level of suspicion is to review the differential diagnosis. At this point in the management scheme, the physician must add up the indicators and arrive at a judgment. If the process does not lead to a clear determination, most state laws imply that reporting suspected abuse is more prudent than not. Physicians are asked to report suspected, not proven, abuse. The major differentiation is between accidental and nonaccidental trauma. The other elements of the differential diagnosis are all uncommon diseases, including (i) bone diseases such as osteogenesis imperfecta, osteoid osteoma, and hypophosphatasia; (ii) hematologic disorders such as idiopathic thrombocytopenic purpura and hemophilia; (iii) neoplasms; (iv) metabolic disorders such as rickets or scurvy; (v) infections such as syphilis or osteomyelitis; and (vi) syndromes in which pain sensation is absent, such as spina bifida or congenital indifference to pain. These diseases occur with much less frequency than abuse but deserve consideration. Simple laboratory and radiographic studies will confirm or deny these diagnoses.

A special note should be made concerning the child younger than 12 months who is brought to the hospital deceased. In this situation, the central differential diagnosis exists between sudden infant death syndrome (SIDS) and child abuse. Other rare causes of sudden death include hypoglycemia, medium-chain fatty acid defects, mitochondrial defects, intoxication, and smothering. Victims of SIDS may appear to have bruising as a postmortem change. Clearly, their parents have no adequate explanation for the death. In this situation, the presumption should always be SIDS. Most localities require an autopsy to be performed. If not required, the physician should insist on a postmortem examination and wait for the autopsy to ultimately make the differentiation. Interrogating parents in cases of SIDS about the possibility of abuse can produce unnecessary psychological harm. With the death of a child, supportive ED treatment becomes paramount and suspicions of abuse can be pursued by the medical examiner and law enforcement personnel if warranted. If two or three SIDS deaths have occurred in the immediate family, the level of suspicion for abuse should be elevated.

Multidisciplinary Consultation. If consultation with a nurse, social worker, or physician with more extensive experience in the management of child abuse is available, it should be obtained. The advantages of consultations are many. They allow for (i) information sharing, (ii) joint decision making, (iii) planning, and (iv) mutual support. Planning an approach to the family and subsequent case management is useful. This brief consultation enables the physician to be more secure in making decisions about matters that are generally unfamiliar and often value laden. Joint interviewing is not only time efficient but also gives the family a uniform approach from the professional staff.

Reporting. Once the suspicion of abuse has been established and consultations obtained, the next step is reporting. Although laws vary from state to state, most have common elements. The emergency physician should become familiar with his or her current state law. The definition of abuse is central to each reporting law. A stated age defines a child. The laws also specify who must report (mandated reporters) and who may report (nonmandated reporters). For most mandated reports, the law requires a specific penalty (as well as malpractice liability) for failure to report and provides protection from liability if the report of suspected abuse turns out to be unfounded once investigated. Finally, the law dictates to whom and how the report should be made. Generally, reports are made to child protective services (CPS) agencies, to police departments, or to some combination of law enforcement and social work personnel. Many states now have statewide central registries for receiving reports.

Notifying the Parents and Managing Their Reactions. An important, but often avoided, step in case management is notification of the parents. This step is often forgotten because it is a difficult interpersonal task; nonetheless, it must be done. Nothing makes parents more resistant to change than completing a "routine" ED visit, only to later receive notification that the physician has filed a suspected child abuse report. Some specific guidelines are helpful in avoiding this breech of trust. The overall approach to the parents must be based on concern for the child. Concern for the child, not accusation, should be stressed. The physician should not confront the parents or attempt to seek an admission of guilt. Often, the parent in the ED may not be the abusive parent and may know as little about the episode as the hospital staff. The physician should explain the requirement for a mandated reporter to report all suspected cases. However, stating the requirement should not be used as an excuse. The desire to report should also be stated.

In many states, the reporter is required to report all injuries that are not fully explained. This requirement may also be stated to the parent. Using the words *child abuse report* is important. This situation is not a time to "soft pedal." However, child abuse does represent a range of behaviors, from the parent who overvigorously disciplines to the parent who sadistically tortures. Parents often have not seen themselves as abusers, and an explanation of the range of abuse is helpful in demonstrating how a child abuse report applies to them. Parents are fearful of what a child abuse report means and of what will happen. Therefore, the consequences of the report should be explained (e.g., "a social worker will call and come visit you in 1 or 2 days"). The physician's natural fear is that the parent will have a dramatic and hostile reaction.

The emergency physician can expect a wide variety of reactions, from hostility to appreciation. To minimize the angry reactions, the physician should stress the focus as being concern for the child. This perspective puts the physician on common ground with the parent. An angry reaction is more likely if guilt or fear is increased. This reaction may be seen as a feedback relationship. Stoking the fire by increasing the parent's guilt or fear results in a flare of angry emotion directed at the staff, the child, or the other spouse. Figure 132.15 illustrates this relationship.

Although the child does not need to be formally notified, the child may often be aware of what is happening and may even ask some pointed questions. The physician may want to discuss

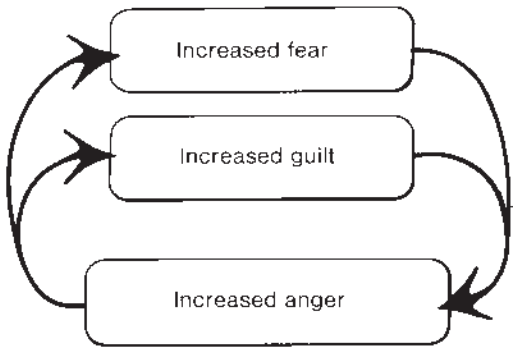

FIGURE 132.15 The cycle of fear, guilt, and anger.

the report with the child. The physician should stress the outcomes of protection and help for the child and the family. The ED staff should never be accusatory or belittling of the parent.

Crisis Hospitalization. In some cases of abuse, the family crisis is at such an acute level that hospitalization is necessary. The physician must ask, "Is the home safe?" If the child's environment poses a potential danger, the child should be admitted, no matter what the extent of injury. Some state laws have included protective custody sections that allow physicians to have virtual police powers in detaining a child for protection. In other states, the physician may need to obtain parental consent for admission.

This task is also difficult. As with reporting, the approach to the parents must be honest and nonaccusatory. The reasons for admission are to observe the child and allow time to evaluate the possibility of such an injury happening again. The focus must be the physician's concern for the child's health. In hospitalizing the child, the physician also makes a statement about the seriousness of the situation and the depth of his or her concern. Most hospitals do not have the resources to hospitalize every abused child, and it is not necessary or advisable to do so in every case. Factors that favor sending the child home are (i) a concerned relative or neighbor available to support the family, (ii) a solution to the inciting crisis, (iii) parental acceptance of responsibility, (iv) prompt (less than 24 hours) CPS or police response, (v) a first episode or minor degree of abuse, and (vi) an alternative environment (e.g., grandmother's house) (vii) older, less vulnerable child. If the physician is unable to hospitalize the child and has lingering doubts, a specific agreed-upon return appointment for the next day may be a solution. If the family is unable to keep the appointment, there should be a grave concern and emergency CPS or police involvement should be requested.

Documentation. Throughout each step of case management, documentation is important. The record of this visit is both a medical and a legal document. A precise description of the injuries enhances the document's value, and small sketches are also helpful. Photographs are invaluable in documenting extensive injuries. Photographs may be used in court to illustrate, for a judge or jury, injuries that would be difficult for most witnesses to describe. Even if the photographs are not admissible in court, they refresh the memory of the physician for testimony. Often, court proceedings may not take place for several months after the ED visit. If photographs are taken, their quality must be good. Poor-quality photographs can damage a case by failing to show all the pertinent findings.

Written descriptions of an injury are adequate for less extensive trauma, but as much detail as possible should be included. The record of the history should be as factual as possible; conclusions or impressions should not be listed. For example, rather than recording "the child looked fearful," describing the physical components or behaviors that prompted that judgment, under standard courtroom procedure, is more appropriate. Direct quotes from the child or parents should be included because quotes from another person are generally considered hearsay and are disallowed. When such quotes are included in the text of a business (medical) record, they may become more acceptable. General legibility and, in particular, a clearly written signature are always important record requirements. At the time of the ED visit, detailed record keeping seems to be a burden and waste of time. When a case record requires review before court testimony, good documentation is a necessity. Upon completion of the record, the physician should read it again as if he or she was the defendant's attorney.

Staff Reactions. Child abuse triggers many emotions in the physician and in the ED staff. Sadness and pity for the child and, often, anger for the parents are exhibited. The staff may have a general feeling of disbelief, "How can this happen?" The case management plan previously described requires that each ED staff member be professional and in control of these emotions. The offhand comment of a clerk or the whispering among nurses can undermine the work being done with the family. If a staff member is too upset by abuse, he or she should be relieved of the responsibility of working in such situations. Physicians or nurses who openly attack the family or who are blatantly accusatory should not be involved in these types of cases. Only after having experience with large numbers of cases can an ED staff member develop an appreciation of abuse as a negative but understandable human response. With such a perspective, the physician can become less angry and more zealous in attempting to provide constructive case management.

If problems relating to the staff reaction exist, as they often will, several corrective actions should be taken. At times, a brief meeting of the involved staff members can be called after the family has been discharged from the ED. This meeting allows staff members an immediate opportunity to ventilate their feelings. In-service education serves the same purpose, providing a forum for staff members to discuss their personal feelings about abuse, as well as their past experiences. ED staff members are always involved in the negative aspects of identifying and reporting abuse, but they never see the long-term treatment and rehabilitation phase. If a therapist, or better yet a family member, can present this side of abuse to the staff, it engenders more positive attitudes. Without learning about the successes, the staff often displaces this anger, charging "incompetence" of the CPS agency or "leniency" of a family court judge. Scapegoating should be put into the proper perspective. Again, in-service education and case reviews are useful. The integrity of the entire treatment team,

both in the hospital and in the community, must be maintained to accomplish the difficult goals of protecting the child and preserving family life.

SEXUAL ABUSE

During the last 30 years, sexual abuse has been increasingly recognized as an important pediatric medical problem. According to the NCANDS, CPS agencies have determined more than 78,000 children in the United States to be victims of sexual abuse in 2006. Research studies, however, suggest that only a small percentage of sexual abuse cases are reported to CPS agencies. Experts estimate that each year, 1% of children become victims of sexual abuse. In addition to leading to increased recognition of the magnitude of the problem, recent research has also led to the development of improved medical guidelines for the identification, evaluation, and treatment of sexual abuse. Prompt diagnosis, humane emergency management, and referral to long-term treatment resources are the goals of the emergency physician. Working in a multidisciplinary fashion with nursing and social work staff is important. As with the physically abused, the sexually abused child engenders a great deal of emotion from the health care professionals in the ED.

Background

The term *sexual abuse* often conjures up images of a violent, forced sexual attack and rape. Many people think of the psychopathic criminal luring children on their way home from school by offering them gifts, but such stereotypes are the exception. Commonly, a relationship exists between the perpetrator and the victim. The misuse of that relationship is central to the sexual abuse of the child. The relationship may be a familial one, such as father–daughter. In more than half of the cases of sexual abuse identified by CPS agencies in 2006, the perpetrator was a relative. The relationship may also be a household relationship, such as mother's live-in paramour and the child, or a more casual relationship, such as that with a neighbor, teacher, or friend of the family. Many experts believe that sexual abuse is the most underreported form of child maltreatment because of the secrecy or "conspiracy of silence" that so often characterizes these cases. Most often, no overt violence is perpetrated, although harsh threats of violence as a consequence of the child's revealing the act to another person may be issued.

The definition of sexual abuse varies from state to state, but federal law under CAPTA provides a minimum definition of sexual abuse that applies to all states. CAPTA defines *sexual abuse* as

- "The employment, use, persuasion, inducement, enticement, or coercion of any child to engage in, or assist any other person to engage in, any sexually explicit conduct or any simulation of such conduct for the purpose of producing any visual depiction of such conduct;
- Or rape, and in cases of caregiver or interfamilial relationships, statutory rape, molestation, prostitution, or other form of sexual exploitation of children, or incest with children."

Sexual abuse encompasses a wide range of inappropriate sexual activities, including fondling a child's genitals, intercourse, incest, rape, sodomy, exhibitionism, and commercial exploitation through prostitution or the production of pornographic materials. Emergency physicians should become familiar with the specific laws governing sexual abuse in their area. For example, in the commonwealth of Pennsylvania, statutory rape occurs when a person engages in sexual intercourse with a complainant younger than 16 years and that person is 4 or more years older than the complainant and the complainant and the person are not married to each other. In Nebraska, however, first-degree sexual assault occurs when a person 19 years or older sexually penetrates a person younger than 16 years. Some state laws define specific acts of sexual abuse such as rape, incest, statutory sexual abuse, and involuntary deviate sexual abuse, but other state laws refer to sexual abuse in more general terms.

Clinical Manifestations

Child sexual abuse victims usually come to medical attention due to one of the following five reasons: (i) a disclosure of inappropriate sexual contact, (ii) anogenital complaints, (iii) nongenital physical complaints, or (iv) inappropriate sexualized behaviors or (v) nonspecific behavioral complaints (Table 132.7).

Disclosure of Sexual Abuse. The majority of child victims of sexual abuse present for care after making a disclosure. Children frequently do not disclose that they have been sexually abused immediately after the event but may wait days, months, or even years before telling anyone and presenting for medical care. Even when a child does disclose, he or she may not fully disclose the extent of the abuse. When a child makes

TABLE 132.7

PRESENTATIONS FOR EVALUATION OF SEXUAL ABUSE

Disclosure	
Child discloses history of inappropriate sexual contact	
Physical complaints	
Anogenital	**General**
Anogenital injury Bruises Lacerations Bleeding Pain Sexually transmitted disease Pregnancy	Abdominal pain Anorexia Dysuria Encoporesis
Behavioral complaints	
Inappropriate sexual behaviors	**Nonspecific behavioral complaints**
Compulsive masturbation Inappropriate knowledge of adult sexual behavior Excessive sexual curiosity, sexual acting out	Excessive fears, phobias Refusal to sleep alone, nightmares Runaways Any abrupt change in behavior

a disclosure and offers the specifics of an encounter, a report to CPS should be made. Reports of suspected sexual abuse are often based on history alone. Children do not usually make up allegations of sexual abuse. Most children who are not abused are not knowledgeable in the details of sexual encounters. The detail of the disclosure varies with the child's age and language development, but even children of 3 or 4 years of age may be able to make statements about someone touching their genitals.

Genital Complaints. Child victims of sexual abuse may present with genital complaints resulting from trauma, infection, or pregnancy. A physical injury such as a laceration, abrasion, or bruising to the genitalia or anus of a child should elicit a suspicion of sexual abuse and be evaluated. Accidental straddle injuries can produce external genital trauma and are the most common form of accidental genital injury to young girls. Straddle injuries, however, rarely produce hymenal injury and do not cause vaginal injury. The premenstrual child who presents with vaginal hemorrhage may be bleeding from a vaginal laceration that is not visible on external examination. Prompt surgical or gynecologic consultation should be obtained to identify and treat unseen sites of trauma. In males, accidental penile trauma may occur from zipper accidents or from a toilet seat that falls. Beyond these common accidental situations, the emergency physician should scrutinize the history given and consider sexual abuse.

The presence of an STI in a prepubertal child raises suspicion for sexual abuse. While some STIs should be considered as evidence of sexual abuse, other STIs may frequently be transmitted through nonsexual modes. On the basis of an understanding of disease transmission, the American Academy of Pediatrics (AAP) and the CDC have placed these infections into four categories. The first category includes those infections that are virtually always transmitted through sexual contact (Table 132.8). In this category, syphilis, *Neisseria gonorrhoeae* infection, and *Chlamydia trachomatis* infection are considered diagnostic for sexual abuse in prepubertal children if perinatal acquisition and rare nonsexual vertical transmission have been excluded. In the absence of perinatal or transfusion-related transmission, human immunodeficiency virus (HIV) infection is also considered diagnostic for sexual abuse. In the second category is *Trichomonas vaginalis* infection, which to the best of clinical knowledge is usually transmitted sexually and should be considered highly suspicious for abuse. Category 3 includes condyloma accuminata (anogenital warts) and herpes simplex, which are suspicious for abuse but may be transmitted by nonsexual contact. Although the CDC and the AAP categorize condyloma accuminata as suspicious for abuse and recommend making a report of suspected sexual abuse to CPS, recent literature suggests that the majority of cases of anogenital warts in children likely result from nonsexual transmission of the human papillomavirus (HPV). Thus, although sexual abuse must be considered during the evaluation of child with genital warts, in the absence of a disclosure or other concerning findings, a report to CPS may not be warranted in a young child infected with HPV. Category 4 includes bacterial vaginosis, which is not considered indicative of sexual abuse. Although not included in the AAP categories, scabies and lice can also be transmitted non-sexually and should be considered inconclusive findings.

The pregnant adolescent may be a victim of sexual abuse. The physician should try to obtain a specific history of conception. Often, the focus of case management centers on how the adolescent plans to notify her parents or whether she considers abortion or adoption as an option. If the issue of paternity is not pursued, sexual abuse escapes detection.

Nongenital Physical Complaints. In addition to presenting with genital concerns, child victims of sexual abuse may be brought for medical evaluation of a broad range of nonspecific physical complaints. Sexual abuse may be related to cases that present with headache; pain in the abdomen and thighs; dysuria; pain on defecation; hematuria; or hematochezia. For example, gonorrhea can present with vaginal discharge but may also appear in cases of less well-defined symptoms such as vaginal pain, itching, urinary frequency, or enuresis. Abuse may manifest as a change in habits, such as urinary frequency, enuresis, constipation, or encopresis; other complaints may include a chronic sore throat. The cause of each of these complaints may be any number of things. For example, in studying a group of children with enuresis, sexual abuse is an uncommon cause of the complaint. Nonetheless, sexually abused children are regularly brought to EDs with nonspecific complaints. If sexual abuse is not considered, it goes unnoticed.

TABLE 132.8

SEXUALLY TRANSMITTED INFECTIONS AND LEVEL OF CONCERN FOR SEXUAL ABUSE

Diagnostic for Sexual Abuse in Most Cases*	Highly Concerning for Sexual Abuse*	Concerning for Sexual Abuse	Inconclusive: Non-Sexual Transmission Possible
Neisseria gonorrhoeae *Chlamydia trachomatis* Syphilis HIV	*Trichomonas vaginalis*	Genital herpes simplex virus (HSV)** Anogenital *Condyloma accuminata***	Pediculosis pubis Scabies Bacterial vaginosis

*In the absence of clear alternative mechanism for transmission of infection, a report should be made to child protective services (CPS). Perinatal transmission and non-sexual transmission (although rare) should be considered for *Neisseria, Chlamydia,* and syphilis. Perinatal or transfusion related transmission should be considered for HIV.
**In the absence of a history of autoinoculation from a non-genital HSV infection a report to CPS is recommended.
***Although the AAP guidelines recommend reporting cases of anogenital warts to CPS, recent research suggests that the majority of cases in children result from nonsexual transmission. If a thorough evaluation reveals no other findings concerning for sexual abuse, a report to CPS may not be indicated.

TABLE 132.9

SEXUAL PLAY

Normal	Needs further assessment
Discreet, private	No regard for privacy
Mutual consent	One child does not freely consent
No power imbalance	Power imbalance
No threats or violence	Actual or implied threats or violence
Infrequent	Frequent, compulsive
Age-appropriate language and sexual knowledge	Language beyond age-appropriate level of sexual knowledge
Does not result in injury	Causes injury
Basic, rudimentary sexual activity	Explicit, graphic, and detailed sexual activity; attempted or actual penetration of genital orifices

Adapted from Haka-Ikse K, Mian M. Sexuality in children. *Pediatr Rev* 1993;14:401–407.

Behavioral Manifestations. Some children manifest behaviors in their play or in their conversation that indicate that they have been exposed to sexual experiences and perhaps abused. These signs are less specific than a clearly stated history, but they are significant enough to require evaluation. All children manifest sexual curiosity and may engage in some form of masturbation, but when either behavior appears in excess, it deserves investigation because sexual abuse may be the cause. For example, children who want to fondle their parents' genitals as an expression of affection are cause for concern. Tables 132.9 and 132.10 help differentiate normal play and masturbation from more worrisome sexually inappropriate behaviors. These behaviors are usually learned. Although, inappropriate sexual behaviors should trigger a suspicion and evaluation for abuse, they are not by themselves diagnostic for abuse. Children may be exposed to sexual material through many routes, including television and the Internet.

TABLE 132.10

MASTURBATION

Normal	Needs further assessment
Occasional	Frequent, compulsive
Discreet, private	No regard for privacy
Not preferred over other activity or play	Often preferred over other activity or play
No physical symptoms or signs	Produces genital discomfort, irritation, or physical signs
External stimulation of genitalia only	Involves penetration of the genital orifices; includes bizarre practices or rituals

Adapted from Haka-Ikse K, Mian M. Sexuality in children. *Pediatr Rev* 1993;14:401–407.

Sexually abused children may also exhibit relatively minor unexplained behavioral changes, such as the recent episodes of nightmares or phobias, or major changes, such as school truancy and adolescent runaways. Children who bear no physical evidence of their abuse and in whom no physical symptoms develop may express themselves behaviorally. Many children demonstrate change in one or more of the important spheres of their life: at home, in school, or with peers. A sudden change in school performance unexplained by the teacher, social withdrawal, and isolation may also be nonspecific behavioral manifestations of sexual abuse. Thus, sexual abuse should be considered in the differential diagnosis of a child with nonspecific behavior changes.

Management

The primary goals in case management of most sexually abused child are the following: (i) identify and report the abuse, (ii) test for and provide prophylaxis and or treatment of STIs if indicated, (iii) test for and provide prophylaxis for pregnancy if appropriate, (iv) collect forensic evidence if appropriate, and (v) provide referral for psychological evaluation and treatment. A minority of pediatric sexual abuse victims will also have traumatic injuries requiring medical treatment. Care should be taken to avoid causing *secondary abuse phenomenon* while completing these goals. *Secondary abuse phenomenon* refers to the physical examination that is so overzealous that it assumes a rape-like quality in the mind of the child. Also to be avoided are parental or staff reactions that make the child feel responsible or blamed for the abuse. To allow long-term sexual assault evaluations to be performed in a less stressful environment, many ED centers have moved to performing a screening function. Children who have been abused within the past 72 hours or have acute symptoms (e.g., bleeding, signs of sexually transmitted disease) need immediate evaluation because forensic evidence may be collected or they may require urgent medical treatment. Children who were abused more than 72 hours ago and do not have any acute symptoms may be referred to a sexual assault center for a nonemergent evaluation. In places where no center is functioning, evaluations must be done in the ED. The following sections offer management techniques to identify suspected sexual abuse and gather enough documentation for legal purposes in a manner that is humane for the child and supportive for the family. Chapter 130 details the management of adolescent rape victims.

Interviewing the Parent. Parents may present the problem of sexual abuse either directly or indirectly. For the parent who is direct (i.e., "My child's been abused"), it is important to provide a controlled, quiet environment because he or she may be upset and angry. With such parents, the interviewer's tasks are calming, limiting, and clarifying. If possible, the parent should be interviewed without the child present. In an example of the indirect presentation, the parent brings the child for complaints such as those detailed in the sections on nonspecific physical or behavioral manifestations. With this parent, the task of the interviewer is to bring the possibility of sexual abuse into the open. Once the topic is nominally broached, it may become apparent that the parent has already considered sexual abuse. With both types of parents, exploring their concerns and their information in detail is important. Most of the parents bringing their child to the ED initiate their visit on the

basis of a real observation or a strong feeling that something has happened to their child. The emergency physician must help clarify what the initiating cause may have been. In some cases, the parent may have responded to anxiety that their child may have been abused and can provide no substantive cause for their concern. In some of the latter cases, a follow-up visit to a sexual abuse center may be needed for the parents to again explore the motivation for their anxiety before their concerns can be put to rest. During the parental interview, information regarding the child's medical history and relevant signs and symptoms should be obtained.

Interviewing the Child. In most cases of child sexual abuse, the key to making the diagnosis rests with the history. Beyond standard history taking from the parents, the emergency physician should obtain a history from the child. This task may difficult for several reasons: (i) the child's level of language development, (ii) the child's level of psychosexual development, (iii) the desire not to contaminate what may be important evidence, (iv) the apprehension of the child and the parent, and (v) the awkwardness and apprehension felt by the interviewer in discussing sexual matters with a child. If possible, the child should be interviewed without the parent or caregiver present. A third party (e.g., a nurse or social worker) should be present. An initial discussion of topics, other than the alleged abuse, may comfort the child and encourages him or her to talk to the interviewer. Information about school, peers, and family adjustment is important in looking for nonspecific behavioral manifestations, and this preliminary conversation also helps evaluate the child's developmental level. Table 132.11 briefly outlines normal sexual developmental stages and appropriate interviewing techniques for each level.

On focusing the conversation on the abuse, one technique may be to ask the child why his or her parents brought him or her to the hospital. More specific questions may be necessary in some cases. One approach is for the physician to explain that sometimes he or she cares for children who have been hurt or touched by someone in a way that they did not like. The physician can then ask the child if anyone has hurt or touched him or her in a way that he or she did not like. Care should be taken to use open-ended questions and avoid leading questions. New words should not be introduced into the child's vocabulary. The physician may establish common vocabulary by asking the child the term used for his or her genitalia. Children offer a rich variety of terms and may have no understanding of the words "vagina" and "penis." In eliciting and using common language, the physician gets to the point of the interview more easily.

Children younger than 3 years are often not able to be interviewed. Techniques using anatomically correct dolls may be useful in preverbal children (Table 132.11). These dolls allow the child to play out the episode. Similarly, some children may choose to draw a picture that tells the story or that may be used by the interviewer to initiate the interview. These techniques are usually only employed by professionals with specific training in interviewing young children and may not be appropriate in the ED setting.

Emotional Support. Throughout the interview and in all contacts with the child, the rightness of his or her decision to discuss the abuse should be stressed. A child experiences conflict about revealing a secret, especially a long-standing secret. The patient may also feel conflict in sensing that his or her actions may be provoking a great deal of emotional turmoil. Often, the child has a relationship with the perpetrator and realizes that this admission may alter or end the relationship. At times, the child is aware or is made aware of getting the perpetrator "in trouble." Reaffirm the importance of what the child has revealed and focus the wrongdoing on the perpetrator. The child may have been threatened not to tell. Thus, bringing the nature of the threats into the open and offering protection to the child are important concerns. Finally, many children have fears about the abuse. Common fears are shown in Table 132.11. The physician may anticipate and address these fears on the basis of the child's development.

Physical Examination. A complete physical examination should be conducted with the knowledge that in many cases, the examination including the genital examination will be normal. Research by Kellogg, Heger, and other experts has repeatedly shown that the majority of pediatric sexual abuse cases do not have physical evidence of abuse on examination. In some cases, the sexual abuse may have involved fondling, labial coitus, or other forms of inappropriate touching that did not cause genital trauma. Even when vaginal penetration occurs, the physical examination may be normal as evidenced by Kellogg's study of pregnant sexually abused adolescents. Despite being pregnant, 86% of the adolescents had normal or nonspecific findings at the time of their examination. In some cases, the child may have sustained trauma that healed by the time of his or her medical evaluation. Many injuries to the hymen can heal rapidly and completely as evidenced by several research studies including the work of McCann and Heppenstall-Heger. Similarly, research has shown that the majority of children who disclose a history of anal penetration have normal physical examinations.

The examination should be conducted in a standard fashion, with all parts of the body examined. The child should be evaluated for signs of physical abuse or neglect. Other physical findings to note carefully are any contusions, abrasions, or lacerations in nongenital areas. Common sites for these signs of trauma are the upper thighs, buttocks, and upper arms. Figure 132.16 shows some of the visible findings of child sexual abuse. The oropharynx should also be carefully examined, especially if the child discloses a history of oral penetration. The genital examination may be a point of significant trauma for the child and care should be taken to minimize the child's anxiety. Young children may prefer to be examined while sitting in their parent's lap. In examining the genitalia of young girls, two positions are recommended. One is a frog-leg posture, which can be done with the child supine on the examination table or in an adult's lap. Alternatively, the child can lie prone with knees tucked under the thorax (i.e., the knee–chest position).

The external genitalia should be inspected for any signs of trauma or infection. In females, the labia majora and minora, clitoris, urethra, periurethral tissue, hymen, fossa navicularis, posterior fourchette, perineum, should all be examined. In particular, the rim of the hymenal opening should be examined for any notches, transections, or lacerations. In postpubertal girls with redundant hymenal tissue, examinations in different positions or the use of a dampened cotton swab or other techniques may be needed to fully visualize the hymenal rim. In

TABLE 132.11

DEVELOPMENTAL ISSUES IN MANAGING THE SEXUALLY ABUSED CHILD[a]

Age		Developmental issues	Fears	Techniques
0 to approximately 3 yr	*General* Depend on protection of adult Little or no ability to label time or sequence events Language only partially intelligible May not be able to identify body parts Toilet training in process	*Sexual* Normal self-exploration of genital area is pleasurable Confused if this behavior is labeled "wrong" or "dirty" If sexual abuse is not painful, it may be accepted By age 3, curious about genitals of others	Terrified of painful assault Terrified of losing protection of adult	May not be able to be interviewed Consider having parent present during interview Use dolls to[a]: Point to body parts Do actions
Preschool, 3–6 yr	Language skills better Able to sequence events Gender differentiation established Cannot tell time but can have established time concepts, "before or after"	Sexually curious Younger children exhibit bodies Modesty develops Vocabulary of sex parts and body functions After abuse, there may be masturbation and/or sexual play	Confused over incident Frightened by parents' anxiety and anger Feel they are "bad" for causing parents to be upset Behavior changes and phobias may develop (e.g., fear of dark, fear of strangers)	Ask children to draw pictures[a] Use doll or puppet play to note response[a]
School age	*General and sexual* Sexual interest increases but usually more curious than erotic Discomfort discussing their bodies, especially outside family Extremely modest with strangers and often with parents Abusive incident may have been pleasurable and nontraumatic		Abuse is perceived as sexual, may feel "sex is wrong" Often have been threatened by adult perpetrator Guilt about what they did vs. guilt over getting adult and family into trouble Fear about their bodies, feel "dirty" or "different" after incident	Use same-sex interviewer Do not assume correct knowledge of body; a physically mature 10-yr-old child is not necessarily emotionally mature or well informed Give reassurance of their nonresponsibility for the abuse Give praise for having reported incident Encourage child to talk about parents' reaction Mobilize family to support victim
Adolescent	Strong urge to conform and be "normal" Knows what is and is not socially acceptable Developing body image and self-esteem is very fragile Conflict between the need to assert independence, and the need for adult protection and approval		Forcible nature of sex is terrifying even to a sexually active adolescent Grief over loss of virginity Feeling that he or she is dirty or abnormal Fear of unavoidable further encounters with perpetrator Fear that a homosexual encounter may have lifelong consequences	Stress the normality of the victim—not branded for life Use charts or models Victims need to know that you have seen others with similar experiences who have recovered well Mobilize active family support Be available—give victim your phone number at work or social worker's phone number Victim advocate groups very helpful

[a]These techniques are usually only employed by professionals with specific training in interviewing young children and may not be appropriate in the emergency department setting.
Adapted from J. Michaelson, J. Paradise, S. Ludwig, unpublished data, 1983.

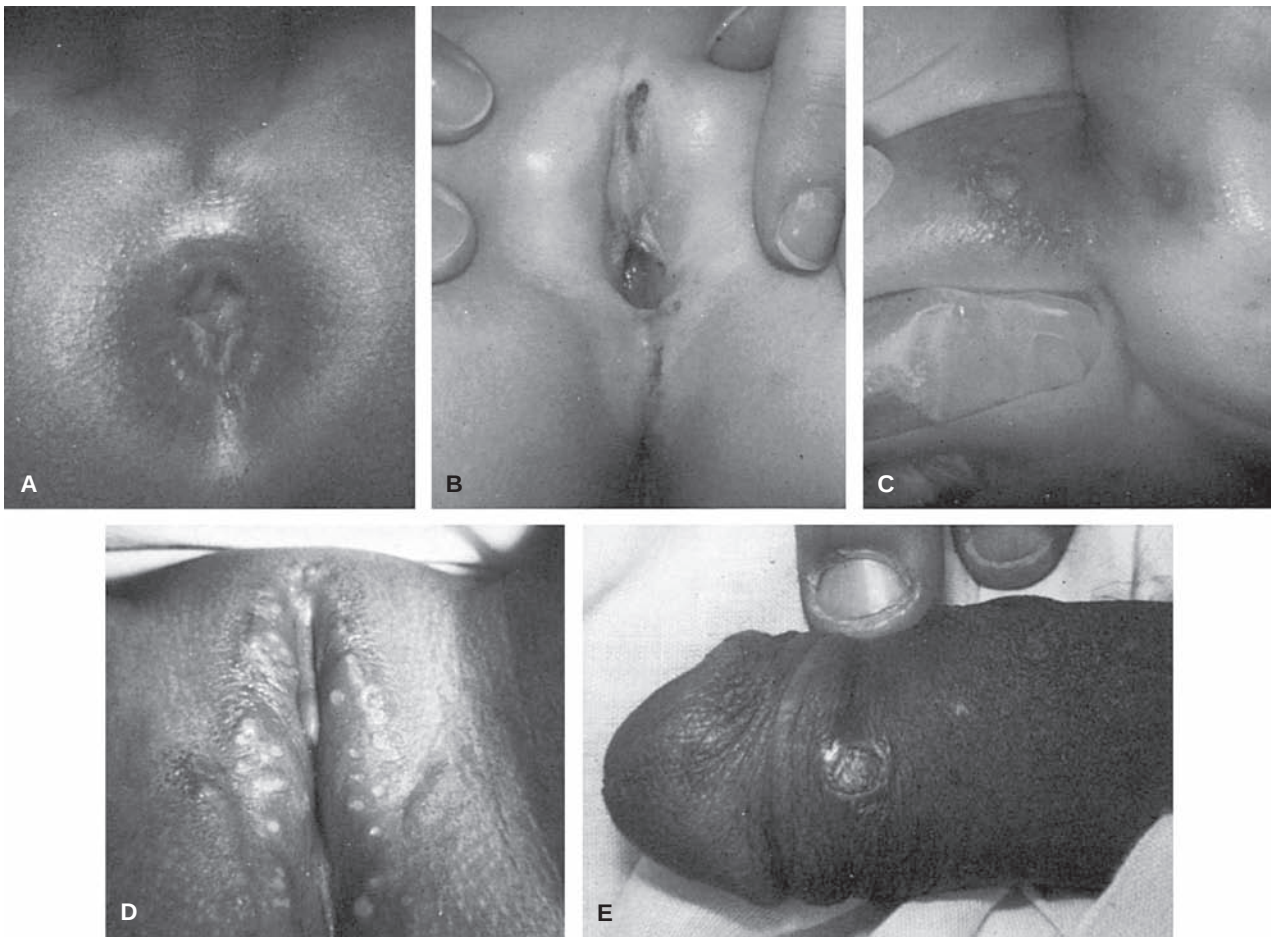

FIGURE 132.16 Physical signs of child sexual abuse. **A:** Rectal dilation and multiple lacerations after sodomy. **B:** Multiple vaginal and paraclitoral lacerations. **C:** Herpes simplex virus infection in perirectal area. **D:** Herpes virus vaginitis. **E:** Syphilis in a sexually abused adolescent.

prepubertal females, the hymen is sensitive and the examiner should avoid touching it if possible. Attempts to measure the size of the hymenal opening are unreliable and are not recommended as part of the examination. The location of any hymenal findings can be described using a clock face. In males, the penis and scrotum should be inspected. The perineum and perianal tissue should be examined in both genders even if the child did not disclose anal penetration. Any lesions, bruises, lacerations, scars, bleeding, discharge, or other findings should be documented. Figure 132.16 shows some of the visible findings of child sexual abuse. The child's tanner staging should be noted as part of the examination.

Only the external genitalia need be examined unless there is concern for internal injury. Speculum or digital examination is not necessary in most cases and should not be performed on prepubertal children unless under anesthesia. If even minimal vaginal bleeding appears to be coming from a more internal source, exploration and possible surgical repair are best done under general anesthesia in the operating room. Digital rectal evaluation is also not necessary.

If the physical examination proves too traumatic for the child, the physician is faced with a significant dilemma. The choices are to further traumatize the child or to perform an incomplete examination and collect inadequate evidence. As with all dilemmas, the best choice is not obvious. Physically or psychologically traumatizing the child should be avoided. Often, no physical evidence is present and the history, if detailed enough, may be sufficient. The guiding principle should be primum non nocere (first do no harm).

Evidence Collection. In cases of acute sexual assault presenting within 72 hours, the physician should consider collecting forensic evidence, including clothing, debris, body swabs, genital swabs, and oral swabs, but recognize that no evidence will be recovered in most cases. Although forensic evidence collection should be considered in up to 72 hours after a sexual assault, research studies by Christian and Young have suggested that forensic evidence is unlikely to be recovered from a child's body after 24 hours. Research by Palusci has suggested that bathing and age less than 10 years are associated with a lower likelihood of forensic evidence recovery. Forensic evidence may be recovered from clothing and bed linens even after 24 hours, however, and these items should be collected in the ED if available. The type of evidence to be collected, the collection methods used, and the procedures for processing the results vary by locale. Whatever the specifics of a particular jurisdiction, some general principles should be followed. Establishing a standard protocol is important so

TABLE 132.12

FORENSIC EVIDENCE COLLECTION KIT

Use a standardized forensic evidence kit that meets the requirements of the police authority in your location. The exact content of the kit may vary based on the jurisdiction but in general most kits will include the following items:

- Container in which most of the evidence will be placed
- Form for obtaining authorization to collect and release evidence and information to law enforcement
- Checklists to guide history taking, physical examination, and specimen collection
- Evidence seals
- Form for documenting chain of custody
- Labels for identifying information and evidence
- Paper bags to hold clothing and other bulky items that do not fit in container*
- Envelopes or other containers for collection of debris, nail scrapings, hair, etc.
- Several cotton swabs for collection of specimens plus or minus glass slides**
- Tubes or containers for collection of secretions
- Blood sample tubes for blood typing and DNA analysis.
- Combs for scalp and/or pubic hair combings
- Instrument for obtaining nail scrapings and/or cuttings
- Gauze or swabs for saliva sample

Other items that may be needed but that are not necessarily in the kit include:

- Camera or colposcope for photographic documentation
- Alternate light source

*Plastic bags should not be used for evidence collection because they retain moisture which can lead to degradation of evidence.
**Slides may be included if the forensic laboratory prefers that the swabs be made into slides at the hospital. Other forensic laboratories may prefer that the swabs be placed in envelopes or containers without slides being made.

that each new case does not force the emergency physician to reformulate the entire process (Table 132.13). The ED should have on hand standard forensic evidence collection kits containing the necessary tubes, swabs, and supplies (Table 132.12). The patient should be instructed not to wash, change clothes, urinate, defecate, smoke, drink, or eat until initially evaluated by the physician, unless medically necessary. Evidence collection should be performed with another health care professional present. Evidence should be collected before obtaining specimens for STI testing. A standard for labeling the specimens should be established, including the patient's name, date of birth, and medical record number. Finally, the protocol should include a procedure for a specified person to give the specimens to law enforcement agency or to take the specimens to a specified safe storage area so that the chain of evidence is maintained. This detail becomes important in the court proceedings against the perpetrator.

Consider a Differential Diagnosis. In any consideration of abuse, the physician must always consider the question, "What else could it be?" There may be plausible explanations for physical findings such as straddle injuries causing accidental injuries to the genitals. Other important alternatives to consider are (i) infections caused by *Streptococcus*, *Haemophilus influenzae*, and *Monilia*; (ii) congenital anomalies such as hydrometrocolpos, hemangioma, and perineal groove; (iii) foreign bodies of the rectum and vagina; and (iv) dermatologic conditions such as lichen sclerosus et atrophicus, diaper dermatitis, and contact dermatitis and other conditions such as a prolapsed urethra, which appears as a hemorrhagic mass covering the upper vaginal area (Table 132.14).

Documentation. Careful record keeping cannot be stressed too strongly. As with the collection and processing of evidence, ED records can make or break a case. The Children's Hospital of Philadelphia has developed a separate form that guides the examining physician to include all pertinent information (Fig. 132.17). The aspects of record keeping mentioned in the "Physical Abuse" section apply. In particular, what the child said in his or her own words should be carefully recorded. Quotations should be used if possible. Good records not only help the police and lawyers involved but also help the physician review the case before a hearing that may not take place months or even years. In some jurisdictions, legal provisions allow videotaping patient interviews. This tool is particularly helpful to the victim in that he or she may not have to repeat the history so many times. It may also be helpful to the physician by serving as another form of documentation. Photographs should be taken of physical examination findings. If photographs are not possible, the physician should draw diagrams of the findings.

Diagnosis. The diagnosis of sexual abuse should be based on a composite of the history, physical examination, and laboratory findings. In the majority of cases, however, no physical examination or laboratory findings are present and reports to CPS are made based solely on the child's statements. In some cases, the diagnosis may be unclear but a report to CPS may be indicated because of a reasonable suspicion of sexual abuse. Many pediatric centers rely on a classification scale for the assessment of suspected sexual abuse cases developed by Adams et al. The classification scale (Table 132.15) was most recently revised in 2007 and incorporates physical and laboratory findings. When using the classification scale to guide the interpretation of findings, the emergency physician must remember that in the vast majority of child sexual abuse cases, there are not any physical or laboratory findings present and a diagnosis may be made on the basis of the child's disclosure. A guideline for assessing the overall level of concern and making the decision to report sexual abuse has been developed by the AAP and is provided in Table 132.16.

Reporting. The laws governing which cases should be reported to the CPS or the police or both vary by jurisdiction. In most jurisdictions, sexual abuse is a criminal offense. Thus, all cases are reported to the police department. When a caregiver is responsible for the abuse, a civil report to the CPS agency is also required. ED protocols for reporting to CPS and police should be developed according to local guidelines and included in an ED sexual assault procedure. In the event of a criminal (police) report, a civil (child abuse) report, or both, the parent should be informed that such reports are being made. The physician or social worker must spell out the practical consequences of the reports for the parent.

Preparing the Parent. Beyond notifying the parent about reporting the sexual abuse, additional preparation must be

TABLE 132.13

GUIDELINES FOR FORENSIC EVIDENCE COLLECTION

General

1. Obtain consent to collect forensic evidence in adolescent sexual assault cases. In cases of child sexual abuse, consent is not needed
2. Instruct patient to not wash, change clothes, urinate, defecate, smoke, drink, or eat until evaluated by examiners, unless medically necessary
3. Wash your hands and wear gloves
4. Use photographs to document physical findings
   a. The first photograph should be that of the child's ID label with full name, date of birth, and medical record number.
   b. Take as many photographs as needed to document injuries.
   c. Document each injury separately with ruler/color guide in photographs.
5. Use anatomical diagrams to document findings including location, size, and appearance.

Initial debris and clothing collection

1. **Debris collection:** Carefully inspect patient's head, hands, and other exposed skin surfaces, as well as outer surface of clothing, for any loose debris including hairs, grass, leaves, fibers, threads, etc. Using one piece of clean white copy paper carefully remove the loose material and place it inside the unfolded paper. Refold paper to retain material; indicate location on patient's body or clothing from which material was collected. Repeat as necessary. Place sealed paper folds into envelope marked "Miscellaneous," seal, and label envelope as indicated.
2. **Clothing collection:** Spread clean sheet on floor, place large paper sheet from "Foreign Material" envelope in the middle of the cloth sheet. Have patient stand in the middle of the sheet and remove clothing one piece at a time, careful not to shake the clothing. If parents or the nurse is helping patient, advise them to not stand on the sheet with the patient. Ask the patient to remove one article of clothing at a time. If the article of clothing has wet stains of potential biological material (blood, saliva, semen, etc.), lay flat to dry. Place each article of clothing in a separate paper bag, labeled with patient identification sticker, date, time, and forensic examiner's initials.
   a. Underpants and/or diapers should be collected even if they are not the pair worn during or immediately after the incident. Vaginal secretions may accumulate, even if the patient has bathed or showered.
   b. Collect all clothing if worn during assault or immediately after. If patient is not wearing the same underwear from the assault, the examiner should inquire about the location of the garment and instruct patient or family to save the garment for police/SVU (ideally unlaundered in a paper bag).

Physical examination evidence collection

1. **Skin surface assessment:** Carefully perform a visual inspection of the patient's external skin surfaces. Locate, describe, and photograph any evidence of trauma or adherent foreign matter.
   a. If areas of dried secretions are noted on external skin surfaces, document findings on anatomical diagrams.
2. **Secretions collection:** Prior to any swabs or evidence collection, an alternative light source should be utilized in a dark room over the patient's entire body. If there is a positive (fluorescent specimen), a sterile swab moistened with sterile water should be used to swab area. Allow to air dry. Place in "Debris or Miscellaneous" envelope—noting where specimens were collected.
   a. Use extra swabs to collect specimens if needed. Be sure to label the "Debris or Miscellaneous" envelopes carefully to what evidence is inside and where it was obtained.
3. **Bite mark evidence:** Document location of bite mark(s) on anatomical diagram form and, where possible, photograph the bite mark with and without scale. Use a lightly moistened swab to gently rub inside the parameters of the bite mark in order to collect any dried saliva left by the offender. Do not moisten the second swab, again gently rub the inside parameters of the bite mark with the second dry swab.
4. **Examination of hands:** Carefully inspect dorsal and palmar surface of hands for any signs of trauma. Document all findings on anatomical diagram. Swab only fingernails if there are dried secretions, if so, follow directions for dried secretions.
5. **Oral swabs:** Open the swab packet from the envelope marked "Oral Swabs," grasp both swabs together by the shaft, and swab the area between the patient's cheek and gum, and behind the back molars on both the upper and lower jaws.
   a. Mucosal membranes swabs do not need to be moistened.
6. **Genital inspection:** Carefully inspect entire external genital area for signs of trauma. Use colposcope or other light source to examine for injuries. Document findings, including size, shape, color and location, on anatomical diagrams of genitalia.
7. **Pubic hair combings:** Remove paper fold from envelope marked "Pubic Hair Combings." Ask patient to sit on unfolded paper so that the paper protrudes between the thighs; comb downward on pubic hair to dislodge any debris or loose hairs onto the paper. Place comb on paper and fold paper to retain debris; place paper in the envelope marked "Pubic Hair Combings," seal, and label as indicated.
8. **Perianal swabs:** Carefully evaluate the anus and buttocks for signs of injury. Document positive findings on gender-appropriate anatomical diagrams. Using two moistened swabs simultaneously, gently rub swabs on anal folds and anal opening. Dry completely and place in the envelope marked "Perianal Swabs."
9. **Rectal swabs:** After external anal swabs have been collected, the anal area should be cleansed by wiping carefully with a moistened gauze pad. Simultaneously insert two sterile cotton swabs approximately 2 cm into the rectum and swab rectal walls. Remove swabs, avoiding contact with the external anal tissue. Dry completely and place in the envelope marked "Rectal Swabs."
10. **External genital swabs:** Use swabs in external genital envelope. For male patients, wipe the surface of the glans and the shaft; for female patients, wipe the inner surfaces of the labia minora with a downward motion. After drying, place in a marked envelope.
11. **Vaginal swabs:** Using two swabs simultaneously, collect secretions from the vagina near the vaginal fornix (area below the cervix). (This step may be performed with a speculum in place in postpubertal children, or by blind sweep without the use of a speculum.)

(continued)

TABLE 132.13

CONTINUED

12. **Cervix swabs:** Using two swabs simultaneously, collect secretions from cervical os. This step should be performed only with the use of a speculum to ensure visualization of the cervix and thus should not be performed in prepubertal children unless under anesthesia. Dry completely and place in envelope marked "Cervix Swabs."
    a. If using a speculum for cervical examination, after evidence is collected, use the Aptima Cervical Swab to obtain specimen for STIs.
13. All tampons, pads, pantyliners should be collected and dried. Once dry, place in the "Miscellaneous" envelope.
14. All evidence should be dry before packaging. To dry swabs, place swabs in swab drying machine, with cotton tip pointing upward to promote drying.
15. Do not allow cotton tip of swabs to contact other objects or surfaces during drying process. (Use the test tube rack not allowing it to touch any other swabs.)
16. After drying, swabs should be placed in swab boxes and then into the envelopes provided for each specimen. (If additional specimens were collected and no swab box or evidence envelope is available for packaging, dried swabs may be placed in a plain envelope.)
17. All envelopes and boxes should be labeled with patient's name, case number, date, and name of the examiner.
18. Seal enveloped: Do not lick envelopes to seal them. Use a clean gauze or cotton and wet with sterile water to moisten adhesive on collection envelopes.
19. All envelopes containing evidence specimens should be placed inside the evidence kit box. The sealed bag containing underpants may be placed inside evidence kit box if space permits; all other clothing bags should remain outside of evidence box. Each item collected must be noted on the evidence receipt form.

Adapted from *Forensic Exam Checklist*, Children's Hospital of Philadelphia, Philadelphia, PA.

given. Many workers believe that, for the young child, the parental reaction to sexual abuse may have as important a role as the abuse itself in producing subsequent manifestations. Long-term follow-up studies of sexually abused children performed by a case–control methodology show that sexually abused children are at long-term risk for various psychological and behavioral consequences. Parents need to be aware of this correlation. Social worker consultation and collaboration for this aspect of case management are essential.

TABLE 132.14

DIFFERENTIAL DIAGNOSIS OF ANOGENITAL ERYTHEMA, EXCORIATION, AND PRURITUS

Local irritation
Sexual abuse
Poor hygiene
Tight/poorly ventilated underwear
Chemical
Sandbox vaginitis

Infection
Sexually transmitted disease
Nonspecific vaginitis
Pinworms
Scabies
Candidal infection
Perianal streptococcal cellulitis

Dermatologic
Atopic dermatitis
Contact dermatitis
Seborrheic dermatitis
Diaper dermatitis/candidal infection
Psoriasis
Lichen sclerosus/balanitis xerotic obliterans

Systemic
Crohn's disease
Kawasaki's syndrome
Stevens-Johnson syndrome

The first step is to focus the parent's attention on the child. Especially in situations of father–daughter incest or surrogate father–daughter incest, the maternal reaction may initially be more self-centered. In directing the parent's attention to the child, the physician returns the parent to a more comfortable traditional role and raises many important issues to which the parent must attend. The physician should review with the parent that manifestations of sexual abuse may be physical and/or psychological. The physical manifestation may seem minor to the physician, but parents must be specifically told that whatever the injury, it can be repaired with no impairment of the victim's sexual functions as an adult.

Parents must be told that the psychological outcome, in part, relates to their reactions to the situation. Their role must be to provide comfort, support, and reassurance to the child. Methods of supporting the child have been raised previously in this section. These techniques must be used by the parents. Unfortunately, parental anger and blame may sometimes be displaced onto the child. All attempts to place responsibility or blame on the victim need to be eliminated. The ultimate responsibility is that of the perpetrator, no matter what the behavior of the child.

Some parents may focus their anger clearly on the perpetrator but want to "take the law into their own hands." Parents should be cautioned about leaving the ED to find and confront the perpetrator. This action is a police responsibility. The parental role is to provide safety for the child. Parental ire can be modified by pointing out that a parent's arrest for assault of the perpetrator will not benefit the child.

Yet, another common parental reaction is the desire to institute several lifestyle changes. Parents may want to change their place of residence, change the child's school, or quit their jobs to be able to guard the child 24 hours per day. The ED staff should stress that returning to as normal a lifestyle as possible is best for the child. Change is always difficult for children, and

TABLE 132.15

APPROACH TO INTERPRETING PHYSICAL AND LABORATORY FINDINGS IN SUSPECTED CHILD SEXUAL ABUSE: DECEMBER 2006

A Product of an ongoing collaborative process by child maltreatment physician specialists, under the leadership of Joyce A. Adams, MD
(Numbering of findings is for ease of reference only and does not imply increasing significance)

Findings documented in newborns or commonly seen in non-abused children: (The presence of these findings generally neither confirms nor discounts a child's clear disclosure of sexual abuse)

Normal Variants

1. Periurethral or vestibular bands
2. Intravaginal ridges or columns
3. Hymenal bumps or mounds
4. Hymenal tags or septal remnants
5. Linea vestibularis (midline avascular area)
6. Hymenal notch/cleft in the anterior (superior) half of the hymenal rim (prepubertal girls), on or above the 3 o'clock - 9 o'clock line, patient supine
7. Shallow/superficial notch or cleft in inferior rim of hymen (below 3 o'clock - 9 o'clock line)
8. External hymenal ridge
9. Congenital variants in appearance of hymen, including: crescentic, annular, redundant, septate, cribiform, microperforate, imperforate
10. Diastasis ani (smooth area)
11. Perianal skin tag
12. Hyperpigmentation of the skin of labia minora or perianal tissues in children of color, such as Mexican–American and African–American children
13. Dilation of the urethral opening with application of labial traction
14. 'Thickened hymen' (may be due to estrogen effect, folded edge of hymen, swelling from infection, or swelling from trauma. The latter is difficult to assess unless follow-up examination is done)

Findings commonly caused by other medical conditions

15. Erythema (redness) of the vestibule, penis, scrotum or perianal tissues. (May be due to irritants, infection or trauma*)
16. Increased vascularity ('Dilatation of existing blood vessels") of vestibule and hymen. (May be due to local irritants, or normal pattern in non estrogenized state)
17. Labial adhesions. (May be due to irritation or rubbing)
18. Vaginal discharge. (Many infectious and noninfectious causes, cultures must be taken to confirm if it is caused by sexually transmitted organisms or other infections)
19. Friability of the posterior fourchette or commisure. (May be due to irritation, infection, or may be caused by examiner's traction on the labia majora)
20. Excoriations/bleeding/vascular lesions. (These findings can be due to conditions such as lichen sclerosus, eczema or seborrhea, vaginal/perianal Group A Streptococcus, urethral prolapse, hemangiomas)
21. Perineal groove (failure of midline fusion), partial or complete
22. Anal fissures (Usually due to constipation, perianal irritation)
23. Venous congestion or venous pooling in the perianal area. (Usually due to positioning of child, also seen with constipation)
24. Flattened anal folds. (May be due to relaxation of the external sphincter or to swelling of the perianal tissues due to infection or trauma*)
25. Partial or complete anal dilatation to less than 2 cm (anterior–posterior dimension), with or without stool visible. (May be a normal reflex, or have other causes, such as severe constipation or encopresis, sedation, anesthesia, neuromuscular conditions)

Indeterminate findings: Insufficient or conflicting data from research studies: (May require additional studies/evaluation to determine significance. These physical/laboratory findings may support a child's clear disclosure of sexual abuse, if one is given, but should be interpreted with caution if the child gives no disclosure. In some cases, a report to Child Protective Services may be indicated to further evaluate possible sexual abuse.

Physical examination findings

26. Deep notches or clefts in the posterior/inferior rim of hymen in pre-pubertal girls, located between 4 and 8 o'clock, in contrast to transections (see 41)
27. Deep notches or complete clefts in the hymen at 3 or 9 o'clock in adolescent girls
28. Smooth, noninterrupted rim of hymen between 4 and 8 o'clock, which appears to be less than 1 mm wide, when examined in the prone knee–chest position, or using water to 'float' the edge of the hymen when the child is in the supine position.
29. Wart-like lesions in the genital or anal area. (Biopsy and viral typing may be indicated in some cases if appearance is not typical of Condyloma accuminata)
30. Vesicular lesions or ulcers in the genital or anal area (viral and/or bacterial cultures, or nucleic acid amplification tests may be needed for diagnosis)
31. Marked, immediate anal dilation to an AP diameter of 2 cm or more, in the absence of other predisposing factors

Lesions with etiology confirmed: Indeterminate specificity for sexual transmission (Report to protective services recommended by AAP Guidelines unless perinatal or horizontal transmission is considered likely)

32. Genital or anal Condyloma accuminata in a child, in the absence of other indicators of abuse.
33. Herpes Type 1 or 2 in the genital or anal area in a child with no other indicators of sexual abuse.

(continued)

TABLE 132.15

CONTINUED

Findings Diagnostic of Trauma and/or Sexual Contact (The following findings support a disclosure of sexual abuse, if one is given, and are highly suggestive of abuse even in the absence of a disclosure, unless the child and/or caretaker provide a clear, timely, plausible description of accidental injury. It is recommended that diagnostic quality photo-documentation of the examination findings be obtained and reviewed by an experienced medical provider, before concluding that they represent acute or healed trauma. Follow-up examinations are also recommended.)

Acute trauma to external genital/anal tissues

34. Acute lacerations or extensive bruising of labia, penis, scrotum, perianal tissues, or perineum (May be from unwitnessed accidental trauma, or from physical or sexual abuse)
35. Fresh laceration of the posterior fourchette, not involving the hymen (Must be differentiated from dehisced labial adhesion or failure of midline fusion. May also be caused by accidental injury or consensual sexual intercourse in adolescents)

Residual (healing) injuries (These findings are difficult to assess unless an acute injury was previously documented at the same location)

36. Perianal scar (Rare, may be due to other medical conditions such as Crohn's disease, accidental injuries, or previous medical procedures)
37. Scar of posterior fourchette or fossa. (Pale areas in the midline may also be due to linea vestibularis or labial adhesions)

Injuries indicative of blunt force penetrating trauma (or from abdominal/pelvic compression injury if such history is given)

38. Laceration (tear, partial or complete) of the hymen, acute.
39. Ecchymosis (bruising) on the hymen (in the absence of a known infectious process or coagulopathy).
40. Perianal lacerations extending deep to the external anal sphincter (not to be confused with partial failure of midline fusion)
41. Hymenal transection (healed). An area between 4 and 8 o'clock on the rim of the hymen where it appears to have been torn through, to or nearly to the base, so there appears to be virtually no hymenal tissue remaining at that location. This must be confirmed using additional examination techniques such as a swab, prone knee-chest position or Foley catheter balloon (in adolescents), or prone-knee chest position or water to float the edge of the hymen (in prepubertal girls). This finding has also been referred to as a 'complete cleft' in sexually active adolescents and young adult women.
42. Missing segment of hymenal tissue. Area in the posterior (inferior) half of the hymen, wider than a transection, with an absence of hymenal tissue extending to the base of the hymen, which is confirmed using additional positions/methods as described above.

Presence of infection confirms mucosal contact with infected and infective bodily secretions, contact most likely to have been sexual in nature

43. Positive confirmed culture for gonorrhea, from genital area, anus, and throat, in a child outside the neonatal period.
44. Confirmed diagnosis of syphilis, if perinatal transmission is ruled out.
45. Trichomonas vaginalis infection in a child older than 1 year of age, with organisms identified by culture or in vaginal secretions by wet-mount examination by an experienced technician or clinician.
46. Positive culture from genital or anal tissues for Chlamydia, if child is older than 3 years at time of diagnosis, and specimen was tested using cell culture or comparable method approved by the Centers for Disease Control.
47. Positive serology for HIV, if perinatal transmission, transmission from blood products, and needle contamination has been ruled out.

Diagnostic of sexual contact

48. Pregnancy
49. Sperm identified in specimens taken directly from a child's body.

*Follow-up examination is necessary before attributing these findings to trauma

Reprinted with minor adaptations from Adams JA, Kaplan RA, Starling SP, et al. Guidelines for medical care of children who may have been sexually abused. *J Pediatr Adolesc Gynecol*; 20:163–172, 2007, with permission from Elsevier.

the stress of entering a new school or meeting a new set of friends is a burden the sexual abuse victim does not need. Parents should be cautioned about limiting the amount of open conversation with friends and relatives that the child may overhear. The victim's desire to discuss the abuse should regulate how much abuse-related conversation should take place between family members. Some children may want repeated reassurances about their parents' approval and about their future safety. Other children may want to let the episode be forgotten and return to school and play. If the sexual abuse triggers disruption and chaos in the parents' life and disapproval of the child, it will surely have psychological ramifications. The best prognosis results if the parents can show their concern in a way that ensures the child of approval, protection, and resumption of a normal lifestyle.

Hospitalization

Two indications for hospitalizing the sexually abused child are (i) severe injury requiring treatment and (ii) an unsafe home. Outpatient management of sexual abuse victims is always preferable. The rationale is to avoid victimizing the child twice. Children who are hospitalized because the home is

TABLE 132.16

GUIDELINES FOR MAKING THE DECISION TO REPORT SEXUAL ABUSE OF CHILDREN

Data Available				Response	
History	Behavioral Symptoms	Physical Examination	Diagnostic Tests	Level of Concern About Sexual Abuse	Report Decision
Clear statement	Present or absent	Normal or abnormal	Positive or negative	High	Report
None or vague	Present or absent	Normal or nonspecific	Positive for *C trachomatis*, gonorrhea, *T vaginalis*, syphilis, or herpes*	High	Report
None or vague	Present or absent	Concerning or diagnostic findings	Negative or positive	High†	Report
Vague or history by parent only	Present or absent	Normal or nonspecific	Negative	Indeterminate	Refer when possible
None	Present	Normal or nonspecific	Negative	Indeterminate	Possible report, ‡refer, or follow

*If nonsexual transmission is unlikely or excluded.
†Confirmed with various examination techniques and /or peer review with expert consultant.
‡If behaviors are rare / unusual in normal children.

unsafe may believe that they are being sent away for their wrongdoing. Another message hospitalization may transmit is that the parent is incapable of providing protection. Both of these messages are harmful to the child's psychological adjustment. If an adult in the home has been the intrafamilial perpetrator, CPS should remove the perpetrator from the home so that the child may return.

Treatment. Whether the child is hospitalized or discharged from the ED, three additional issues should be considered: (i) STI testing (ii) STI prophylaxis, and (iii) pregnancy prevention. SITs are identified in approximately 1 in 20 sexually abused children. All children who have symptoms of a possible STI should be tested and treated. All asymptomatic postpubertal children should also be tested for STIs. The rate of asymptomatic STIs in prepubertal children is lower and the decision to screen for STIs should be made on a case-by-case basis. The presence of any of the following risk factors for STIs may indicate a need for testing: (i) high prevalence of an STI in the community, (ii) presence of an STI in a family member or close contact, (iii) suspected perpetrator has a known STI, (iv) suspected perpetrator is at high risk for an STI, and (v) there is evidence of penetration or ejaculation. STI testing should also be performed at the patient's or family's request. When STI screening is indicated in prepubertal children, testing for *N. gonorrhoeae* and *C. trachomatis* infection is performed. Testing can be expanded to also include syphilis, hepatitis B, *T. vaginalis* infection (Table 132.17). Hepatitis C testing is not included in CDC guidelines for STI testing in victims of sexual assault, but some centers do send hepatitis C PCR and antibody because hepatitis C can be transmitted via sexual contact. HIV testing is already an issue on the minds of most parents of sexual abuse victims. Transmission of HIV during child sexual abuse contacts is uncommon but has been reported. Testing for HIV may depend on the nature and extent of sexual contact, regional rates of HIV infection, ability to test the alleged perpetrator, and parental desires for testing. See Chapter 85 for more on HIV infections. Routine screening for HPV and herpes simple virus (HSV) in the absence of lesions is not indicated in prepubertal children. Genital warts from HPV can often be diagnosed on the basis of clinical appearance. If any vesicular lesions suspicious for HSV are present, testing should be performed to confirm the presence of the virus and to distinguish type 1 form type 2.

Antimicrobial prophylaxis for STIs should be offered to postpubertal victims of sexual assault who present within 72 hours. Specimens for STI testing should be obtained before providing prophylaxis. Recommended prophylaxis regimens for adolescents are shown in Chapter 94 and for preadolescents in Table 132.18. Routine antimicrobial prophylaxis is not indicated in prepubertal children unless the history or examination suggests that the child is at an increased risk of having an STI. All children who receive prophylaxis should have testing performed for STIs first. HIV prophylaxis should also be considered for sexual assault victims presenting within 72 hours. The efficacy of the HIV postexposure prophylaxis in children has not been established and the decision to start HIV prophylaxis must be made on a case-by-case basis. The AAP and the CDC recommend that physicians consider the following factors: (i) local HIV/AIDS epidemiology, (ii) risk of HIV infection in alleged perpetrator, and (iii) risk of HIV transmission based on circumstances of abuse. If the physician determines

TABLE 132.17

STI TESTING IN SUSPECTED VICTIMS OF CHILD SEXUAL ABUSE

Specimen Source	Infections	Recommended Test
Vaginal	*Neisseria gonorrhoeae*	Culture*
	Chlamydia trachomatis	Culture*
	Trichomonas vaginalis	Wet mount and culture
	Bacterial vaginosis	Wet mount and culture
Urethral (male)**	*Neisseria gonorrhoeae*	Culture*
	Chlamydia trachomatis	Culture*
Rectal	*Neisseria gonorrhoeae*	Culture
	Chlamydia trachomatis	Culture
Throat	*Neisseria gonorrhoeae*	Culture
Serum	Syphilis	Serologic tests at time of presentation and 6, 12, and 24 weeks after last episode of sexual abuse.
	HIV	Serologic tests at time of presentation and 6, 12, and 24 weeks after last episode of sexual abuse. Serologic testing of alleged perpetrator if available.
	Hepatitis B virus	Hepatitis B surface antibody if child did not complete 3 dose series of Hepatitis B vaccine. If concern for Hepatitis B infection and initial test is negative, test can be repeated at 6, 12, and 24 weeks.
Lesion Specimen	Human papilloma virus	Biopsy of wart
	Herpes simplex virus	Culture PCR is more sensitive than culture and should be performed if the lesion has crusted.
	Syphilis (chancre)	Darkfield examination of ulcer exudate

*Initial studies in prepubertal children have suggested that nucleic acid amplifications tests (NAATs) performed on urine or vaginal specimens for *C trachomatis* and *N gonorrhoeae* are sensitive and specific and may be an alternative to cultures. According to the 2006 CDC guidelines and the 2009 AAP Red Book recommendations, however, the evidence to support the use of NAATS in children is currently insufficient. The CDC and AAP state that NAATs might be used if culture is not available and if confirmation with a second FDA approved NAAT targeting a different sequence was performed. The CDC recommends using culture or FDA approved NAATs in adolescents.

** If urethral discharge is present a meatal discharge specimen can be performed instead.

American Academy of Pediatrics. *Sexual Victimization and STIs*. Pickering LK, ed. *Red Book:2009 Report of the Committee on Infectious Diseases*. 28th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2009: 167–172

Black CM, Driebe EM, Howard LA, et al. Multicenter Study of Nucleic Acid Amplification Tests for Detection of Chlamydia trachomatis and Neisseria gonorrhoeae in Children Being Evaluated for Sexual Abuse. *Pediatr Infect Dis J*. Jul 2009;28(7):608–613.

Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines – 2006/ MMWR 2006;55(No. RR-11):80–85.

the child may be at risk of HIV transmission, he or she should consult with a specialist in HIV prophylaxis. The risks and unknown efficacy of postexposure prophylaxis should be discussed with the child's caregiver. If HIV prophylaxis is started, a 3- to 7-day supply should be given and the child should be seen in follow-up visits. A prescription for the remainder of the HIV prophylaxis can then be given.

Pregnancy prophylaxis should be considered if the child has reached menarche and presents within 72 hours of genital–genital contact. For pregnancy prophylaxis, one 1.5 mg or two 0.75 mg of levonorgestrel tablets are taken. Documenting that the patient does not have an existing pregnancy is important. Antiemetic therapy may be considered and offered to children provided with pregnancy prophylaxis and antimicrobial prophylaxis because of the risk of nausea and emesis, although now considerably less with levonorgestrel-based prophylaxis.

Children with physical injuries on examination in the ED should be referred from medical follow-up in 2 weeks. In some cases, particularly if there are new symptoms, repeat evaluation for STIs may be indicated even if the initial STI screening finding was negative. In addition, if there is a concern for hepatitis B, syphilis, or HIV infection with negative baseline testing, repeat testing should be performed at 6, 12, and 24 weeks after the last exposure. Recommendations for treating identified STIs in children are included in Table 132.19. See chapter 85 for information on STI treatment in adolescents.

Psychosocial Referral and Follow-up. All sexually abused children need some form of referral and careful follow-up care. Referral may initially be to the hospital social worker for monitoring of the child's symptoms and the family's ability to cope with this stress. In some locales, volunteer self-help groups organized for women who have been raped may provide support to the child victim and parent. Referral for more in-depth mental health counseling depends on the (i) symptoms manifested by the child, (ii) state of family organization, (iii) length of time the abuse has occurred, and (iv) the child's age. In general, the older the child and the longer the abuse has occurred, the more likely he or she may have or may develop a serious mental health problem. All children should be referred to mental health services.

TABLE 132.18

STI PROPHYLAXIS AFTER SEXUAL VICTIMIZATION OF PREADOLESCENT CHILDREN

Weight <100 lb (<45 kg)		Weight ≥100 lb (≥45 kg)
	For prevention of gonorrhea	
1. Ceftriaxone, 125 mg, intramuscularly, in a single dose		1A. Ceftriaxone, 125 mg, intramuscularly, in a single dose **OR** 1B. Cefixime, 400 mg, orally, in a single dose
	For prevention of *Chlamydia trachomatis* infection	
PLUS 2A. Azithromycin, 20 mg/kg (maximum 1 g), orally, in a single dose **OR** 2B. Erythromycin base or ethylsuccinate, 50 mg/kg per day, divided into 4 doses for 14 days		**PLUS** 2A. Azithromycin, 1 g, orally, in a single dose **OR** 2B. Doxycycline, 100 mg, twice daily, for 7 days (if at least 8 years of age)
	For prevention of hepatitis B virus infection	
PLUS 3. Begin or complete hepatitis B virus immunization if not fully immunized		**PLUS** 3. Begin or complete hepatitis B virus immunization if not fully immunized
	For prevention of trichomoniasis and bacterial vaginosis	
PLUS 4. Consider adding prophylaxis for trichomoniasis and bacterial vaginosis (metronidazole, 15 mg/kg per day, orally, in 3 divided doses for 7 days; maximum 2 g)		**PLUS** 4. Consider adding prophylaxis against trichomoniasis and bacterial vaginosis (metronidazole, 2 g, orally, in a single dose)

Follow-up health care visits should be arranged with an informed and sympathetic practitioner who can continue the humane and supportive care initiated in the ED.

Suspected Sexual Abuse in the Setting of Parental Conflicts

In some cases, children will present for evaluation when one parent suspects another parent of sexually abusing the child in the setting of parental divorce. These cases can be challenging, especially if the physician is concerned that the allegations of sexual abuse may be related to a custody dispute or conflict between the parents. The physician, however, cannot ignore concerns of sexual abuse in theses cases and must perform a thorough evaluation. If the child makes a disclosure of sexual abuse or the evaluation is concerning for sexual abuse, the physician is obligated to make a report to the CPS agency. If the evaluation does not support a history of sexual abuse but a parent continues to express concern, the ED physician may need to refer the family for further evaluation by a pediatric child abuse expert and or mental health expert.

NEGLECT

Child neglect is by far the most prevalent form of child abuse. When neglect is blatant, it is easily recognized and reported. More often, neglect is not obvious and goes undetected for long periods. Although the manifestations of neglect are less dramatic than those of physical abuse, the long-term effects may be more destructive to the child. The indolent nature of child neglect makes it a serious public health problem. For ED staff members, neglect cases are difficult because they require that certain value judgments be made. The balance between supporting the independent rights of the child and maintaining the privacy and sanctity of family rights is delicate. With neglected children, the questions are as follows: (i) How much should the family be doing? (ii) How much are they capable of doing? (iii) How much support from the community or society do they require? and (iv) How much support or help are they willing to accept on behalf of their child? As with the other forms of child abuse, the management of child neglect cases is made easier by working with a multidisciplinary team. In the ED, the team would generally consist of the physician, nurse, and social worker. Particularly in situations in which the line between adequate child care and neglect needs to be drawn, the diversity of personal and professional opinions adds credibility to decision making and lessens the burden on the single practitioner.

Background

The definition of child neglect is difficult because no societal standards for child care are explicitly stated. This vagueness creates a situation in which parents and professionals are left

TABLE 132.19

TREATMENT OF SEXUALLY TRANSMITTED INFECTIONS IN CHILDREN

Infection	Recommended Treatment
Chlamydia trachomatis (vulvovaginitis and urethritis)	***Children <45 kg:*** Erythromycin base or ethylsuccinate 50 mg/kg/day orally divided into 4 doses daily (maximum 2 g/day) for 14 days ***Children >45 kg but <8 years old.:*** Azithromycin 1g orally in single dose ***Children >8 years old:*** Azithromycin 1 g orally in single dose OR Doxycycline 100 mg orally twice a day for 7 days
Neisseria gonorrhoeae (vulvovaginitis, urethritis, cervicitis, pharyngitis, & proctitis)	***Children <45 kg:*** Ceftriaxone, 125 mg, in a single dose
Treponema vaginalis	***Children <45 kg:*** Metronidazole, 15 mg/kg per day, orally, in 3 divided doses (maximum 2 g/day) for 7 days
Bacterial vaginosis	***Children <45 kg:*** Metronidazole, 15 mg/kg per day, orally, in 2 divided doses (maximum 1 g/day) for 7 days
HSV—primary infection	***Children <45 kg:*** Acyclovir, 80 mg/kg per day, orally, in 3–4 divided doses (maximum 1.2 g/day) for 7–10 days
Treponema pallidum	Treatment regimen depends on syphilis stage. See Chapter 85.3, Table 85.3 for details.
Human papillomavirus (external anogenital warts)	***Children <45 kg:*** Patient-applied: Podofilox 0.5% solution or gel* OR Imiquimod 5% cream* Provider-administered: Cryotherapy OR Podophyllin resin 10%–25%* OR Trichloroacetic acid OR Bichloroacetic acid OR Surgical removal

*Contraindicated in pregnancy.
Based on data from the following sources:
Centers for Disease Control and Prevention. Sexually Transmitted Diseases Treatment Guidelines – 2006/ MMWR 2006;55(No. RR-11):1–94.
Prophylaxis After Sexual Victimization of Preadolescent Children. Sexual Victimization and STIs. Pickering LK, ed. Red Book: 2006 Report of the Committee on Infectious Diseases. 26th ed. Elk Grove Village, IL: American Academy of Pediatrics; 2006:172–177.

to define their own standards, which may produce many problems. Defining *abandonment* (the ultimate neglect) is an excellent example of the difficulties encountered in setting standards. No societal norm is established for either the age of the child left alone or the duration of time. Thus, if a parent leaves a 3-year-old child unattended in a home for several hours, most neighbors and professionals would consider that neglect. But what if the child was 10 years old and the parent was gone for 20 minutes? Then the situation becomes less clear.

Many states have tried to partially define the condition by making it depend on a physical manifestation in the child. Thus, the child left alone who stays out of trouble is not neglected; the one who burns himself or herself and cries to the point that the neighbors become aware is neglected. The NCANDS uses the following definition: child neglect is characterized by failure to provide for the child's basic needs. Neglect can be physical, educational, or emotional. Physical neglect includes refusal of or delay in seeking health care, abandonment, expulsion from the home or refusal to allow a runaway to return home, and inadequate supervision. Educational neglect includes the allowance of long-term truancy, failure to enroll a child of mandatory school age in school, and failure to attend to a special educational need. Emotional neglect includes actions such as significant inattention to the child's needs for affection, refusal of or failure to provide needed psychological care, spouse abuse in the child's presence, and permission for drug or alcohol use by the child. The assessment of child neglect requires consideration of cultural values and standards of care, as well as recognition that the failure to provide the necessities of life may be related to poverty.

Other apparent societal conflicts are inherent in defining neglect. One conflict centers on the relationship between neglect and poverty. This situation relates to the questions asked previously and the issue of what the family should be doing versus what they are financially capable of doing. Certainly, at times, poverty may be coincident with neglect, but the issues are distinctly separate. Most poor families find a way to provide the material essentials and, more important, the emotional essentials for their children. The contrasting example is that of families who are in the middle or upper socioeconomic scale and who could provide for their children but are neglectful. Another conflict is based on the failure to recognize the evils of excess. The child who is underfed and wasted is promptly labeled *failure to thrive*. The child who is overfed to the point of obesity may face as many serious consequences. The child who is developmentally delayed from understimulation may be labeled *neglected*. The child who has psychosomatic illness from being stressed to overachieve also deserves identification and help. The term *neglect* generally refers to underprovision on the part of the parent. Overprovision may be as deleterious, which presents a serious conflict to the definition of neglect. The true incidence of neglect is not ascertainable.

Dynamics

The dynamics of child neglect have been explained by several different theorists. Some theories are based on purely individual dynamics and point to the immature, overwhelmed, overstressed parent who responds by withdrawal. Polansky has well documented and labeled this condition as the "apathy futility syndrome." Theories that have a more social orientation point to societal pressures and the existence of poverty. David Gil considers all children existing on a welfare stipend as neglected and recommends a change in the distribution of societal resources as a solution. Most theories would support the notion that the neglectful parent does not see himself or herself as such. Most parents are caught up in a neglectful lifestyle that is self-perpetuating. Most neglect is not purposeful, it just happens. Studies have clearly shown that women who fail to seek prenatal care are also likely to not obtain health care for their children. In the parents' view, it is a pattern of living that seems to be the norm. This facet of the dynamics of neglect is important to the ED management.

Manifestations

The manifestations of neglect are countless. The manifestation may be tangible, such as the weight loss of a child whose diet has been inadequate, or intangible, such as the psychological effects of unsatisfactory relationships. A categorization of neglect can be made by looking at the standard functions of the family and then considering the failure to fulfill these functions. A family must (i) provide and distribute material goods—food, clothing, and shelter; (ii) ensure health; (iii) promote safety; (iv) socialize and educate; and (v) provide emotional support, security, and love. The manifestations of neglect may occur in one or more of these functional areas. The most commonly reported manifestations are (i) nonorganic failure to thrive—a lack of food and feeding skills; (ii) medical neglect—a failure to provide needed health care; (iii) abandonment—total neglect, generally viewed as a lack of supervision and as a safety hazard; and (iv) truancy and school avoidance.

Failure to Thrive. The term *failure to thrive* has been used as a diagnostic term to group several diseases and disorders that result in growth failure. Growth failure is generally measured in weight, length, and head circumference as compared with standard growth curves for these parameters. Growth failure may be defined as measurements that fall below 2 SD for age or patterns that cross percentile lines (i.e., move 2 SD) and do not follow the normal lines of growth. Patients diagnosed as failure to thrive may be subcategorized into three groups: (i) organic, (ii) nonorganic, and (iii) mixed group. *Organic* refers to children whose failure to thrive is based on a physical cause such as congenital heart disease, renal disease, or a genetic abnormality. *Nonorganic* refers to the group whose growth failure is environmentally related. When these children are hospitalized and fed standard diets, they grow rapidly and thrive. The group of patients with nonorganic failure to thrive include a substantial number of neglected children who may be brought to the ED for care. The mixed group refers to patients who have a combination of physical and environmental factors. An example might be a physical condition that so overstresses a family that they cannot function; thus, they neglect the child in some aspect of the feeding process.

In recognizing the patients with nonorganic failure to thrive, the following factors are suggestive:

- *History:* (i) an idealized feeding history; (ii) a chief complaint and history that do not identify the child's growth pattern as a problem; (iii) no description of losses such as vomiting or diarrhea; and (iv) failure to give a history of a schedule or scheduled pattern of feeding (e.g., baby eats about every 4 hours).
- *Physical examination:* (i) measurements in which weight is more depressed than length, which is more depressed than head circumference; (ii) other signs of neglect such as poor hygiene, diaper rash, and flat and balding occiput; (iii) dull, apathetic facies; (iv) body posture of an understimulated child; (v) excessive oral self-stimulation; and (vi) developmental delay, particularly in the social adaptive and language areas.
- *Parental observation:* the parent who (i) has an uninterested attitude; (ii) does not respond to child's needs (e.g., react to crying); (iii) lacks concern about health issues; and (iv) appears to be a drug or alcohol abuser.

These factors are shown in Fig. 132.18.

Medical Neglect. The differentiation between medical neglect and noncompliance is often difficult. The key to differentiating them is to ask, "Has identifiable harm come to the child?" If a parent fails to complete a course of therapy prescribed by a physician, noncompliance exists. However, if the failure to give medication results in further illness in the child, medical neglect exists. The manifestations of medical neglect can be documented and reported as such. Noncompliance merely results in a worsening doctor–patient relationship. Proving that the failure to give medication, attend follow-up appointments, or obtain a procedure directly resulted in damage to the child's health may be difficult. Intervening variables, such as the complexity of the disease (e.g., the exacerbations of an asthma attack), or the proven efficacy of the treatment often exist. The ED is often the central place for identifying the manifestations of medical neglect. Good documentation of prescribed treatments and good communication with the source of the child's ongoing health care are important.

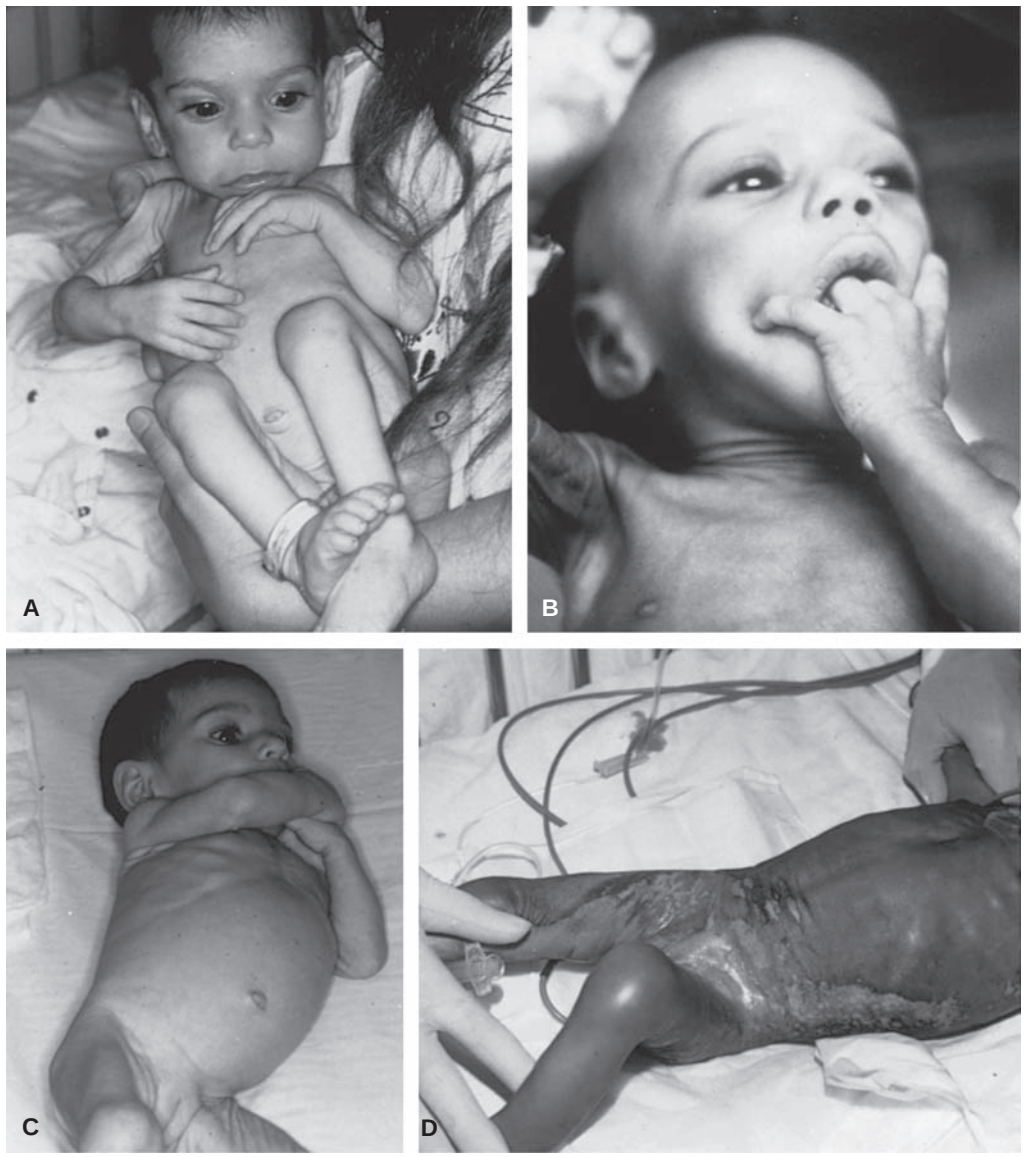

FIGURE 132.18 Physical signs of failure to thrive. **A:** Dull, apathetic eyes that avoid eye contact. **B:** Oral self-stimulatory behavior. **C:** Wasted extremities and protuberant abdomen. **D:** Severe diaper rash as a sign of overall neglect.

Abandonment. Local jurisdictions may dictate the length of time a child must be without supervision before he or she is declared legally abandoned. These cases often come to the ED as the result of a neighbor's call or the initiative of a relative who is aware of the neglect. At times, the situation may become apparent as the ED attempts to obtain permission to treat a child and has difficulty locating a parent or responsible adult. Manifestations of abandonment include (i) physical findings such as excessively dirty diapers, poor hygiene, or hoarse cry; (ii) excessive hunger documented by unusual intake; and (iii) dehydration as documented by urine-specific gravity or blood urea nitrogen. Other manifestations may relate to a lack of supervision and protection and may include burns, ingestions, or repeated accidents. Children with these manifestations may be brought to the ED for treatment. Good case management results in their identification.

Truancy. Truancy as a manifestation of neglect may be less commonly recognized in the ED. The section on school avoidance (see Chapter 133) details many of the aspects of this complex psychosocial emergency. The emergency physician may recognize truancy as a neglect problem when the truant child presents with multiple somatic complaints. As the complaints are explored and no organic basis is found, the parent may be instructed to return the child to school. A failure to comply with this aspect of treatment constitutes medical neglect. For the child who makes frequent visits to the ED, neglect needs to be considered.

Management

The management of cases of child neglect follows the principles detailed in the "Physical Abuse" section. The steps are to (i) suspect and recognize neglect manifestations, (ii) obtain

multidisciplinary consultation, (iii) report the neglect, (iv) inform the parents, (v) determine the need for hospitalization, and (vi) arrange follow-up. These steps are reviewed in the following sections to underscore those aspects unique to neglect.

Suspect Neglect. As with other forms of abuse, the open mind of the physician allows neglect to be recognized. Because the manifestations are more subtle than with physical abuse, recognition is more difficult. The physician can overcome this difficulty by only obtaining a more detailed history and observing the parent–child interaction. In-depth social work evaluation can often uncover previous reports of neglect or involvement with child welfare agencies. Piling the building blocks of suspicion to the height of a threshold point may be more difficult because the size of each block may be smaller and less dramatic than that in physical abuse.

Multidisciplinary Consultation. Because much of defining neglect is value laden, using a multidisciplinary consultation is vital. Such consultation can broaden perspectives on "normal" lifestyles and child-rearing practices. The difficulty any one professional feels in making a value judgment can be shared by a group. The multidisciplinary consultation may be made with someone outside the ED. Speaking with a schoolteacher, nurse, or counselor may be informative. A public health nurse or visiting nurse may have worked in the family's home and have excellent insights. Any multidisciplinary consultations are of value.

Reporting. Most states provide that reports of child neglect go to the CPS agency. Some states have joint police and social work (CPS) reporting. Criminal charges under the rubric of "endangering the welfare of another" may be brought against some neglectful parents. However, most neglect cases come under the supervision of CPS. Police involvement becomes almost essential in cases of abandonment, and police have special skills in locating a missing parent.

Informing Parents. Informing the parents is more difficult in cases of neglect. Responses may be either active or passive. The term *neglect* often triggers an active and angry response. This reaction occurs because neglectful parents believe they are trying to parent as best as they can. Their perceptions of the neglect are different from those of the ED staff. This difference invariably creates conflict and evokes guilt and anger. When informing the parents, the focus should be on the child. The physician may need to verbally recognize the positive efforts of the parent. Nonetheless, if the result in the child is inadequate, action needs to be taken to help the child. Taking this approach often directs the parents' energy toward the child and sufficiently quiets emotional reactions.

The passive response may be equally disquieting to the physician. It may be seen in parents who are overwhelmed, have inadequate personalities, or are depressed, intoxicated, or mentally retarded. Separating these parental problems from each other may be difficult. The physician may incorrectly assume the parent does not care what happens to the child because of the lack of response. With extremely passive parents, even engaging them in conversations may be difficult. Approaching the withdrawn parent with simple questions that do not directly relate to the neglect may be helpful. Often, by initiating a neutral conversation, the physician can learn about the parental problem. Asking the parent to perform a task that requires reading or writing may also be instructive. When informing the parent of the neglect report does not trigger active resistance, the physician may be left with an uneasy feeling that the communication was not clearly understood. However, repeat explanations may not stimulate more parental response.

Hospitalization. The need for hospitalization depends on several factors. Certainly, if the child's physical condition warrants treatment, hospitalization is indicated. For example, a child failing to thrive in the first 6 months of life should be hospitalized. Another indication relates to the degree of parental dysfunction. If the parents are assessed as being so overwhelmed, withdrawn, depressed, or inadequate that they are unable to assume parental responsibility, the child should be protected regardless of his or her current physical status. A third indication stems from the chronicity of neglect. Because of the indolent nature of neglect, the physician may need to make a point of hospitalizing the child to dramatize a long-term or recurrent situation. The final factor in determining the need for hospitalization is the time required for community agency response. If the report of neglect triggers an immediate investigation and institution of therapeutic services, the need for hospitalization is diminished. The response to neglect reports varies by community.

Follow-up. In cases of neglect, arranging follow-up care by a physician or clinic is important. Often, the step of informing the receiving physician is overlooked. The staff providing the long-term care is expected to have the capacity to closely monitor patients and to become aggressive about correcting failure to keep appointments. The treatment of neglected children is often a long and frustrating process. Thus, special referral resources should be sought. Attempts to provide treatment in standard health care facilities may be doomed because the passive and indolent character of neglect may escape health care providers and thereby injure the child.

EMOTIONAL ABUSE

Emotional abuse is the form of child abuse that most seriously and most often affects children. With every episode of physical or sexual abuse, a negative psychological message is being inflicted. The child is told, "You are bad!!" and often comes to believe this statement. When the bruises, burns, and broken bones are healed, psychological injury may remain untreated. The neglected child also feels devalued and unloved. Emotional abuse always accompanies other forms of abuse and at times is inflicted independently.

Yet, this form of abuse is the least well understood. Furthermore, a report of suspected abuse is rarely based solely on emotional abuse. Gathering enough objective data to prove that emotional abuse has occurred is difficult. Courts and legal authorities remain unconvinced that a given parental behavior or set of behaviors can be shown to be responsible for effects in the child. Emotional abuse rarely results in a psychosocial emergency. More often, similar to neglect, it is a long-term impediment to normal growth and development.

Background

Emotional abuse has been defined in many different ways. The NCANDS defines it simply: "Child abuse which results in impaired psychological growth and development. Frequently occurs as verbal abuse or excessive demands on a child's performance and results in a negative self-image on the part of the child and disturbed child behavior." The Pennsylvania Child Abuse Law provides for reporting a serious mental injury, which is defined as a psychological condition determined by a psychologist, psychiatrist, or pediatrician, and caused by the acts or omissions of a parent or person responsible for the child's welfare, which: (i) renders the child chronically and severely anxious, agitated, depressed, socially withdrawn, or in reasonable fear of his or her life; (ii) makes it extremely likely that the child will be chronically and severely anxious, agitated, depressed, socially withdrawn, or be in reasonable fear that his or her life is threatened; or (iii) seriously interferes with the child's ability to accomplish age-appropriate developmental milestones or school or community tasks or peer relations.

The Pennsylvania law identifies some of the potential manifestations of emotional abuse but does not define the difficult issue of a child's behavior as "caused by" an act or omission on the part of the parent. The issue of causality hampers the reporting of emotional abuse. The incidence of emotional abuse is unknown, and reasonable estimates of its frequency are not available. Although neglect is reported most often, emotional abuse is the most common form of abuse because it occurs along with all other forms of abuse and neglect, as well as independently.

Dynamics

Emotional abuse occurs when a parent attacks, belittles, humiliates, or devalues a child. Such behavior is not the infrequent reaction of a normal angry parent, but it is an often-repeated message to the child. An emotionally abusive parent appears to be determined to verbally destroy his or her child. The reasons for this behavior are many. The dynamics responsible for physical abuse may be operative for emotional abuse. Often, poor parental self-image is a strong component. The child either threatens the parent or reflects unwanted parental characteristics. In either case, the parent is unable to withstand the stress and attacks the child. When there are many children in a family, a parent may scapegoat the one child with whom he or she most identifies. At times, the child may be identified with another family member, such as an estranged father or a grandparent.

Helfer capsulized the intergenerational nature of emotional and physical abuse in his "World of Abnormal Rearing" formulation (Fig. 132.19). The child who is told repeatedly that he or she is "bad" and "worthless" eventually accepts it. Once the belief that "I'm no damn good" exists, the child's behavior matches the expectation. Ultimately, the poor self-image is reflected in the inability to choose friends or a mate and to accept help. The cycle is completed with poor parenting and emotional abuse of the next generation of children. The intergenerational potential for emotional abuse makes it a serious public health problem.

Manifestations

Emotional abuse manifests in many forms, including children who are excessively withdrawn and passive and those who are aggressive and act out. The manifestations are so varied that it is difficult to identify any constant characteristics of the emotionally abused child. To identify emotional abuse, the physician must witness family interactions on repeated occasions; however, the emergency physician does not often have the opportunity for such comprehensive evaluation.

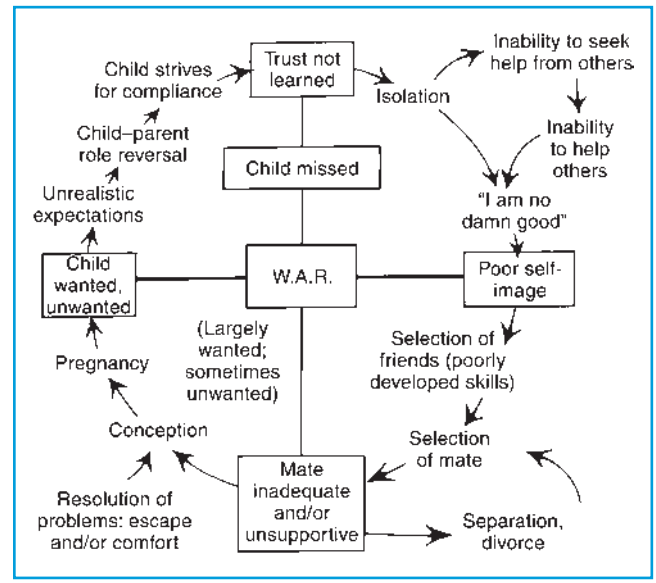

FIGURE 132.19 World of Abnormal Rearing (W.A.R.). (Adapted from R.E. Helfer.)

Rarely, more direct presentations of emotional abuse may be seen in the ED. Some children may seek hospital asylum because of excessive fear of their parents. Adolescent "runaways" may include a subset of children who are emotionally abused (see Chapters 130, 131, and 133). Developmental delay may be recognized in the ED, but the cause of the delay can rarely be identified. Finally, children with drug or alcohol abuse may be in a high-risk group for prior emotional abuse. The effects of emotional abuse closely parallel the findings in children with substance abuse (e.g., poor self-image, difficulty in establishing relationships).

Another group of emotionally abused children frequently seen in the ED are youngsters caught in the conflict between estranged parents. These victims have been called "yo-yo" children because they are pulled between arguing parents. Sometimes the children are virtually kidnapped by one parent. These presentations to the ED are based on one parent's attempt to document the poor parenting or neglect of the other. The misuse of the child as a pawn in the marital dispute constitutes emotional abuse. Despite the credibility and motivation of the parent in the ED, emotional abuse should be reported to remove the child from the middle.

Management

The management principles for emotional abuse are the same as those for other forms of abuse. To substantiate emotional abuse, documentation of behavior must be precise. The physician, nurse, and social worker must record observed interactions in behavioral terms using a minimum of subjective assessments and personal conclusions. Recording significant

statements from the parents and the child is good documentation. Citing a pattern of abuse or repeated episodes of abuse may be necessary to strengthen a report.

It is often difficult and painful for parents to see themselves as emotionally abusive. Thus, informing the parent in a constructive and sensitive way is also difficult. The informant must keep the discussion child focused and nonaccusatory. Child welfare agencies and the family court system also have difficulty in identifying and treating emotional abuse. As the rights of children become better established and standards for child care more widely accepted, management of cases of emotional abuse will become less difficult.

Prevention

As with many childhood injuries, the key to managing abuse is its prevention. Several reviews have been published that emphasize the need for such methods of prevention.

CHAPTER 133 ■ PSYCHIATRIC EMERGENCIES

EMILY R. KATZ, MD, LAURA L. CHAPMAN, MD, AND THOMAS H. CHUN, MD

The emergency department (ED) is frequently the setting for the initial evaluation of various emotional and psychiatric difficulties of children and their families. As such, ED physicians must be proficient in psychiatric diagnosis, crisis intervention, and disposition planning, regardless of whether a mental health professional is consulted to evaluate the patient. Even when a consultant is involved, the ED physician still shares responsibility for the patient's care and disposition. As in any other situation involving a consultant, it is critical that the ED physician and the consultant agree on a treatment plan, both from a patient care perspective and from a medicolegal standpoint.

CRISIS AND CRISIS INTERVENTION

Psychiatric emergencies are best understood as crisis situations. Crisis involves the acute development of circumstances or events that render the usual coping and adaptive patterns of an individual or social unit inadequate. A useful conceptual approach to these crises is "Why now?" (i.e., what in the person's behavior or their overall situation has become unmanageable). It is at this point that patients and/or families seek professional help and the patient may be brought to the ED.

Psychiatric emergencies during childhood may be defined as crises in which the adults around the child are no longer able to help the child control his or her emotions and can no longer provide adequate support and control of the child's emotional reactions and behavior. Therefore, comprehensive assessment and treatment of psychiatric emergencies in children must involve the participation of the child's family.

Requirements of the ED

The ability to respond effectively to psychiatric emergencies of children and families requires special capacities of the ED and its staff. The safety of patients and the ED staff is of paramount importance. Ensuring safety includes not only the physical characteristics of the patient room but also the access to medical and hospital security personnel, as well as appropriate safety procedures and policies.

It is vitally important to ensure patients do not bring weapons or other dangerous objects into the ED. Procedures to achieve this end may include use of metal detectors or a physical search of the patient and their belongings for such objects. Some EDs use a protocol whereby all patients must wear a hospital gown and slippers while in the ED. This separates the patient from their belongings and can facilitate a search for harmful objects. Such a policy may also theoretically reduce the risk of patient elopement.

A safe and adequate physical space is an absolute requirement of the ED. Patients should be under constant supervision by ED personnel—by either by the medical staff or the security staff. ED staff must always be able see the patient, either by direct visualization of the patient or by continuous video monitoring. At the minimum, the room in which patients are medically evaluated must be free of objects with which the patient can harm him- or herself. This includes not only sharp objects but also objects with which they could strangle themselves (e.g., medical tubing, electrical or equipment cords). Such objects should be either inaccessible to the patient (e.g., in locked cabinets) or physically removed from the room. Ideally, the ED should have a separate holding or observation area for patients recovering from overdoses or being stabilized with psychotropic medication, where they can be observed and evaluated regularly.

The optimal setting for a psychiatric evaluation would have the following characteristics. It would be a quiet, low-stimulus environment in which interruptions are uncommon and privacy and confidentiality are assured. A specific area for psychiatric emergencies distinct from the main ED may be calming and may enable a mood of concern and deliberation. Examination rooms should have seats for each family member and the clinician. This area should be adequately staffed by medical and security personnel and have rapid access to additional personnel. There should also be the capacity for using restraints, if necessary.

Clinicians in the ED should have a preexisting relationship with a mental health team that is committed to providing child psychiatric consultation at all times. The emergency physician and the consultant need to collaborate in the care of these patients. The ED should also have relationships with various psychiatric inpatient units so that hospitalization, when needed, can be arranged efficiently. The staff should be thoroughly familiar with the procedures for psychiatric hospitalization, including the specific legal requirements for involuntary commitment. In certain situations, such as children recovering from medically serious suicide attempts, medical hospitalization may be necessary. The hospital should have specific guidelines or protocols for the management of psychiatric patients on medical floors.

Finally, the ED should have relationships with other social agencies and an awareness of relevant laws. The police should be aware of which children to bring to the ED for psychiatric assessment and should be prepared to remain in the ED until adequate security has been arranged. Relationships should be developed with mental health base service units, temporary shelters, and other crisis intervention centers, ensuring effective referrals when necessary. Staff should be aware of child protection laws and the procedures for emergency intervention in situations of abuse and neglect.

Independent disposition planning

Physician Responsibilities and Skills

The responsibilities of the emergency physician with psychiatric emergencies are shown in Table 133.1. The physician needs to handle the family's anxiety and uncertainty by approaching the family crisis calmly and systematically. In doing so, the physician establishes the leadership and authority that enables the family to discuss its problems freely and to consider and act on recommendations. Another important skill of the emergency physician involves the ability to obtain and assess relevant information about the child, the family, and their community supports. This topic is covered subsequently in the "Evaluation of Psychiatric Emergencies" section.

Family Responsibilities

A childhood psychiatric emergency implies a limitation of effective interaction between the child and his or her caregivers. The emergency physician must establish who the child's actual caregivers are and try to involve as many of them as possible in the ED. When evaluating the child, the caregivers, and their relationships with each other, the emergency physician should assess the degree to which the parents (or other caregivers) are meeting the following responsibilities:

1. Ensure the physical and emotional safety of the child. Parents need to protect the child as much as possible from external danger (e.g., getting lost, walking into traffic, going off with strange adults) and internal family danger (e.g., neglect, physical and emotional abuse, sexual abuse).
2. Provide support and nurturance, especially to younger children, such that an emotional bond is established between the child and parent.
3. Provide enough socialization to set limits on the child's behavior.
4. Promote the child's efforts in age-appropriate tasks, including consistent school attendance and performance, learning to relate to peers, and assuming greater autonomy within the family as the child grows older.
5. Assist the child in coping with unexpected failures and losses, including academic disappointment, family disruption, and disability resulting from physical illness.

By keeping these family responsibilities in mind, the emergency physician can assess families in crisis, determining which functions are being met and which need to be supported.

Working with Strengths

The emergency physician working with a family in crisis must look for problem areas, as well as areas of competence in both the child and the family. These areas of strength form the basis for a successful treatment plan that enables the family to master the crisis. Typically, families in crisis do not use their existing abilities enough as they pursue a narrow range of responses to the problem at hand. Once a family's assets are recognized, these skills enable the parents to be more confident and competent in dealing with their child. The emergency physician should help the family recognize its capabilities at a time when confidence is at its lowest level.

EVALUATION OF PSYCHIATRIC EMERGENCIES

The evaluation of acute psychosocial emergencies can be divided into five sections (Table 133.2). Orienting data and relevant history indicates the general living situation and previous psychosocial adaptation of the child or adolescent patient. It also provides a complete description of the current crisis, including apparent precipitants. Medical history and physical evaluation determine the child's current physical status. The mental status examination of the child provides information about the patient's current psychological well-being. A family evaluation, using both history and observation of the family's behavior during the ED visit, enables the physician to determine the family's ability to respond to the child's distress. By integrating these sources of information, the emergency physician is well equipped to understand the crisis and to pursue appropriate treatment alternatives.

Orienting Data and Relevant History

Psychosocial orienting data, as shown in Table 133.3, provide information that enables the physician to appreciate the basic living situation of the child and family. This information can be quickly obtained and includes the child's age, gender, and race; the child's grade in school and the type of classroom setting; and the address and type of neighborhood where the family lives. Family composition includes who lives at home, what their relationships are to each other and to the identified patient, and who are the primary and secondary caregivers.

TABLE 133.2

CHILDHOOD/ADOLESCENT PSYCHIATRIC EMERGENCIES: CATEGORIES OF NECESSARY INFORMATION

1. Orienting data
2. Relevant history
3. Medical history and physical examination
4. Mental status of the child
5. Family evaluation

TABLE 133.3

CHILDHOOD/ADOLESCENT PSYCHIATRIC EMERGENCIES: ORIENTING DATA

Age of child, gender, race
Grade in school, name of school, classroom setting
Family address, type of neighborhood, parental occupations
Family composition
- One- or two-parent family; approximate ages of parents
- Siblings of patient and their ages
- Other family members, if any, living in the home
- Other significant relatives and caregivers

Relevant history, as shown in Table 133.4, builds on identifying information to provide a more complete description of the problem at hand. Historical information should include a thorough understanding of the current crisis and its apparent precipitants, as well as similar problems in the past and previous psychiatric involvement for either child or family. The recent school performance of the child and the adequacy of his or her relationships with peers and family members should also be determined.

The history of the current crisis should be obtained directly by asking family members in turn to give their account. Usually, beginning with the parents and other adults in the room is easiest. The physician must also obtain the child's version of the current difficulties. If the family does not provide a coherent history, the physician should guide the interview by interrupting respectfully and asking relevant questions. The physician can ensure a more complete understanding of the problem by periodically summarizing what family members have said and then checking for accuracy. When accounts and opinions differ among family members, this disparity should be made explicit. When important issues such as suicidal thinking and severe depression are not brought up, the physician should inquire about them directly. This inquiry often reassures the family that its distress is understood and enables the emergency physician to have all the relevant information needed for assessment.

Medical History and Physical Examination

"Medical clearance" of psychiatric patients is one of the prime reasons why children with psychiatric emergencies are sent to an ED. There are several major objectives of this medical evaluation. First and foremost is to determine whether a patient has an unstable medical condition or acute injuries requiring immediate treatment. Many psychiatric facilities do not have the capacity to care for acute medical problems. Such problems must thus be stabilized and/or treated before the patient can be safely transferred to the psychiatric facility. The second aim is to evaluate the patient for possible medical causes of their psychiatric symptoms. Many medical conditions, as well as acute intoxications, can mimic psychiatric disorders (Table 133.5). Failing to diagnose an underlying medical condition may result in significant morbidity to the patient. It is important to note that psychiatrically ill children may also have concomitant medical problems and, in fact, are at greater risk for presenting with emergent medical conditions such as injuries and ingestions than are nonpsychiatrically ill children.

TABLE 133.4

CHILDHOOD/ADOLESCENT PSYCHIATRIC EMERGENCIES: RELEVANT HISTORY

History of presenting crisis and apparent precipitants
Past episodes or other major psychosocial problems
Psychiatric treatment, past or current, for child or family member
School performance of child
Child's relationships with siblings and peers

The emergency physician must obtain a thorough medical history of the child, including current medication and possible medicines available to the child, followed by a complete physical examination, including assessment of neurologic functioning. There is no "standard" set of laboratory evaluations that must be obtained to "clear" a psychiatric patient. Many psychiatric patients, particularly those with preexisting psychiatric diagnoses, can be medically cleared by history and physical examination alone. Patients with new onset of or acute change in psychiatric symptoms, especially psychosis or alterations in mental status, must be carefully evaluated for possible underlying medical conditions. These patients frequently require at least some laboratory evaluation. In addition, some inpatient psychiatry facilities require baseline laboratory data before accepting a transfer.

Toxicologic screens and pregnancy tests in women of childbearing age are the most frequently obtained laboratory tests. Table 133.6 lists laboratory evaluations that may be considered for psychiatric patients.

Mental Status of the Child

Evaluation of the child's mental status takes place throughout the entire ED visit. The mental status examination provides a psychological profile of the child at the same time that it assists in determination of a psychiatric diagnosis. Generally, the physician does not need to perform a formal mental status examination of the child because most of the relevant data emerge from history, the physical examination, and the interactions that the child has with family members and with the physician during the emergency assessment. However, the emergency physician should have a systematic and thorough understanding of the mental status examination and should follow up areas of concern with more specific questions. Table 133.7 lists the major categories of the mental status examination. These categories are described as they apply to emergency psychiatric assessment.

Orientation

The level of consciousness and orientation of the child is the first area of assessment. The child not under the influence of drugs or with severe medical illness should be oriented in all spheres: person, place, time, and situation.

Appearance

The physical appearance of the child reveals important information about both the way the child feels about and cares for him- or herself and the supervising care by the family. The examiner

TABLE 133.5

MEDICAL CONDITIONS THAT MAY MANIFEST WITH NEUROPSYCHIATRIC SYMPTOMS

Neurological
Cerebrovascular disorder (hemorrhage, infarction)
Head trauma (concussion, posttraumatic hematoma)
Epilepsy (especially complex partial seizures)
Narcolepsy
Brain neoplasms (primary or metastatic)
Normal-pressure hydrocephalus
Parkinson's disease
Multiple sclerosis

Metabolic and systemic
Fluid and electrolyte disturbances (e.g., syndrome of inappropriate antidiuretic hormone secretion)
Hepatic encephalopathy
Uremia
Porphyria
Hepatolenticular degeneration (Wilson's disease)
Hypoxemia (chronic pulmonary disease)
Hypotension
Hypertensive encephalopathy

Toxic
Intoxication or withdrawal associated with drug or alcohol abuse
Adverse effects of prescribed and over-the-counter medications
Environmental toxins (volatile hydrocarbons, heavy metals, carbon monoxide, organophosphates)

Nutritional
Vitamin B_{12} deficiency (pernicious anemia)
Nicotinic acid deficiency (pellagra)
Folate deficiency (megaloblastic anemia)
Thiamine deficiency (Wernicke–Korsakoff syndrome)
Trace metal deficiency (zinc, magnesium)
Nonspecific malnutrition and dehydration

Infectious
AIDS
Neurosyphilis
Viral meningitides and encephalitides (e.g., herpes simplex)
Brain abscess
Viral hepatitis
Infectious mononucleosis
Tuberculosis
Systemic bacterial infections (especially pneumonia) and viremia
Streptococcal infections
Pediatric infection-triggered, autoimmune neuropsychiatric disorders

Autoimmune
Systemic lupus erythematosus

Neoplastic
Central nervous system primary and metastatic tumors
Endocrine tumors
Pancreatic carcinoma
Paraneoplastic syndromes

AIDS, acquired immunodeficiency syndrome.

Insight and judgment
Synthesis of evaluation

should carefully observe factors such as physical size, personal hygiene, choice of clothes, neatness, grooming, posture, and gait.

Memory

The child's memory can be evaluated while listening to the history and through direct questioning. Impairment of memory in a child is a strong indication that his or her emotional and behavioral disturbance may have an underlying medical cause.

Cognition

Intelligence, fund of knowledge, and the ability to think and reason are evaluated while talking with the child. Intelligence and fund of knowledge only need to be categorized as adequate or inadequate for the child's age.

Behavior

The child's behavior can be observed throughout the visit. Activity level may be at the appropriate age level and goal directed, too rapid and random (hyperactive), or too slow and diffuse (psychomotor retarded). The child may appear well focused or may be distractible. Behavioral tendencies are revealed in the child's talking with the examiner and in interactions with various family members. Psychotic youngsters may act in a bizarre, disorganized manner or seem completely disconnected from the world around them. Nonpsychotic children, when aggressive, tend to be more oppositional and defiant than psychotic children. The child's ability to control his or her behavior in response to the examiner's or family's request should be carefully noted.

Relating Ability

The child's capacity to relate to the examiner is a key element in the mental status evaluation. In a sense, the examiner is a window to the outside world, and the degree to which a positive relationship can develop during the assessment suggests the child's current capacity for forming relationships in general. The examiner should be concerned with what occurs at any moment during the evaluation and, even more important, how the interaction evolves during the course of the visit. The following questions should be considered: (i) to what degree does the child offer eye contact and speak spontaneously; (ii) how trusting does the child appear to be and to what degree does the child appear to desire the examiner's approval; and (iii) in contrast, is the child too friendly and open, suggesting extreme neediness? The child's cooperativeness and tendency to alter his or her mood in response to the examiner's encouragement are important components of his or her capacity to relate.

Speech

Speech includes elements such as spontaneity, coherence, articulation, and vocabulary. As such, the category of speech overlaps with the capacity to relate, the quality of thought processes, and the level of intelligence. Rapid speech that is difficult or impossible to interrupt may be a sign of mania or ingestion (e.g., a stimulant). Poor vocabulary and articulation may suggest mental retardation, psychosocial deprivation, specific language disabilities, or combinations of these.

Affect

The child's affect, as the external manifestation of predominant feeling states, is assessed informally during the course of the interview. Fluctuations of affect according to changes in content and interactions should be carefully observed, with more serious concern raised by children whose affect does not change as different subjects are discussed. Depressed children may show both sad and angry affect, which suggests the way in which the child sees both self and the external world. Some angry children express their anger directly, even in the form of rage. Other children become so well defended that their affect appears flat and constricted. Frankly psychotic children, in addition to blunted affect, show an inappropriate response to internal and external events, such as smiling while serious topics are discussed. Manic children may have either an irritable or elated affect.

Thoughts

Thoughts include both thought processes and thought content. The evaluation of the preceding categories necessarily yields much information on thinking. Thought process involves the coherence and goal directedness of verbal communication. Evasiveness and guardedness must be distinguished from the looseness of associations of the psychotic child or adolescent. Loose associations have no logical coherence or connection with previous statements. Flight of ideas, as found in bipolar disorder, involves rapid shifting from one topic to another, often triggered by the patient's ongoing monologue. Thought content involves the major themes that emerge as the child talks spontaneously and responsively to the examiner. If themes of violence and insecurity are evident, are other more hopeful and positive themes also present? Such information can often be obtained by eliciting fantasy material, such as three wishes, personal goals, and views of the future. Self-concept, when low, may become apparent as persistent themes and fantasies are pursued. Thorough screening also involves determining the possible presence of psychotic phenomena (hallucinations, delusions, grandiosity, and ideas of reference) and present or past tendencies toward suicide or homicide.

Insight and Judgment

Insight involves the degree of recognition and acknowledgment of current problems by the child. A child with a high degree of insight can also identify possible precipitating factors. Judgment involves the child's ability to think before acting. Over the course of the interview in the ED, the examiner can assess these elements informally.

Synthesis

After the component parts of the mental status examination have been determined, the physician should integrate them into a comprehensive picture of the child. For example, a 14-year-old boy presents to the ED fully alert and oriented, but disheveled and malnourished. His cognitive abilities appear to be intact, but his actions are slow and labored. The child's thinking shows no evidence of incoherence, but themes of disappointment emerge from the conversation. The boy relates to the physician in a withdrawn manner and appears to be preoccupied. The data from this mental status examination suggest that the adolescent described is depressed. This impression should then be integrated with historical, medical, and family information as the examiner plans appropriate treatment.

Family Evaluation

To assess families, the physician needs to have an organized framework to guide the evaluation process (Table 133.8). The goal of a family evaluation for childhood psychiatric emergencies is to determine the methods that the family uses to help its members when distressed, the adequacy of these efforts, and the possibilities for new alternatives that will help the family cope successfully with the current crisis. In obtaining the history from the family and proceeding with the assessment, the emergency physician should keep in mind these specific aspects of family functioning so that he or she can evaluate the family systematically during the ED visit. When conducting the interview with child and family, the emergency physician is encouraged to remember that, despite the disruption caused by the crisis, families know their child the best. When the physician approaches parents as partners, the likelihood of an effective collaboration between parents and medical staff is maximized.

Family Mental Status

Just as it is important to know the child's mental status, the emergency physician must also determine the mental status of the rest of the family. This task can be accomplished as the physician observes the family members and listens to their presentation of the history. The history should be coherent and logical and should follow a temporal sequence. Families that do not present an organized history may have serious difficulties resolving crises. Family members under the influence of drugs or alcohol may not be fully alert and oriented. Their history may not be clear. Depressed parents appear withdrawn and downcast. They may be so preoccupied with their depression that they do not focus effectively on the child's problem or they may describe the problem in extremely hopeless terms.

Although anxiety, distress, and even anger may be appropriate responses to a psychiatric emergency, parents should be able to use the physician's support to control these responses so that the crisis can be approached systematically. When this cooperation does not occur, the emergency physician should consider psychiatric consultation. Other indications for psychiatric consultation include the presence of psychosis or other severe psychiatric disturbance in a parent or caregiver. When the family presents a disorganized history, the physician can indicate that he or she is confused and ask for clarification. The physician can also suggest that only one person talk at a time and can repeat the history given and ask the family to confirm it. When these attempts to provide structure to the family fail, psychiatric consultation is needed.

TABLE 133.8

Intoxication/drug abuse
Depression
Violence
History of abuse (physical, emotional, sexual) and/or neglect

Conflict Resolution Versus Conflict Avoidance

All families have disagreements among their members. In some families, disagreements are acknowledged and confronted directly, whereas in others, potential conflict is consistently avoided. Other families disagree openly but are unable to reach a constructive resolution. The capacity of the family for conflict resolution is an important area for the emergency physician to assess because unresolved disagreements typically lead to chronic hostility, undermining of relationships, and ineffective parenting.

Families that are unable to resolve conflict often have significant marital problems. The parents, unable to deal effectively with each other, instead become overinvolved with one of the children. The child may have a chronic illness, may be either the oldest or the youngest, or may be chosen for another reason. The child gets caught in the marital struggle of the parents, in part through their efforts and in part through his or her own desire to remain close to the parents and keep them together. This child often develops physical and psychiatric symptoms and may present to the ED with the family.

The emergency physician may observe several possible patterns of conflict avoidance. The parents may agree that the only problem in the family is the child and that, if it were not for him or her, everything would be fine. However, the physician notes that the parents do not look at each other or talk to each other. Their one common ground of agreement is the scapegoated child and his or her symptoms. In a related pattern, the parents suppress all conflict by focusing excessive concern on the symptomatic child, who is seen as vulnerable and weak. This reaction often occurs in families with a child with psychosomatic symptoms, where the child is overprotected and his or her symptoms are typically exacerbated by family conflict. The third pattern involves parental focusing on the child and his or her symptoms as the battleground for overt parental and spousal disagreements. The parents deny the existence of any disagreements except those related to the identified patient, about whom they disagree openly and angrily.

Using Social Support

Some families come to the ED feeling isolated, overwhelmed, and exhausted. Often, such families have not used all the family and community resources available to them. Effective crisis intervention for psychiatric emergencies involves not only emergency treatment but also effective disposition planning for the family. The ED staff should determine what community resources are available, or potentially available, to the family. The parents should be asked about relatives or neighbors who might be able to help them.

AGITATED OR VIOLENT BEHAVIOR AND THE USE OF RESTRAINT

Background

Agitated or violent behavior is a frequent reason that children and adolescents are brought to the ED for evaluation. Such behavior may be especially problematic for the ED physician in that it may interfere with the physician–patient relationship and impair the physician's ability to fully assess and treat the patient. ED physicians may need to rapidly decide on a treatment strategy with little or no input from the patient. Differentiating among the varied possible causes is critical in successfully selecting the least restrictive yet efficacious treatment strategy, while minimizing the potential for adverse effects to the patients.

Clinical Manifestations

Agitation may manifest in a wide variety of behaviors, depending on the patient's age and developmental and physical state. Signs and symptoms may include catatonic withdrawal, restlessness, hyperactive motor activity, confusion or disorientation, uncontrollable crying, verbal threats, and overt physical violence toward oneself, others, or physical property.

It is important to remember that agitated or violent behavior may be situation dependent. Once removed from that situation, the child's or adolescent's behavior may significantly improve. In fact, the behavior may appear to be normal by the time he or she arrives at the ED. It is potentially a grave mistake to equate the lack of significant symptoms in the ED with the absence of a significant problem. The problematic behavior may easily reoccur if the patient is returned to the same situation without any appropriate intervention(s).

Assessment

Agitation or violence is not a diagnosis unto itself. Such behavior is the final common pathway for various psychological, medical, and toxicological disturbances. An agitated or violent patient may be experiencing dysfunction in one or more of these areas. The ED physician's assessment should thus focus on differentiating among the many possible causes.

Paramount in evaluating these patients is assessing their potential for violence, both imminently in the ED and in the future should they be discharged. Table 133.9 lists signs and symptoms commonly used in assessing and predicting violent behavior. Table 133.10 lists other commonly cited predictors of dangerousness to others. Patients should be asked if they currently have any violent or homicidal thoughts. Do they have any specific plans or thoughts on how they would hurt someone? Do they have access to firearms or other weapons? No single sign, symptom, or set of criteria successfully identifies all patients with significant risks for violence. When there is a concern for such violence, prompt psychiatric evaluation should be obtained. Appropriate safety measures should be undertaken in the ED, including searching the patient for weapons or potential

TABLE 133.9

ASSESSING AND PREDICTING VIOLENT BEHAVIOR

Signs of impending violence
Recent acts of violence, including property violence
Verbal or physical threats (menacing)
Carrying weapons or other objects that may be used as weapons (e.g., forks, ashtrays)
Progressive psychomotor agitation
Alcohol or other substance intoxication
Paranoid features in a psychotic patient
Command violent auditory hallucinations—some but not all patients are at high risk
Brain diseases, global or with frontal lobe findings; less commonly with temporal lobe findings (controversial)
Catatonic excitement
Certain manic episodes
Certain agitated depressive episodes
Personality disorders (rage, violence, or impulse dyscontrol)
Assess the risk for violence
Consider violent ideation, wish, intention, plan, availability of means, implementation of plan, wish for help
Consider demographics—gender (male), age (15–24), socioeconomic status (low), social supports (few)
Consider the patient's history—violence, nonviolent antisocial acts, impulse dyscontrol (e.g., gambling, substance abuse, suicide or self-injury, psychosis)
Consider overt stressors (e.g., marital conflict, real or symbolic loss)

From Sadock BJ, Sadock VA, eds. *Kaplan & Sadock's synopsis of psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003.

TABLE 133.10

PREDICTORS OF DANGEROUSNESS TO OTHERS

High degree of intent to harm
Presence of a victim
Frequent and open threats
Concrete plan
Access to instruments of violence
History of loss of control
Chronic anger, hostility, or resentment
Enjoyment in watching or inflicting harm
Lack of compassion
Self-view as victim
Resentful of authority
Childhood brutality or deprivation
Decreased warmth and affection in home
Early loss of parent
Fire setting, bed-wetting, and cruelty to animals
Prior violent acts
Reckless driving

From Sadock BJ, Sadock VA, eds. *Kaplan & Sadock's synopsis of psychiatry*. 9th ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003.

weapons and placing the patient in a room where he or she does not have access to items that could be used as a weapon and where he or she can be constantly observed by ED or security personnel.

In the rare event that an ED physician is the sole person evaluating and managing a truly homicidal patient, the ED physician has a duty to both warn the potential victim and to take actions to protect the potential victim from harm, that is, by psychiatrically hospitalizing the patient. This duty was established in the landmark case of *Tarasoff versus the University of California* and has withstood numerous court challenges. This duty to warn and protect the potential victim supersedes the physician's duty to maintain patient confidentiality.

Management

Verbal De-escalate

The importance and impact of verbal de-escalation strategies should not be overlooked. Several studies have shown that when hospital staff is trained in verbal restraint techniques, the result is a significant decrease in the need for and use of chemical and physical restraint in the care of psychiatric patients. Ideally, all ED staff participating in the care of psychiatric patients should have training in verbal de-escalation techniques (see Table 133.11). Various verbal de-escalation programs have been described in the psychiatric literature. Some of these programs have developed training manuals, which are readily available for purchase. Other programs offer courses in verbal de-escalation.

All verbal de-escalation techniques share common features. The agitated patient should be approached with a calm, nonjudgmental manner. Asking the patient to verbalize what is on his or her mind and being an empathetic listener may be all that is needed to calm him or her. The simple act of listening can have a powerful effect. The patient should be reassured that the ED staff is there to help and work with the patient. Discussing what the patient can expect (e.g., what will happen while they are in the ED, how long he or she will be there, who will be working on him or her) provides structure, which will reassure the patient and alleviate much of his or her agitation.

Patients should be given as much autonomy as possible. This can be achieved by presenting them with as many reasonable treatment options as possible and allowing them to choose among the options. By promoting the patient's autonomy, patients often feel empowered and, in feeling so, are better able to control themselves. That said, it is equally important to set clear limits with the patient. Setting limits are for the safety of all involved. Limit setting may include discussing what is acceptable and unacceptable behavior and what are the consequences of the patient's behavior. With few exceptions, one should avoid "bargaining" with patients because this often encourages testing of limits. It is imperative that the limits and consequences for patient behavior are discussed and applied in a nonpunitive manner. Feeling threatened or punished may exacerbate a patient's agitation and/or behavior.

TABLE 133.11

VERBAL DE-ESCALATION/CALMING TECHNIQUES

Clearly introduce yourself
Use simplified language, a soft voice, and slow movements
Explain what will happen in the ED
Reduce environmental stimulation, if possible (less noise or light, fewer people)
Remove access to breakable objects/equipment
Allow room for pacing, if possible
Offer food or drink, which is inherently calming
Reassure child that you are there to keep him or her safe, that this is your job
Listen and empathize (a treatment cornerstone)
Tell child how you plan to honor his or her reasonable requests
Clarify the child's goal and then try to link his or her cooperation to that goal
Find things for the child to control, like choice of drinks
Engage available consultants: security, social work, psychiatry
Offer distracting toys/sensory modalities
Remain engaged; perceived ignoring may encourage escalations
Remember not to take their anger personally

ED, emergency department.

Restraints

Physical and chemical restraint may be necessary to contain the patient's violent behavior toward self, others, or medical staff. However, controversy exists regarding in what situations and when restraint is indicated. While the use of restraints can prevent significant and potentially life-threatening violent outbursts and can help an out-of-control patient calm down, restraints can also be physically harmful to the patient and traumatizing to the patient, the family, and the staff who witness it.

It is important to be cognizant that restraint has the potential to harm patients. Adverse reactions to chemical restraint, physical harm and death due to physical restraint, as well as psychological harm [e.g., feelings of shame and/or of being personally violated, frank symptoms of posttraumatic stress disorder (PTSD)] have all been reported. Both the Centers for Medicare & Medicaid Services (CMS) and the Joint Commission for the Accreditation of Healthcare Organizations (JCAHO) mandate that health-care institutions monitor their use of restraints, as well as develop and maintain protocols in which patients are treated in the least restrictive manner possible. ED physicians and staff thus need to be familiar with their institution's restraint policies, practices, and guidelines.

Chemical Restraint. CMS defines chemical restraint as "a medication used to control behavior or to restrict a patient's freedom of movement and not standard treatment for the patient's medical or psychiatric condition." Although such medications are extensively used and there are numerous published studies of their use in the adult ED and psychiatric settings, there is scant literature on their use in pediatric populations. In addition, as is the case with many medications and pediatric populations, these medications have not been approved by the U.S. Food and Drug Administration (FDA) for the purpose of chemical restraint in children and adolescents. Any medication(s) used for chemical restraint is thus an "off-label" use of the medication(s). Although there are

published studies of using the oral forms of the newer, atypical antipsychotics in children and adolescents, there are no published studies of the parental forms of these medications used in this population. These limitations aside, it is widely held by experienced psychiatric and pediatric emergency physicians that these medications are both safe and efficacious. Adverse reactions to these medications in the acute setting are rare and usually easily managed should they arise.

Table 133.12 lists medications that are commonly used for chemical restraint and the appropriate initial dose of these medications. When using these medications, it is acceptable to round the dose to the nearest half or whole milligram or the nearest whole pill dose. Alternatively, for patients already on psychiatric medications, their current dose or an increased dose of one of their medications may be appropriate.

The choice of medication(s) for chemical restraint should be based on the level of the patient's agitation or dangerousness. For mild agitation, antihistamines, such as diphenhydramine and hydroxyzine, or benzodiazepines are the first line of treatment. For moderate agitation, possible medications include benzodiazepines, antipsychotics, and atypical antipsychotics. The ED physician should choose between these different agents on the basis of the degree of agitation, the patient's willingness to take oral medications, and the medication side effect profile. The newer, atypical antipsychotics may have fewer adverse effects than traditional antipsychotics [e.g., extrapyramidal symptoms (EPS), dystonic reactions, neuroleptic malignant syndrome]. However, their use in the ED may be limited in that ziprasidone and olanzapine are the only atypical antipsychotics that have a parenteral form, and there is only limited experience using these medications in pediatric populations. The rapidly dissolving oral forms of olanzapine and risperidone may be an acceptable alternative to physicians and patients.

For patients with severe agitation, *rapid tranquilization* is the strategy favored by most experts. In this approach, a dose of a benzodiazepine and an antipsychotic are given simultaneously. These medications can be given orally but almost always will need to be given parenterally. If needed, subsequent doses can be given 60 and 120 minutes after the initial dose. This approach is more effective than medication alone and results in the use of less total medication. A variation of this approach is to give a dose of one of these medications and reassess the patient 30 minutes later. If the patient's agitation has not sufficiently resolved, a dose of the other medication is given. The patient is reassessed every 30 minutes and redosed with the appropriate medication if needed.

Both haloperidol and the atypical antipsychotics, ziprasidone to the largest degree, may cause QTc prolongation. As such, patients receiving these medications should be closely monitored. There is no consensus regarding the prophylactic use of benztropine [1 mg oral (PO)/intramuscular (IM)] or other anticholinergic agents in patients receiving antipsychotics. Some experts favor giving such medications to all patients receiving

TABLE 133.12

CHEMICAL RESTRAINT MEDICATIONS

Medication	Initial dose[a]	Onset of action (min)	Half-life, $t_{1/2}$ (h)	Comments/adverse effect
Diphenhydramine	1.25 mg/kg[b] Teen: 50 mg	5–15 (IM/IV) 20–30 (PO)	2–8 2–8	Paradoxical reaction[a]
Hydroxyzine	1.25 mg/kg[b] Teen: 50 mg	5–15 (IM/IV) 20–30 (PO)	7–10 7–10	Paradoxical reaction[a] Paradoxical reaction[a]
Lorazepam	0.05–0.1 mg/kg[b] Teen: 2–4 mg	5–15 (IM/IV) 20–30 (PO)	12 12	Paradoxical reaction[a]; respiratory depression
Midazolam	0.05–0.15 mg/kg[b] Teen: 2–4 mg	5–15 (IM/IV) 20–30 (PO)	3–4 3–6	Paradoxical reaction[a]; respiratory depression
Haloperidol[c]	0.1 mg/kg[b] Teen: 2–5 mg	15–30 (IM) 30–60 (PO)	21 21	EPS/NMS Transient hypotension, may prolong QTc[d]
Risperidone[e,f]	<12 yr: 0.5mg Teen: 1mg	45–60 (PO) 45–60 (PO)	20 20	EPS/NMS may prolong QTc[d]
Olanzapine[e]	<12 yr: 2.5 mg Teen: 5–10 mg	30–60 (IM) 45–60 (PO)	30 30	EPS/NMS may prolong QTc[d]
Quetiapine	25 mg	45–60 (PO)	6	EPS/NMS may prolong QTc[d]
Ziprasidone	<12 yr: 5 mg Teen: 10–20 mg	30–60 (IM) 60 (PO)	2–5 7	EPS/NMS may prolong QTc[d]

IM, intramuscular; IV, intravenous; PO, oral; EPS, extrapyramidal symptoms; NMS, neuroleptic malignant syndrome.
[a]A paradoxical reaction, such as behavioral disinhibition, agitation, hyperexcitability, and insomnia may occur.
[b]Round dose to nearest milligram or half milligram.
[c]Although not U.S. Food and Drug Administration approved, haloperidol lactate has been used IV (with dosage usually approximated at PO dose × 0.625).
[d]Relative risk for QTc prolongation: ziprasidone > quetiapine > risperidone, olanzapine, haloperidol.
[e]Rapidly disintegrating oral tablet available.
[f]Liquid formulation available.

antipsychotics, for the prevention of EPS. Others prefer to use these medications only if and when EPS develop.

Neuroleptic malignant syndrome (NMS) is a rare complication of antipsychotic use. It is more commonly seen in young, muscular males, although it may occur in patients of any age, gender, and body habitus. Preexisting dehydration and chronic antipsychotic use are other risk factors for developing NMS. Because there is no test that absolutely confirms it, NMS can be vexing to diagnose. In addition, the clinical picture of fever, altered mental status, and autonomic hyperactivity may be difficult to differentiate from meningoencephalitis, intracranial injury, various toxins, serotonin syndrome, or an underlying psychiatric condition. It should be strongly considered in any agitated patient whose conditions worsen or do not resolve when given antipsychotic medication.

Two antipsychotics, thioridazine and droperidol, currently carry FDA "black box" warnings against their use because they may cause fatal arrhythmias. Thioridazine has been largely replaced by newer agents with more favorable side effect profiles. Droperidol is a high-potency butyrophenone (typical) antipsychotic that has been widely used in the ED setting for agitated patients. There is a wealth of literature supporting droperidol's efficacy, as well as numerous papers citing its safety. Currently, the safety record of droperidol and the issue of whether the FDA's black box warning is justified remain unresolved and is being hotly debated.

Physical Restraint. Any device that restricts a patient's mobility is a physical restraint. Theoretically, a bed rail is a form of restraint. In the treatment of agitated patients, however, physical restraints specifically refer to devices (e.g., leather restraints) with the express purpose of restraining a patient's limbs. Only such approved devices should be used for physical restraint. "Soft restraints" or other makeshift devices should not be used.

Physical restraints are not without risks. In 1999, the *Hartford Courant* reported that in the previous 10 years in the United States, 142 people had died during or shortly after being physically restrained. A disproportionate number of deaths were in children. In response to these concerns, the JCAHO Board of Commissioners analyzed a number of these cases. They identified several risk factors associated with patient deaths.

Asphyxiation was associated with excess weight being placed on the back of prone patients, a towel or sheet being placed over the patient's head to protect against spitting or biting, and airway obstruction due to placing the patient's arm across the neck area. A minimum of five trained staff are needed to restrain a patient, one to control each limb and one for the patient's head. For extremely violent or agitated patients, the prone position, although more restrictive, is safer for both the patient and the care provider. Physically restrained patients need constant observation by medically trained personnel because the patient may medically decompensate. JCAHO standards were developed in response to the previously mentioned analysis. They mandate documentation of patient's vital signs and observation, assessment of behavioral status, and offering of food, water, and access to bathroom facilities at regular intervals. These standards also mandate a face-to-face evaluation of the patient by the physician ordering the restraint within 1 hour of the patient being placed in restraints. Orders for restraint can be renewed, but each order cannot exceed 1 hour for children younger than 9 years, 2 hours for children and adolescents between 9 and 17 years, or 4 hours for adults.

Once a patient has calmed down and follows instructions, consideration should be given to removing the restraints. Restraints should be removed in an organized manner, taking into account the severity of the patient's agitation. The same number of personnel needed to place the restraints should be present when the restraints are removed, in case the restraints need to be reapplied. There is no consensus as to the optimal method for removing restraints. Some remove all restraints once the patient is judged to be safe. Others prefer a stepwise approach, releasing an arm first, then the opposite leg, and finally the remaining limbs. Between each step, the patient is informed that if they remain under control, the removal process will continue. Patients should not be left with only one limb restrained. They have too much mobility and could injure themselves or others if they become combative.

SUICIDE ATTEMPTS

Background

Suicidal behavior involves thoughts or actions that may lead to self-inflicted death or serious injury. A distinction is made between suicidal ideation and suicidal attempts in which deliberate attempts to take one's life occurred.

The increasing trend toward suicidal behavior by children and adolescents is alarming. Table 133.13 provides information on the nature and scope of this problem.

TABLE 133.13

CHILDHOOD AND ADOLESCENT SUICIDE: NATURE OF THE PROBLEM

Adolescent Suicide
Now epidemic
44% rise in suicide rate, adolescents ages 15–19 yr, since 1970
4,000 completed adolescent and young adult suicides, 2000
Estimated 400,000 adolescent attempts, 2000 (1:50–1:100 attempts succeed)
Suicide is the third leading cause of death, ages 15–24 yr (after accidents, homicides)

Childhood Suicide
Serious problem
Younger children attempt suicide as a result of depression and/or poor judgment
Increase in attempted and completed suicides, children ages 6 yr and older
Suicide attempts via ingestions (children ages 5–14 yr) five times more common than all forms of meningitis

Additional Data
Girls *attempt* at least three times more often than boys
Boys *succeed* at least two times more often than girls
80% of attempts are pill ingestions
More lethal means—gun, knife, jumping, running into car—more common with boys
Many car "accidents" are not accidents

Suicide can be seen as the final common pathway for various situations in which the child experiences a pervasive sense of helplessness, with a perceived absence of alternative solutions. To the distressed child, suicide appears to be the only solution to his or her problems and also to the family's problems. Most suicide attempts occur in depressed children. Others occur with children experiencing major losses, such as serious illness or death in the family. Still others occur in children with depression in association with problems of impulsivity. A small but significant percentage of suicide attempts occur in psychotic children and adolescents. Table 133.14 outlines the potential sources of adolescent suicide attempts.

A factor that complicates the discussion of suicide in children is their differing conceptions of death at various ages. Up to age 5, death is seen as a reversible process in which the activities of life still occur. From 5 to 9 years, the irreversibility of death is beginning to be understood, but death is personified rather than seen as an independent event. It is not until about age 9 that death is seen as irreversible in the adult sense of being both final and inevitable. Even then, however, the child may imagine his or her own death as being reversible. Under such circumstances, a suicide attempt may have a different meaning than for an adult, where suicide corresponds to a definite end of one's life.

TABLE 133.14

POTENTIAL SOURCES OF ADOLESCENT SUICIDE ATTEMPTS

Developmental stress—identity crisis
Dependence/independence
Accepting disappointments/limitations
Planning for future
Body changes and self-image
Physical growth
Onset of puberty
Awareness of sexuality/need to look attractive
Peer pressures
Friendships and competition with peers of same gender
Dating, romantic involvements, dealing with sexuality
Rejection by special person or peer group
School pressures
Academic competition
Personal need to succeed
Meeting parental expectations
Family pressures
Parent–child expectations/problems
Parental impairment (medical, psychiatric, drug or alcohol)
Parental conflict or divorce
Financial/job-related crises
Societal influences
Mobility and social isolation
Romanticizing of violence and suicide
Lack of confidence in secure future
Adolescent depression
Physiologic vulnerability
Situational stresses
Homosexuality or other minority sexual identity

TABLE 133.15

CHARACTERISTICS ASSOCIATED WITH CHILDHOOD AND ADOLESCENT SUICIDE ATTEMPTS

Positive family history
Hopelessness
Low self-esteem
Active desire to die
Depression
Anger/desire for revenge

Clinical Manifestations

In school-aged children, certain risk factors have been identified that distinguish children with suicidal behavior from other children with emotional problems (Table 133.15). Suicidal children are likely to be depressed and hopeless. Self-esteem is low, and they see themselves as worthless. The want to die is present, as are preoccupations with death. The family history may include past episodes of parental depression and suicidal behavior. Suicidal children tend to view death as temporary and pleasant rather than irreversible.

Adolescent suicide attempts are usually not simply impulsive acts. Before the suicide attempt, preceding family problems often have been present. These problems include a parent or close relative attempting suicide, many residential and environmental changes, and unexpected separations from meaningful relationships (divorce, separation, or death). With the onset of adolescence, an escalation phase occurs in which frustration results from the teenager's desire for autonomy and the belief that his or her parents do not understand. The teenager withdraws or rebels, becoming alienated from his or her parents at a time when they are still needed. The scene is then set for the final stage, in which some precipitating event leads to the suicide attempt.

Table 133.16 indicates the high-risk situations for suicidal behavior in which direct questioning about suicide should occur. The first two situations immediately alert the physician to the danger of suicidal behavior. The other situations involve a different chief complaint, masking possible suicidal ideation

TABLE 133.16

CHILDHOOD AND ADOLESCENT SUICIDE: HIGH-RISK SITUATIONS FOR SUICIDE ATTEMPTS

Suicide attempt just made
Suicidal threat made
"Accidental" ingestion
Child complains of depression
Psychotic child
Significant withdrawal by child
History of aggressive or violent behavior
History of substance abuse
History of previous suicide attempt(s)
Medical concerns, but child appears depressed
Highly lethal method of suicide attempt
Availability of or access to firearms

TABLE 133.17

ASSESSING CHILDHOOD/ADOLESCENT SUICIDE ATTEMPTS: FOUR MAJOR DIMENSIONS

Medical lethality
Suicidal intent
Impulsivity
Strengths/supports

or behavior. All accidental ingestions should be screened for the possibility of a suicide attempt. Overtly depressed children are at risk for suicide, as are depressed children who present with somatic complaints. Children who have acted violently are also at risk because violence can be turned inward. Psychotic children present a special problem and may present with inadvertent suicide attempts as the result of impaired judgment, hallucinations, and delusions of persecution. The isolated, withdrawn child may harbor suicidal thoughts that are uncovered only by direct questioning.

Assessment

The emergency physician should specifically ask about suicidal thinking in all high-risk children. The dichotomy sometimes drawn between suicide "attempts" and suicide "gestures" is ill conceived. All suicidal behavior should be regarded as suicide attempts, which are best evaluated by appreciating the medical lethality of the act, the suicidal intent of the child, the impulsivity of the act, and the strengths and supports within the family (Table 133.17). The lethality of a suicide attempt by itself may be misleading because suicidal children may miscalculate, causing at times more harm than was intended and at other times less harm than was intended. As an example, the child who takes 10 tablets of his mother's tricyclic antidepressant (TCA) medication could make a fatal miscalculation because TCAs can cause fatal arrhythmias in children. In contrast, a child who takes 10 aspirins may be far more suicidal than the lethality of his or her ingestion would suggest. In general, more violent methods of attempted suicide (e.g., hanging, shooting, jumping) usually reflect greater suicidal intent (Table 133.18). However, the physician cannot conclude that attempts with low lethality are not serious attempts until he or she has specifically asked about and assessed the child's suicidal intent, that is, just how seriously the child wanted to end his or her life (Table 133.19). These questions should be asked of the child without the parents in the room.

TABLE 133.18

CHILD AND ADOLESCENT SUICIDE: ASSESSING MEDICAL LETHALITY

Vital signs
Level of consciousness
Evidence of drug/alcohol intoxication (e.g., pupils, smell on breath)
Need for emesis, lavage, or catharsis
Acute medical complications (cardiac, respiratory, renal, neurologic)
Indications for medical hospitalization, including intensive care
Residual abnormalities

TABLE 133.19

CHILDHOOD AND ADOLESCENT SUICIDE: ASSESSING SUICIDE INTENT

Circumstances of Suicide Attempt
Nature of suicide attempt (e.g. ingestion vs. violent means)
Use of multiple methods
Method used to extreme (all vs. some pills ingested)
Suicide note written
Secrecy of attempt (attempt concealed vs. revealed)
Premeditation (long planned vs. impulsive attempt)
History of prior attempts
Child Self-report
Premeditation of attempt
Anticipation of death
Desire for death
Attempt to conceal attempt
Nature of precipitating stresses
Child's Mental Status
Orientation/cognitive intactness
Presence/absence of psychosis
Manner of relating to physician
Current suicidality
Response to being saved/being unsuccessful in attempt
Active plan for another attempt
Readiness to discuss stresses
Readiness to accept external and family support
Nature of orientation toward future

In addition to asking directly about suicidal intent ("When you took those pills, what did you think would happen? What did you hope would happen?"), the physician should gather as much information as possible about the attempt itself to help infer the degree of suicidal intent on the part of the child. Did the child take all the pills that were available? Did he or she expect to wake up? Did he or she tell anyone after taking the pills? Did he or she leave a suicide note? Now that he or she is awake, is the child pleased or displeased to be alive? Does he or she intend to try again?

Children who threaten suicide without making an actual attempt should also be questioned carefully about suicidal intent. How long has the child considered suicide; what methods are planned; when will this take place? Has the child ever made previous attempts? How about other family members? Psychotic and depressed children, especially when the parents appear unable to supervise the child, should elicit particular concern.

Assessment of the child's level of impulsivity is also important (Table 133.20). Does the attempt appear to have been impulsive rather than planned? Is there a history of prior impulsive behaviors? Is there evidence of impulsivity during the ED interview?

The physician should ask the child and family about possible precipitating events to determine what changes in the environment may be needed. The strengths of the family should be assessed to determine whether sufficient social support exists to allow for outpatient management (Table 133.21).

TABLE 133.20

CHILDHOOD AND ADOLESCENT SUICIDE: ASSESSING IMPULSIVITY

Management

Evaluation for Hospitalization

No universally agreed-on criteria have been established for when to hospitalize a child with suicidal behavior and when to manage him or her on an outpatient basis. Garfinkel and Golombek identified seven areas to assess to determine whether hospitalization is indicated (Table 133.22).

Social set involves the degree of privacy that the child arranged at the time of the attempt. Did he or she tell anyone before or after the attempt, or were pains taken to set up a situation in which detection was unlikely? Intent may be reflected in a suicide note left by the child, by the degree of detail of the suicide plans, and by direct questioning of the child regarding his or her suicidal intent at the time of the attempt and at the time of examination. The choice of method also helps in the assessment of the suicide attempter. Was a method with high lethality used or desired? Did the child understand the likely outcome of the method used? The history reveals both the presence of past suicide attempts by the child and past attempts by other family members. The evaluation of the stressful precipitating events is important in planning disposition, as is the mental status of the child at present and in comparison with the past. Finally, the degree of support expected from within the family and outside the immediate family (extended family, neighbors, peers, and teachers) must be assessed. To what degree can the family unconditionally commit itself to support the child's safety and well-being? Are there resources present for the family and larger network to implement this commitment? The decision to hospitalize the child is made when the child's safety is still in doubt after these questions have been answered.

In general, any suicide attempt deserves a thorough assessment by the emergency physician and a complete psychiatric consultation. Hospitalization should be used in the circumstances listed in Table 133.23. These are as follows: (i) the physician has had difficulty in gaining the cooperation of the child and the family, (ii) the child has made a serious suicide attempt, (iii) the child is continuing to be actively suicidal, (iv) the child is unwilling/unable to provide a no-suicide commitment to the parents, (v) the child is psychotic, (vi) the family appears unable to provide necessary supervision and support to the child, and (vii) the child and family deny the significance of a serious suicide attempt.

Initiating Treatment

The critical goal in dealing with suicidal behavior in a child is to create a context for living—an immediate response to the crisis that increases the likelihood that the child remains alive. The emergency physician creates a context for living through his or her thorough assessment of child and family, the eventual disposition, and the encouragement of family and child to increase communication and develop alternative solutions to problems that have arisen.

Parents should be encouraged to tell the child that they want him or her to live and that suicidal behavior is forbidden. Parents can be tender in expressing their love for the child, but they need to be firm in establishing the rule that self-destructive

TABLE 133.23

INDICATIONS FOR PSYCHIATRIC HOSPITALIZATION FOLLOWING CHILDHOOD/ADOLESCENT SUICIDE ATTEMPT

1. Failure of rapport among physician, child, and family
2. Serious suicide attempt (lethality and intent)
3. Continuing active suicidality
4. Inability to provide no suicide commitment to parents
5. Psychosis of child
6. Divisive/disturbed family, incapable of support and supervision
7. Denial of significance of suicide attempt

behavior is an unacceptable response to problems. The child should also be told that he or she has a responsibility to him- or herself and the family to keep him- or herself alive. The emergency physician may need to remind tentative parents that, regardless of whether hospitalization is used, they still have primary responsibility for their child.

A critical moment occurs when the parents, guided by the emergency physician, ask the child to make a no-suicide commitment, also known as a *safety contract*. This commitment signifies the child's promise to the parents that he or she will not try to harm him- or herself again, no matter how upset he or she is. Instead, the child will seek out the parents or another responsible adult for assistance. The emergency physician should recognize the common tendency toward denial by the child in the ED after the actual suicide attempt. As a result of this denial, or in an effort to simply appease the parents, the child may make an insincere no-suicide commitment. Therefore, when this commitment is being made, parents and child should discuss it carefully and thoughtfully, so that the parents and ED physician can determine the real intentions of the child and convey the urgency of the no-suicide commitment. While there are no well-controlled studies to support to contention that a no-suicide commitment is protective against future suicidal or self-injurious acts, it can still be diagnostically and therapeutically useful to discuss this concept. When a child and his or her parents are able to agree on a contract for safety, it can help foster a sense of collaborative problem solving and open communication. Alternatively, if an earnest contract for safety cannot be established, this failure alone is often sufficient indication for inpatient admission.

If inpatient treatment is required, the child and family should be informed about how the hospital operates and what to expect. The goals of the hospitalization should be discussed and the active role of the family in the treatment emphasized. In many states, voluntary consent forms need to be signed. In instances in which the child or parents do not agree to hospitalization, involuntary commitment may need to be used, although every effort should be made to enlist the concurrence of the parents first. When possible, the child and family should be accompanied to the psychiatric hospital by the consultant psychiatrist or an involved social worker so that the transition to the psychiatric facility is made smoother.

Outpatient management of suicidal behavior becomes feasible when (i) the child and family are cooperative and engageable, (ii) the attempt is determined not to have been too serious in terms of intent and medical lethality, (iii) the child is not actively suicidal or psychotic at the time of the evaluation, (iv) the child provides an earnest no-suicide commitment, and (v) the family can take responsibility for the child until formal psychiatric treatment is begun the next work day and appears capable of managing the child within the home setting as mental health treatment is provided. Before sending a family home, the psychiatrist or emergency physician should have the family formulate a concrete plan concerning how it will manage the child. The expectations and responsibilities of each family member, including the suicidal child, should be spelled out.

Outpatient psychotherapy can begin immediately with emergencies that occur during the workday. When outpatient treatment cannot begin until the next day, the physician should give the family a therapist's name or the name of the "intake person" at the mental health agency. This information personalizes the agency and increases the chances that the family will follow through. The family should be instructed to use the physician's name as the source of referral and should be reassured that the physician will contact the agency before the family's call. At least one parent and the child, if an adolescent, should be asked to sign a release of confidentiality to authorize communication between the physician and the mental health agency. This release also enables the agency or the psychiatrist to contact the family if the family fails to follow through in making an appointment to be seen. Any discussion of suicide must contain careful consideration of prevention. Parents should be given guidelines for the prevention of suicide (Table 133.24) and instruction in the early warning signs (Table 133.25).

TABLE 133.24

PREVENTION OF CHILDHOOD AND ADOLESCENT SUICIDE: GUIDELINES FOR PARENTS

Understand nature of parent–child dilemma during adolescence
Maintain physical contact—be around, combat tendency toward isolation
Maintain emotional contact—stay involved, show positive regard
Listen to child before responding—promote safety in talking
Respond to child once child has finished—take child seriously, do not dismiss or attack
Encourage choices by adolescent
Acknowledge child and provide respect

TABLE 133.25

PREVENTION OF CHILDHOOD AND ADOLESCENT SUICIDE: WARNING SIGNS FOR PARENTS

Withdrawal (peers, parents, siblings)
Somatic complaints
Irritability
Crying
Diminished school performance
Sad or anxious appearance
Significant loss (rejection by peer group, breakup of romance, poor grades, failure to achieve important goal)
Major event or change within family
Casual mention of suicide or being "better off dead"
Explicit suicide threat
Minor, seemingly unimportant suicide "gestures"
Apparent "accidents"
Other unusual behavior pattern—housebound behavior, breaking curfew, running away, drug or alcohol abuse, bizarre or antisocial actions

DEPRESSION

Background

Depression can refer to the symptom of feeling sad, but most appropriately, it describes a symptom complex or syndrome that includes cognitive and physiologic components in addition

to mood symptoms. Depression involves a pervasive inflexibility of sad mood, accompanied frequently by self-deprecation and suicidal ideation. Depression also implies a change in functioning from an earlier state of relatively good adjustment, rather than a temperamental or personality type. The depressed child typically experiences a profound sense of helplessness, feeling unable to improve an unsatisfactory situation.

Data on the incidence of depression in children and adolescents vary. In one suburban Boston study of high school students who were aged 11 to 15 years, 33% of these early adolescents were believed to have moderate to severe symptoms of depression. Other estimates put the incidence of depression in children and adolescents in the 20% range. The incidence of depression is higher in children with school problems (including learning disabilities and attention-deficit/hyperactivity disorder (ADHD)) and in children with significant medical problems. Because most children with depression come to the ED with another chief complaint (e.g., somatic symptoms, school problems, behavior problems), the physician must keep in mind the possibility of depression in all children seen with recurrent or vague somatic complaints.

Considerable evidence suggests that a genetic predisposition exists for depression, particularly severe depression. Depressive episodes may be triggered by environmental events of significance to the child.

Clinical Manifestations

Depression appears differently at different stages of development. In infancy, depression is usually the result of loss of mother and/or lack of nurturance and is seen as a global interference of normal growth and physiologic functioning. Thus, some of the manifestations of depression in infancy include apathy and listlessness, staring, hypoactivity, poor feeding and weight loss, and increased susceptibility to infection.

In school-aged children, depression can appear as part of a syndrome or may be masked by other symptoms. Petti described the two key features in childhood depression as dysphoric mood and self-deprecatory ideation. Dysphoric mood is manifested by looking or feeling sad and forlorn, being moody and irritable, and crying easily. Self-deprecatory thoughts are reflected by low self-esteem, feelings of worthlessness, and suicidal ideation. Depression in this age can also appear as other common symptoms, including irritability, multiple somatic complaints, school avoidance or underachievement (including learning disabled children or children with ADHD), angry outbursts, runaway behavior, phobias, and fire setting.

Depression during adolescence is more similar to adult-onset depression. The major symptom is a sad, unhappy or irritable mood, and/or a pervasive loss of interest and pleasure. Other symptoms may include a change in appetite, change in a sleep behavior, and psychomotor retardation or agitation. Also present in many depressed teenagers are loss of energy, feelings of worthlessness or excessive guilt, decreased ability to concentrate, indecisiveness, and recurrent thoughts of death or suicide. Depressed teenagers can also present with somatic complaints, academic problems, promiscuity, drug or alcohol use, aggressive behavior, and stealing. Many teenagers with behaviors such as these are unaware of their depression because it is not on the surface. Others simply deny the painful depressive affect. In talking with these patients about their lives at home, at school, and with peers, the underlying depression usually becomes apparent.

As with all children presenting with psychiatric symptoms, especially those that are acute in onset or significantly changed in severity or character, a medical evaluation in indicated to rule out potential medical causes of their symptoms or concurrent medical illness, to assess for physical or laboratory signs of self-injurious/suicidal behaviors and, when indicated, to screen to side effects of prescribed medications (e.g., renal dysfunction in a child on lithium). See Table 133.5 and the section on medical history and physical examination for additional information.

Management

The three major goals in the management of depression involve (i) determining suicidal potential, (ii) uncovering acute precipitants, and (iii) making an appropriate disposition.

The emergency treatment of depression can usefully be thought of as the prevention of suicide attempts. The task of the physician is to carefully determine whether any suicide attempts have been made and whether suicidal ideation is present. The physician should not be hesitant to ask the child about suicidal deeds, thoughts, or wishes. Such questions represent a positive confrontation of the problem of depression and are unlikely to catalyze a subsequent suicide attempt. In fact, questions about suicide may actually provide a sense of relief for the depressed child.

The physician should attempt to determine possible acute precipitants of the current depression to guide subsequent recommendations. The duration of the depression should be determined, as well as the family response. Assessing overall adjustment at home, in school, and with peers is important, as well as looking for the strengths of child and family for use in the treatment plan.

When suicidal ideation is present, the emergency physician should request psychiatric consultation. A decision can then be jointly made regarding outpatient or inpatient treatment. Whether suicide is an imminent danger, the task of the physician is to create a sense of hope that things will improve. To achieve this goal, the physician must form a solid doctor–patient relationship with child and family. Outpatient management can be used when adequate social support is present. The parents must first acknowledge the existence of depression in the child and then come to understand that the solution involves a strong commitment on their part, including, at times, their participation in family therapy.

Although fluoxetine is the only psychotropic medication approved by the FDA for depression management in children and adolescents, it and other medications are commonly being used in the treatment of childhood and adolescent depression. As an acute intervention, however, the emergency physician should not prescribe antidepressant medication because its desired mood-elevating effects generally require up to 1 month to take effect, and the act of prescribing medication in the ED may decrease the likelihood of successful referral for follow-up mental health treatment.

The emergency physician should be familiar with commonly used antidepressants, which are used in the treatment of

depression. In more recent years, the selective serotonin reuptake inhibitors (SSRIs) have displaced TCAs as first-line medications. Advantages of SSRIs over TCAs include a decreased likelihood of cardiotoxicity, the absence of anticholinergic side effects, and the relative safety of these medications when used in overdose. Another commonly prescribed antidepressant is bupropion, which is chemically distinct from other agents and primarily acts on the dopaminergic system. A side effect of potential concern with bupropion involves seizures. Newer mixed mechanism agents such as duloxetine, venlafaxine, and mirtazapine are also being used in children and adolescents.

Currently, a hotly debated topic is the safety of antidepressants in the treatment of adolescents. In 2003, the British counterpart of the FDA banned the use of SSRIs in children and adolescents, citing cases where patients' symptoms, including suicidality, worsened while on these medications. In December 2004, the FDA mandated a "Black Box" warning label on all antidepressants. The labels warn about possible increase risk of suicidality with these drugs and about the need to monitor patients for the worsening of depression and the emergence of suicidal ideation. The FDA has not yet taken a position on whether antidepressants cause the emergence of suicidal thinking and behavior. The agency advises that children and adolescents on antidepressants should be closely monitored, particularly after starting or increasing the dose of medication.

PSYCHOSIS

Background

Psychosis is the term used to describe severe disturbances in a patient's mental functioning. It is manifested by significant aberrations in cognition, perception, mood, impulses, and reality testing. Behavior may also become extremely agitated and potentially violent or excessively withdrawn to the point where the patient does not recognize and attend to his or her physical needs. Psychotic patients are actively attempting to regain control over their mental capacities and are trying to understand and deal with highly unusual thoughts, perceptions, and impulses. Their subjective experience is often one of helplessness and extreme anxiety.

Psychosis in children and adolescents can be divided into two groups based on cause: medically based psychosis and psychiatrically based psychosis. Psychiatrically based psychosis in children and adolescents has three major causes: (i) adult-type schizophrenia with onset in adolescence, (ii) brief psychotic episode, and (iii) bipolar or depressive illness with onset in late childhood or adolescence. Emergency management of psychosis due to a medical condition and the three major types of psychiatrically based psychosis are described in the following sections.

Misdiagnosing children and adolescents with psychosis is a significant problem. Werry and Thomsen each described groups of patients initially diagnosed as psychotic, who ultimately were found to have bipolar disorder and personality disorders. In addition, there are numerous case reports of patients with medical causes of their symptoms, who suffered morbidity because of inaccurate diagnosis and inappropriate treatment. Developmental and cultural factors contribute to the difficulty in accurately diagnosing psychosis. Hallucinations can be seen in various normal developmental conditions and may be difficult to differentiate from those of true psychosis. In addition, cultural and religious beliefs, taken out of context or inadvertent clinician biases, may be misconstrued as psychotic symptoms. For these reasons, patients with new onset of or sudden change in psychotic symptoms need to be carefully evaluated for underlying medical conditions and thoroughly evaluated by a psychiatrist.

Psychosis due to a Medical Condition

Differentiation of psychosis secondary to a medical condition as a separate class does not imply that psychiatrically based psychosis is completely independent of brain processes. On the contrary, all psychosis is assumed to be associated with aberrant brain function. The term *psychosis due to a medical condition* merely implies that the cause of the aberrations in mental functioning is known, and resolution of the psychosis depends on improvement in the underlying medical problem(s). Psychiatrically based psychoses, in contrast, are those in which specific medical causes have not yet been determined (Table 133.26). The causes of medically based psychoses can be acute or chronic illnesses, trauma, or intoxications with an exogenous substance (Tables 133.27 through 133.29).

Clinical Manifestations

The child or adolescent with psychosis due to a medical condition often presents to the ED in an agitated and confused state. The child's orientation to time and place is often disturbed, and he or she may be highly distractible, with significant disturbance of recent memory. Evidence of bizarre and distorted thoughts is apparent, and disconnected ideas may be juxtaposed. The child may also have significant difficulty controlling behavior and may persist in activities without regard for personal safety. The child may get up to leave the room without saying where he or she is going or why he or she needs to leave. Intellectual functioning may also be impaired, and the child may be unable to concentrate on simple reading or arithmetic tasks.

The child with psychosis due to a medical condition may experience visual hallucinations, which may be frightening in nature. Tactile hallucinations may be present. Auditory hallucinations, more common in psychiatric illness, are less common in medically based psychoses. As a result of impaired reality testing, children and adolescents with psychosis due to a medical condition are often extremely difficult to control and may strike out at family or staff when attempts are made to control their behavior.

An accurate and thorough history is essential in the evaluation of any child or adolescent for psychosis and is also helpful in appreciating its underlying cause. A complete medical history helps determine whether the psychosis is a concomitant feature of an already existing chronic illness (e.g., lupus cerebritis), a result of medication prescribed to treat an ongoing disease (e.g., steroids for lupus erythematosus), or a result of drug ingestion (e.g., amphetamine psychosis). Typically, an acute intoxication or drug ingestion causes the acute onset of psychosis and represents an abrupt change from the child's previous psychological functioning. The possibility of alcohol use must also be considered in the cause of psychosis, and the

TABLE 133.26

MEDICALLY VERSUS PSYCHIATRICALLY BASED PSYCHOSIS: MAJOR DIFFERENTIATING FEATURES

Assessment feature	Medically based psychosis	Psychiatrically based psychosis
History		
Nature of onset	Acute	Insidious
Preillness history	Prior illness/drug use	Prior psychiatric history (self or family)
Medical Evaluation		
Vital signs	May be impaired	Usually normal
Level of consciousness	May be impaired	Normal
Pathologic autonomic signs	May be present	Normal
Laboratory studies	May be abnormal	Normal
Mental Status Evaluation		
Orientation	May be impaired	Intact
Recent memory	May be impaired	Intact
Cognitive/intellectual functioning	May be impaired	Intact
Nature of hallucinations	Usually not auditory (e.g., visual, tactile)	Auditory
Response to support and medication	Often dramatic	Often limited

history should explore the possibility of trauma. No specific features of the mental status examination differentiate the various causes of psychosis.

The physical examination is often extremely helpful in both differentiating medically based from psychiatrically based psychosis and determining the underlying cause of an acute psychosis. Fever is likely to be present in infections, and tachycardia is often associated with chronic illness or intoxication. The general physical examination gives indications of pulmonary, cardiac, liver, or autoimmune disease, and the neurologic examination assists in the diagnosis of central nervous system (CNS) disease. Abnormalities of reflexes or of motor, sensory, or coordination systems always require complete neurologic evaluation. Signs of increased intracranial pressure may be indicative of a cerebral vascular accident, CNS tumor, or cerebral edema. Signs of autonomic dysfunction, such as pupillary abnormalities, are often indicative of acute intoxication.

In instances of suspected psychosis due to a medical condition, laboratory evaluation should include a complete blood cell count, urinalysis, serum electrolytes, calcium, blood urea nitrogen, blood glucose, and complete drug and alcohol screens. Serum and urine should be obtained for toxicology screening. Other laboratory and radiologic studies depend on abnormalities noted in the history and physical examination. If CNS disease is suspected, CNS imaging studies and a lumbar

TABLE 133.27

CAUSES OF MEDICALLY BASED PSYCHOSIS

Medical conditions (acute and chronic)
Trauma (acute and chronic)
Prescribed medications (toxicity/side effects/withdrawal)
Drug intoxications
- Accidental, including misuse of proprietary medication
- Drug abuse/experimentation
- Alcohol abuse (alone or with drugs)
- Deliberate suicide attempt

TABLE 133.28

MEDICAL CONDITIONS THAT MAY LEAD TO PSYCHOSIS

Central Nervous System Lesions
Tumors
Brain abscess
Cerebral hemorrhage
Meningitis or encephalitis
Temporal lobe epilepsy

Cerebral Hypoxia
Pulmonary insufficiency
Severe anemia
Cardiac failure
Carbon monoxide poisoning

Metabolic and Endocrine Disorders
Electrolyte imbalance
Hypoglycemia
Hypocalcemia
Thyroid disease (hyper and hypo)
Adrenal disease (hyper and hypo)
Uremia
Hepatic failure
Diabetes mellitus
Porphyria

Rheumatic Diseases
Systemic lupus erythematosus
Polyarteritis nodosa

Infections
Malaria
Typhoid fever
Subacute bacterial endocarditis

Miscellaneous Conditions
Wilson's disease
Reye's syndrome

TABLE 133.29

EXOGENOUS SUBSTANCES THAT CAUSE PSYCHOSIS FOLLOWING INGESTION OF SIGNIFICANT QUANTITY

Alcohol
Barbiturates
Antipsychotics (e.g., phenothiazines)
Amphetamines
Hallucinogens—Lysergic acid diethylamide (LSD) peyote, mescaline
Marijuana
Phencyclidine (PCP)
Quaalude
Anticholinergic compounds
Heavy metals
Cocaine and crack
Corticosteroids
Reserpine
Opiates (e.g., heroin, methadone)

puncture may be necessary. Liver function studies, thyroid studies, and other specialized and specific laboratory tests may be obtained as required.

Brief Psychotic Episode

Brief psychotic episode, a relatively uncommon psychiatrically based psychosis, involves a time-limited loss of reality, caused by the accumulated effects of externally imposed traumatic events. Although vulnerability may vary from child to child, children and teenagers can develop acute psychotic symptoms in response to trauma. The diagnosis of reactive psychosis can be made partly by history, but only after a complete medical and psychiatric evaluation has eliminated medically based and other psychiatrically based psychoses. The acuteness of the clinical presentation and its precipitating events differentiates brief psychotic episode from PTSD.

Clinical Manifestations

The clinical picture of brief psychotic episode varies, in some instances resembling schizophrenia and in others a less-defined disorganized state characterized by loss of contact with reality, panic, and specific hallucinations (usually auditory or visual).

Different traumatic experiences, including physical or sexual abuse, rape, homelessness, and running away, may elicit a reactive psychosis. All such situations impose stress on the child and may also disrupt usual patterns of living. Confronted with a new environment and a new reality, the child's familiar cues are absent and confusion or frank psychosis may occur.

Schizophrenia

Schizophrenia often has its onset in adolescence and occurs in approximately 0.5% of the population. This disorder is equally common in male and female patients, although the age of first diagnosis tends to be earlier in male patients. It is more prevalent among family members of known individuals with the disease.

TABLE 133.30

ACUTE SCHIZOPHRENIA IN ADOLESCENCE: MOST COMMON FEATURES

Flat affect (Patient uninvolved and without emotion)
Auditory hallucinations (Physician: "Have you been hearing voices even when no one is there?")
Thoughts spoken aloud (Physician: "Can other people read your mind? Can you read their minds?")
Delusions of external control (Physician: "Is anyone trying to kill you? . . . trying to control your mind or your body?")

Clinical Manifestations

Symptoms of schizophrenia involve impairment of basic psychological processes, including perception, thinking, affect, capacity to relate, and behavior (Table 133.30). Impaired thought content includes delusions (strongly held beliefs involving the self with no basis in reality), such as delusions of persecution and external control. For example, an adolescent with schizophrenia may think that others can read and insert thoughts into his or her mind. Significantly illogical thinking occurs. Speech is often characterized by loose associations, in which ideas shift from one subject to another entirely unrelated subject without the speaker recognizing that the topics are not connected. Auditory hallucinations are common and may include direct commands for suicide or violence to others. Typically, but not always, the voices talk to the patient in the third person, with a highly critical and demeaning message. Affect may be blunted and flat or inappropriate and bizarre. Sudden and unpredictable changes in mood may occur. These teenagers may appear extremely agitated or may be withdrawn, speaking only in monosyllables and describing only concrete objects. Schizophrenic patients typically have significant distortions of their identity and their abilities and demonstrate behavior that is not goal directed.

The history often reveals a prodromal phase that includes social withdrawal, peculiar behavior, failure to look after one's appearance, and significant reduction in performance in school or work. This phase is followed by an acute phase in which the previously described symptoms develop, sometimes as a result of an acutely stressful event. The overall course of schizophrenia is often chronic and associated with remissions and exacerbations. Exacerbations often occur when treatment, including medication, is suspended. However, other individuals experience a schizophrenic-like acute psychosis and recover completely with appropriate treatment, experiencing no further deterioration.

Management

Psychosis due to a Medical Condition

Management of these children and adolescents involve several steps (Table 133.31). First and foremost is diagnosing the underlying cause. Medical treatment is then pursued as

TABLE 133.31

GUIDELINES FOR MANAGEMENT OF ACUTE ADOLESCENT PSYCHOSIS

Diagnose underlying cause.
Request immediate psychiatric consultation.
Use medical hospitalization, if clinically indicated, with medically based psychosis.
Request psychiatric consultation with psychotic drug intoxications, either immediately or when mental status stabilizes.
Use quiet room, family and friends, and constant medical supervision.
Use restraints, if necessary.
Recognize clinical variations of extrapyramidal reactions to antipsychotic medications.

indicated for the specific medical condition. Any child with psychosis in which underlying medical condition is suspected should be admitted to a medical inpatient unit for diagnostic evaluation and treatment. This treatment is especially important because psychosis may be a transitory condition in a child or adolescent whose illness or intoxication is progressive and life-threatening.

Other important components of the management of a psychotic child involve controlling the child's behavior, preventing injury to him- or herself or others, and alleviating the child's fear and anxiety. This goal should be attempted first through supportive statements indicating the physician's appreciation of the child's condition and his or her distress. Specific instructions to the child (e.g., "Try to relax and look at your mother") may also be effective. Often, such interventions calm the child, but because the child is distractible and anxious, instructions may need to be repeated frequently.

Brief Psychotic Episode

The emergency physician should appreciate that most children who present with brief psychotic episode do not have a permanent psychiatric disorder. The emergency management is similar to that of other psychotic states. Physical and emotional protection of the child is the first priority. The child should be given support and time to reconstitute. Efforts to avoid antipsychotic medication should be made in the beginning, but, when necessary, low-dose antipsychotic medication can be used. When the parents or other caregivers are not implicated in the traumatic events, emergency staff members should encourage their active involvement with the child. When the parents are implicated in the trauma or when the facts are unclear, immediate investigation should take place and contact made with appropriate child protection authorities, if indicated.

After emergency treatment, the prognosis of the child depends in large measure on the restoration—or creation—of a safe and dependable family support system. Referral for outpatient family therapy should be made unless the child requires psychiatric hospitalization for further evaluation or treatment. In the absence of adequate family support, some of these children may eventually require foster placement, residential treatment, or other placements.

Schizophrenia

The management of an acute schizophrenic episode should always take place in collaboration with psychiatric consultation. Patients with suicidal or homicidal ideation should receive psychiatric hospitalization. Psychotic patients from disorganized home environments should also be hospitalized for initial treatment. In general, the approach to the psychotic patient in the ED depends on the condition of the patient and the anticipated site of the ongoing treatment. For agitation and dangerous thoughts or behaviors, approaches include reassurance and a quiet setting, psychotropic medication, and/or physical restraint. Antipsychotic medication is discussed in the next paragraph. The patient's vital signs, general condition, and possible side effects should be monitored frequently. If the patient does not respond to medication, inpatient psychiatric hospitalization is necessary. If significant improvement occurs, suicidality and homicidality are absent, and side effects do not occur, the patient can be considered for discharge to outpatient psychiatric treatment with careful follow up, as long as the parents or caregivers are well organized, appreciate the child's condition, and feel capable of managing the child at home.

Commonly used antipsychotic medications, their trade names, relative potency, and usual dosage ranges are listed in Table 133.32. Long-standing antipsychotic medications, now referred to as *typical antipsychotics*, exert their influence primarily on dopaminergic neurons. A new class of antipsychotic medications, called *atypical antipsychotics*, has emerged. These medications affect multiple neurotransmitter systems, most frequently dopamine and serotonin. In this growing class are risperidone (Risperdal), clozapine (Clozaril), olanzapine (Zyprexa), aripiprazole (Abilify), quetiapine (Seroquel), and ziprasidone (Geodon). Clinical advantages offered by this new class of medications include clinical effects on the "positive symptoms" of schizophrenia (e.g., an improvement in the ability of the individual to relate to the environment and to others, not just a positive effect on hallucinations and delusions) and a decreased likelihood of EPS and long-term tardive dyskinesia.

The major side effects of typical antipsychotic medications are EPS, including acute dystonic reactions (abnormal muscle tone or posturing), akathisia (motor restlessness), and parkinsonian effects (rigidity, tremor, slowed movement, and loss of balance). Acute dystonic reactions are best treated by PO, intravenous, or IM administration of diphenhydramine (25 to 50 mg) or PO or IM administration of benztropine (1 to 2 mg per day).

MANIA/BIPOLAR DISORDER

Childhood and adolescent bipolar disorder is one of the most active areas of research in child and adolescent psychiatry. It is now generally accepted that the clinical presentation of mania in childhood may be atypical by adult standards. In contrast, symptoms of bipolar disorder in adolescents are similar to those in adults. Between 20% and 40% of adolescents initially diagnosed with major depressive disorder develop bipolar disorder within 5 years.

Clinical Manifestations

Unlike adults, mania in childhood is not typically characterized by euphoric mood. Irritable mood is much more common.

TABLE 133.32

ANTIPSYCHOTIC MEDICATIONS

Generic name	Brand name	Estimated equivalent dosage (mg)	Total daily dosage
Phenothiazines			
Chlorpromazine	Thorazine	100	50–1,000
Trifluoperazine	Stelazine	5	5–30
Fluphenazine	Prolixin	2	1–20
Butyrophenone			
Haloperidol	Haldol	2	2–40
Atypical Antipsychotics			
Clozapine	Clozaril	75	300–450
Risperidone	Risperdal		1–6
Olanzapine	Zyprexa		2.5–20
Quetiapine	Seroquel		150–400
Ziprasidone	Geodon		20–200
Aripiprazole	Abilify		10–30

Children often have remarkable shifts in mood, involving sudden changes from depressed to irritable or happy, and then back to irritable or depressed. This emotional lability can be disorienting to parents, who cannot understand why the child changes so much and so dramatically, possibly even several times the same day. Unlike the older adolescent, the child often does not have a clear recovery from identified episodes but rather may continue to present in at least a mildly unstable way with irritability and anger for much of the time. Explosive, disorganized behavior may also be seen. True psychotic features are rare in childhood bipolar disorder. The course of childhood bipolar disorder tends to be chronic and continuous, rather than episodic. Approximately 90% of children with bipolar disorder have concurrent symptoms of ADHD, which may, in fact, present before the onset of the mood instability.

Symptoms of bipolar disorder in adolescents are often similar to the adult form, but atypical presentations are also common. Psychotic symptoms, suicide attempts, inappropriate sexual behavior, and a "stormy" first year of illness may be typical of adolescent mania. However, when compared with adults, adolescents may have a more prolonged early course and be less responsive to treatment.

The adolescent with mania has a distinct period of predominantly elevated, expansive, and/or irritable mood (Table 133.33). The patient has a significant decrease in need for sleep, high distractibility, hyperactivity and pressured speech, and emotional lability. These patients also exhibit what is called *flight of ideas*—a nearly continuous flow of accelerated speech with abrupt changes from topic to topic, usually based on understandable associations, distractions, or plays on words. Unlike the loose associations of the schizophrenic patient, the flight of ideas of a manic patient retains logical connection from one idea to the next but moves quickly from one topic to another. The manic patient may at times have a remarkably inflated self-esteem, with uncritical self-confidence and significant grandiosity. This grandiosity may also include delusional ideas. The individual may be aggressive and combative. He or she may go on buying sprees or pursue other reckless behaviors or be hypersexual. Manic patients usually have a history of previous depressive episodes, but an acute manic episode in adolescence may be the initial presentation of the disorder. A family history of psychiatric disturbance usually exists in patients with manic–depressive disorder. Typically, manic patients report feeling extremely well, and they are brought to the ED against their will.

Sometimes, patients will present with symptoms of both mania and depression. In these instances, referred to as *mixed episodes*, the mania is usually primarily characterized by irritability. Mixed episodes are particularly dangerous, as patients are at significantly increased risk for suicidal behaviors.

The differentiation of mania and schizophrenia in an initial episode of psychosis in adolescence may at times be difficult. Hyperactivity, distractibility, and expansive and euphoric mood are often helpful in identifying manic individuals. Both groups may have auditory hallucinations and delusions, but someone listening to the speech of the manic adolescent should recognize the flight of ideas and their connection with each other.

Children presenting with symptoms suggestive of mania should receive a thorough medical evaluation to rule out any potential medical causes of their symptoms (Table 133.5). Special attention should be paid to the possibility of toxic ingestions or drug-induced symptoms. For example, steroids

TABLE 133.33

Anxiety/irritability
Combativeness/panic
Hypersexuality

at doses commonly used in patients undergoing chemotherapy or treatment for chronic diseases such as inflammatory bowel disease are a common culprit of iatrogenically induced mania. Patients with mania should also be assessed for potential medical sequelae of behaviors that they engaged in as a result of their impaired judgment, for example, exposure to sexually transmitted diseases (STDs), emergency contraception, occult head trauma. Laboratory and imaging work-up should be based on history and clinical findings.

Management

Psychiatric consultation should be obtained whenever a new diagnosis of bipolar disorder is being considered, a manic/mixed episode is present, or if the patient is engaging in any unsafe behaviors. In younger children, especially those who are not floridly manic, outpatient management—usually with the combination of mood-stabilizing medications and intensive behavioral treatment—may be sufficient. However, inpatient hospitalization is often required to maintain the patient's safety while effective treatments are being initiated. Patients who are manic can have severely impaired insight and judgment. This can lead them to engage in dangerous behaviors that can have lifelong consequences or even lead to the death of themselves or others, such as unprotected sex with multiple partners, unsafe driving, engaging in felony-level criminal offenses. Involuntary commitment may be necessary.

Initial emergency treatment of the agitated manic patient may require the use of restraints and the acute administration of antipsychotic agents, in doses equivalent to those used for schizophrenic patients.

AUTISM AND OTHER PERVASIVE DEVELOPMENTAL DISORDERS OF CHILDHOOD

Because of the subacute nature of presentations and the chronicity of their course, it is unusual for children with either infantile autism or other pervasive developmental disorders (PDDs) to present to an ED undiagnosed. However, children with these disorders may present in the ED for the treatment of intercurrent illnesses or an acute exacerbation of the child's behavior. Given the limited verbal skills of many of these children, they are often unable to effectively communicate what is causing them distress. As a result, these children can exhibit behavioral or mood in response to a wide variety of stressors or physical symptoms (as seemingly minor as constipation or a sore throat or as potentially life-threatening as a septic joint). Therefore, the ED clinician should obtain a thorough history from caregivers and maintain a high suspicion for a medical etiology of the patient's altered behavior.

Autism

According to the *Diagnostic and Statistical Manual*, fourth edition (*DSM-IV*), autism is a specific type of PDDs of childhood. The major differentiating feature between autism and other forms of PDDs is the age of onset. Autism always has an onset before 30 months of age. Children with autism have a generalized lack of responsiveness to other people and a failure to develop normal attachment behavior. They do not develop relationships and instead play alone, often showing stereotyped behavior and using objects in bizarre, inappropriate ways. The autistic child becomes extremely upset if objects in his or her environment are disturbed or changed. Language development is impaired or absent. Only 30% of autistic children have an IQ higher than 70. Some autistic children have underlying illnesses, such as maternal rubella syndrome or previous encephalitis or meningitis, but in many cases, the cause is unknown. Many autistic children have coexisting seizure disorders. The course of infantile autism is generally chronic, with two-thirds of all autistic children remaining severely disabled throughout life.

A comprehensive educational and socialization program with psychiatric monitoring is essential for autistic children. If an autistic child seen in the ED is not participating in such a program, outpatient psychiatric referral is indicated. Medication management of autism at times may involve careful use of psychotropic medication, including antipsychotics, antidepressants, and α-adrenergic agents. Such psychotropic strategies should be used only in conjunction with ongoing psychiatric treatment. Clear justification must be present for psychotropic medication use, not just the diagnosis of autism. In general, acute psychiatric hospitalization is rarely necessary with autism. In instances of extremely disturbing behavior or acute agitation, sedation with either diphenhydramine or risperidone may be helpful. Alternatively, if a child is already prescribed a standing medication for aggressive behaviors, treating the child additional dose of that medication can be considered. Children with autism or related disorders are often exquisitely sensitive to medications and their side effects, so the use of medications to control agitation should be avoided or minimized whenever possible. General calming interventions and behavioral techniques that are used by caregivers in the school or home setting should be employed to help the child remain safe and calm while in the ED. Child life specialists, when available, should be consulted. If the parents are distressed by their child's immediate behavior and the child is receiving psychiatric treatment, phone contact with the psychiatrist may be helpful to both the emergency physician and the family. In the absence of ongoing care, a psychiatric consultation should be requested.

Other Pervasive Developmental Disorders

Pervasive developmental disorder of childhood is a generic term that includes other developmental impairments in which an incapacity to form reciprocal relationships with others results in severe, sustained impairment of attachment and social relationships. Other features may include extreme anxiety and severe emotional reactions to minor difficulties, with inappropriate affect and extreme mood lability. Abnormalities of speech, hypersensitivity to sensory stimuli, peculiar posturing, and self-mutilation may also occur. PDD other than autism has onset after 30 months and before 12 years of age.

The term PDD incompletely incorporates entities such as childhood schizophrenia, symbiotic psychosis, and atypical psychosis, as well as other recently added conditions. One type of PDD with which the emergency physician should be familiar is

Asperger's syndrome. Children with this disorder typically have normal or above-average intelligence, with a well-developed capacity for speech and language. The impairment is in the capacity to form reciprocal relationships, and emotional rigidity, idiosyncratic thinking, and intense pursuit of a narrow range of interests may be present. Children with Asperger's syndrome may be confusing to the emergency physician because they present as higher functioning than other children with PDD and are not psychotic, yet they may appear to be significantly strange.

All children with PDD, including children with autism, require comprehensive psychiatric and educational treatment. Parents of children with autism and PDD should be given appropriate referrals because children who receive services early in their development are believed to have an improved prognosis. When necessary, the same acute pharmacologic approaches for children with autism are also relevant for other PDDs. Low-dose antipsychotic medication may also be used. With the acute exacerbation of a child with PDD, psychiatric hospitalization may be necessary, both to provide assistance to the parents and to develop or modify a comprehensive treatment program. Families with acute concerns about their child's behavior should receive psychiatric consultation.

POSTTRAUMATIC STRESS DISORDERS

PTSD can occur in childhood and adolescence, typically based on the experience of severe trauma during earlier years. Children may be more sensitive to the effects of trauma than are adults and thus may have higher rates of PTSD. Either the reemergence of the old trauma, the emergence of a new similar one, or the recollection of the original trauma can activate a PTSD. A summary of the official *DSM-IV* description of PTSD is helpful in understanding this concept.

The person has been exposed to a traumatic event in which the person experienced, witnessed, or was confronted with an event that involved actual or threatened death or serious injury, or a threat to the physical integrity of self or others. The person's response involved intense fear, helplessness or horror, or, in children, disorganized or agitated behavior. In addition, the traumatic event is persistently reexperienced in one or more ways, there is persistent avoidance of stimuli associated with the trauma and numbing of general responsiveness, and there are persistent symptoms of increased arousal.

Highly stressful situations that may precipitate severe emotional reactions by the child and PTSD include physical beatings and other violence, repeated threats and belittling by adults, long-standing hunger and poverty, sexual abuse, and rape. PTSD symptomatology has also been reported following bone marrow transplant, severe burns or injuries, or motor vehicle accidents. In some cases, a separate dissociative reaction may occur instead (see the next section). With the child, PTSD probably emerges through a combination of traumatic events, along with a silent or nonaccepting environment that fails to provide the child with adequate protection and support.

Symptomatically, the child may persistently reexperience the traumatic event in many ways, including recurrent and distressing recollections of the event, which may be observed through repetitive play by young children in which themes or aspects of the trauma are expressed. Recurrent and distressing dreams of the event may also occur. Hallucinations and flashbacks may follow the child's sudden reliving of the experience. In addition, events that symbolize or resemble some aspect of the traumatic event may produce intense anxiety and distress; the connection between precipitating event and distress is not always evident to parents or child.

Other PTSD symptoms experienced by children include generalized numbing of responsiveness to events and people. Stimuli associated with the trauma may be consistently avoided. The emergency physician should also be alert for signs of increased arousal—anxiety and agitation, difficulty falling asleep, irritability or anger, suspiciousness, difficulty concentrating—and various physiologic complaints in response to events that resemble or symbolize the traumatic event.

The key task for the emergency physician is to recognize PTSD in the differential diagnosis of an agitated, confused, or even psychotic child or adolescent. A careful history usually provides clues to this diagnosis. Supportive management in the ED, including using family and friends, is often sufficient. Low-dose antipsychotic medication should be reserved for children who are frankly psychotic and who do not respond to reality-based support. Often, an antihistamine or anxiolytic medication may suffice.

The ED physician may also have an important role in the prevention of PTSD. When patients are being treated for an acute traumatic episode, the ED should have forethought. The PTSD may be a consequence and attempt to refer a patient for mental health counseling.

When parents dismiss or doubt the child's symptoms or worries, the emergency physician can encourage the parents to respond supportively to their child. When the physician suspects parental abuse, this concern must be addressed directly with the family and with appropriate authorities brought in, if justified. Many children with PTSD benefit significantly from individual and family therapy. If child and family are not already in treatment, a referral is appropriate.

DISSOCIATIVE DISORDERS

Some children develop a dissociative disorder in response to extreme trauma. In a dissociative disorder, the child separates the usually integrated functions of identity, memory, and consciousness. As a result, the child's affect appears split off from the rest of the person. Specific symptoms vary, but in most cases, the child appears distant, even weird, but is not psychotic. Dissociative disorders occur most commonly in female patients, with sexual abuse a common original trauma.

The function of dissociative reactions is believed to decrease the child's awareness of emotional pain caused by the trauma. The process of splitting off the affect from the body may help a severely traumatized child deal with and survive the assault. This response probably begins at the time of the trauma, especially if it occurs repeatedly, and is then continued afterward as a form of coping. However, a consequence is that the child may continue to split off full emotional responsiveness to daily experiences, creating a profound isolation. This process may continue into adulthood.

The emergency physician may encounter a child with depersonalization, a feeling of detachment from one's self or a feeling of being an automaton or in a dream. Another dissociative

response is psychogenic amnesia, the sudden inability to recall important personal information (or even know one's own identity). Some runaway adolescents may present with a psychogenic fugue, another dissociative disorder. In a fugue state, the individual leaves home unexpectedly with no apparent justification and may at times assume a partial or complete new identity.

The most extreme form of dissociative disorder is dissociative identity disorder (formerly *multiple personality disorder*). In this condition, the child has two or more personalities and appears puzzling to parents, teachers, and physicians. At least two of these personalities recurrently take full control of the child's behavior, with the child unaware of the process. Children with this disorder are aptly described as erratic, inconsistent, and even mercurial.

The emergency physician should consider the possibility of dissociative disorders in all children and adolescents who present in a confused and confusing way. None of these children are psychotic; in fact, an entirely different emotional process is operating. A thorough history is most rewarding and may reveal a female patient with repeated sexual abuse who often appears far off into her own world. Psychiatric referral is appropriate for patients with dissociative disorders. The emergency physician should also determine any possible ongoing abuse before releasing the child to the family.

Panic Attacks

It is not uncommon for children experiencing panic attacks to present to the ED for medical attention. After ruling out any medical cause for the child's symptoms, the ED physician should educate the patient and their family about the nature of panic attacks and explain that no additional medical testing or observation is indicated at this time. Benzodiazepines should be avoided when possible, so as to help the patient and their family recognize that the symptoms of a panic attack are time limited and self-resolving. The patient and their family should be receive brief bedside teaching about basic anxiety management techniques and the appropriate level of response should symptoms recur, for example, when to forego versus when to seek medical attention. It can sometimes be helpful and instructive to ask the patient to practice deep breathing or relaxation techniques while they are connected to a cardiorespiratory monitor, so they can receive immediate feedback on how anxiety level and physical signs/symptoms are related. If the panic attacks are frequent, cause significant distress, or are leading the patient/family to repeatedly seek medical care, use of antianxiety medication and referral to an outpatient mental health provider is indicated. If left untreated, panic attacks can blossom into life-long and severely impairing anxiety disorders. However, with appropriate and early treatment, future panic attacks and their sequelae can be prevented.

SCHOOL REFUSAL

Background

School refusal, also called *school avoidance* and *school phobia*, entails a child's not attending school and expressing somatic complaints that keep him or her at home. Usually, some somatic complaint is the justification for school absence. School refusal involves the knowledge and complicity of the family. A parent, usually the mother, is aware of the child's school absence and has endorsed his or her being home, in part because the parent may consider the child to be physically ill. Children with school refusal often meet criteria for what psychiatrists would refer to as a *somataform disorder* or what medical specialists might refer to as a *functional syndrome*. In some circumstances, they may even present with neurological symptoms suggestive of a conversion disorder. Therefore, the ED evaluation and management recommendations discussed below can be applied to these children as well.

School refusal is an important condition with which the emergency physician should be familiar. Usually, it is not the initial complaint. Typically, one or more physical complaints bring the child to the ED, and information about school attendance is not offered. The physician must maintain an "index of suspicion" in a child with recurring complaints for which no medical cause is apparent.

Clinical Manifestations

Certain school attendance patterns are suggestive of but not necessary for the diagnosis of school refusal. More absences occur in the fall, when school begins, than in the spring. The child often exhibits a reluctance to return to school after weekends and holidays. There may be a lessening of somatic complaints on weekends and over the summer. Similar sporadic attendance patterns may often be elicited at some other time in the child's past. In other instances, however, school refusal may develop in a child who has previously given no cause for concern.

Schmitt formulated a diagnostic triad of the clinical manifestations of school refusal: (i) vague physical symptoms; (ii) normal physical and laboratory findings; and (iii) poor school attendance. The child may have one or more complaints. Schmitt also pointed out that many of the symptoms are reflective of depression and anxiety. This finding is consistent with the fact that many children with school refusal are also depressed. Other psychiatric conditions that may be comorbid with school refusal are specific phobias, other anxiety disorders, conduct disorder, substance abuse, or family psychopathology.

Characteristics of families with school refusal have been noted. An illness orientation is revealed by physical complaints in other family members and frequent somatic references in verbal communication. The closeness between the mother and child may be manifested by the mother's frequent use of "we" when talking about the child. Active undermining by the parents may at times be observed.

Management

The major responsibility of the emergency physician is the detection of school refusal. Although the emergency physician cannot guide the entire treatment of school refusal, he or she can get the process going. The physical examination should be done in the presence of the parents in a thorough manner, with the physician emphasizing the absence of physical findings. Appropriate, but not excessive, laboratory work should be

performed, and medication should not be prescribed. After acknowledging the genuineness of the child's symptom so that there is no misunderstanding that the child is "faking it," the physician should provide a firm and unequivocal statement to the family that the child has no serious illness. He or she should then ensure that the family understands what has been said and accepts it. In this way, misunderstandings or disagreements can be confronted directly, thereby decreasing the likelihood of subsequent "doctor-shopping" by the family. The emphasis is then placed on the child's learning to function despite his or her symptoms.

Once school refusal is recognized and the possibility of medical diseases are ruled out, the principal goals in the treatment of school refusal are (i) getting the child back to school as soon as possible, (ii) ensuring continuity of medical care, and (iii) referring the patient and family to a mental health professional to address underlying individual and family issues that contributed to the development of the problem.

It may be helpful for the parents rather than the physician to tell the child that he or she needs to return to school. In this way, the family takes responsibility for the resolution of the problem from the beginning of the intervention. The parents should be encouraged to work closely together to achieve their desired goal.

CONDUCT DISORDERS

Background

A child with a disorder of conduct engages in repetitive, socially unacceptable behavior, without evidence of medical or other psychiatric disorder. The diagnosis of conduct disorder implies a continuing pattern of disruptive or deviant behavior, rather than isolated antisocial acts. This may involve behavior this is violent and aggressive (e.g., vandalism, mugging, assault, rape) or behavior that is socially unacceptable but nonaggressive (e.g., truancy, running away, lying, stealing, substance abuse). Therefore, a disorder of conduct involves more serious behavior than ordinary mischief and pranks of children and adolescents. Because violent and other unacceptable behaviors may be performed by children with medical illnesses and intoxications, these causes must be ruled out before the diagnosis of conduct disorder can be made. Similarly, because children with psychosis and depression can also behave in socially unacceptable ways, these serious psychiatric disorders must also be considered and eliminated before diagnosing a conduct disorder (see Chapter 19). However, even with primary medical and psychiatric causes of socially unacceptable behavior ruled out, some youth with conduct disorder may have ill-defined physiologic predispositions that contribute to its emergence.

Society disagrees about whether to regard children and adolescents with conduct disorders as psychiatrically impaired and needing treatment, or as delinquent and needing detention or incarceration. No consistent agreement exists about the appropriate criteria for taking such children to an ED as opposed to a juvenile center. In actual practice, certain factors probably influence the choice of disposition, such as age (younger children are more likely to receive medical evaluation), socioeconomic level (children belonging to middle- and upper-level income family are more likely to be taken to an ED), race (Caucasian children are more likely to be taken to an ED than are African American or other minority children), and nature of the infraction (children with aggressive acts directed outside the family are more likely to be taken to a detention center). Aggressive children should always undergo an emergency medical and psychiatric evaluation any time intoxication, an underlying medical condition, or other psychiatric disorder is suspected.

Clinical Manifestations

Children with conduct disorders typically have poor adjustment at home and in the community. Peer relationships are superficial, based more on what the child can get from the other person than on a sense of empathy. The child thinks primarily about him- or herself, trying to manipulate situations to personal advantage without significant concern for the feelings and needs of others. The child with a conduct disorder is unlikely to extend him- or herself for others when no immediate advantage can be gained. When the child is apprehended, little sense of remorse or guilt is exhibited, but rather a sense of anger at being detected and detained. Such children rarely accept responsibility for their own actions and instead tend to blame others for their mistakes.

School attendance of children with a conduct disorder is often sporadic, and academic performance is often poor. This may be caused by various factors, including lack of interest and discipline, but may also be caused by specific learning disabilities and a concurrent ADHD, diagnoses that are remediable but often missed.

The child or adolescent with a conduct disorder shows low frustration tolerance, irritability, and temper outbursts. He or she may be reckless in behavior and project an image of "toughness." Smoking, drinking, drug use, and precocious sexual activity may all occur. In addition to possible legal difficulties, the child may have other problems, including school suspensions, drug dependence, STD, pregnancy, and physical injury from accidents and fights.

The presence of a conduct disorder implies a failure of the child's environment to instill familial and societal values, and to implement their rules effectively. As a result, the child comes to believe that he or she can act as he or she chooses and does not develop control of impulses. The specific pattern of inadequate limit setting varies, but families share an inconsistency in enforcing rules and do not hold the child accountable for his or her behavior. In some families, discipline may fluctuate from being perfunctory at times to being harsh and even physically abusive at other times. Parental role models may show poor impulse control themselves and disregard societal norms.

In addition to inconsistent limit setting, parental separations and divorce, mental illness, and alcohol or drug abuse may also be factors. Parental criminality and incarceration occur in some families. Families with aggressive and impulsive children often do not know how to effectively use social service resources and may consider themselves helpless in controlling their child and in dealing with the world at large.

When brought to the ED, children with a conduct disorder have variable presentations. For example, the child or adolescent may be angry, hostile, uncooperative, and even violent,

refusing to answer questions directed to him or her, but quick to interrupt to defend him- or herself when others speak. Alternatively, the child may present with a superficially smooth and pleasant facade, hoping to persuade the physician and authorities of his or her innocence. Often, once the child realizes that he or she will not be permitted to act out or manipulate in the ED, he or she may settle down and cooperate more fully. At other times, the child maintains an essentially impenetrable persona.

Management

The goals for managing aggressive and disruptive children in the ED are to (i) ensure the safety of the child, family, and staff; (ii) rule out possible medical conditions and severe psychiatric disorders before making the diagnosis of conduct disorder; and (iii) gather sufficient information to make an appropriate disposition.

The safety of the child and staff and control of the child's unacceptable behavior must be achieved in the ED. In many instances, the disruptive behavior occurred and ended before the child's coming to the ED and gaining the child's cooperation is not a problem. In other instances, however, the child may remain combative and aggressive in the ED. Dealing with such a problem requires the presence of adequate security staff and a quiet space where attempts to control the patient do not disrupt the remainder of the ED. The patient should be told firmly that he or she is in the hospital for medical and psychiatric evaluation and will not be permitted to harm him- or herself or others. The child should be informed of the need to cooperate with the staff and control his or her behavior. The child's parents, if present, should be asked to assist in controlling the child. The child can be reassured that he or she will get a chance to tell his or her side of the story completely. These interventions are usually sufficient to gain the child's cooperation.

The history and physical examination assist in ruling out medical conditions and intoxications. The presence of ongoing medical conditions should be specifically asked about, as should any recent alcohol use or drug ingestion because substance abuse is common. As indicated, specimens for toxicologic screening should be obtained. Epilepsy can be ruled out as the cause of the abnormal behavior in the presence of a normal neurologic examination and the absence of an aura, abnormal neurologic signs, or postictal phenomena.

Children with medical conditions and acute intoxications are best managed through medical hospitalization. The presence of psychosis or depression requires psychiatric consultation and possible psychiatric hospitalization. Psychiatric consultation should be obtained for children with presumptive conduct disorder and no underlying medical condition. Less severe and complicated cases can be managed through referral for outpatient therapy. More severe cases may require more intensive community-based services, such as partial hospitalization or even psychiatric hospitalization, which should be considered in cases of severe, chronic conduct disorders, especially when the child's behaviors are escalating and treatment to date has been ineffective. For intervention to be effective with such children, the family must be willing to participate actively, with the goal of altering persistent patterns of disturbed behavior.

Involuntary hospitalization may be necessary when the child's condition continues to pose a threat to him- or herself or others or when overt homicidal or suicidal ideation is present. When the child is not suicidal or homicidal and refuses to make a commitment to work in psychotherapy and when the family does not support the proposed psychiatric hospitalization, problematic behaviors are more likely to continue and the child may eventually enter the juvenile justice system.

FIRE SETTING

Virtually all children in our society develop a fascination with fire and may experiment with it at a relatively early age. For most children, this experimentation is transient and consists mainly of playing with matches or lighting small fires. However, some children may persist with fire-setting behavior, actually planning to set larger fires that are destructive to both people and property. At this point, the child is demonstrating evidence of a significant psychiatric disorder and requires intensive treatment. The exact incidence of fire setting is unknown, but serious repetitive fire setting is believed to be uncommon in children and adolescents. In general, fire setting is a symptom of serious underlying emotional difficulty and is often associated with other disturbances of behavior and impulse control. Fire setting is also associated with significant anger and aggressiveness on the part of the child. The background of fire-setting children is likely to be highly unstable. These children may have had multiple contacts with social agencies in the past, and some may have been placed outside the home in foster homes or institutions. Although the exact percentage of fire setters with underlying ADHD is unknown, many of these children are described as having been hyperactive, with significant learning problems and long-standing truancy from school.

Management

The clinical manifestations of fire setters in the ED are similar to those of other children with conduct disorders as previously described. Effective ED evaluation should always consider psychiatric hospitalization. As psychiatric hospitalization is arranged, the facility must be informed about the child's previous fire-setting behavior so that appropriate behavior monitoring and safety measures can be employed during the admission.

ATTENTION-DEFICIT/ HYPERACTIVITY DISORDER

Background

ADHD refers to a syndrome found in school-aged children, characterized by a pervasive difficulty in maintaining attention and goal-directed behavior. ADHD has an incidence of between 5% and 10% of school-aged children, occurring two to five times more often in boys than in girls. It is presumed to have an underlying neurologic cause. It is the most common cause of chronic behavioral problems for school-aged children.

The emergency physician should be familiar with ADHD because many children so affected become depressed and may make suicide attempts. ADHD is also common in children with bipolar disorder and may in fact initially mask the bipolar disorder. During adolescence, ADHD may itself be masked by antisocial behavior. Because identification and treatment can produce significant improvements in the clinical picture, the diagnosis of ADHD should not be missed.

Clinical Manifestations

Although some children with attentional problems present without hyperactivity, most children have hyperactivity in association with inattention and impulsivity and, therefore, fit within the full ADHD umbrella. Wender described the various possible components of the ADHD picture. Attentional difficulties occur both at home and in school and are often more severe in school. Rather than persisting in schoolwork and other tasks, the child often appears not to be listening to the teacher, and discipline may be a problem.

Impulsivity is another essential characteristic of ADHD. The child has difficulty with self-control, exhibiting behaviors that get him or her in trouble with parents, siblings, teachers, and peers. At home, the child typically has outbursts and temper tantrums, and enforcement of discipline may be difficult. Lack of self-control may also manifest through stealing, lying, playing with matches, and other forms of acting out.

ADHD symptoms tend to be worse in a group situation than at home or in one-to-one interactions. This characteristic at times creates difficulty in the diagnosis of ADHD because the telltale signs are least likely to occur during an individual assessment by the physician.

The child with ADHD may be labile, with fluctuations in mood and a tendency toward overreaction and temper tantrums, but such responses are not always extreme. Appreciating the low self-esteem and possible depression that may be present in these children as a result of academic failure, conflicts at home, and peer and sibling rejection is important. In acute situations, the depression may find expression as suicide attempts or violent behavior. ADHD children are a high-risk group for self-destructive behavior. The physician often perceives the child's sense of sadness beyond a cocky bravado that masks feelings of frustration and inadequacy.

Family problems are typically found in the families of ADHD children, if only as a consequence of the child's impulsivity and challenging behaviors. The child may provoke the parents, interrupt family members, and fail to learn consistently from experience. The child is often difficult to discipline effectively. Conflicts with siblings may occur.

Management

The principal responsibility of the emergency physician is to recognize the possibility of ADHD in children who present with other problems—including depression, mood instability, and conduct disorder—and consider the diagnosis. The physician is then in a position to clarify the meaning of this disorder with the family, as well as to restore hope for the child's improved behavior and adaptation by making a psychiatric referral when indicated. The history is the most reliable diagnostic indicator. Once a presumptive diagnosis is made, appropriate referral and treatment can follow.

Psychostimulant medication is often helpful in alleviating the symptoms of ADHD. Although psychostimulant medication should not be prescribed in the ED, the emergency physician should have a familiarity with the commonly used drugs, including stimulants, such as methylphenidate and D-amphetamine, and their long-acting forms. Tricyclic antidepressants, bupropion, modafinil, and α-adrenergic agents have also been successfully used in the treatment of ADHD but constitute a second line of medication and are not approved by the FDA for this purpose. Atomoxetine is a noradrenergic reuptake inhibitor that is FDA approved for the treatment of ADHD. In general, response rates to the stimulant medications are higher than 75%. The principal short-term side effects of the stimulants are appetite suppression and insomnia. The principal concerns of long-term use of stimulants are suppression of weight gain and linear growth. However, rebound growth appears to occur when the medication is discontinued. Recently, cardiac dysrhythmias and sudden death secondary to the use of stimulants has come under greater scrutiny and is the subject of ongoing research.

ATTACHMENT DISORDERS OF INFANCY

Occasionally, infants will be seen in the ED who are withdrawn and apathetic. These infants demonstrate severe disturbances of attachment with their primary caregivers, often have feeding disturbances, and may fail to thrive. The most significant disability of these children is a dramatic failure of social development. They do not track with their eyes, and they rarely smile. They do not interact with caregivers in age-appropriate fashion, and facial responsiveness may be entirely absent. The child may be noted to be weak, may have poor muscle tone, and may emit a feeble cry. The child demonstrates little spontaneous activity, sleeps excessively, and has a generalized lack of interest in the environment.

The cause of attachment disorders in infants is a continuing lack of adequate caregiving. Features that interfere with maternal–infant bonding are often noted in the history. These may include significant maternal depression and isolation, other maternal incapacitation including substance abuse, maternal indifference toward the infant, history of prolonged separation between mother and infant following birth because of perinatal difficulties, and actual physical abuse. Infants who are temperamentally placid, those who make their needs known quietly, often have more difficulties in the presence of maternal depression or maternal preoccupation than more active and responsive infants.

Underlying chronic illness may also lead to the development of social withdrawal and apathy. Also, children with physical problems in infancy may be more difficult to care for, thus parental reactions to the child's illness may interfere with attachment. Children with mental retardation, although they develop slowly, do not generally demonstrate the profound apathy of the child with an attachment disorder. Furthermore, children with mental retardation receive generally adequate caregiving and do not fail to thrive.

Management

Children with attachment disorders require complete medical evaluation, along with careful assessment of their environment. Such children are often seen in the ED for minor physical complaints and may not be receiving regular pediatric care. Thus, the emergency physician must recognize attachment disorders and make effective referrals for ongoing health care for child and family. When parental apathy accompanies severe failure to thrive, hospitalization may be necessary to initiate needed changes and to plan continuing treatment. The physician should recognize that attachment disorders and the associated failure to thrive are often reversible once adequate caregiving is instituted and maintained. If the physician suspects that the child's problems are a result of actual abuse or neglect, this belief should be reported to the appropriate agencies. (Child neglect is discussed in detail in Chapter 132.)

RICHARD M. RUDDY

CHAPTER 134 ■ ULTRASOUND

JASON LEVY, MD

INTRODUCTION

Emergency bedside ultrasound has been used in the emergency department (ED) for more than two decades. Its beginnings are rooted in the general ED adult population, which now has well-established, evidence-based applications, such as the focused assessment with sonography in trauma (FAST) or evaluation for abdominal aortic aneurysm. It is now a required component of emergency medicine residencies and is considered as core content by the American Board of Emergency Medicine and the American College of Emergency Physicians (ACEP).

Traditionally, ultrasound performed by imaging specialists involves comprehensive examinations in which entire anatomic areas are evaluated. In contrast, emergency bedside ultrasound is intended to answer a focused, limited clinical question (e.g., "Is there cardiac activity or not?") or assist in a specific procedure. As such, each examination type listed below will be presented with this type of question in mind.

Pediatric emergency medicine has been later to adopt bedside ultrasound into everyday clinical practice. In recent years, however, it has gained more widespread acceptance as the body of literature has expanded and training has become more accessible. Besides the obvious advantage of being conducted directly at the patient's bedside, emergency ultrasound offers several other benefits to the pediatric patient. It is generally pain free and does not require sedation to complete; it is readily available; and it does not expose the patient to ionizing radiation. Furthermore, published data support its use with respect to improved patient care and patient satisfaction with decreased ED lengths of stay. Although a substantial amount of pediatric-specific research exists, its growing use will necessitate further investigation to determine which adult applications can be adopted in children. Innovative development of sound bedside ultrasound examinations specific to the pediatric patient will also be required.

ADMINISTRATIVE ASPECTS

Starting an Ultrasound Program

The process of implementing an ultrasound program requires ED leadership, a partnership with hospital leadership in clinical care, and support for an appropriate credentialing and quality assurance protocol. Appointment or recruitment of a point person who either is already well trained in bedside ultrasound or is prepared to undertake additional ultrasound training is a first step. Responsibilities of the lead person are to develop the skills necessary to conduct the evaluation and teach other clinicians and to work to set the standards by which to judge competencies as the program grows.

Second, starting a program is best done in concert with hospital leadership, including radiology and surgery and with the hospital physician–credentialing committee leaders. Whenever possible, evidence-based data should be employed to justify implementation of specific bedside ultrasound examinations. There must be a consensus that this will improve patient outcomes and will be of high quality.

Third, the program requires an ultrasound system designed for the purposes of ED usage, which should be immediately available. Staff and trainees must be able to put what they have learned into use, and only those who perform ultrasound scans routinely will gain sufficient facility to incorporate it into their everyday practice. There are now many companies that recognize the need for ED-specific machines and have numerous quality products that cater to this niche.

Although some standards for training in ultrasound have been published, there is still debate among different governing bodies as to minimal requirements. Guidelines from the American College of Radiology and the American Institute of Ultrasound in Medicine are geared toward comprehensive, diagnostic examinations and are not applicable to emergency bedside ultrasound. ACEP has published consensus guidelines based on expert opinion and previous published data that have now become the current standard for emergency medicine. In general, programs should establish a minimum number of didactic hours, a minimum number of overall ultrasound examinations, and a minimum number of examinations to look for a specific finding. These requirements will form the basis of the credentialing process for staff physicians.

Equipment Considerations

Most important, the anticipated type of ultrasound scans should guide the purchasing of all equipment. If a machine were being purchased only for vascular access, then one with a high-quality cardiac application would not be justified. There are ultrasound systems that are tailored to the practice of emergency medicine, and the technology is ever advancing. All machines should be portable and maneuverable enough to fit into the cramped spaces of an ED. A cart-based system is ideal for ease of movement, changing of probes, storage space, and housing considerations. A device's ease of use is important, as the more complicated systems may intimidate novice users and

be a roadblock to gaining experience. Other factors to consider when buying a system include durability, image quality, storage capability, power supply (battery option), boot-up times, and service plans.

There are numerous types of transducers (probes) from which to choose. Transducers are generally classified based on frequency, with low-frequency probes for improved penetration (but poorer image quality) and high-frequency probes for better image resolution (but weaker penetration into deep tissue). Transducers should be purchased based on the anticipated type of ultrasound examinations. For example, if a significant percentage of patients present with pregnancy-related complaints, an endocavitary probe would be warranted. The footprint of the probe should also be considered. The footprint is that portion of the probe that comes into contact with the skin and sends out the ultrasonic waves. Probes with a large footprint can give a wider field of view but are difficult to fit into the small intercostals spaces of infants and children. Generally speaking, at least two probes should be considered essential when purchasing an ultrasound machine, a low-frequency probe that can be used for abdominal and cardiac examinations, and a high-frequency linear probe that can be used for procedural applications (Fig. 134.1).

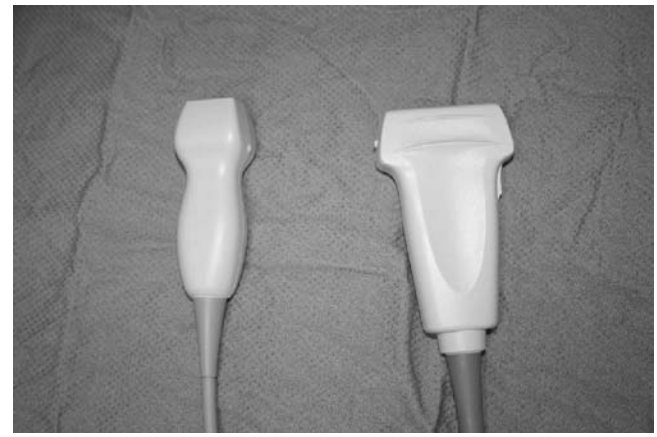

FIGURE 134.1 On the left is a low-frequency phased array probe commonly used in cardiac or abdominal applications. On the right is a high frequency linear probe used for procedures and identifying superficial structures.

ULTRASOUND BASICS

Ultrasound Physics

This section will review the basic principles to help lead to a higher comfort level with machine operation and to greater facility with image acquisition and interpretation.

Ultrasound refers to sound waves that have a frequency greater than 20,000 Hz (the upper range of audible sound). Frequencies used in diagnostic and procedural ultrasound generally range from 2 to 15 MHz. The general principle of diagnostic ultrasound is the pulse–echo effect. Sound waves are generated from the transducer and sent into a medium (the body). The transducer then "listens" for the return, or echo, of that sound. The emitted sound wave encounters the body tissues, with different densities at different distances from the surface of the skin. Some of the wave is reflected back to the transducer footprint. Once the transducer "hears" a returning echo, the ultrasound system calculates the distance of an object from the transducer on the basis of the time it took the echo to return. The intensity of the returning sound wave determines the grayscale assignment on the image. For example, fluid does not reflect sound waves at all, leading a fluid-filled bladder to appear black or anechoic (i.e., the transducer did not "hear" any sound waves reflected back). The diaphragm is highly reflective and appears bright on the screen (Fig. 134.2). The overall ultrasound image consists of all the pixels on the screen that are generated in this fashion.

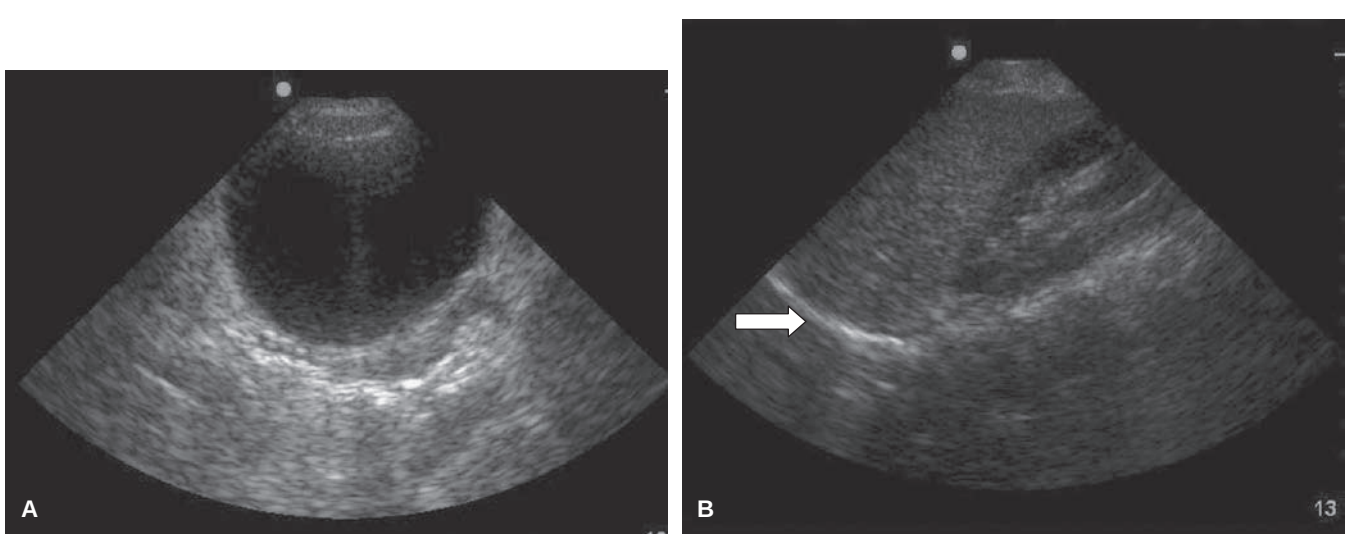

FIGURE 134.2 **A:** A full bladder. Note that fluid is anechoic *(black)*. **B:** Morison's pouch. Note the bright reflection of the diaphragm just superior to the liver *(arrow)*.

Basic Controls

Ultrasound machines, at first glance, can appear complicated with the presence of multiple buttons and knobs, and it remains important to gain an understanding of the equipment to avoid being overwhelmed or disheartened. The good news is that the controls simply allow one to adjust and optimize the image on the basis of the basic principles of the ultrasound image.

Gain refers to the intensity of the returning echoes on the display screen. Adjusting the gain essentially changes the brightness without improving the quality of the image. *Depth* of the image can be adjusted as well. For superficial structures, decreasing the depth allows for higher image quality, increasing the size on the screen of the structure under scrutiny and reducing wasted space on the screen. Increasing the depth allows for visualization of deeper structures (i.e., farther away from the skin and transducer). *Zoom* allows the sonographer to magnify a section on the display screen. This can be especially useful when attempting to focus on smaller, deeper structures, such as foreign bodies. Finally, the *freeze* button allows the sonographer to hold an image. On most machines, several seconds of memory are saved when the freeze function is used, and the image can be toggled forward and backward to find a desired image.

Other control panel functions on ultrasound machines vary widely but often include color flow, Doppler, motion-mode (m-mode), focus, and tissue harmonics. As the practitioner gains more and more experience, these machine capabilities will become more familiar and will allow for more advanced applications of emergency bedside ultrasound.

General Scanning Techniques

One of the greatest advantages of ultrasound is that it is dynamic, with the ability to capture images in multiple imaging planes and different orientations. However, because this may lead to confusion in interpretation, standard and consistent orientation should be used whenever possible.

The standard ultrasound examination is performed with the sonologist and machine on the right-hand side of the patient's bed. The probe should be held in the right hand and ultrasound system adjustments made with the left hand during scanning.

All transducers have some marking that correlate with a dot (or some other identifier) on the monitor screen (Fig. 134.3). By convention, the transducer marker is always placed on the patient's right-hand side in transverse views and on the cephalad side in sagittal views and the dot on the screen is located at top, left side of the monitor (with the exception of cardiac scanning). Adhering to this principle allows for uniformity of images and makes interpretation and review more seamless. Objects that are closer to the probe marker appear closer to the dot on the monitor and vice versa.

Most ultrasound imaging is performed in B-mode (brightness), which is the standard, 2-D representation of the reflected ultrasound waves. As mentioned above, each pixel represents the intensity of echo (black, no echo; white, very echogenic) and distance from the probe (determined by time of a returning sound wave). M-mode (motion) creates a single line of a sound wave through an object of interest and then displays the grayscale image along that vertical scanning line with respect to time on the horizontal access. M-mode is useful to document movement of a structure, such as cardiac valves or the fetal heart.

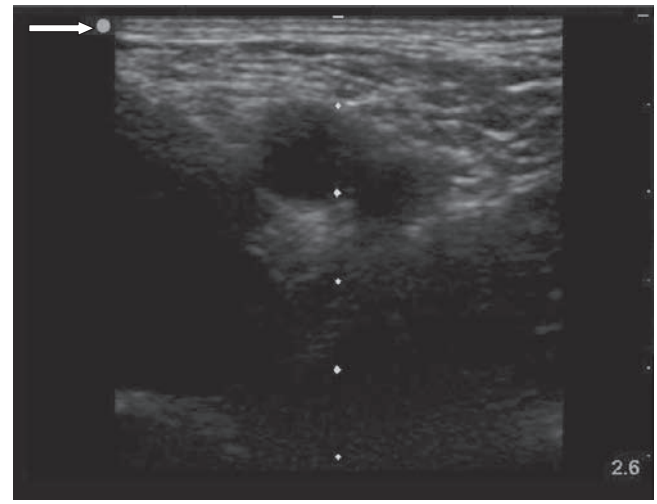

FIGURE 134.3 Image of femoral anatomy. Note the marker on the screen *(arrow)* is a large at upper left dot. By convention, the marker should always be on the left, upper side of the monitor.

Finally, Doppler senses the movement of the ultrasound waves as they encounter a moving medium, represented by either color changes or audible sound generated by the ultrasound machine. Doppler ultrasound is especially useful when identifying vessels, discerning between arterial and venous flow or possible vessel obstruction.

DIAGNOSTIC EXAMINATIONS

Focused Assessment with Sonography in Trauma

Introduction

The use of sonography in trauma was one of the very first applications of emergency bedside ultrasound, and many now consider it a standard part of the evaluation of the injured patient. The basic sonographic question when performing the FAST examination is: "Is there free fluid in the peritoneum or pericardium?" Initially, the FAST scan was meant to detect peritoneal blood in patients with blunt or penetrating abdominal injuries. The FAST scan has evolved to include a view of the pericardial space and, in some cases, the pleural space (referred to as the *enhanced FAST* or *eFAST*). The overarching principle of the examination is that hemoperitoneum or hemopericardium is an indication of organ injury in the setting of blunt or penetrating torso trauma. Blood in the abdomen or thorax will appear hypoechoic or anechoic (dark) against the hyperechoic (bright) background of the internal organs (Fig. 134.4). Thus, the detection of peritoneal or pericardial fluid by sonography may be evidence of injury to the abdominal organs or heart, respectively.

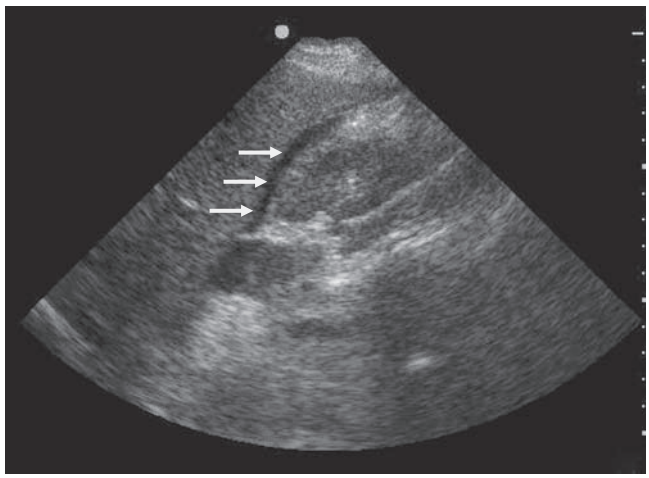

FIGURE 134.4 A positive FAST examination. Note the anechoic stripe of fluid *(arrows)* in Morison's pouch, between the liver and kidney. FAST indicates focused assessment with sonography in trauma.

Although computed tomography (CT) remains the study of choice for the stable pediatric patient with suspected intraabdominal injury, the FAST scan has several distinct advantages. First, it can be performed immediately at the bedside and is interpreted by the person performing the test, who is privy to the clinical context. Second, there is no exposure to the ionizing radiation of CT. Sedation, which may be required for CT scan, is not required. The FAST scan can be repeated with serial examinations as the patient condition changes. Last, for unstable patients, CT is often not a viable option and the FAST scan can frequently provide valuable information that may guide therapeutic or operative interventions.

Research pertaining to the FAST scan has been plentiful, mainly focused in the adult population, with several pediatric studies. Published data indicate that the sensitivity of FAST scan in children is not as robust as in adults but indicate that specificity remains very high. Thus, a positive FAST scan should always prompt either further investigation or therapeutic intervention. A negative FAST scan does not necessarily obviate the need for CT scan but still be valuable in patients with a low pretest probability of intraabdominal injury.

Anatomy

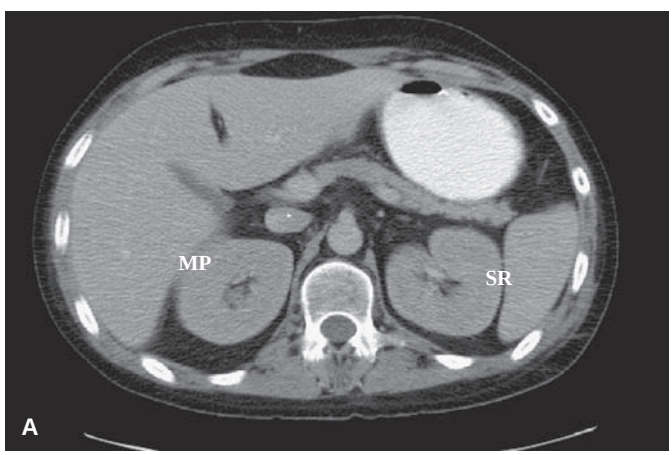
When supine, there are several dependent areas of the peritoneal cavity where blood or fluid has a tendency to accumulate. The hepatorenal recess, also known as *Morison's pouch*, is the space located between the liver and right kidney. In a normal person, this is a potential space and, thus, fluid is not usually found here. The splenorenal recess is the space located between the spleen and left kidney. Again, no fluid should be seen here in the healthy person. The rectovesical pouch (male patients) and the pouch of Douglas (female patients) are formed by the space between the rectum and bladder or uterus, respectively. These potential spaces form the basis of the FAST abdominal views (Fig. 134.5).

In the supine patient, free fluid from the right upper quadrant will tend to collect in Morison's pouch first, but free fluid from the left upper quadrant will often accumulate in the left subphrenic space initially (i.e., not the splenorenal recess). The amount of intraperitoneal fluid needed for detection by ultrasound has been reported to be as little as 100 mL in adults and will depend on the source of the bleeding and patient positioning.

Technique (Also See Chapter 135 Procedure 13.2)

Probe selection is the first step. Any low-frequency (2–5 MHz) probe should be chosen for adequate penetration. Most commonly, a large footprint (the transducer head) curvilinear probe is used. In pediatric trauma, however, the smaller head of a phased array probe or microconvex probe may be more useful to obtain images in the small intercostals spaces.

There are 4 views of the FAST examination: (i) hepatorenal recess or Morison's pouch, (ii) splenorenal recess, (iii) pelvic/bladder view, and (iv) subcostal pericardial view (Fig. 134.6). Many are now also incorporating views of the thorax to assess for hemothorax or pneumothorax, referred to as the enhanced FAST or eFAST. The sonographer should perform the FAST



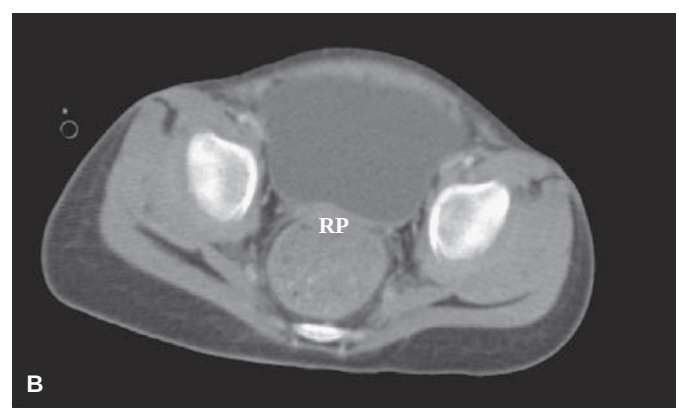


FIGURE 134.5 **A:** Computed tomography cross-sectional view of abdominal anatomy. Note the dependent areas of Morison's pouch (MP) and the splenorenal recess (SR). **B:** Pelvic anatomy. Note the dependent rectovesical pouch (RP) between the posterior wall of the bladder and stool-filled rectum.

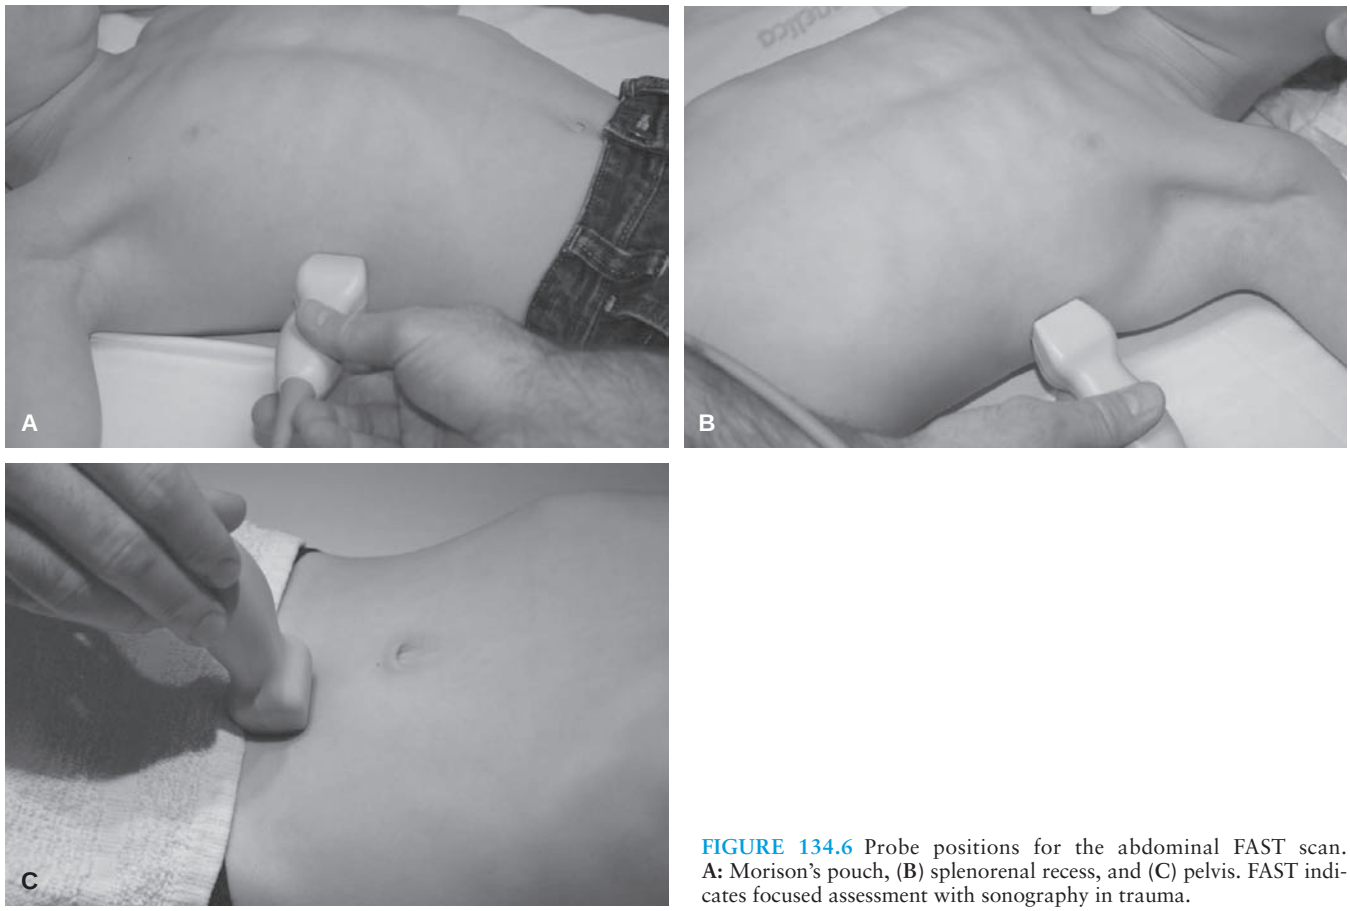

FIGURE 134.6 Probe positions for the abdominal FAST scan. **A:** Morison's pouch, (**B**) splenorenal recess, and (**C**) pelvis. FAST indicates focused assessment with sonography in trauma.

examination in a systematic manner in a standard sequence. This will allow greater focus on image acquisition and optimization as the examination order becomes routine.

A view of Morison's pouch can be obtained by placing the probe coronally (marker toward the patient's head) in the anterior axillary line between the seventh and ninth ribs on the patient's right-hand side. If rib shadows prevent optimal images, the probe can be rotated slightly in a counterclockwise fashion such that the head is oriented in between and parallel to the ribs. Once the hepatorenal recess comes into view, the probe can be moved superiorly toward the head and inferiorly toward the feet to visualize Morison's pouch completely, as well as the inferior portions of the liver and kidney (Fig. 134.7). As mentioned earlier, blood will tend to accumulate in these dependent portions of the peritoneal cavity initially.

The splenorenal recess is a more difficult view to obtain. Because the left kidney sits more superior and posterior than the right kidney, starting position for the probe is the coronal plane (marker to the patient's head) between the fifth and seventh ribs in the posterior axillary line on the left. Rotation of the probe slightly should help avoid rib shadows. In this view, blood will frequently accumulate between the spleen and diaphragm, so it is important to visualize the superior portion of the spleen in addition to the splenorenal junction (Fig. 134.8).

The pelvic view is obtained by placing the probe transversely (marker to the patient's right), just above the symphysis pubis and angling the probe inferiorly toward the feet. A full bladder will appear as a large anechoic structure and free fluid will be seen either posterior to or superior to the bladder wall (Fig. 134.9). For this reason, a sagittal view visualizing the superior bladder wall is always necessary for a complete examination.

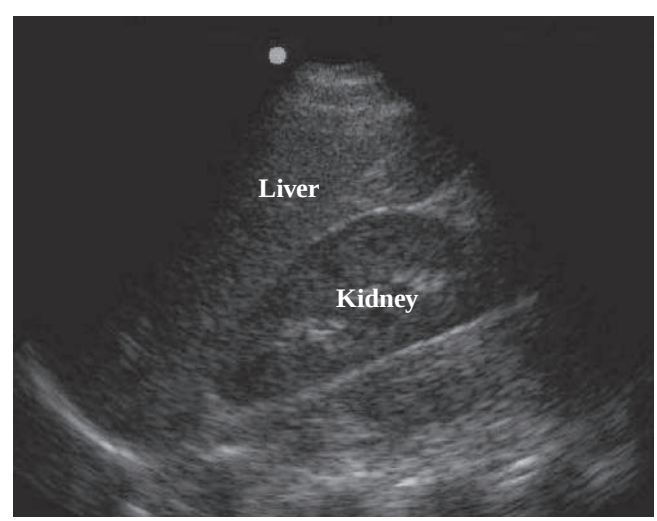

FIGURE 134.7 Normal view of Morison's pouch. In a positive study, there would be an anechoic *(dark)* stripe between the liver and kidney (see Figure 134.4).

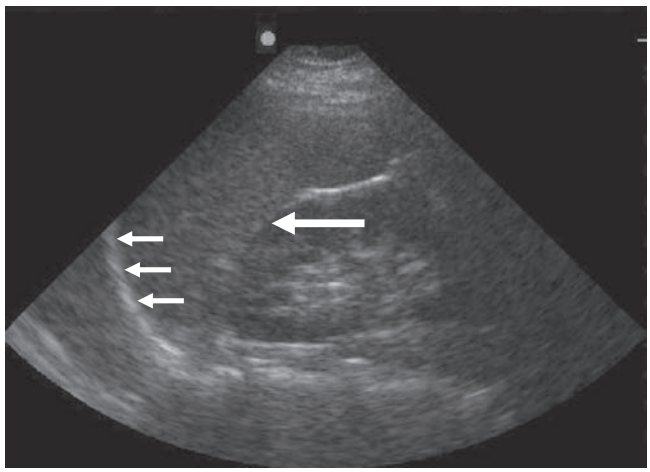

FIGURE 134.8 Normal view of splenorenal junction. Fluid may accumulate between the spleen and the kidney *(single arrow)* or between the spleen and the diaphragm *(multiple arrows)*.

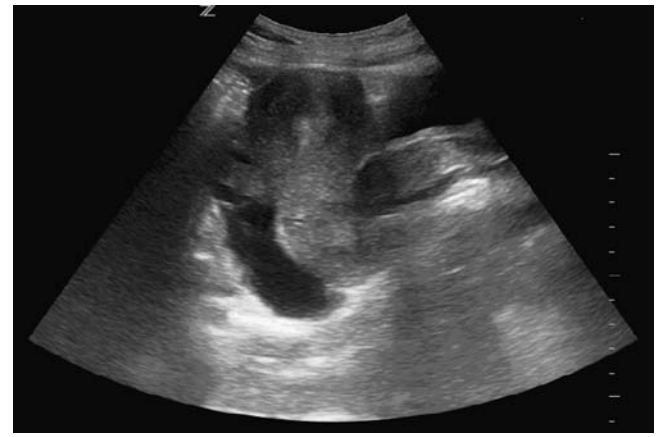

FIGURE 134.9 Positive FAST pelvic view. FAST indicates focused assessment with sonography in trauma.

Finally, the subcostal or subxiphoid view of the heart is obtained. It is important to remember that the heart sits slightly rotated in the thorax, with the right ventricle most anterior and the left ventricle posterior and toward the patient's left hip. The transducer should lie almost parallel to the abdomen, just below the xiphoid process, with the marker to the patient's right-hand side and angled toward the left shoulder (Fig. 134.10). The probe can be slid rightward along the inferior portion of the rib to avoid the acoustic artifacts caused by air in the stomach, using the liver as an acoustic window instead. The normal pericardium is seen as a hyperechoic (bright) line surrounding the heart. Pericardial fluid will appear as an anechoic collection between the myocardium and bright pericardium (Fig. 134.11). A more detailed description of bedside echocardiography is discussed in the next section.

Pitfalls

For the Morison's pouch and splenorenal recess views, the most common difficulty arises from rib shadows. The probe can be rotated about 20 degrees such that the orientation of the head is parallel to the course of the rib above and below. The probe can also be moved either anterior or posterior to optimize images. It is also important to recognize the inferior vena cava in the right upper quadrant scan. The inferior vena cava can mimic free fluid in Morison's pouch for the inexperienced sonographer.

The splenorenal recess is more difficult to visualize than Morison's pouch because of the relative superior position of the left kidney and smaller spleen size. Often, the probe is not positioned posterior or cephalad enough to visualize these structures.

A frequent pitfall with the pelvic view is the inability to visualize the bladder. Sometimes the bladder is empty (i.e., when a Foley catheter has been placed). More often, the probe is positioned too superior and should be slid and/or angled toward the feet. Less commonly, the bladder is off of midline to the right or left.

FIGURE 134.10 Probe position for the FAST subxiphoid cardiac view. FAST indicates focused assessment with sonography in trauma.

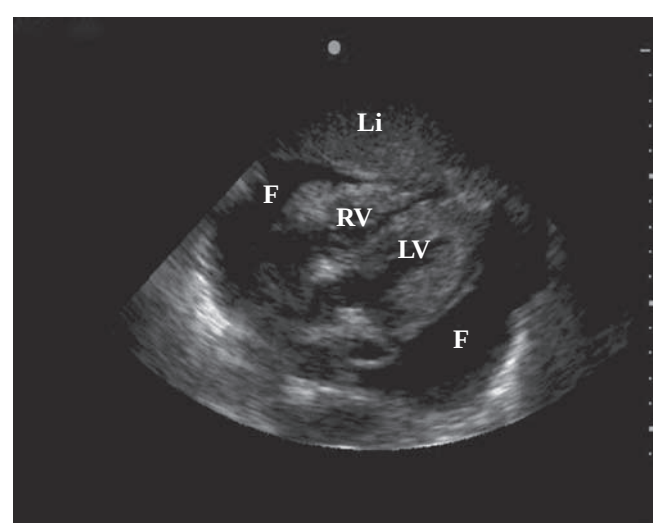

FIGURE 134.11 Pericardial effusion: An anechoic fluid collection *(F)* surrounds the myocardium. Note the liver *(Li)*, right ventricle *(RV)*, and left ventricle *(LV)*.

There are several reasons why a sonographer may not view the heart during the cardiac examination. First, the depth has not been adjusted from the abdominal scans. The abdominal organs lie relatively closer to the skin than the heart does to the subxiphoid process, and thus, the heart will often be deeper than the maximal depth set on the monitor. By increasing the depth prior to the cardiac scan, the heart will come into view easily. Second, the angle of the probe may be too steep. Remember that from the subcostal position, the heart lies superiorly and the head of the transducer must be pointed in that direction. Third, air from the stomach can scatter the ultrasound beams, rendering the image unreadable. The probe should be slid to the patient's right, away from the stomach, thereby using the liver as an acoustic window instead.

Cardiac

Introduction

Cardiac ultrasound as part of the FAST examination was one of the first applications of bedside ultrasound. Subsequent to its use in trauma, however, more focused cardiac examinations have become frequent. The basic questions asked when performing focused bedside echocardiography are: (i) "Is the heart beating?" and (ii) "Is there a pericardial effusion?" As such, the two most common indications for bedside cardiac ultrasound are (i) assessing for pericardial effusions and (ii) evaluating for cardiac activity in patients with cardiac arrest or pulseless electrical activity (PEA). Although these scenarios are much less common than in the adult patient, their relative clinical importance makes cardiac ultrasound an invaluable tool when examining pediatric patients with these conditions. Evaluating global cardiac function and overall volume status can also have an immediate impact on patient care. These echocardiographic skills, however, are much more difficult to acquire and necessitate more extensive, cardiac-focused training. As such, practitioners should know their limits and use ultrasound accordingly. The purpose of focused echocardiography is to provide the clinician with immediate bedside information and is not meant to replace comprehensive, formal echocardiograms.

Much of the early research regarding emergency physician–performed echocardiography centered on the identification of pericardial effusion and cardiac activity in the pulseless patient. Numerous studies of adult patients have shown that emergency physicians can accurately identify pericardial effusions in the setting of both traumatic and nontraumatic etiologies. In penetrating chest trauma, early identification of pericardial effusion has been shown to dramatically improve patient outcomes. Although case reports exist, there have been no prospective studies evaluating the use of bedside ultrasound to identify pericardial effusions in the pediatric emergency department.

In adult patients with cardiac arrest, the use of ultrasound has been shown to be valuable. Patients with PEA who have cardiac activity demonstrated on bedside ultrasound are more likely to survive when compared with patients with cardiac standstill. Because cardiac arrest is such a rare event in children, prospective studies have not been performed and single-institution protocols may not be practical in pediatric patients. Studies of adults indicate that emergency bedside ultrasound may be valuable in guiding resuscitative efforts or identifying life-threatening causes of PEA such as cardiac tamponade.

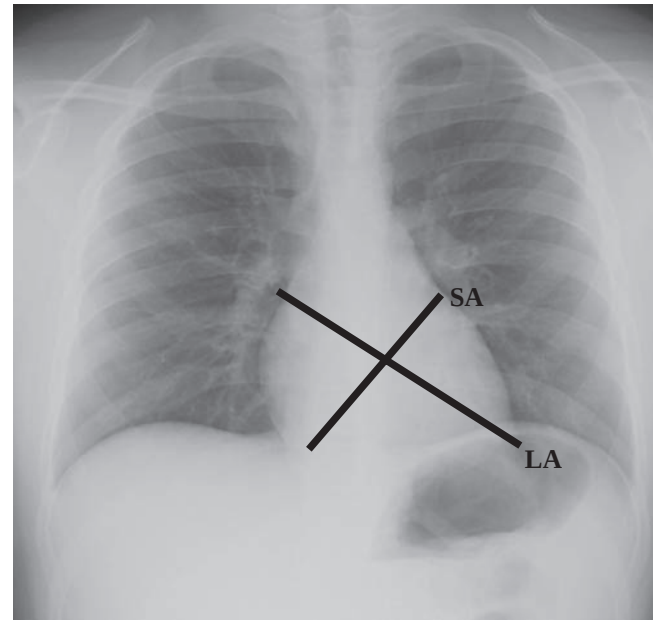

FIGURE 134.12 Ultrasound axes of the heart. Long axis *(LA)* and short axis *(SA)*.

Anatomy

The standard terminology used in other ultrasound examinations is less useful when discussing cardiac ultrasound due to the position of the heart in the thorax. Instead, standard views are along two different cardiac planes. The cardiac long axis views the heart along its plane from the atria to apex. The short axis cuts across the heart from anterior to posterior, along the plane from the right hip to the left shoulder (Fig. 134.12). These axes form the basis for the standard cardiac views used in emergency bedside echocardiography.

Technique (See Also Chapter 135, Procedure 13.4)

The subcostal or subxiphoid view is the same view as obtained when performing the FAST examination. A low-frequency (2–5 MHz) curvilinear or phased array probe should be chosen. Phased array probes (Fig. 134.1) are more ideal for moving structures such as the heart. Furthermore, smaller footprint probes may prove useful when attempting cardiac views in between rib spaces of pediatric patients.

Some controversy still exists in emergency medicine as to the direction of the probe marker and location of the marker indicator on the monitor. This author has found that for the novice sonographer, keeping the "dot" on the left side of the screen and marker toward the patient's right for the subcostal four-chamber view maintains consistency and convention. Classic echocardiography dictates the opposite approach, with the probe marker directed leftward and the marker indicator on the right side of the machine. In both instances, the same image orientation will appear on the screen.

Recall that the heart lies obliquely in the chest, with the apex pointed toward the left hip. The subcostal four-chamber view cuts across the heart from its atria to apex and is thus considered a long-axis image. The transducer should lie almost parallel to the abdomen, just below the xiphoid process and the head of the

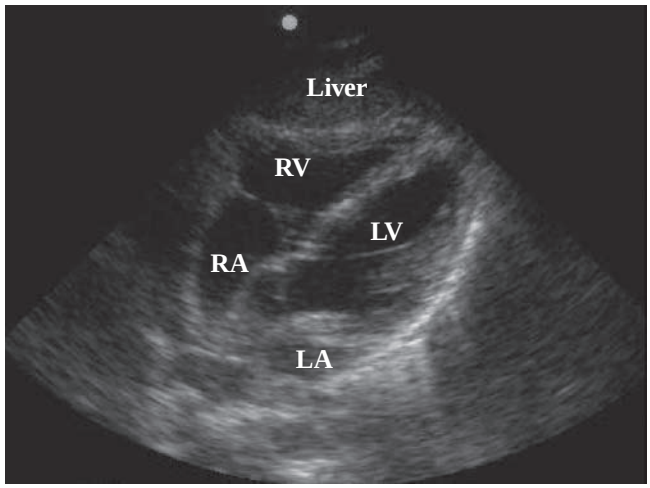

FIGURE 134.13 Normal subxiphoid cardiac view. Note the right ventricle *(RV)*, left ventricle *(LV)*, right atrium *(RA)*, and left atrium *(LA)*.

FIGURE 134.14 Probe position for the parasternal long cardiac view.

probe angled toward the left shoulder (Fig. 134.10). The probe can be slid rightward along the inferior portion of the last rib to avoid the acoustic artifacts caused by air in the stomach, using the liver as an acoustic window instead. As the ultrasound wave moves toward the left shoulder from the subxiphoid space, it will encounter the liver first, then right ventricle and right atrium, followed by the left ventricle and left atrium. The image obtained will correlate such that the liver is at the top of the screen and the left ventricle is near the bottom of the screen (Fig. 134.13). Normally, the bright white pericardium abuts the gray myocardium. When a pericardial effusion is present, a hypoechoic (dark) stripe will appear between the two (Fig. 134.11).

The left parasternal long view is obtained by placing the probe in the third or fourth intercostal space, immediately left of the sternum, with the marker pointed toward the left hip. Unlike the subcostal view in which the probe can lie almost flat, it should be perpendicular to the chest wall in the parasternal long view (Fig. 134.14). The image acquired should cut across the long axis of the heart, from the atria (right shoulder) to apex (left hip). This view can be quite useful in obese patients in whom the subcostal view is often difficult to obtain. Just as in the subcostal view, the right ventricle is the first cardiac structure encountered by the sound wave as it lies most anterior and closest to the probe (Fig. 134.15).

The subcostal and parasternal long views are the most useful when assessing for cardiac activity or pericardial effusions. Other cardiac windows include the parasternal short view and apical four-chamber view. While these can provide further information about global cardiac function and potential valvular pathology, they are beyond the scope of this chapter.

Pitfalls

There are several reasons why a sonographer may not see the heart during the cardiac examination. In the subcostal view, the heart often lies deeper than the depth set on the screen. To avoid this, the depth should be set to its maximum level and once the heart is located, the depth should be changed accordingly to optimize and center the image. In addition, the angle of the probe in the subcostal view may be too steep. Remember that from the subxiphoid position, the heart lies superiorly, and thus the head of the transducer must be pointed in that direction, toward the left shoulder. In the subxiphoid view, air from the stomach can scatter the ultrasound beams, rendering the image useless. Slide the probe to the patient's right, away from the stomach, thereby using the liver as an acoustic window instead. In the parasternal view, rib shadows are often encountered. The probe may be shifted to the patient's left, be rotated, or be angled obliquely to better fit the transducer footprint in between adjacent ribs.

First Trimester Ultrasound

Introduction

Abdominal pain in the pregnant adolescent female is a common presenting complaint to many pediatric EDs. The differential

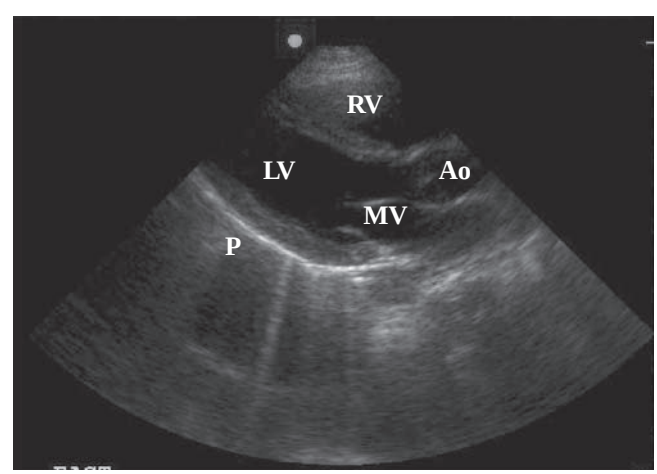

FIGURE 134.15 Normal parasternal long cardiac view. Note the right ventricle *(RV)*, left ventricle *(LV)*, mitral valve *(MV)*, aortic root *(Ao)*, and pericardium *(P)*. Fluid will accumulate just above the pericardium in a pericardial effusion.

diagnosis is broad, ranging from benign self-limited conditions to a spectrum of life-threatening and organ-threatening conditions. Ectopic pregnancy must be identified and treated rapidly. It is the leading cause of maternal mortality in the United States and has a reported prevalence as high as 8% for any pregnant patient presenting to the ED.

Multiple studies have shown emergency bedside ultrasound to be valuable in the evaluation of first-trimester pregnant women who present with vaginal bleeding or abdominal pain, specifically in *ruling in* those patients with normal intrauterine pregnancy (IUP) and, thus, ruling out ectopic pregnancy. Studies have demonstrated excellent sensitivity and specificity not only for identifying IUP by bedside ultrasound but also in shortening the time to definitive therapy and ED length of stay.

The basic question that needs to be answered in a first-trimester ultrasound is: "Is there an intrauterine pregnancy?" By visualizing an IUP, an ectopic pregnancy may be ruled out in most cases. In other words, finding the ectopic pregnancy is not the goal and is, in fact, much more difficult. In patients with increased risk of heterotopic pregnancies, confirming an IUP does not obviate the need to search for an ectopic pregnancy when there is any clinical suspicion. This subset of pregnant patients should always have a formal comprehensive ultrasound performed by the radiology or gynecology service.

The value of bedside ultrasound in the nonpregnant woman with abdominal pain is less clear. Conditions such as ovarian cysts, ovarian torsion, and tuboovarian abscesses require a greater amount of sonographic skill, and it is not yet clear that emergency physicians will identify these conditions with adequate reproducible accuracy.

Anatomy

The important anatomical consideration to remember is that the bladder lies anterior to the uterus. This relationship allows a full bladder to be used as an acoustic window to visualize the uterus. An empty bladder makes the transabdominal approach much more difficult. When the bladder is empty, the uterus will often lie more anterior and superior, making the transvaginal approach less difficult.

Technique

Before undergoing sonography for evaluation of the pregnant woman, one must consider that a pregnancy of less than 5 weeks' gestational age (3 weeks postconception) may not be visible. Either a transabdominal or transvaginal approach can be used. A low-frequency curvilinear or phased array probe should be used for the transabdominal approach. Ideally, transabdominal sonography should be performed through a distended urinary bladder, which serves as an acoustic window. This may not be practical in a busy ED. A pregnancy of 5 to 6 weeks' gestation can usually be seen. The probe should be positioned longitudinally just above the pubic symphysis and directed through the bladder to visualize a longitudinal view of the uterus, cervix, and the pouch of Douglas, with cephalad structures on the left side of the monitor (Fig. 134.16). In the nonpregnant woman, the endometrial stripe will be visualized without any uterine contents. The ovaries can often be visualized by sliding the probe laterally and directing the beam toward the opposite side. Transverse images should also be obtained and may allow for visualization of the uterus and adjacent adnexa in the same image.

FIGURE 134.16 Normal transabdominal view of the female pelvis.

An endocavitary probe should be used for the transvaginal approach. Although the transvaginal transducer is of higher frequency and produces sharper images, the field of view is more limited. The bladder should be emptied before performing the scan. After the probe is cleaned and covered, it is inserted into the vaginal canal with the marker facing up (to the sky). It often helps to have the anxious patients insert the probe into the vaginal canal themselves. A standard transvaginal longitudinal view is obtained (Fig. 134.16). Once the longitudinal view is obtained, the probe should be rotated such that the marker is to the patient's right-hand side, to obtain a transverse view. With each planar view, it is important to fan the probe along the scanning plane axes to visualize the entire body of the uterus. One with greater sonographic skill may be able to also view the fallopian tubes and ovaries, but it is important to emphasize again that the purpose of the examination is to determine whether there is an IUP or not.

In normal pregnancy, the earliest sonographic finding of an IUP is the gestational sac, which appears as a round fluid collection within the uterus (Fig. 134.17). In transabdominal scanning, the gestational sac can be seen at 5 to 6 weeks' gestational age. Transvaginal scanning can reliably detect this finding about 7 to 10 days earlier. Visualization of the gestational sac alone is not adequate in confirming an IUP. The yolk sac can be seen inside the gestational sac at approximately 6 to 7 weeks' gestational age (5 to 6 weeks by transvaginal scanning), and most authors consider this as definitive evidence of IUP. A normal embryo will appear at the margin of the yolk sac at about 6.5 to 7.5 weeks' gestational age, and cardiac activity can be detected shortly thereafter (Fig. 134.18).

In the pregnant woman, the standard for confirming an IUP for emergency physician–performed bedside ultrasound requires visualization of an intrauterine yolk sac, fetal pole, or intrauterine fetal heartbeat. Visualizing only the gestational sac is not adequate as this can be the result of hormonal stimulation from an ectopic pregnancy. When a fetal heartbeat can be seen, it should be documented with m-mode.

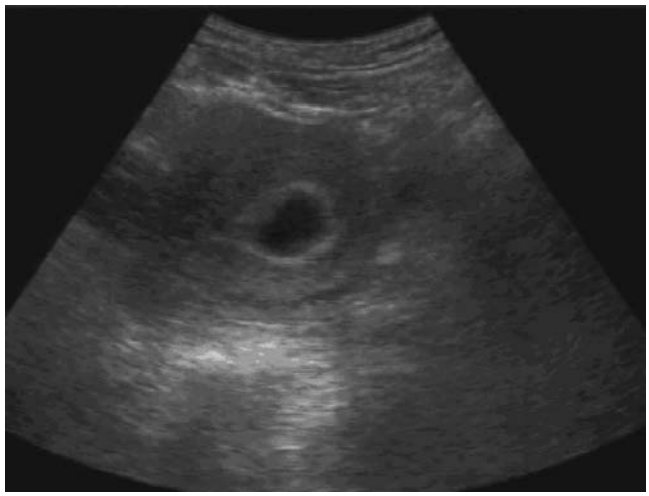

FIGURE 134.17 Normal intrauterine pregnancy with gestational sac within the uterus.

In an ectopic pregnancy, an adnexal mass or free fluid in the pelvis can sometimes be seen. Again, visualization of the ectopic pregnancy, however, should not be the goal of the emergency physician. Several protocols have been developed, addressing the use of bedside pelvic sonography in the pregnant woman. In general, if an IUP is not seen in a woman with a positive urine β-human chorionic gonadotropin (β-hCG), gynecology consultation should be arranged and a formal ultrasound conducted. A low serum-hCG level, implying an early IUP, may prompt the practitioner to arrange outpatient follow-up instead, with ectopic precautions taken.

Bladder Ultrasound

Introduction

Bladder ultrasound is performed for a variety of reasons. For the child who has not voided for a prolonged period, simply assessing bladder size can inform the practitioner whether a problem exists and where (anatomically) it is located. More commonly, bladder ultrasound is performed prior to bladder catheterization or suprapubic aspiration to assess volume of urine and thereby improve success rates of the procedure. It may be used dynamically as well to guide needle placement during suprapubic aspiration.

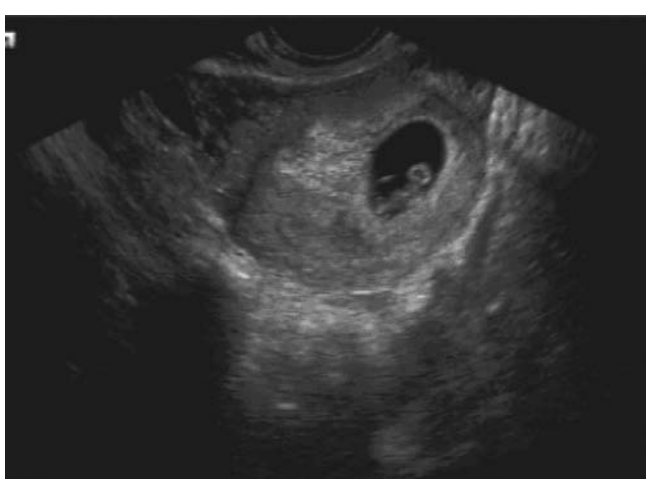

FIGURE 134.18 Normal intrauterine pregnancy with gestational sac and embryo.

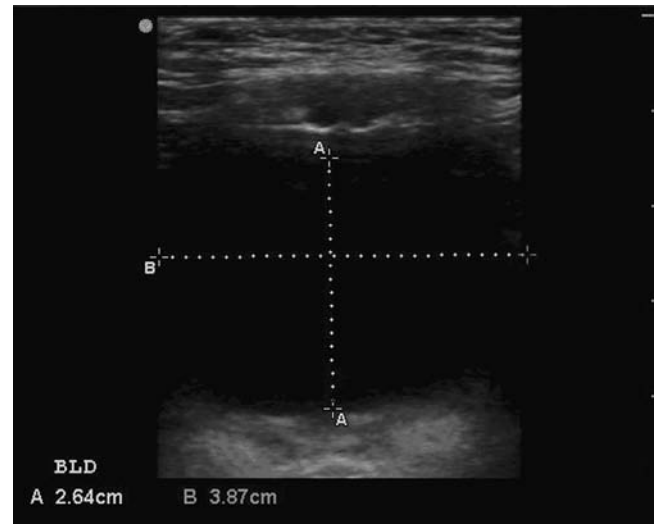

FIGURE 134.19 Full bladder measured in two different planes.

Numerous studies have been conducted using ultrasound prior to both bladder catheterization and needle aspiration. Authors have found that use of ultrasound leads to increased success rates and can reliably predict successful and unsuccessful catheterizations. Similarly, ultrasound use has been shown to increase success rates of suprapubic aspiration and decrease number of needle passes when used dynamically.

Technique (See Chapter 135, Procedure 13.3)

The same approach as the pelvic view of the FAST examination should be taken when performing a bladder ultrasound. A high-frequency linear probe or low-frequency abdominal probe may be used. A full bladder will appear as a well-circumscribed, fluid-filled (anechoic) structure within the pelvis (Fig. 134.2). Once the bladder is identified, it should be measured in at least two planes (Fig. 134.19). Although studies differ with respect to exact measurements, generally speaking, if the wall-to-wall distance measures more than 2 cm in both planes, catheterization or suprapubic aspiration will likely be successful.

PROCEDURAL APPLICATIONS

Bedside ultrasound for diagnostic purposes can direct care and decision making. By contrast, use of bedside ultrasound for procedures is aimed at improving patient care. The pediatric ED is replete with opportunities in which bedside ultrasound can not only improve success rates of the procedure itself but also augment patient safety by reducing complications. It can be the driving force behind both implementing an emergency ultrasound program and compelling staff to acquire ultrasound skills.

Central Vascular Cannulation

Introduction

Utilization of ultrasound for vascular access is not a new application. Interventional radiologists and anesthesiologists have used sonography to aid in vessel cannulation for decades. More recently, it has become the standard of care for cannulating the internal jugular vein in adults in the ED. Moreover, the Agency for Healthcare Research and Quality has stated that ultrasound for central venous access is a clear opportunity for safety improvement and listed it as one of the "top 11 highly proven" patient safety practices that are not routinely practiced. This use of ultrasound represents a unique opportunity for the pediatric emergency medicine physician to reduce morbidity associated with line placement and may soon represent the standard of care for all central venous cannulation.

The literature supporting ultrasound use for central line placement is vast. In the ED setting, bedside ultrasound has been shown to increase success rates and decrease the number of procedural complications in adults. Similar reports exist in the pediatric population but not in the acute care setting. The overwhelming evidence in the adult population, however, along with the generalizability of the procedure, suggests that ultrasound is a necessary skill for the practitioner who places central venous lines in children. Given the relative infrequency of attaining central access in children when compared with adults, multiinstitutional studies may be needed to confirm the utility of ultrasound in the pediatric population.

Technique (See Chapter 135, Procedure 13.1)

A high-frequency linear probe should be used. Relevant anatomy for the particular site chosen (femoral, internal jugular) should be reviewed. It is also advisable to survey and confirm the target vessels with ultrasound before the procedure begins. Preprocedure steps are important to maximize success and include adjusting the height of the bed and positioning of the patient, positioning of the ultrasound machine, and having equipment and extra personnel ready for assistance. Aseptic technique should be used with sterile probe covers and sterile gel (if probe covers are unavailable, a sterile glove will suffice).

Either a static or dynamic approach may be used. In the static approach, the vasculature and surrounding anatomy are identified by ultrasound prior to vessel cannulation. The position of the vein should be marked on the skin at two points. The machine is then set aside and the procedure continues using the landmarks identified under ultrasound but without active ultrasound assistance. Data have shown that this method does improve success rates, although complications are less reduced when compared with the dynamic method.

The dynamic method uses ultrasound in real time to visualize the needle puncturing the vein. When using ultrasound dynamically, a one- or two-person approach can be used. The author feels that, for femoral vein catheterization, the ultrasound machine should be positioned across the bed from the side chosen. For example, when attempting to cannulate the right femoral vein, the machine should be situated across the bed, on the patient's left. This enables the proceduralists to maintain a direct line of site with both the patient and the image on the screen without having to turn their head, making the process more fluid. The marker on the transducer should face in the same direction as the marker on the screen. In other words, if the marker is on the left side of the screen (the standard convention), the probe marker should face to the *proceduralist's* left. This becomes useful when repositioning the needle; when the needle is moved toward the left of the probe, it moves toward the left side of the screen.

The vascular bundle should be identified in cross section. Color flow, Doppler, and compressibility can aid in the identification of the medially located femoral vein (Fig. 134.20, see also color plate). Ultrasound scanning during a Valsalva maneuver may make the vein larger and easier to visualize. Once the vein is identified, the sonographer should attempt to center the vein the screen. Some probes have an electronic guide that can be placed directly in the center of the image and that represents a marked point on the probe. Once the vein is positioned appropriately in the center of the screen, the finder needle can be inserted, lining up with the center of the probe. When viewed in cross section, the needle may appear as a single bright dot, with or without artifact, or not at all (Fig. 134.21). When the needle encounters the vein, tenting of the vessel wall will be seen and will "pop" back once the needle tip punctures the vessel wall. At this point, blood should be aspirated and the ultrasound probe can be laid aside as the procedure is continued in normal fashion.

The two-person technique may be easier for the more inexperienced ultrasound user. In this situation, one person is responsible for holding the probe and keeping the vein centered on the screen. The proceduralist can thus focus his attention solely at the site of puncture on the patient, without having to look away at the screen. The more experienced ultrasonographer should be the one holding the probe and centering the vein on the screen.

For internal jugular vein catheter placement, the same principles apply. Here, the machine may be placed on the same side of the procedure as this creates the most direct line of site. Once again, the vein should be identified, placed in the center of the screen, and cannulated under ultrasound guidance. Although ultrasound-guided catheter placement of the subclavian vein has been described in the literature, it is much more difficult due to the shadows created by the clavicle and should only be undertaken by the experienced sonographer.

The long-axis approach is more difficult and requires much finer movements of the transducer. Again, the short-axis approach has been shown to be more successful for the novice user and should be the method of choice for most users. For the experienced sonographer, however, the long-axis view offers the advantage of visualizing the vein (and thus needle and catheter) along its entire course of cannulation (Fig. 134.22). In general, the long axis technique should be reserved for peripheral access.

Pitfalls

While ultrasound can certainly enhance placement of a central venous catheter, there are certain caveats one must keep in mind. First, the depth of the vessel and distance the needle must travel to hit the vessel calculated should be noted. Remember that when the needle is inserted into the skin, it is traveling along the hypotenuse of a right triangle, and the distance it must traverse before hitting the vein should be calculated. This concept becomes important when the angle of

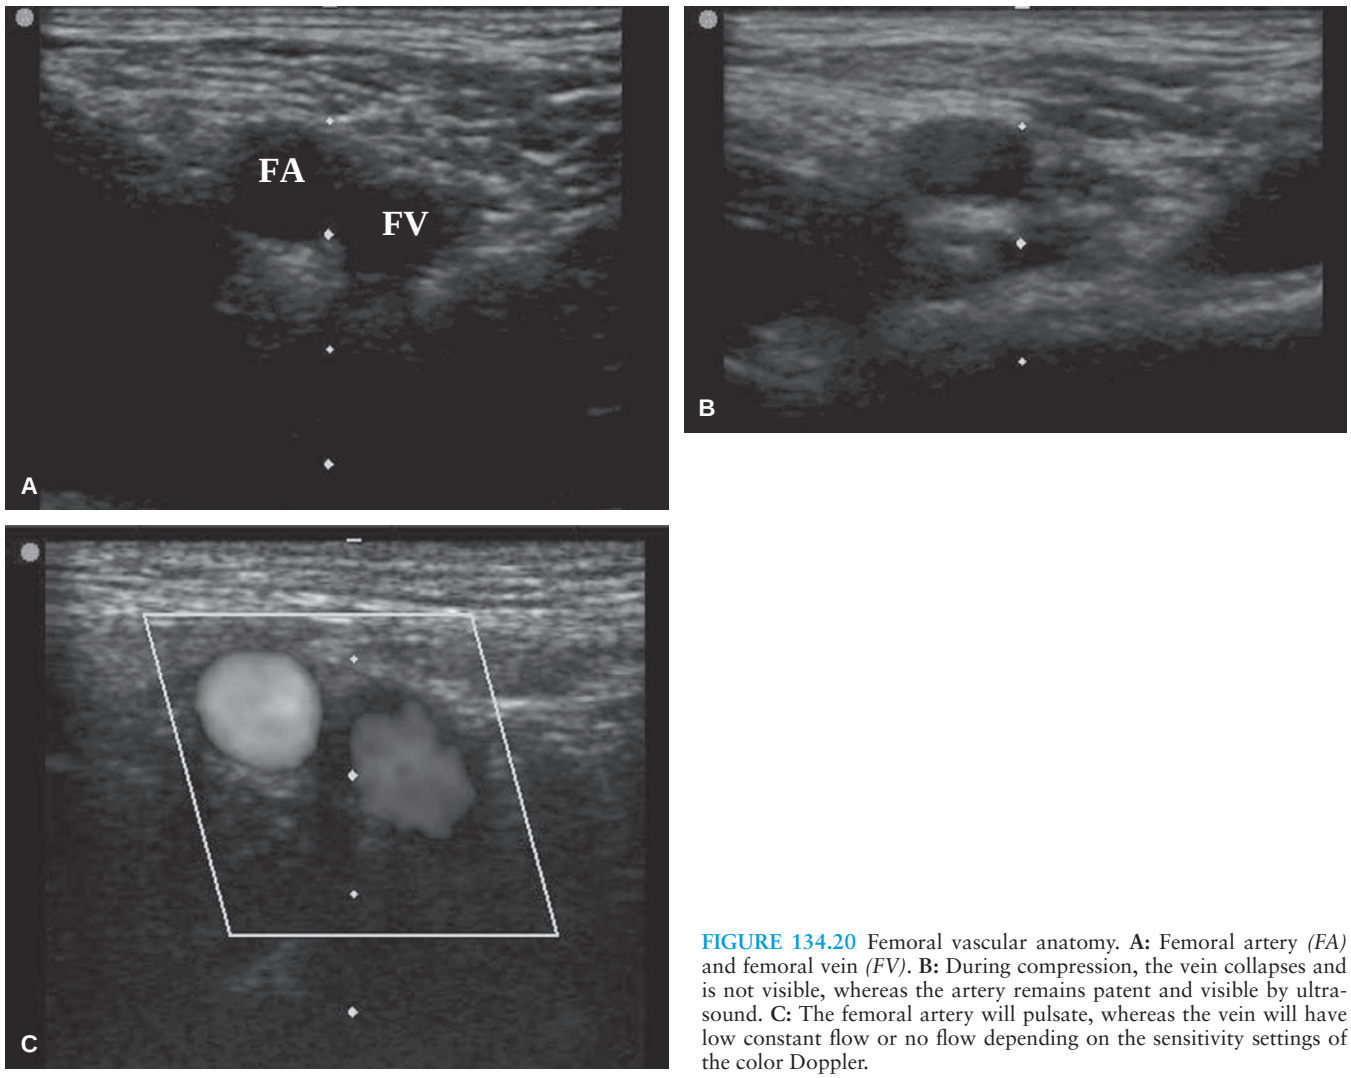

FIGURE 134.20 Femoral vascular anatomy. **A:** Femoral artery *(FA)* and femoral vein *(FV)*. **B:** During compression, the vein collapses and is not visible, whereas the artery remains patent and visible by ultrasound. **C:** The femoral artery will pulsate, whereas the vein will have low constant flow or no flow depending on the sensitivity settings of the color Doppler.

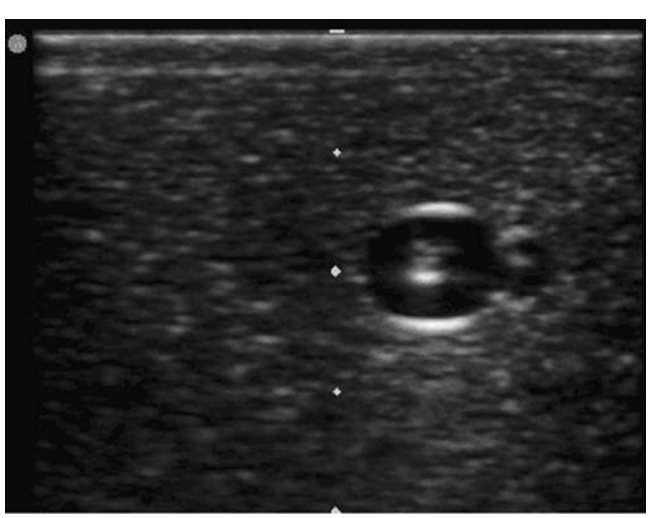

FIGURE 134.21 Transverse-axis image of a needle within a "vessel" of an ultrasound phantom model.

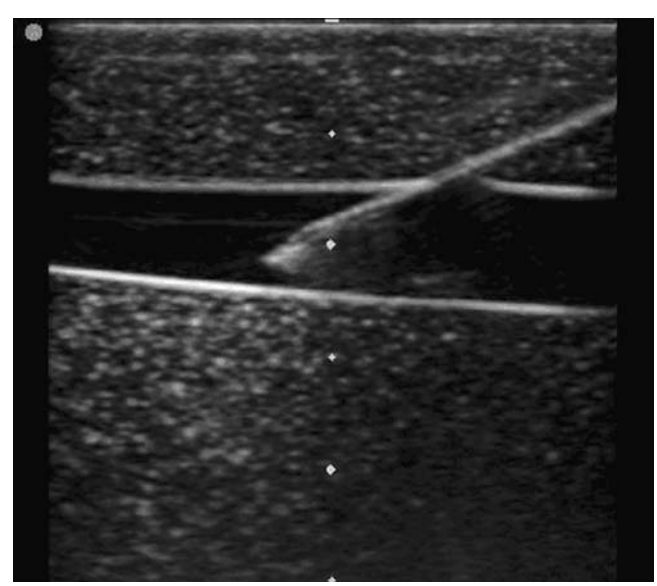

FIGURE 134.22 Long-axis image of a needle entering a vessel. Note that the entire course of the needle can be followed.

insertion is, closer to parallel to the skin surface increasing the distance the needle must travel before puncturing the vein.

Puncturing the skin either too close or too far from the transducer may be problematic. If the needle is inserted too close to the transducer, it will pass under the probe (i.e., through the plane of sound waves) before encountering the vessel. The point at which the needle contacts the vessel will not be visualized unless the probe is repositioned. If the needle is inserted into the skin too far from the transducer, it will encounter the vessel before being visualized. In the short-axis view, the transducer should always be repositioned such that the plane of ultrasound waves follows the tip of the needle. In the long-axis view, the opposite is true. As long as the transducer is correctly centered over the target vessel, the needle should be repositioned to follow the ultrasound waves. In other words, the transducer should never be repositioned to find the needle in the longitudinal view, as this may lead to cannulation of the wrong vessel (and potentially an artery).

Using ultrasound statically should be performed always *after* the patient has been positioned. Repositioning the patient after identification can lead to changed anatomic relationships and may result in failed attempts at catheterization.

The proceduralists must pay attention to both the ultrasound image on the screen and the site of the procedure. All too often, the inexperienced sonographer will focus too heavily on the screen and a flash of blood in the hub will go unnoticed. A slow and methodical approach, along with experience, can help minimize this occurrence.

Peripheral Venous Cannulation

Introduction

Peripheral intravenous catheter placement can be difficult in children as well. Multiple attempts are sometimes needed for successful placement. Ultrasound has been shown to improve. success rates of placement of peripheral catheters in adult patients who are difficult to access and to reduce failure rates when used in children. The most common anatomical sites attempted under ultrasound guidance are the brachial, cephalic, and basilic veins of the upper arm. In obese older children, ultrasound can be useful to locate the antecubital veins when palpation proves difficult.

Technique

Cannulation of the peripheral veins uses the same principles as central venous catheter placement. The desired vein for cannulation should be identified in cross section once the relevant anatomy has been reviewed. Color flow, Doppler, and compressibility should again be noted, although in smaller veins, velocity of blood flow may not be adequate to generate a color change or Doppler signal. The vein image should be centered on the screen, and catheter placement should proceed in the same fashion as central venous catheter placement.

Pitfalls

Several additional pitfalls must be considered when placing an ultrasound-guided peripheral catheter. Standard intravenous catheters are usually not long enough to reach the deeper veins of the upper arm. Long catheters are available and should be used, but even these catheters may fall out when the patient's arm is moved because of excessive subcutaneous tissue. Second, peripheral veins are much easier to compress than central veins, and it is not uncommon for the inexperienced sonographer to apply too much pressure with the probe during the procedure, thereby compressing the vein. Third, the angle of insertion of a peripheral catheter may be shallower than that of a central catheter. One must avoid the temptation to take a steeper approach when using ultrasound guidance as this often leads to inability to advance the catheter over the needle.

Abscess Identification and Drainage

Introduction

Soft-tissue infection is not an uncommon presentation to the pediatric ED. The decision to incise and drain is often straightforward based on physical examination findings. Clinical findings are sometimes ambiguous, where an abscess may be present when only cellulitis is suspected clinically. Ultrasound has been shown to be accurate not only in correctly diagnosing abscesses but also in appropriately guiding management plans when it is unclear whether a skin infection represents an indurated cellulitis versus a fluid-filled abscess. Moreover, ultrasound can identify blood vessels that may lie near or deep to the abscess. Knowledge of important anatomical structures in close proximity allow the practitioner to proceed with caution when incising, thereby maximizing patient safety.

Technique

A high-frequency linear probe should be used. The probe should be placed directly over the site of interest to look for areas for drainage and to evaluate for nearby vascular structures. Skin infections may appear in multiple, different stages. Some are filled with thin, hypoechoic pus and are clearly ripe for drainage (Fig. 134.23), while others have a "cobblestone" appearance and need more time to coalesce (Fig. 134.24). It is advisable to conduct ultrasound with color flow over the area of interest in instances when clinically a vascular structure such as an arteriovenous malformation is possible. Once a drainable collection is identified and important surrounding structures are noted, incision and drainage may proceed in normal fashion.

Pitfalls

Some soft-tissue infections progress in stages, and in the preabscess phase, it may be difficult to determine if there is a drainable collection of thick pus, even with the aid of ultrasound. Abscesses are not always hypoechoic or anechoic, and clinical examination should help guide decision making when ultrasound is inconclusive.

Hematomas, inflamed lymph nodes, and vascular malformations may appear similar to abscesses on ultrasound imaging. Color flow will differentiate abscesses from vascular malformations. Lymph nodes will appear more homogenous with smoother borders and a rounded appearance (Fig. 134.25). Discerning a recent hematoma from the thick pus of an abscess can be difficult and clinical context becomes important. The experienced sonographer may notice a slightly more homogeneous appearance and the noninflamed epidermis of a hematoma.

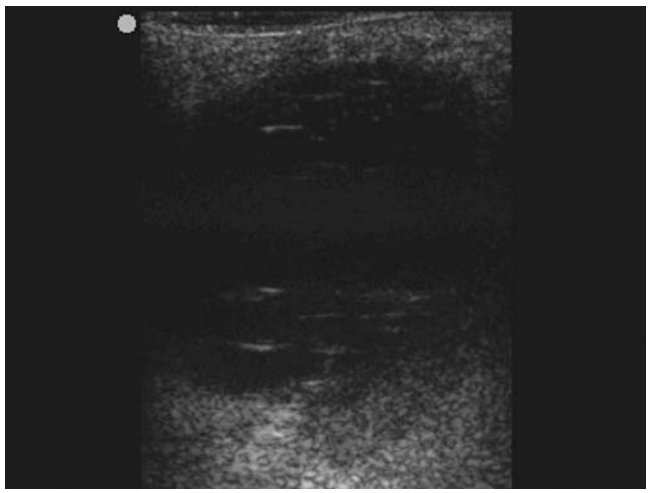

FIGURE 134.23 Pus-filled abscess.

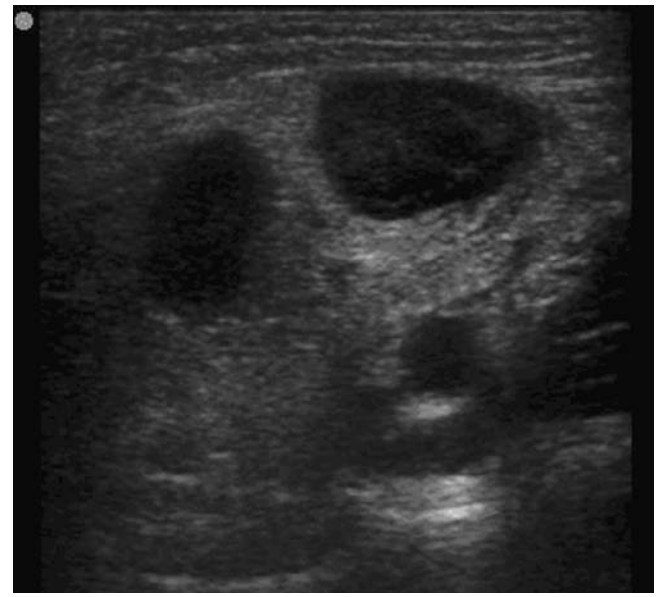

FIGURE 134.25 Inguinal lymphadenitis.

Foreign Body Identification and Removal

Introduction

Ultrasound may be used to both identify subcutaneous foreign bodies and aid in their removal. Literature has demonstrated that physical examination can be unreliable for foreign body detection and that adjunct imaging is often required. There are numerous types of materials that will not be apparent by radiography, and ultrasound may help not only in locating these radiolucent foreign bodies but also in pinpointing a more exact location by imaging in multiple different planes.

The use of ultrasound for detection of soft-tissue foreign bodies is well established, especially when the suspicion of a radiolucent foreign body is high. Studies have demonstrated similar rates of accuracy between emergency medicine physicians and more experienced personnel, as well as greater sensitivity in foreign body detection in children when using ultrasound in combination with radiography.

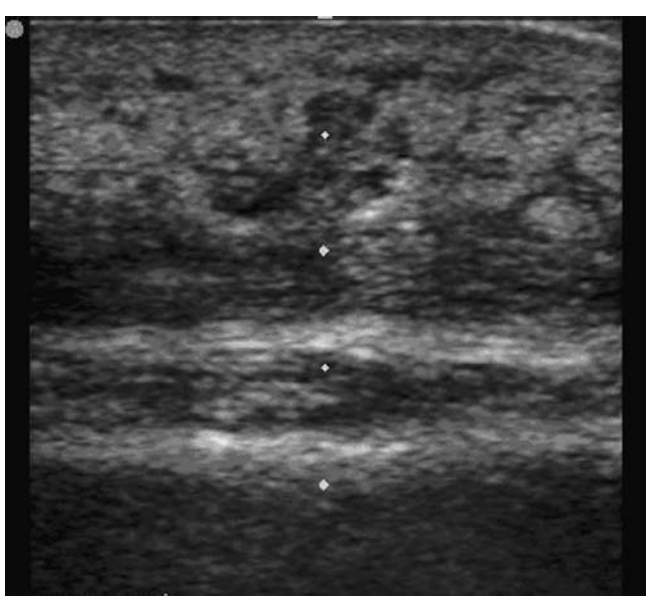

FIGURE 134.24 Ultrasound of inflamed skin with "cobblestone" appearance.

Technique

A high-frequency linear transducer should be used. The operator should scan over the area of interest. A foreign body may appear hyperechoic or isoechoic but with a shadow cast distal to the object (Fig. 134.26). Once the foreign body is located, the area may be marked with a pen and removal may proceed under normal fashion. Alternatively, ultrasound may be used to guide the procedure.

When ultrasound is used to guide foreign body removal, a long-axis approach should be used. The object should be identified along its long axis and the needle (for local anesthesia)

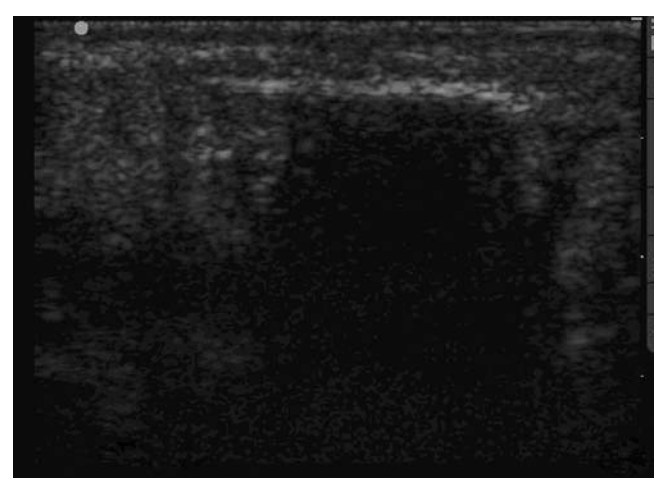

FIGURE 134.26 Bedside ultrasound was able to identify this toothpick in the foot of a pediatric patient, not identified by radiography. The hyperechoic toothpick is more obvious due to distal shadowing artifact.

inserted along that same line toward one tip of the embedded material. Once the tip of the needle comes in close contact with the tip of the object, anesthetic should be injected. This will not only anesthetize the area but also allow for better visualization of the object as it will now be surrounded by anechoic fluid. After local anesthetic is injected, forceps should be inserted along the same track and axis under ultrasound guidance. Once the object is encountered, the forceps jaws are opened slightly and the foreign body may be grasped and pulled out along the same track.

Using ultrasound dynamically to remove a foreign body is technically challenging. It requires a moderate amount of ultrasound experience and dexterity. The novice user may have greater success in identifying the foreign body statically in multiple planes, marking the site and attempting removal in standard fashion.

CHAPTER 135 ■ ILLUSTRATED TECHNIQUES OF PEDIATRIC EMERGENCY PROCEDURES

LYNN BABCOCK CIMPELLO, MD, ROBERT JAY DEUTSCH, MD, MPH, FAAP, CINNAMON DIXON, DO, JAVIER A. GONZALEZ DEL REY, MD, DEE HODGE III, MD, DAVID M. JAFFE, MD, LISA L. LEWIS, MD, MATTHEW MITTIGA, MD, JOHN M. LOISELLE, MD, CONSTANCE M. MCANENEY, MD, MS, AND RICHARD M. RUDDY, MD

1.0. PREPARATION OF THE CHILD

Proper preparation of the child and family is important to effectively perform diagnostic and therapeutic procedures on children in the emergency department (ED). Even a relatively short procedure may be very prolonged or difficult to complete without the best preparation possible. The ED staff should be prepared to team up and assist in the procedure to minimize delay, by having the necessary equipment available in the ED, and by providing the needed support. The medical team should consider whether the ED is the appropriate location and environment in which to care for the consequences and complications of a procedure, particularly one in a high-risk patient or where the length of the procedure depletes resources or would suggest doing it more safely in the operating suite. Delay in care for other potentially ill or injured children must be minimized.

Except when the procedure is immediately necessary for a life-threatening emergency, approval and support for the procedure should be obtained from the child and parents beforehand. An informative, efficient discussion of risks and benefits of the procedure for a particular child almost always reassures the parents of the need for the procedure. Written consent may not be necessary for all simple procedures, but it is key for the ED to have standards around which procedures require this to be completed, what defines the emergency to forgo the written consent, and under what conditions the minor should also assent. During the advanced life support of resuscitation or other life-threatening situation, the ED staff should provide a professional staff member to privately prepare the family for the ensuing issues and questions.

The child's developmental maturity should be assessed to determine how capable the child is of understanding and cooperating in the performance of the procedure. Substantial variations in developmental age also affect the fears of children. Specifically, the parents need to understand the risk–benefit ratio of the procedure being performed, the need for it to be done safely and with the best success. This may require tools such as guided imagery or forms of hypnosis such as performed by child life specialists, the need for pharmacologic sedation, and the need for the use of various well-known physical or mechanical restraints to minimize discomfort and maximize safety and efficiency. The parents should be made aware of possible complications, the effects of sedation and of equipment that will be attached to their child, and any discomfort subsequent to the procedure. The assurance that restraint may minimize repeated discomfort cannot be overemphasized. It needs to be emphasized that the ED staff and clinician should be prepared to set up and perform the procedure with a positive attitude.

Lastly, prior to starting a procedure on any patient the use of a team time-out prior to starting needs to part of the culture of performing procedures to maximize safety. The use of a check list followed by a time-out to make sure that the right procedure is being done on the right patient, on the right anatomic location.

1.1. RESTRAINTS

Indications

Restraint should be considered in the performance of all procedures in which patients may be unmanageable; it is possible that they may directly hurt themselves or may indirectly delay important treatment. Physical restraints are usually more effective than human restraints and may be necessary in a proportion of infants, toddlers, and preschool children. In conjunction with restraint, standard methods of pharmacologic sedation and local anesthetic are often indicated. Clearly, the use of anxiety-reducing methods by trained staff, as well as the continued calm presence of the parents, may be of great benefit to the child.

Complications

1. Bruising, edema
2. Vascular compromise (too tight a restraint or restraint for excessive time)
3. Mistrust and future medical procedure fears (if not discussed truthfully or if highly traumatized)
4. Airway compromise or musculoskeletal injury (rare except in high-risk patients or with unsafe restraint practice)

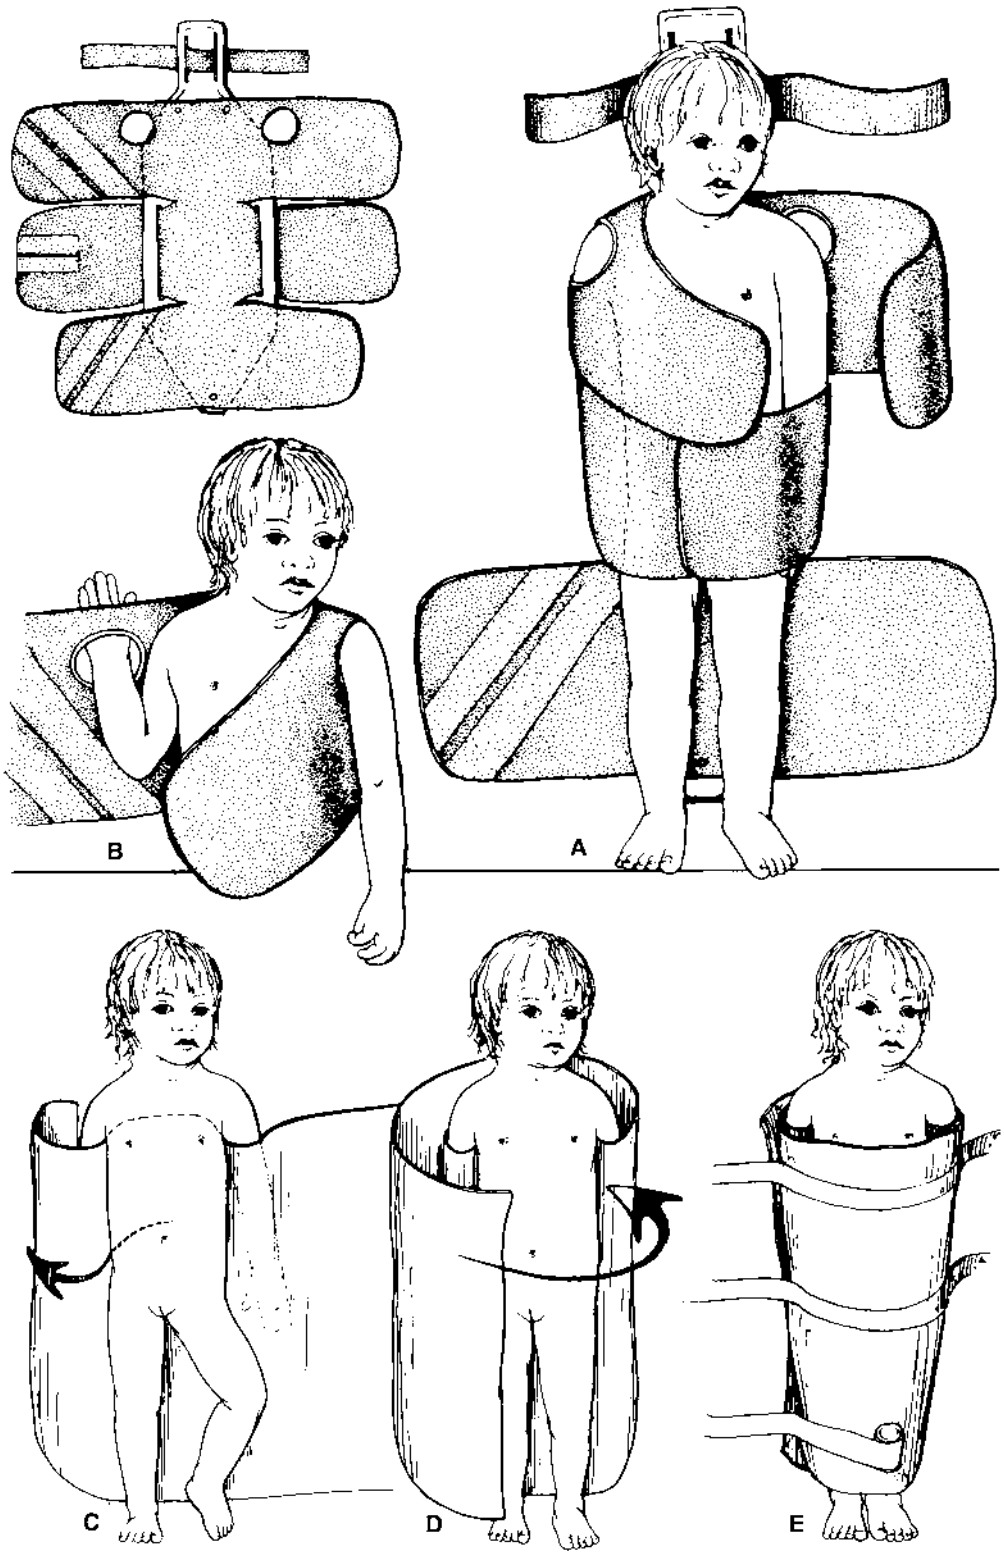
Procedure

Papoose

Figure 1.1A represents the example of the papoose, which is commonly used for restraint during repair of lacerations and other wounds. It is used to expose the head, face, and extremities with minimal discomfort to the child. In recent years, with child life presence many centers have narrowed the use of this tool a good deal. After explaining the procedure to the family, open the papoose across the ED stretcher. Place the child supine on the papoose and expose the body area necessary for treatment. Beginning with the midabdominal restraints, cover the child across the midline with the Velcro-lined sides (Fig. 1.1A). Better exposure of the extremities, such as the hand, is obtained by flexion of the area under the harness (Fig. 1.1B). Before starting a wound repair or other procedure, reassess for the safety and adequacy of the immobilization of the child and correct it if necessary.

Mummy Wraps

The mummy wrap is an alternative restraint to use for treating emergency problems of the head, especially minor trauma. By slight variation, it also provides access to the distal extremities. Prepare the patient and family for the procedures. Fold a bedsheet on itself so the width measures from the axillae to the heel of the child. Stand the child on the bed and place the bedsheet behind his/her back, under the axilla, and in front of the arms as in Figure 1.1C, with the short end of the sheet tucked behind one



1.1

arm around the child's back. With the child standing, wrap the long end of the sheet on the child's other side, around the back to the front and across the trunk again, finishing behind the child, as in Figure 1.1D. Lay the child supine or prone to best expose the injury to be treated. Extend several lengths of 2- or 3-in wide adhesive tape across the patient, attaching it to the sides of the stretcher to firmly hold the child's trunk in place (Fig. 1.1E). In some settings, using the mummy wrap inside of a papoose without the need for adhesive tape is an excellent alternative. An injured extremity can be left out of the wrap for better exposure.

Head Box

A head box can be placed behind the head and along the sides to help keep the child's head midline when supine. It will fit under the papoose, and the side should fit snugly (not tightly) on the lateral aspect of the child's head. It is of great value when repairing facial lacerations in young infants. Be careful that the head box is not excessively tight.

Restraint by Personnel

Many physical methods can be used to restrain children for simple emergency procedures. Often, a single assistant can grasp and immobilize a child. The specific positioning for procedures is illustrated with individual procedures. The assistant's hold must be firm enough to prevent movement that would make the procedure more difficult to perform or more likely to induce complications. Though uncommon, the use of excessive force may cause superficial or more serious injury.

2.1. EXTERNAL JUGULAR VENIPUNCTURE

Indications

Venous blood sampling in infants generally younger than 2 years of age with inadequate peripheral veins on the extremities or during resuscitation measures at any age

Complications

1. Hematoma
2. Pneumothorax (apical)
3. Infection

Equipment

Butterfly (21 to 23 gauge); 5- to 10-mL syringe; povidone–iodine or chlorhexidine solution; 70% alcohol; sterile gauze

Procedure

Place the infant on the examining table in the supine position with the infant's shoulders 7 to 10 cm from the end of the table. Have the assistant lean over the patient to stabilize the trunk. The assistant then holds the shoulder ipsilateral to the external jugular vein to be punctured with one hand and places the other hand over the ipsilateral zygoma and forehead, turning the head toward the contralateral shoulder and dropping the head 15 to 20 degrees over the table top.

Attach the butterfly to the syringe and check for patency. Cleanse the skin over the vein circumferentially with the povidone–iodine or chlorhexidine solution. After drying, povidine–iodine may be wiped off with alcohol and them the skin dried with sterile gauze. If the vein is not easily visualized in this position, it may be necessary to stimulate the infant to Valsalva or to cry to improve filling and visualization of the blood vessel. Align the butterfly needle parallel to the vessel as shown in Figure 2.1, and pierce the skin near the white circle shown overlying or just next to the vein approximately one half to two thirds of the distance between the angle of the jaw and the clavicle. The puncture often improves venous engorgement by stimulating the infant to cry. Then with constant suction on the syringe, advance the needle (Fig. 2.1, *dotted line*) until the external jugular vein is entered, keeping the needle steady with the heel of the hand on the infant's head. After withdrawing an adequate blood sample, relieve the suction on the syringe and withdraw the needle. Apply sterile dry gauze immediately. The assistant should bring the infant to the upright position and compress the venipuncture site for 5 minutes.

2.2. RADIAL ARTERIAL PUNCTURE

Indications

Procurement of blood samples, especially for arterial blood gas analysis

Complications

1. Arterial occlusion by thrombosis/hematoma
2. Infection—thrombophlebitis
3. Ischemia (especially if the ulnar collateral circulation is insufficient)
4. Hematoma—from hemostatic problems or inadequate pressure afterwards

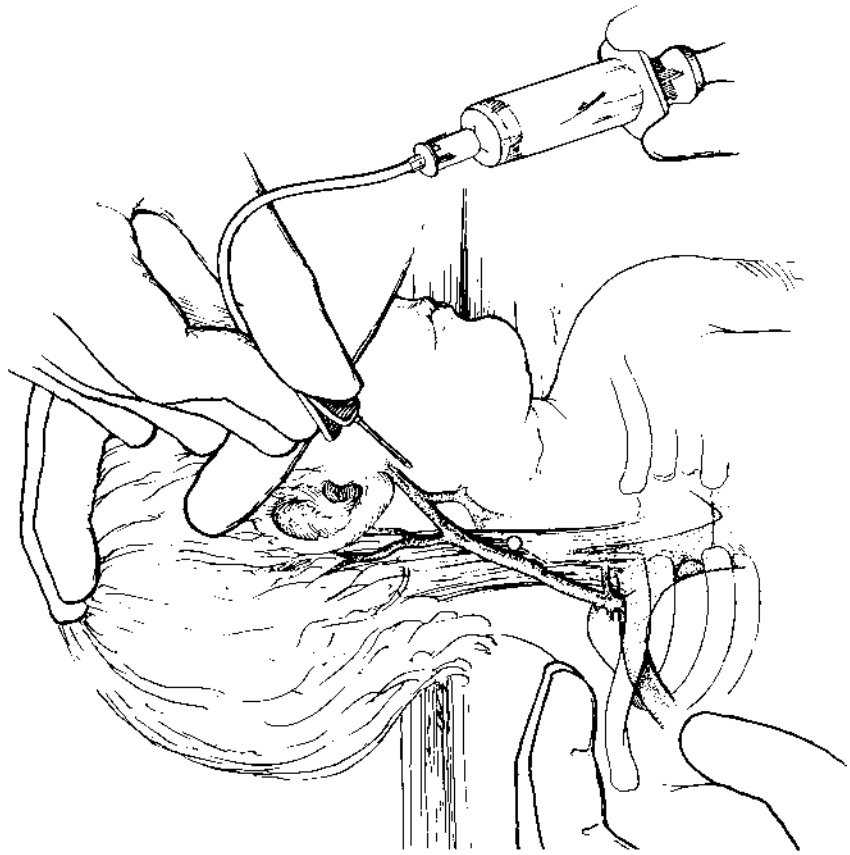
Equipment

Butterfly (23 to 25 gauge); 1- to 3-mL syringe or standard blood sample collecting system; heparin flush (10 U per mL); povidone–iodine or chlorhexidine solution; 70% alcohol; sterile gauze

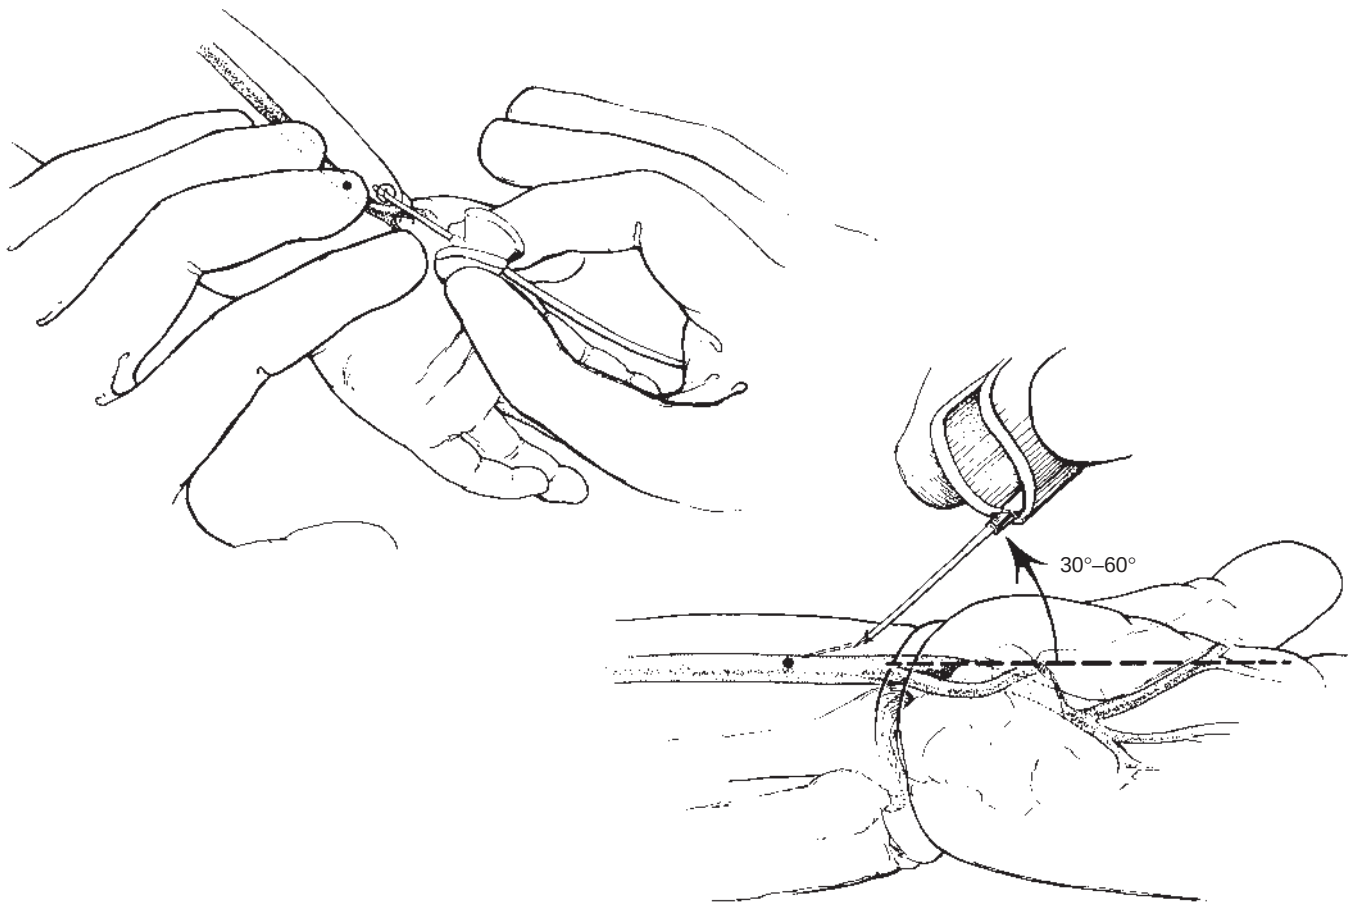
Procedure

Prepare the equipment—attach the butterfly to the syringe and flush the system with the heparin solution and empty it. Assess the adequacy of both radial and ulnar arterial flow by palpation before the puncture (i.e., Allen test). Have the assistant firmly restrain the infant or child by holding the arm just proximal to the wrist in supination and hyperextending the hand approximately 20 to 30 degrees.

Cleanse the skin overlying the radial artery with povidone–iodine or chlorhexidine solution followed by 70% alcohol and then dry with sterile gauze. Using gentle pressure with the gloved palpating fingers, locate the vessel. Hold the needle as shown in Figure 2.2 and pierce the skin between index and middle fingers of the palpating hand, directing the needle at 30 to 60 degrees from the horizontal plane. When the needle enters the radial artery, blood begins to flow into the tubing. It will freely flow into a glass syringe, but slight suction is needed to fill plastic syringes. If the initial thrust is unsuccessful, attempt to enter the artery from a different angle, either medially or laterally as determined by careful palpation. To reduce the likelihood of vessel injury and to obtain a more reliable



2.1



2.2

blood gas analysis, every effort should be made to minimize the number of punctures.

After obtaining the specimen, quickly remove the needle and apply pressure to the puncture site for 5 minutes. Any air bubbles must be immediately removed from the sample to achieve accurate results.

2.3. FEMORAL ARTERY/VEIN PUNCTURE

Indications

1. Arterial or venous blood sampling during acute resuscitations
2. Venous blood sampling in infants with inadequate peripheral veins

Contraindications

Avoid femoral punctures in children who have coagulation defects, hypercoagulable states, or cardiac shunts.

Complications

1. Hematoma of femoral triangle
2. Thrombosis—femoral artery or vein
3. Superficial infection
4. Osteomyelitis/arthritis—proximal femur, hip joint

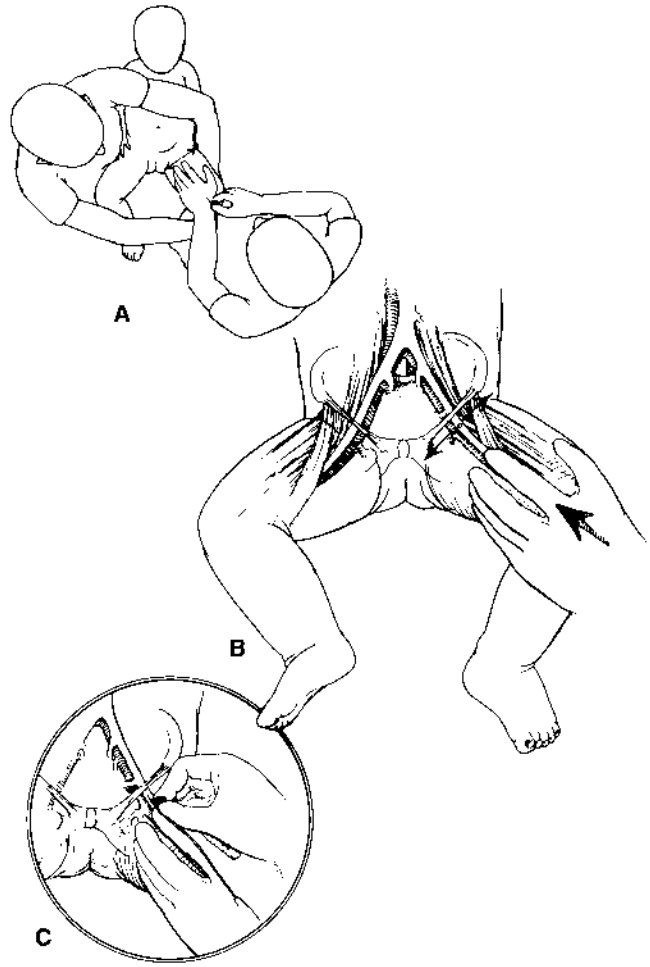
Equipment

Butterfly needle (1-in, 21- to 23-gauge needle in a child 2 to 3 years of age or older); syringe on 1.5-in, 19- or 21-gauge needle when child is 9 to 10 years of age or older; 5- to 10-mL syringe; povidone–iodine or chlorhexidine solution; 70% alcohol; sterile gauze; blood sample containers

Procedure

Have the assistant restrain the infant. This can be done using one of the two methods. The first method is illustrated in Figure 2.3A, whereby the trunk and contralateral leg are restrained by the assistant and the ipsilateral leg is restrained by the operator. The second method is diagrammed with the illustration for suprapubic bladder aspiration (see Procedure 11.2), in which the assistant leans over the infant with arms pressing on the infant's arms above and holding the distal thighs below in the frog-leg position.

Gently flex the knee and externally rotate the hip to identify the landmarks of the femoral triangle. Locate the inguinal ligament, and gently palpate midway between the anterior superior iliac spine and pubic symphysis. The femoral artery lies halfway between the two landmarks; the vein lies 0.5 to 1 cm medially (Fig. 2.3B). The empty space between flexor and extensor muscles of the medial thigh will also reveal the location of the vessels.



2.3

Cleanse the femoral triangle circumferentially with povidone–iodine or chlorhexidine solution several times, and then wipe the dried povidone–iodine off with 70% alcohol and dry with sterile gauze. With the palpating index finger, relocate the femoral artery approximately 2 cm below the inguinal ligament. Use the palm of this hand to control the movement of the child's leg. Minimize the infant's agitation and movement because this will make the abdominal musculature taut and the transmitted pulse difficult to palpate.

Direct the needle 60 to 75 degrees from the horizontal, just cephalad on the leg to the palpating finger, as shown in Figure 2.3C. Puncture the skin over the pulsatile femoral artery or 0.5 cm medially for the vein, whichever is desired. Apply constant suction to the syringe as the needle is advanced into the thigh to ensure blood is obtained on entering the vessel. The assistant should work to avoid uncontrolled leg movements by the infant because this makes it possible to lose alignment of the needle and vessels. If unsuccessful, withdraw the needle to just below the skin surface and reattempt vessel puncture after shifting the medial or lateral alignment of the needle tip. After obtaining the sample, stop suction on the syringe. Concomitant with needle withdrawal, the assistant should provide constant pressure on the puncture site for 5 minutes with sterile gauze.

3.1. GREATER SAPHENOUS VEIN CUTDOWN

Indications

Emergency intravenous (IV) access if percutaneous attempts are unsuccessful. It is especially useful because of its consistent location when venous access is necessary during cardiopulmonary resuscitation. Due to taking 5 to 10 minutes, it should not replace rapid intraosseous needle placement when indicated as first line of IV access.

Complications

1. Bleeding
2. Infection/phlebitis
3. Laceration of sensory nerves
4. Catheter loss into the vein

Equipment

Cutdown tray including drapes; 4″ × 4″ sponges; hemostats (Kelley and mosquito); scalpel with no. 11 or 15 blades; scissors, iris and sharp; needle holder; forceps, toothed; povidone–iodine or chlorhexidine solution; 70% alcohol; lidocaine 1%; syringes, 5 and 10 mL; normal saline flushing solution; central venous pressure (CVP) catheters (3.0F to 5.0F) or over-the-needle catheter (16 to 20 gauge); ties, silk (3-0); other ties (4-0); needles (21, 22, 25 gauge)

Procedure

Prepare the catheter by attaching it distally to a stopcock and 10-mL syringe. Fill the catheter system with routine flushing solution. Prepare the child for the procedure. Place the patient supine and externally rotate the leg and ankle. Restrain the patient's foot while allowing proper exposure of the area.

Palpate the medial malleolus of the tibia and anterior tibial tendon between which the saphenous vein lies. Cleanse the ankle with povidone–iodine or chlorhexidine solution followed by 70% alcohol and dry with sterile gauze. Using sterile technique, drape the area with sterile towels, leaving a rectangular 5 ×8 -cm^2 field exposed over the ankle. Inject 1% lidocaine to achieve local anesthesia at the incision site.

After relocating the landmarks, make a 2-cm transverse incision with a no. 15 scalpel blade just proximal and anterior to the bony prominence of the medial malleolus, as shown by the dotted lines in Figure 3.1. In infants <1 year, a 1-cm incision may be sufficient. Do not use a proximal tourniquet because it may increase capillary bleeding and obscure the field.

With a curved hemostat, spread the subcutaneous tissue proximal from distal along the course of the vein. The vein can be located by lifting up the tissue directly on top of the fascia. Just anterior to the vein is a sensory nerve, which will be spared if the vein is separated well from the surrounding tissue. Isolate the vein and pass two 3-0 or 4-0 silk ties underneath it. Tie the distal suture, as shown in Figure 3.1A, and hold the suture with a clamp distally. Then loosely knot the proximal tie.

As shown in Figure 3.1B, incise the vein after applying traction to it by exerting tension on the distal ligature. Use a no. 11 scalpel blade and insert its sharp point at 45 degrees from the horizontal to produce a vein wall flap halfway through the vein. Figure 3.1C shows the procedure in small veins and how grasping the vein on either side flattens it out. This method exposes the lateral vein surface and makes it easier to incise the 45-degree flap. Often it is helpful to make a hook to hold the proximal vein flap. This is accomplished by using a hemostat to bend the tip of a 22-gauge needle into a curved hook. Lift the top of the vein flap with it to expose the venotomy opening. Next, as in Figure 3.1D, hold the vein flap open with the curved hook and insert the beveled catheter through the vein opening and up the leg. Figure 3.1E shows the technique for advancing the catheter once patency is confirmed. Running IV fluids while advancing the catheter dilates the vein and facilitates passage of the remaining 15-cm length of catheter. At this point, secure the proximal tie around both the vein and the indwelling catheter, and distal to the cutdown site, suture the catheter to the skin. The incision may be closed with several sutures. Apply a sterile dressing.

Alternative

Rather than making an incision in the vein, the emergency physician may choose to insert an "over-the-needle" catheter into the vessel after it has been exposed. This may be done without tying off the distal end of the vein. The technique is similar to that of percutaneous venipuncture, except the vein is under direct visualization. After the catheter has been advanced and patency confirmed, secure the catheter and close the incision as previously described. If the vein is not ligated, disconnect the distal tie. This may assist in reuse of the vein if the patient may require it later. In most instances where the vein may have not been tied off, future attempts for IV placement will not be tried unless it is well documented.

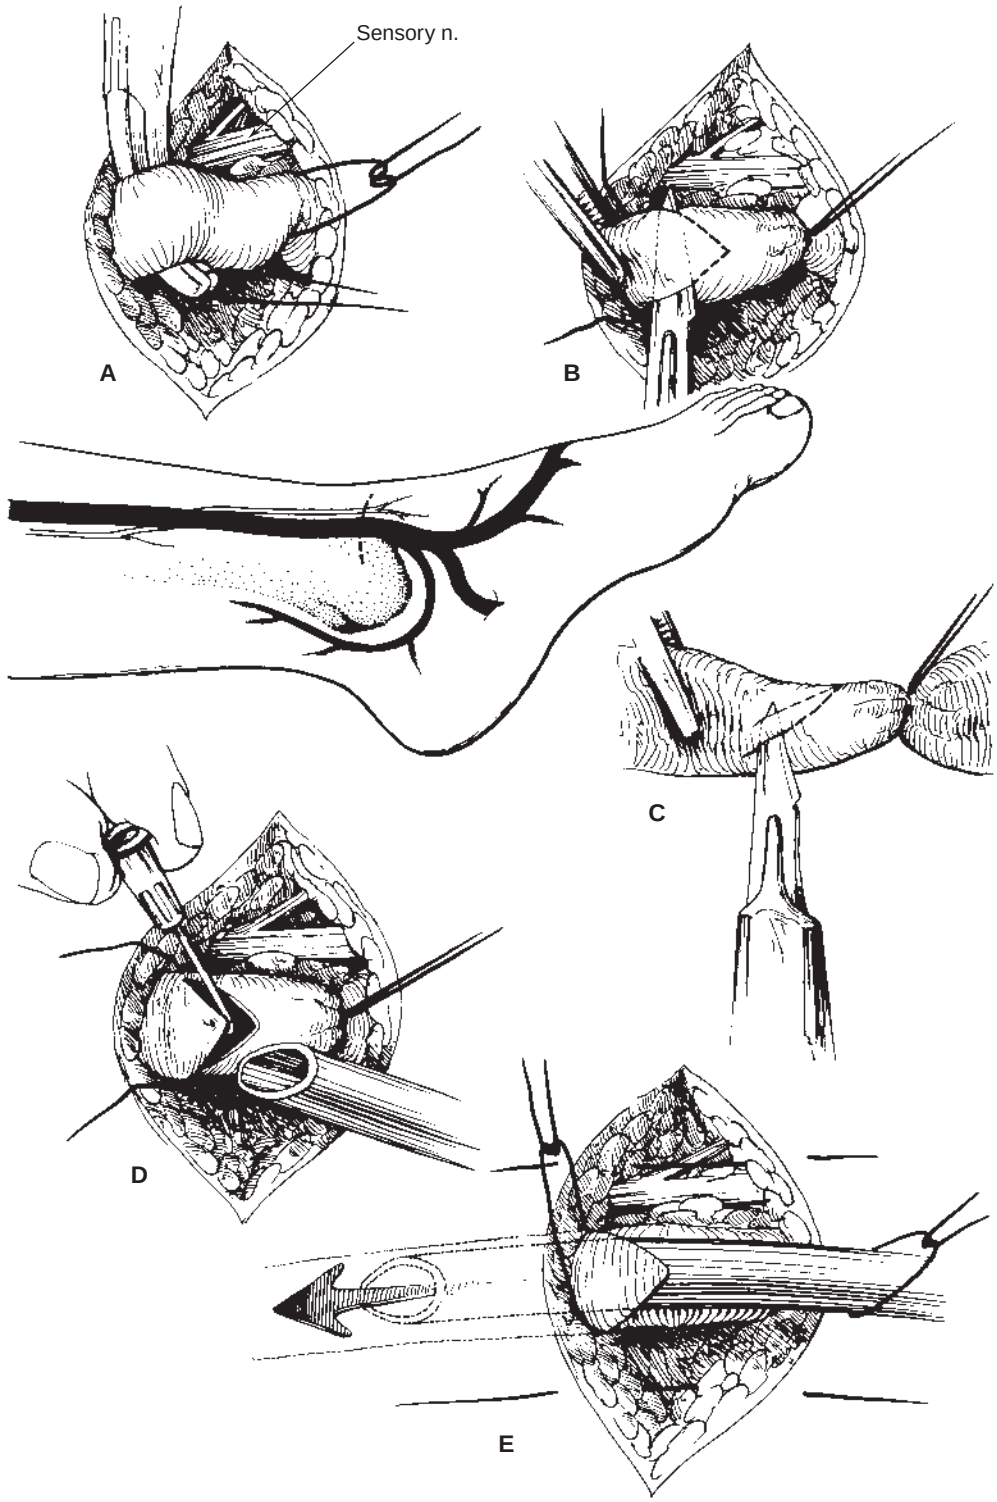
3.2. CENTRAL VENOUS CATHETER: PERCUTANEOUS SELDINGER TECHNIQUE—FEMORAL

Indications

Emergency access to central venous circulation. See Procedure 13.1 for ultrasound guidance. The femoral vein is more accessible than the external or internal jugular vein during resuscitation but should be avoided when possible interruption of the inferior vena cava exists, such as in trauma or severe abdominal catastrophe.

Complications

1. Arterial or venous laceration
2. Infection (especially if placed in emergency without reliable use of infection control technique)
3. Catheter fragment in circulation



3.1

Equipment

Commercial tray (i.e., Abbott®, Arrow®, Cooke®, Viggo-Spectramed®), with metal catheter; guidewire; 3F, 20-gauge (younger than 2 years of age) or 4F, 18-gauge (2 to 7 years old) or 5F, 16-gauge (older than 8 years of age) infusion catheter; sterile drapes and gloves; 5- to 10-mL syringe; T-connector; three-way stopcock; infusion fluid; povidone–iodine or chlorhexidine solution; 70% alcohol; sterile gauze pads; use larger set in trauma patients

Procedure

Femoral Approach

Restrain the lower extremities and trunk of the child. Externally rotate the hips to facilitate palpation of the femoral triangle. Consider use of a towel under the gluteal muscle to improve exposure of the vein. Palpate the femoral artery 1.5 cm below the inguinal ligament, halfway between the anterior superior iliac spine and symphysis pubis. The femoral vein lies 0.5 cm medially.

Cleanse the site with povidone–iodine or chlorhexidine solution and 70% alcohol. Dry with gauze. Wearing sterile gloves, mask and gown, drape the area. Check all equipment and attach a 5-mL syringe to the metal catheter. Repalpate the femoral artery. Hold the metal catheter parallel to the blood vessel and 30 degrees above the horizontal (Fig. 3.2A). Stabilize it with the heel of the lateral aspect of the hand against the child's leg. Puncture the skin 0.5 cm medially to the arterial pulsation. Apply suction to the syringe while advancing the needle. When venous blood returns, advance the metal catheter 1 to 2 mm and recheck for flow. Stabilize it against the thigh and detach the syringe. Place a gloved thumb over the catheter to decrease bleeding.

Using the free hand, grasp the guidewire near the end that has a soft, straight tip. Insert the wire through the metal catheter (Fig. 3.2B). Pass the end several centimeters past the catheter tip cephalad into the vein. If it does not pass easily, the metal catheter is usually not in the lumen of the vein. If so, remove the wire and reposition the catheter to establish blood flow again. Then replace the wire.

Stabilize the wire (against the thigh distally) with the hand that inserted it (Fig. 3.2C). Withdraw the metal catheter from the vein along the wire. Move the hand to stabilize the guidewire proximally once the wire is exposed at the puncture site. Support the wire and pull the metal catheter off the guidewire. Pick up the infusion catheter at the proximal end and advance it over the wire to the skin entry site. Twist it at the skin entry site (Fig. 3.2D) and advance it over the wire in a cephalad direction while stabilizing the wire distally. This rotary motion is helpful to enlarge the cutaneous puncture site. When introducing a larger catheter, make an incision over the wire.

Last, as in Figure 3.2E, withdraw the wire while holding the catheter in place; blood flows immediately if the vein has been cannulated. Attach the infusion system to the catheter and tape or suture it in place. Larger catheters can be placed by reinserting the wire and increasing the size of the skin entry site.

3.3. JUGULAR VENOUS CANNULATION

Indications

Emergency central vein access. The internal or external jugular veins are preferred entry sites particularly when abdominal trauma with possible vena cava injury is present. This is a relative contraindication to femoral vein cannulation. The main delay in early access to the jugular vein is the need to stabilize the airway or maintain protection of the C-spine.

Complications

1. Arterial or venous lacerations
2. Infection
3. Catheter fragment in central circulation
4. Pneumothorax, hemothorax
5. Pneumomediastinum
6. Cardiac trauma

Equipment

See Procedure 3.2. One may substitute both over-the-needle catheters of similar diameter

Procedure

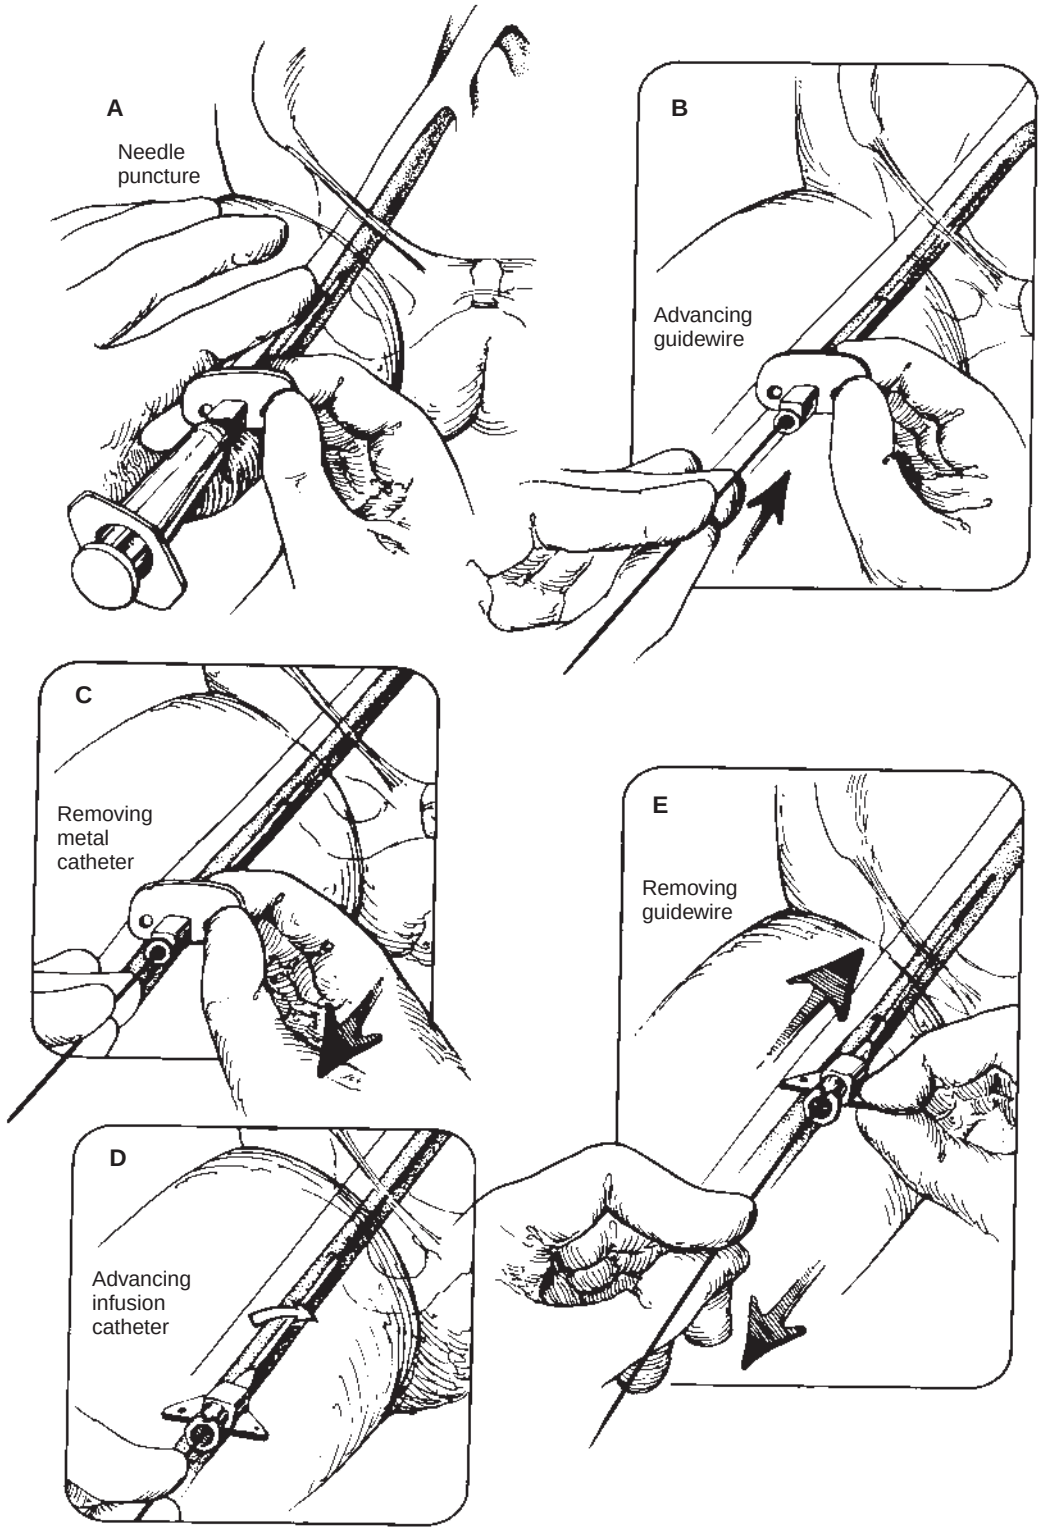
External Jugular Vein

In infants younger than 6 months, catheterization by the Seldinger technique is difficult because of the short length of the infant's neck. Use a catheter-over-needle, usually a 20F or 22F. It can be difficult to use a safety needle IV set up for this procedure, so it is best to use standard catheter-over-needle product. Place the infant on the examining table in the supine position with a towel roll under the shoulder or tilt the bed 15 to 20 degrees into the Trendelenburg position to maximize venous filling.

Have an assistant hold the head over either the forehead or the chin ipsilateral to the external jugular vein to be punctured. Cleanse the skin over the vein with povidone–iodine or chlorhexidine solution. Don sterile gloves and assemble the equipment. Align the catheter–needle system parallel to the vessel as shown in Figure 2.1, and pierce the skin one half to two thirds of the distance between the angle of the jaw and the clavicle. Advance the catheter to enter the jugular vein. After withdrawing blood, proceed to further advance the over-the-needle catheter. If the Seldinger technique is being used, remove the syringe and introduce the wire to cannulate the vein. A guidewire with a flexible, curved end (J-wire) may help make the turn toward the right atrium on entry of the subclavian vein. As described in the femoral technique, pass enough wire to ensure venous entry. Remove the metal catheter and then place the infusion catheter over the wire. If difficulty is encountered at the skin, make a small nick in the skin over the wire to ensure passage of the catheter. Pass the catheter into the vein far enough to reach the level of the right atrium. Remove the wire from within the catheter and check the line for blood return. Connect the IV tubing, and then secure the line to the neck with a suture and tape. A radiograph is necessary to assess the location of the catheter (because it may be placed distal in the subclavian vein or if into the ventricle).

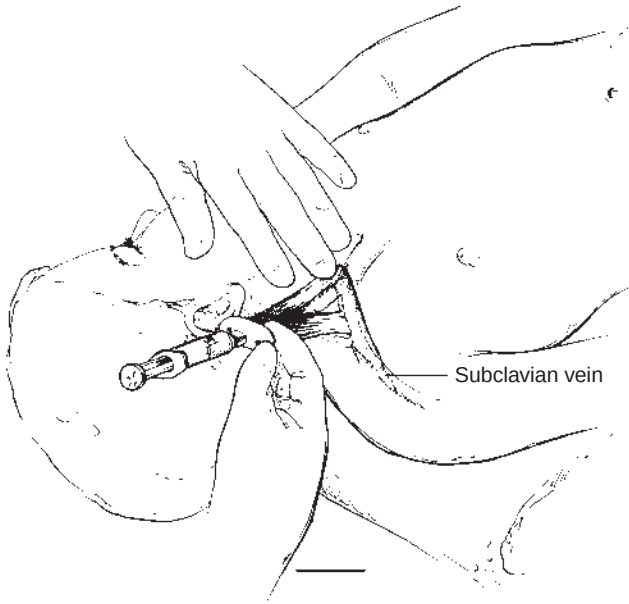
Internal Jugular Vein

Position the infant or child in 15 to 20 degrees of Trendelenburg with the head turned over the bed or table edge. Mild hyperextension of the neck tenses the sternocleidomastoid muscle to localize the landmarks. The medial approach uses the apex of the triangle formed by the sternal and clavicular heads of the sternomastoid muscle as the entry site (Fig. 3.3). Using a needle attached to a tuberculin syringe, advance it at a 45-degree angle



3.2

to the skin in the caudal direction. Aim toward the ipsilateral nipple. Aspirate on the syringe as advancing; the vein should be entered at a depth of 1 to 2 cm. If this fails, withdraw the needle slowly with constant traction on the plunger of the syringe. If blood return does not signify venous entry, reattempt cannulation by advancing the needle slightly lateral to the initial attempt (do not advance the needle more medial to the ipsilateral nipple line). After obtaining blood flow, introduce the guidewire and then the catheter, as previously described. Check for blood return, and secure the line with suture and tape. A radiograph of the chest should be taken to check for line position and assess for pneumothorax.



3.3

3.4. TECHNIQUE OF SUBCLAVIAN VEIN PERCUTANEOUS CATHETERIZATION

Indications

Emergency access to the venous circulation in the absence of percutaneous peripheral, femoral, or external jugular access

Complications

1. Pneumothorax, hemothorax, or hydrothorax
2. Infection, especially after prolonged maintenance following emergency placement

Equipment

Venous catheter—newborns (20 gauge), children younger than 9 years (18 gauge), older children (14 gauge); sterile drapes and gloves; 5- to 10-mL syringe; T-connector, three-way stopcock; infusion fluid; povidone–iodine or chlorhexidine solution; 70% alcohol; sterile gauze pads; anesthetic (see following text); no. 11 scalpel blade; knife handle; needle holder; 4-0 or 5-0 nylon suture; sterile needles (22 to 25 gauge)

Procedure

Anesthesia

Except in premature infants or obtunded children, adequate restraint in the Trendelenburg position can be difficult without pharmacologic sedation or general anesthesia; this requirement precludes the insertion of a subclavian line in many situations. However, in children older than 6 years of age who are stable and cooperative, the procedure can be done with a local anesthetic of 1% lidocaine and/or sedation with IV midazolam (0.05 to 0.1 mg per kg) or a combination of fentanyl (1 to 2 μg per kg) and midazolam. Experienced providers may have other options of safe medications (see Chapter 4).

Technique

The technique of subclavian venous catheterization in children varies somewhat from the approach used in adults, but the positioning is similar. Place the child in the Trendelenburg position with a small towel roll under the thoracic spine to hyperextend the back.

After preparation of the neck and upper chest on the side selected for catheterization with povidone–iodine or chlorhexidine, cover the area with a sterile aperture drape and towels. If the patient is awake but sedated, the intended tract of the subclavian line is anesthetized with 1% lidocaine, including the periosteum of the clavicle and adjacent first rib.

Make a small puncture at the intended entry site, a depression bordered by the deltoid and pectoralis major muscles, under the distal one third of the clavicle, as shown in Figure 3.4A; use a no. 11 blade. This more lateral entry point maintains a greater distance between the skin surface and the entrance to the subclavian vein, decreasing the chance of infection. A more medial site is less ideal, but it is an acceptable alternative.

Insert the needle through the puncture site as depicted in Figure 3.4A, and direct it toward the junction of the first rib and clavicle. The needle is advanced underneath the clavicle at its midpoint while gentle steady aspiration is applied to the syringe. When the needle enters the vein, blood flows back briskly (Fig. 3.4B). Advancing the needle and catheter for several more millimeters ensures the catheter itself is in the vein.

Remove the needle, leaving the catheter in the vein. If blood continues to return easily, insert the appropriate size catheter through the plastic cannula (Fig. 3.4C). If the blood return is not brisk, withdraw the plastic cannula 1 mm at a time until the blood flows rapidly.

After the long catheter has been inserted, attach it to a 10-mL syringe and a T-connector that have been filled with heparinized (10 U per mL) saline. After assessing for adequacy of blood return and infusion by alternately pushing and pulling on the plunger, secure the catheter temporarily while a chest radiograph is performed. This should confirm both the position of the catheter tip in the superior vena cava and the absence of pneumothorax or hemothorax. After the results of the chest radiograph are judged to be satisfactory, suture the catheter to the skin using 4-0 or 5-0 nylon and cover the area with sterile dressing.

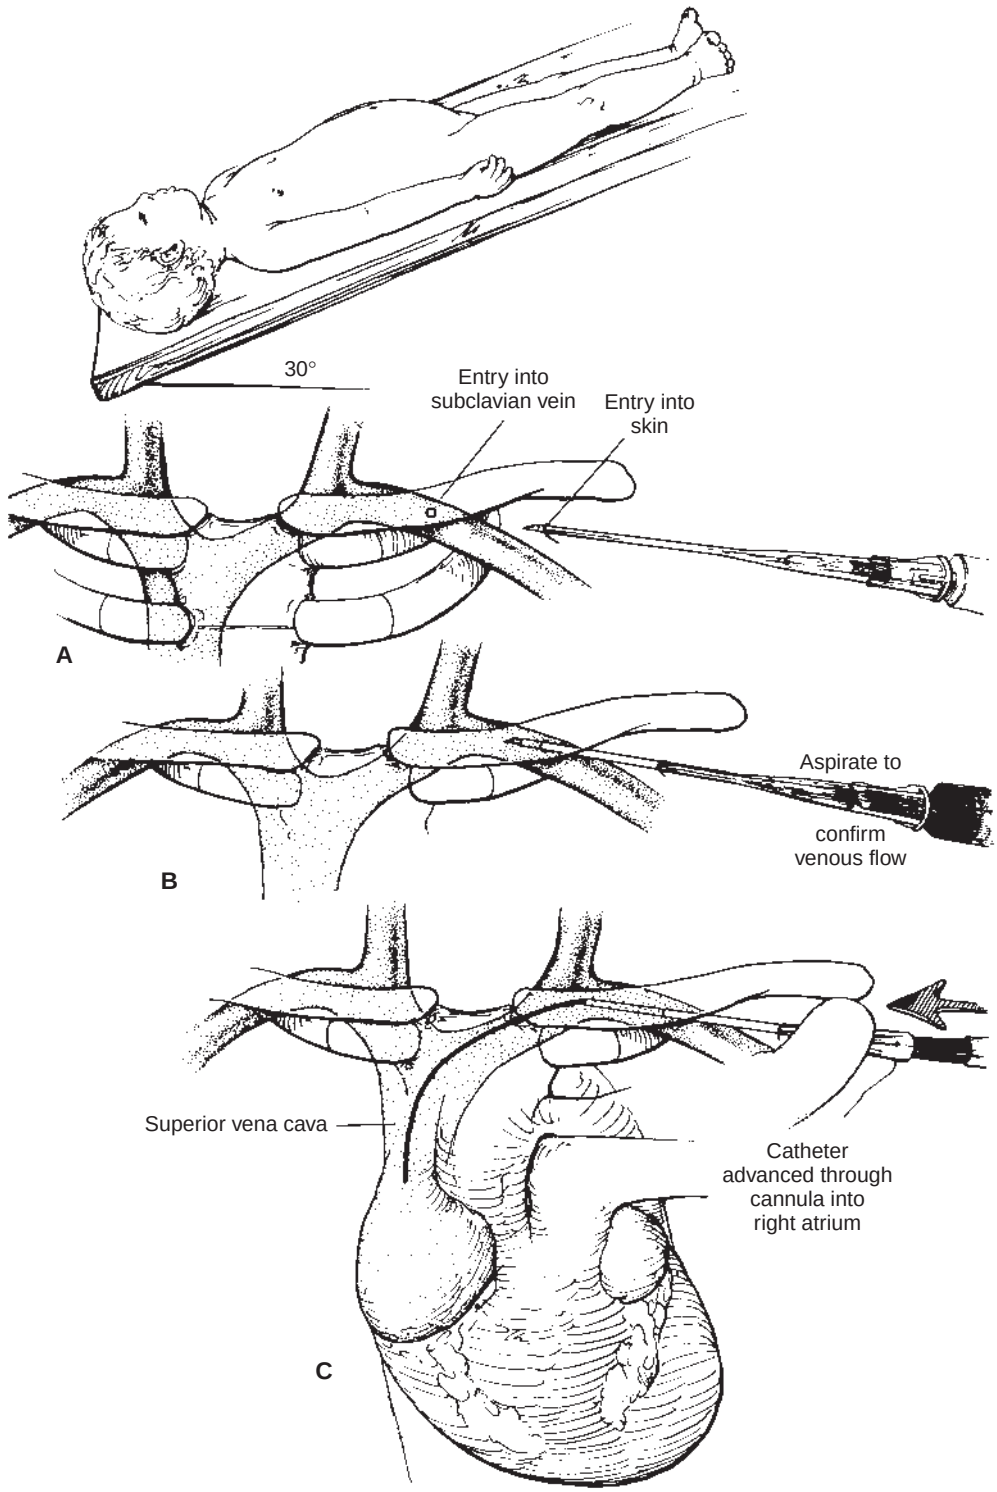
3.5. SCALP VEIN CATHETERIZATION (FIG. 3.5)

Indications

To achieve IV access for delivering fluid and/or medication in an infant usually younger than 1 year of age, when peripheral extremity veins are unavailable

COMPLICATIONS

1. Inadvertent arterial puncture
2. Ecchymoses and hematoma of the scalp



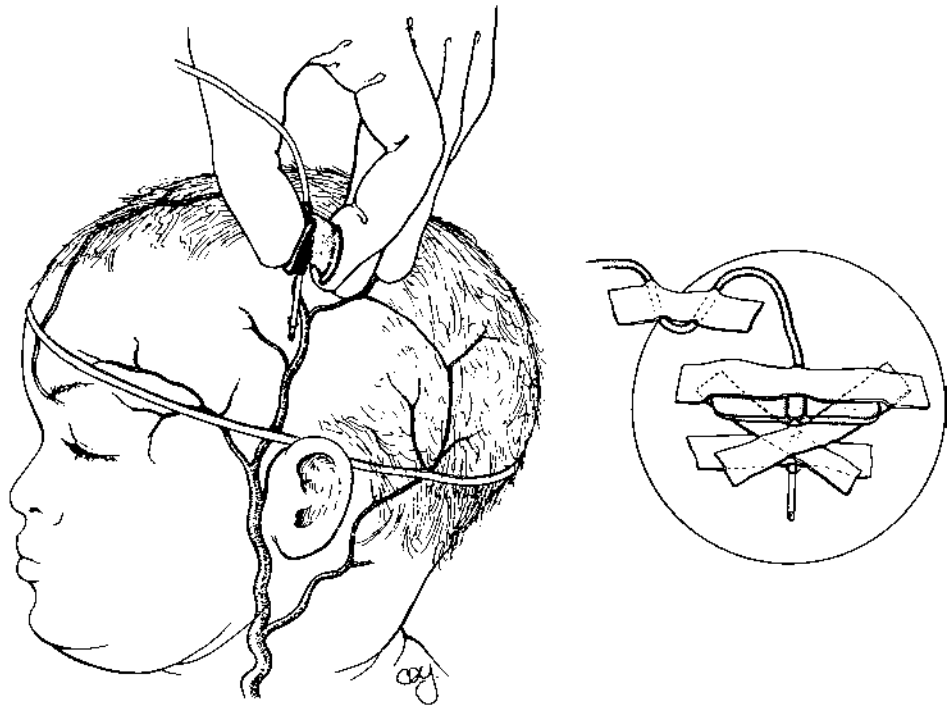
3.4

EQUIPMENT

Butterfly scalp vein needle no. 23, 25, or 27, or an over-the-needle catheter, 22 or 24 gauge; rubber band with tape; flush solution; 3-mL syringe; tincture of benzoin; tape; razor blade; povidone–iodine or chlorhexidine solution; 70% alcohol; sterile gauze

PROCEDURE

The infant younger than 1 year of age has several easily accessible scalp veins. These include the frontal, supraorbital, posterior facial, superficial temporal, and posterior auricular veins and their tributaries. Restrain the patient in a supine position and have an assistant stabilize the infant's head.



3.5

After assessment for the most accessible veins, shave an area large enough to expose not only the desired veins, but also an area of surrounding scalp for adequate taping of the infusion needle. In this area, select a vein with a straight segment that is as long as the part of the needle that is to be inserted. Verify the chosen vessel is a vein by palpating it to ensure it does not pulsate.

Place a rubber band around the infant's head after attaching a small piece of tape to the rubber band to make it easier to lift and cut the rubber band after successful venipuncture.

Prepare the skin by cleansing with povidone–iodine or chlorhexidine solution followed by alcohol. Grasp a butterfly scalp vein needle by the plastic tabs or "wings" or the over-the-needle catheter at the base. Keep the needle and syringe unattached initially to facilitate evaluation of free blood return. Insert the needle in the direction of blood flow and pierce the skin approximately 0.5 cm proximal to the actual site where entry into the vein is anticipated. While applying mild traction on the skin of the scalp, slowly advance the needle through the skin toward the vein. Blood will enter the clear plastic tubing or the plastic tubing over the catheter with successful venipuncture. Carefully cut the rubber band tourniquet, attach the syringe filled with saline flush solution, and slowly inject 0.5 mL of flush. If the needle is satisfactorily inserted into the lumen of the vein, the solution will flow easily. Thread the catheter over the needle further into the vein continuing to assess for flow. Appearance of a skin wheal indicates that the vein has not been satisfactorily cannulated, and another attempt must be made.

After successful catheterization, carefully tape the scalp vein needle as shown in the diagram. To prevent accidental removal or infiltration of the vein, look for ways to position the infant safely.

3.6A. Umbilical Artery Catheterization

Indications

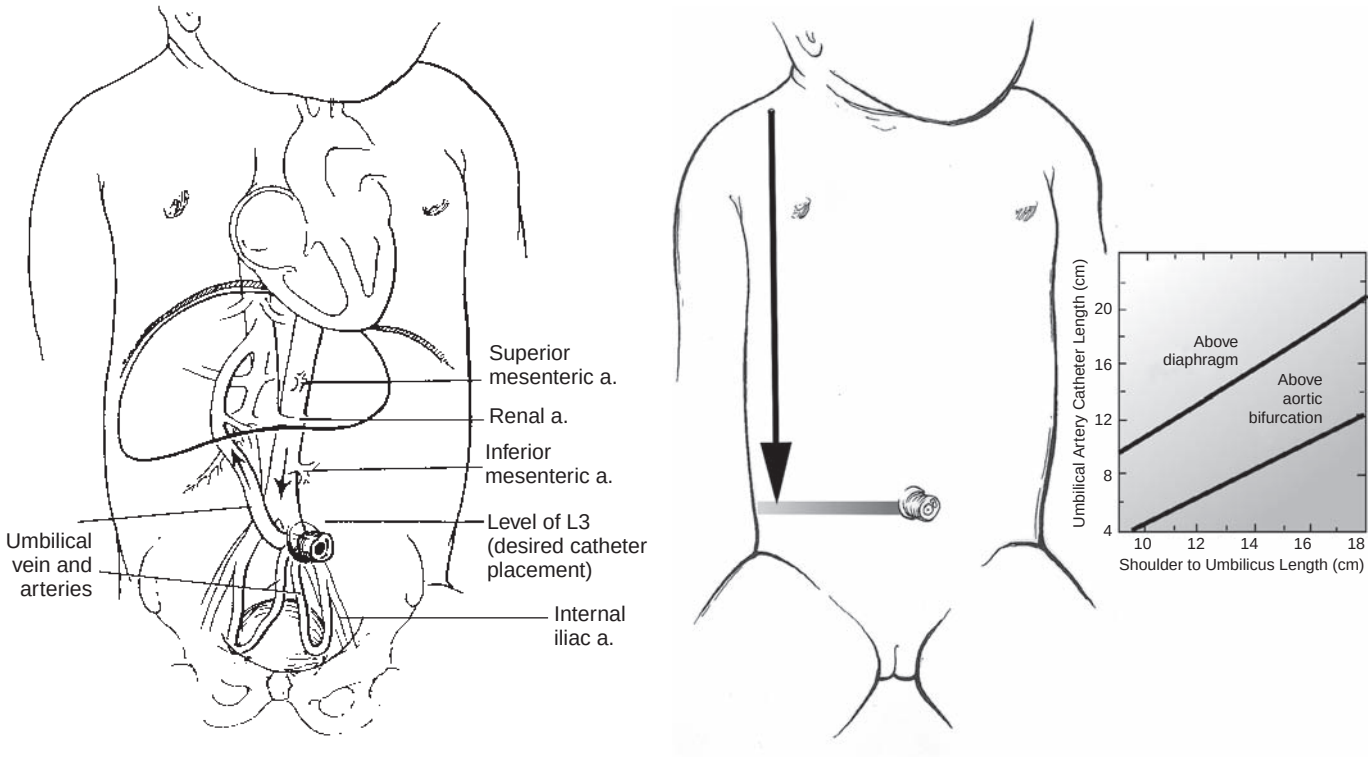
Respiratory failure or cardiovascular collapse in the newborn infant for whom percutaneous attempts for vascular access have failed. Arterial catheterization is possible until around 1 week of age.

Complications

1. Embolization or thrombosis—inferior mesenteric, renal, or iliac arteries
2. Infection
3. Ischemia/infarction from vasospasm
4. Hemorrhage—from dislodgment of catheter or perforation of the vessel wall
5. Arrhythmias—from direct cardiac stimulation if the catheter enters the heart
6. Air embolism

Equipment

3-0 or 4-0 silk suture on straight or curved needle; antiseptic solution (povidone–iodine); sterile gauze pads; drapes and gloves; hemostats (four pairs), curved non-tooted iris forceps (4 in) or metal dilator and iris scissors; needle holder, sterile scalpel and no. 11 or 15 blade; 22-gauge needle; 10-mL syringe filled with normal saline; T-connector (optional); three-way stopcock; nonthrombogenic umbilical catheter, 3.5,



3.6A

4 Fr (premature babies) or, 5F (full-term); infusion solution, often normal saline, containing heparin (1 U per mL)

Procedure

Initiate therapy for any cardiorespiratory disturbances before beginning procedure. During the catheterization, monitor the cardiac rate and keep the infant under a radiant heater to maintain normothermia. Figure 3.6A shows the pertinent anatomy.

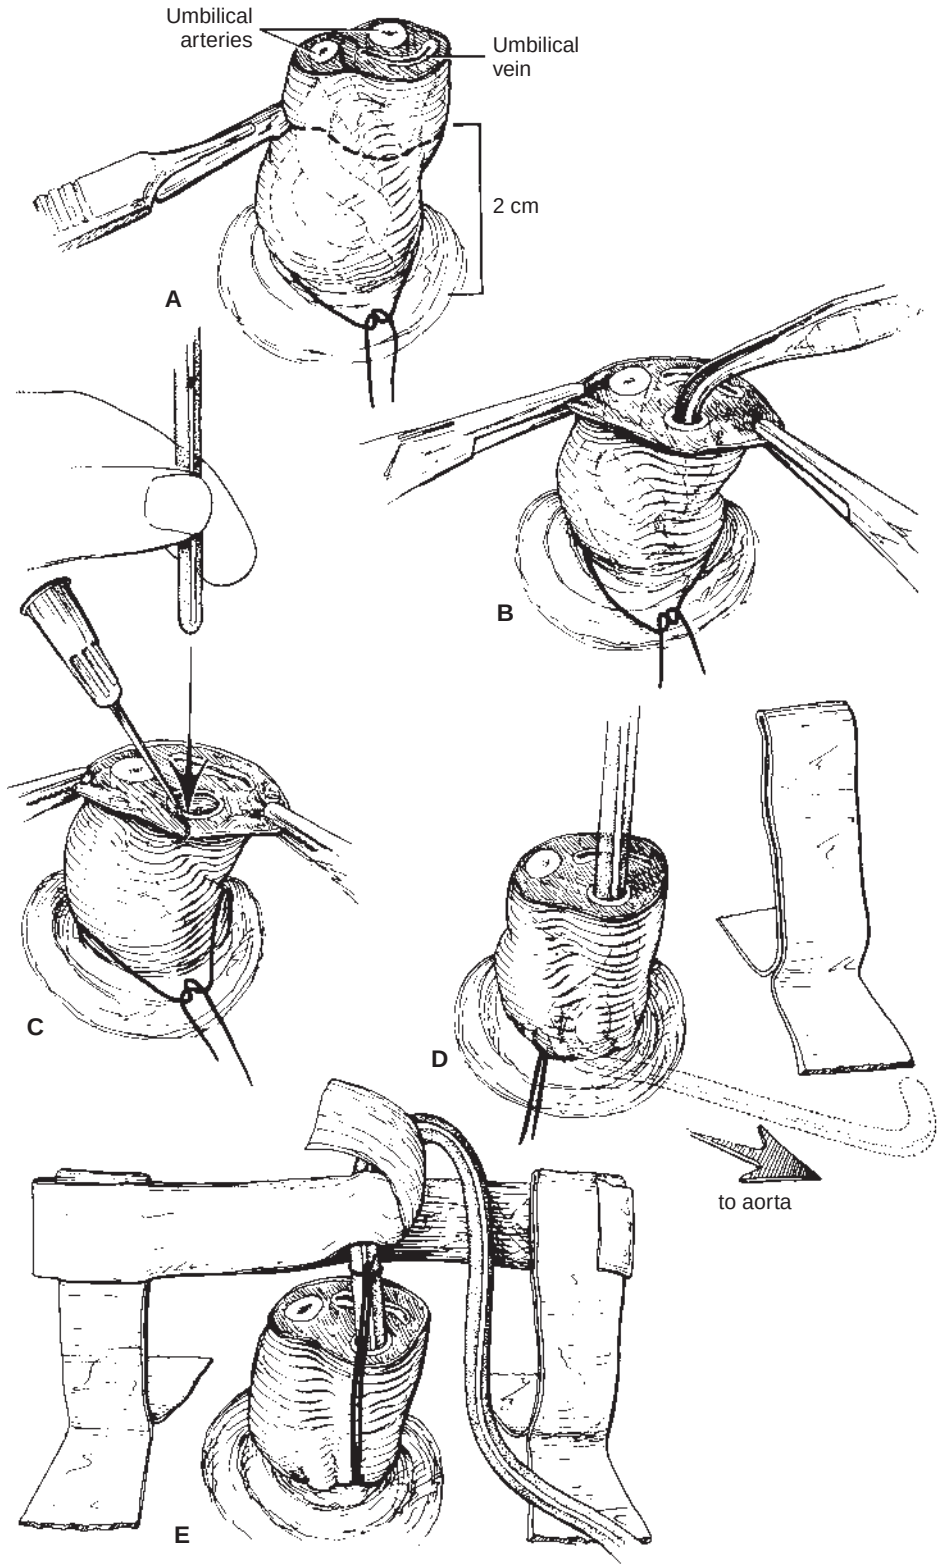
Place the infant supine in the frog-leg position and restrain him/her as necessary. Gauze pads may be wrapped around the ankles and wrists and either pinned or taped securely to the bed/sheet. Wearing mask, gown, and gloves, hold the sterile umbilical catheter over the infant to measure the vertical distance from the lateral aspect of the clavicle to the umbilicus. The catheter will be advanced into the artery 60% of this distance, beginning at the skin surface so its tip will reach the bifurcation of the aorta, the subdiaphragmatic location. For catheters that may need to be longer, use the nomogram, Figure 3.6A, to establish the length to place it. These amounts do not account for the length of catheter that is within the umbilical stump from the abdominal wall. Mark the catheter appropriately and attach it to the T-connector, stopcock, and syringe. Flush it, leaving it full of fluid. While lifting the umbilical cord with gauze in one hand, scrub the lower umbilical cord and abdomen from the xiphoid process to the symphysis pubis with povidone–iodine solution. Drape the infant on both sides by folding two drapes into triangles or use an aperture drape; cover the area below the umbilicus with a third square drape.

At the base of the umbilical stump, suture a 3-0 or 4-0 silk tie around the cord to make a purse string, but leave the knot untied. While holding the gauze on the nonsterile distal umbilicus, sever the cord 1.5 to 2 cm above the abdominal wall with the scalpel as shown in Figure 3.6B, part A. Remove the cut umbilicus and gauze from the sterile area. Bleeding is usually minimal, stopping with gentle pressure or wiping; rarely, the purse string must be tightened.

Locate the umbilical vessels, usually two thick, white-walled arteries on one side, and a larger vein on the other. If the arteries in the stump are tortuous, cut it closer to the abdominal wall to facilitate cannulation.

Attach two clamps on opposite sides of the umbilicus, being careful to grasp a fibrous portion of the cord and not just Wharton's jelly or an artery. Evert the clamps to immobilize and expose the cord, and use the small curved forceps, as in Figure 3.6B, part B, to enter and then stretch the lumen of the artery. Gentle, repetitive stretching is most effective with a solid metal dilator. An attempt at catheter placement should be undertaken when the artery remains dilated to a diameter that is greater than that of the catheter for the depth of 1 cm.

To insert the catheter, hold the distal end near the tip as in Figure 3.6B, part C, and place it in the arterial lumen between the prongs of the forceps that are holding open the artery. An alternative method, pictured in Figure 3.6B, part C, shows the inner wall of the vessel held with a 22-gauge needle (bent in the shape of a hook by a hemostat), allowing the vessel to be entered directly. Pass the catheter under gentle, constant tension to overcome the resistance encountered at the points where the artery turns (just below the skin surface and where the arteries turn upward toward the iliacs; see Fig. 3.6A). Blood should flow readily after the second bend when the iliac artery is entered.



3.6B

As shown in Figure 3.6B, part D, advance the catheter as far as the mark made on it at the outset; confirm blood flow at the final point. Turn the handle of the stopcock toward the infant. Then, tighten and knot the purse string, leaving both ends of the suture long. Approximately 5 cm from the knot at the base of the cord, make a square knot and then loop and tie the suture around the catheter to help secure it in place, as shown in Figure 3.6B, part E. An alternative is to suture in a purse string circumferentially around the umbilical cord. Then tie the knot around the catheter to assist in maintaining it securely. Also

place tape on the abdominal wall as shown in the figure. Verify with an abdominal radiograph that the tip of the catheter lies below the level of third lumbar vertebral body, or withdraw it to this position manually if the tip is higher on radiograph.

Infuse solutions containing heparin (1 U per mL) unless contraindicated for bleeding diathesis.

3.6B. Umbilical Vein Catheterization

Indications

To gain vascular access rapidly in a newborn with respiratory failure or cardiovascular collapse. Venous catheterization is possible until around 2 weeks of age.

Complications

1. Infection
2. Embolization or thrombosis
3. Vessel perforation
4. Hemorrhage
5. Air embolus

Equipment

Umbilical tape or 3-0 silk suture on straight or curved needle, antiseptic solution (povidone–iodine), sterile gauze pad, drapes, mask, gown, gloves, small curved hemostat

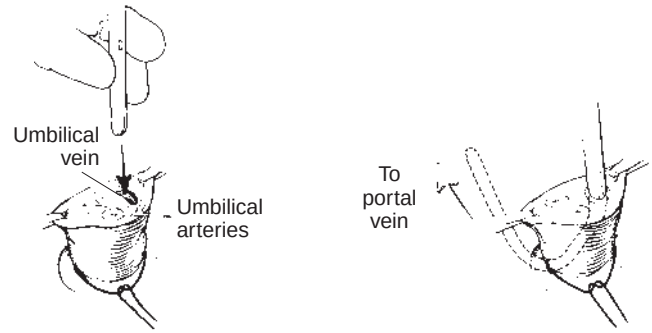
Sterile scalpel and no. 11 or 15 blade, iris scissors, 5F umbilical catheter three-way stopcock, 10-mL syringe with normal saline, infusing solution

Procedure

The umbilical vein is preferred for vascular access during neonatal resuscitation because the vessel is readily located and cannulated. Catheterizing the umbilical vein is generally much easier than catheterizing the umbilical artery.

Place the newborn supine and restrain the extremities as necessary. The newborn should be on a radiant warmer bed, and the heart rate and pulse oximetry ideally should be monitored throughout the procedure. Prepare the equipment. Attach a 5F umbilical catheter to a three-way stopcock and a saline-filled syringe. Prime the catheter with normal saline. Wearing mask, gown and sterile gloves, cleanse the umbilical cord and the abdomen from the xiphoid process to the pubic symphysis with povidone–iodine solution. At the base of the umbilical cord, loosely tie umbilical tape or insert 3-0 silk suture around the cord to make a purse string. Cut the cord 1 to 2 cm from the abdominal wall. Locate the vein orifice and remove any visible solid clot with fine forceps.

Gently grasp the umbilical vein catheter about 2 cm from the tip with either a small clamp or your gloved fingers (Fig. 3.6C). Introduce the catheter tip into the umbilical vein. Apply gentle pressure and advance the catheter through the venous lumen. The catheter is inserted until blood flows freely. This generally occurs when the catheter tip is just beyond the junction of the umbilicus and the abdominal wall. The catheter is inserted a short distance further to avoid infusing fluids directly into the liver. Take the vertical lateral clavicle to umbilicus measure and 0.6 times this is the distance to insert it to be above the level of the diaphragm. When placing it higher, it is important to confirm location with an x-ray.



3.6C

When good blood flow has returned, tighten the umbilical tape or the purse string suture. Tape the catheter in place to further secure it. The umbilical vein catheter is usually withdrawn at the end of resuscitation to minimize the danger of infection or portal vein thrombosis; therefore, it is generally not necessary to suture this line in place.

3.7. RADIAL ARTERY CATHETERIZATION

Percutaneous and cutdown techniques

Indications

Percutaneous

1. Frequent blood gas determinations
2. Continuous blood pressure monitoring in cardiovascular collapse/shock syndromes and major surgical procedures

Cutdown

1. Infants weighing less than 5 kg
2. Emergency arterial access if percutaneous attempts are unsuccessful

Complications

1. Hemorrhage
2. Embolization or thrombosis
3. Ischemia and/or infarction of hand
4. Infection

Caution

No medications or hyperosmolar solutions should be administered through peripheral arterial catheters.

Equipment

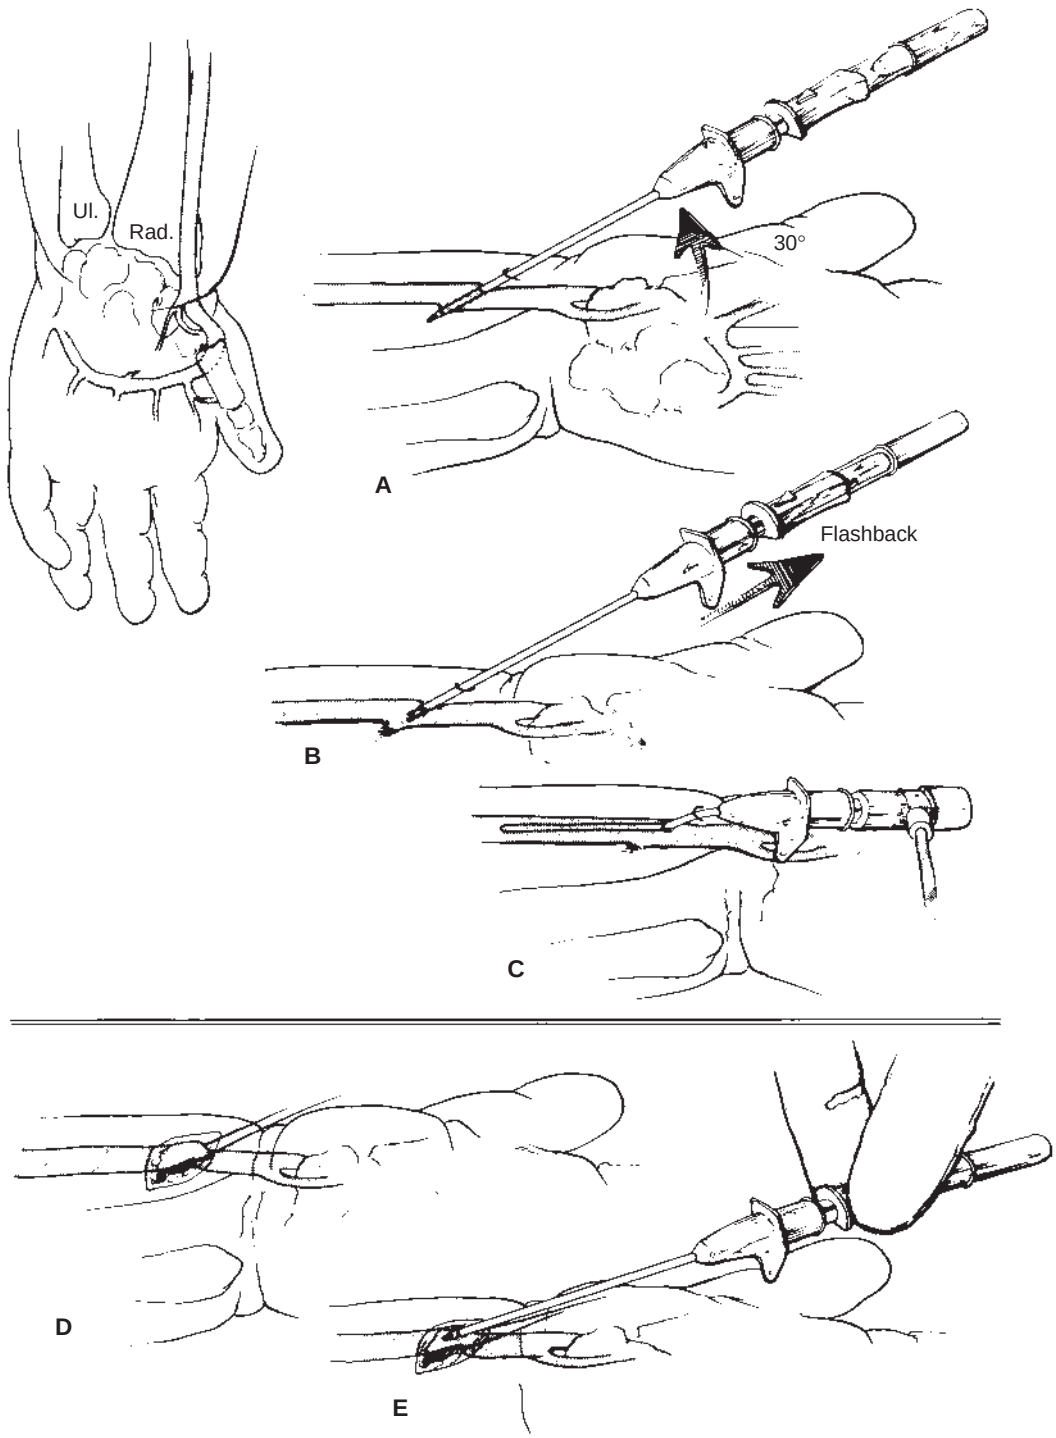
Arm board; 1- and 2-in tape; 1% lidocaine solution in a 3-mL syringe with a 25-gauge needle; 18- or 19-gauge sterile needle; povidone–iodine or chlorhexidine solution; 70% alcohol; gauze pads; catheter (20- to 24-gauge catheter over needle); T-connector, 5- or 10-mL syringe with heparin flush solution

(10 U per mL); cutdown tray; drapes; scalpel blade; 4-0 silk ties; hemostats, transparent sterile dressing

Procedure

Percutaneous

Prepare the patient and the necessary equipment. Consider a 24 gauge in less than 10 kg, young infants, 22 gauge in 10 to 40 kg and 20 gauge in more than 40 kg. Secure the child's hand and forearm to an arm board with the wrist in moderate extension using a gauze roll under the wrist. Cleanse the wrist with antiseptic solution several times and allow to dry followed by 70% alcohol and dry with sterile gauze. Locate the radial artery by palpating distally over the distal volar forearm as shown in Figure 3.7. Then, assess collateral circulation by palpation of the ulnar pulse and performance of the Allen test. After infiltration at the intended puncture site with lidocaine, make a



3.7

puncture wound with the sterile needle of the skin over the radial artery 0.5 to 1 cm proximal to the distal wrist crease.

Remove the syringe from the over-the-needle catheter system. Again, palpate the radial artery proximally to the previous puncture site while advancing the catheter through the site. After puncturing the artery and obtaining blood flow, advance the needle 1 to 2 mm farther, and then hold the needle steady and slowly advance the catheter into the vessel.

If blood flow never occurs or stops spontaneously, the needle tip may have penetrated the posterior wall of the vessel, as shown in Figure 3.7A. Remove the needle, holding the catheter steady, and begin pulling back the catheter 1 mm at a time until a sudden flash of arterial blood is identified (Fig. 3.7B). Then, advance the catheter forward into the artery. If no blood returns, make another attempt starting over again with new equipment as previously described.

If blood flow is satisfactory in the position shown in Figure 3.7C, attach the connecting tubing to the catheter with a T-connector, stopcock, and syringe, and recheck arterial flow. The catheter should be securely taped or sewn to the forearm to prevent dislodgment. Use of a transparent sterile dressing is recommended to enhance visibility and security.

Cutdown (Figs. 3.7D and 3.7E)

After preparing the equipment and the patient, the wrist is restrained, cleansed, and anesthetized as before. Wearing sterile gloves, drape the area. Make a 1-cm transverse skin incision proximal to the crease closest to the wrist joint (Fig. 3.7D). By carefully spreading the subcutaneous tissue along the incision line, visualize the artery with care to avoid cutting the adjacent veins.

The best approach is to directly puncture the exposed artery with the over-the-needle catheter setup, as shown in Figure 3.7E. A 4-0 silk tie is placed distally to the entry site and pulled to give back traction on the artery. This secures and accentuates it, usually enabling easy puncture and threading of the catheter. Attach the syringe and stopcock system, and check for patency.

The system is secured by suturing the catheter to the skin distal to the incision. Closure of the incision should be accomplished with several 4-0 skin sutures, and a dressing should be applied to stabilize and protect the system.

3.8. INTRAOSSEOUS INFUSION

Indications

This emergency intravascular access is a rapidly placed alternative if percutaneous attempts after 1 to 2 minutes are unsuccessful for life-threatening therapies. This method is especially useful in children up to 6 years of age with circulatory collapse and/or cardiac arrest but can be used at any age. In most instances, the goal is to remove the needle in 3 to 4 hours.

Complications

1. Extravasation of fluids or medications into subcutaneous tissue
2. Subcutaneous abscess, osteomyelitis, and bacteremia
3. Epiphyseal injury and fracture
4. Fat embolus

Equipment

Povidone–iodine solution; sterile gauze; gloves; drapes; 1% lidocaine; 3- to 5-mL syringe; 18- or 20-gauge intraosseous infusion needle; or IO devices (EZ-IO (Vidacare) or bone injection gun (WaisMed). Alternatives: bone marrow aspiration needle; 20-gauge lumbar puncture (LP) spinal needle; saline flush solution; IV fluids and tubing

Procedure

The preferred locations are the proximal tibia or distal femur for both ease of access and safety. The distal tibia may be used in children 3 to 4 years of age or older. By aseptic technique, prepare the selected site; then inject the skin to the periosteum with 1% lidocaine for anesthesia in the awake patient. The site for penetration of the proximal tibia is the flat, medial surface of the proximal shaft (tibial plateau) 1 to 2 cm below the tibial tuberosity (Fig. 3.8A). Alternatively, use the lower third of the femur in the midline approximately 3 cm above the lateral condyle (Fig. 3.8B). In the absence of an intraosseous needle, use a spinal needle with bevel or a bone marrow sampling needle. The distal tibia site is 1 to 2 cm proximal to the medial malleolus of the tibia (Fig. 3.8C).

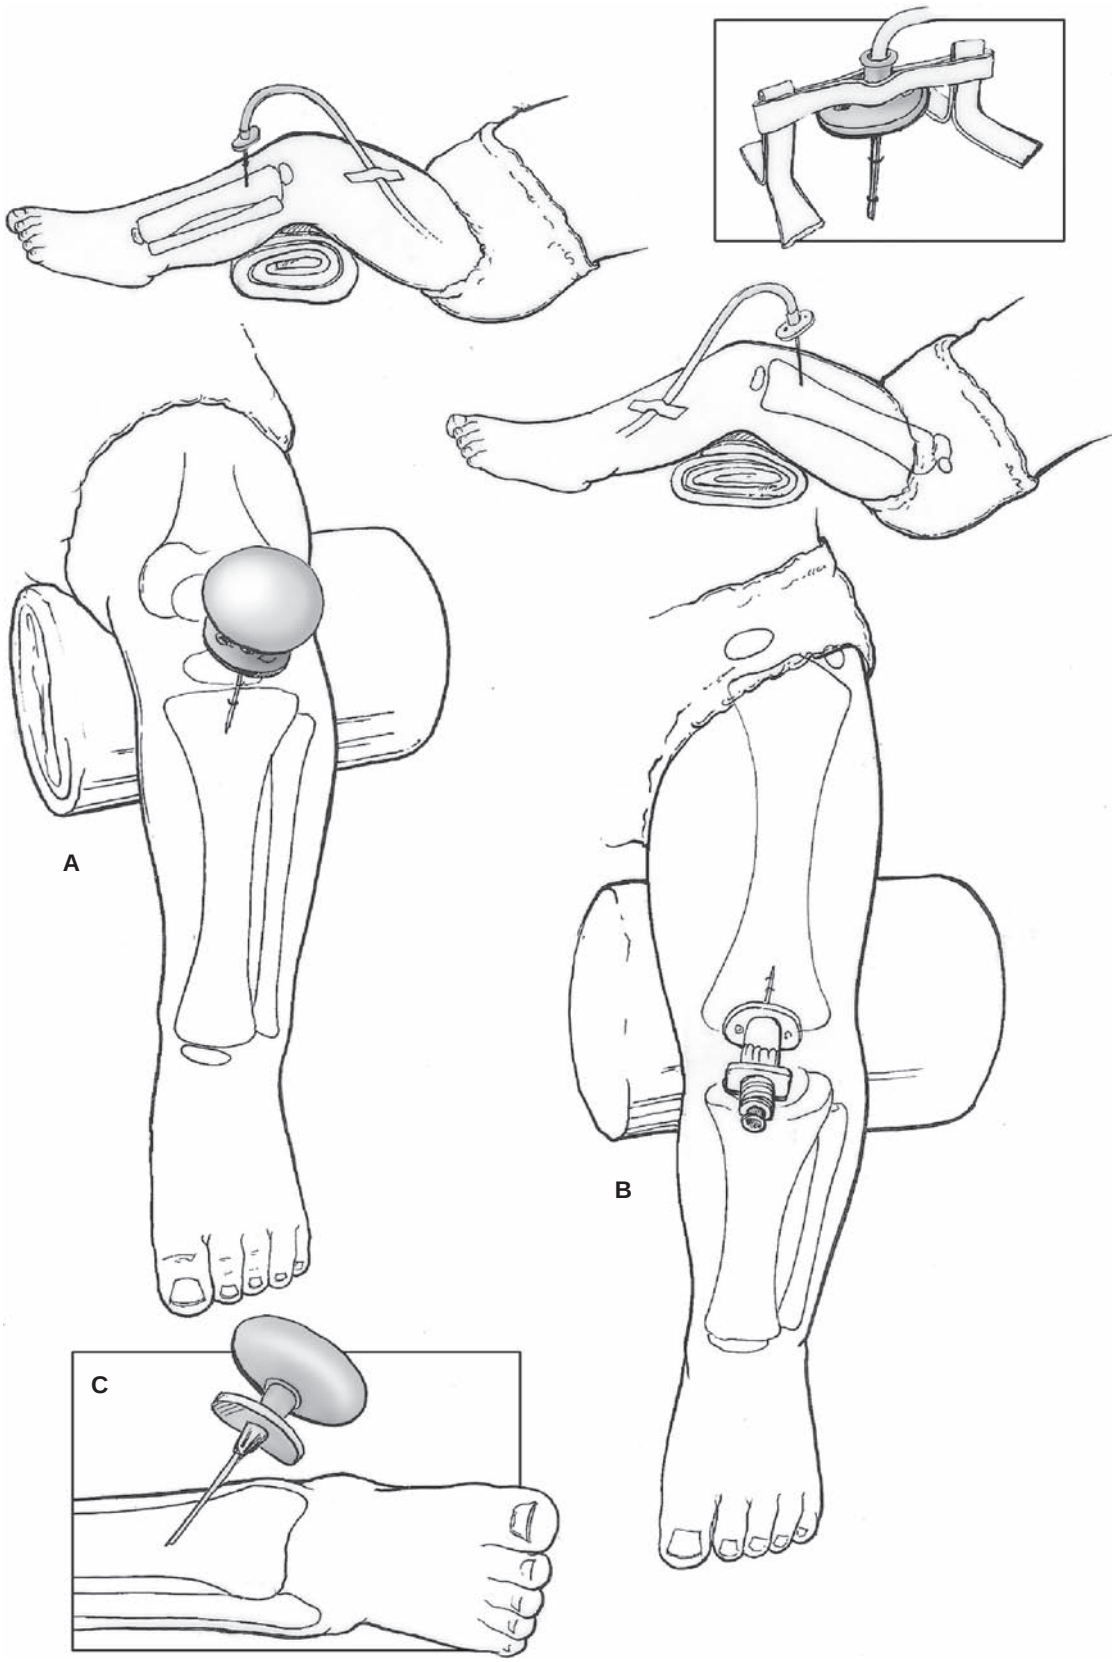
After penetrating the skin with the needle, direct it at a slight angle 10 to 15 degrees from vertical and away from the growth plate of the long bone (caudad for the tibia insertion; cephalad for the femur insertion). Apply downward pressure with a "to-and-fro" rotary motion to advance the needle. When the needle passes through the cortex of the bone into the marrow cavity, resistance will suddenly decrease (a "trap door effect"). Now the needle should stand without support. Remove the stylet and connect a 5-mL syringe to the needle. Confirm proper placement by aspiration of bone marrow; then flush the needle with heparinized saline and connect it to conventional IV infusion tubing. Observe the site for extravasation of fluid, which is an indication that either the placement is too superficial or the bone has been pierced through both sides. Restrain the leg and maintain a clean infusion site while the needle is in place.

Use of an EZ-IO for placement involves all the same preparation. Use the 15 mm size for patients under 40 kg and 25 mm for those over 40 kg. After marking of the spot to place the IO, aim the needle away from the growth plate with pressure against the skin and pull the trigger. The needle will pass into the bone and stop xx after entry to insure not advancing too far. As in the manual placement, it is important to maintain a steady pressure to guide it directly into the bone.

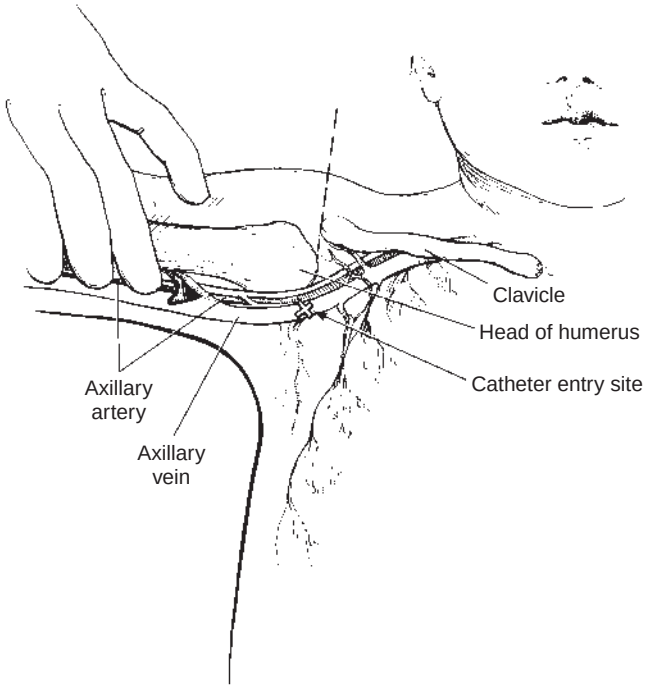
3.9. AXILLARY VEIN CATHETERIZATION

Indications

For difficult peripheral or central venous access in emergency conditions



3.8



3.9

Complications

1. Pneumothorax
2. Hematoma
3. Injury to axillary artery, median, or ulnar nerve
4. Thrombosis
5. Infection

Procedure

Use a catheter over needle (peripheral) or Seldinger technique (central) to access the vein.

Prepare the patient for the procedure, preferably placing him/her in the Trendelenburg position. Abduct the arm 90 to 130 degrees to maximize exposure. Palpate the course of the axillary artery (usually the vein is not visible, except in neonates). Prepare the site with povidone–iodine solution. Puncture the skin and enter the vein distal to the humeral head (Fig. 3.9) just inferior and anterior to the axillary artery. Be sure to be parallel to the palpated course of the axillary artery. After entering the vein, advance the catheter or place the wire through the needle as indicated. After securing the catheter, check again for flow. In use for peripheral venous placement, short catheters occasionally have flow problems with arm positioning. Apply a transparent clean dressing.

3.10. ACCESSING CENTRAL VENOUS CATHETERS

Types

1. Central venous access catheters—include brands such as Arrow, Broviac®, Hickman®, Bard®, Corcath®, Leonard®, Raaf®, and Hemed®. The access to central circulation is via cephalic, external jugular, internal jugular, brachiocephalic subclavian, or saphenous veins. Peripherally inserted central lines—PICC
2. Implanted venous access catheters—Port-A-Cath, Infuse-A-Port, and Mediport and Babyport. These devices are subcutaneous chambers attached to an IV catheter, which are surgically implanted.

Indications

1. IV fluid administration
2. Medication administration
3. Phlebotomy

Equipment

Central Venous Catheters

1. Sterile gloves, mask, and eyewear
2. Povidone–iodine solution
3. Sterile drapes
4. Catheter clamp or hemostat without teeth
5. Three needles (18-, 19-, or 20-gauge)
6. 10-mL syringe with normal saline flush
7. 5-mL syringe with heparin (100 U per mL)
8. Two sterile 10-mL syringes (for phlebotomy)
9. Fluids and/or medications to be administered
10. 4 × 4 gauze pads

Implantable Venous Access Catheters

1. Sterile gloves, mask, and eyewear
2. Povidone–iodine solution
3. Sterile drapes
4. Two Huber needles (19-, 20-, or 22-gauge) with 90-degree bend or standard 19-gauge needle in an emergency
5. Extension tubing with clamp or stopcock
6. 10-mL syringe with normal saline flush
7. 5-mL syringe with heparin solution (100 U per mL)
8. 4 × 4 gauze pads
9. Silk tape
10. Fluids and/or medications to be administered

Complications

1. Line sepsis
2. Air embolus
3. Perforation of catheter
4. Embolization of thrombi while flushing
5. Catheter displacement
6. Cardiac arrhythmias
7. Infusion of medications that interact with silicone, i.e., phenytoin, diazepam
8. Infusion of incompatible medications.

Procedure

Central Venous Catheters

Sterile technique should be maintained at all times. Clamp catheter (clamp will be on catheter or a hemostat without teeth

can be used). Remove cap. Place a 10-mL syringe with normal saline flush, unclamp, and inject 5 mL; then withdraw from the central catheter to ensure patency. Clamp catheter. Bolus medication or venous fluids should be attached to end of catheter. Unclamp and open solutions to infuse.

If a blood specimen needs to be drawn, clamp catheter. Place a 10-mL syringe on the end of the catheter. Unclamp and withdraw approximate dead space solution (5 to 10 mL). Clamp. Place a separate 10-mL syringe and withdraw the desired amount of blood sample. Clamp. When blood drawing is completed, flush with normal saline and then heparin. In small infants or when sampling may be frequent, consider reinfusing the initial blood sample to clear the line to the patient prior to the saline flush and heparin. After completion, clamp and replace the cap.

If difficulty occurs with blood flow from catheter, this may be secondary to catheter placement, clot, or malfunction. Certain maneuvers that may aid in blood flow include placement of the patient in reverse Trendelenburg position, placing slight tension on the catheter, holding patient's arms over head, or use of a Valsalva maneuver. Withdrawing with force will only collapse the tubing. If the aforementioned maneuvers are not successful, gently flush catheter with 3 to 5 mL of heparin solution (100 U per mL). If this attempt fails, streptokinase or urokinase may be used, which is detailed to follow.

Implantable Venous Access Catheters (Fig. 3.10)

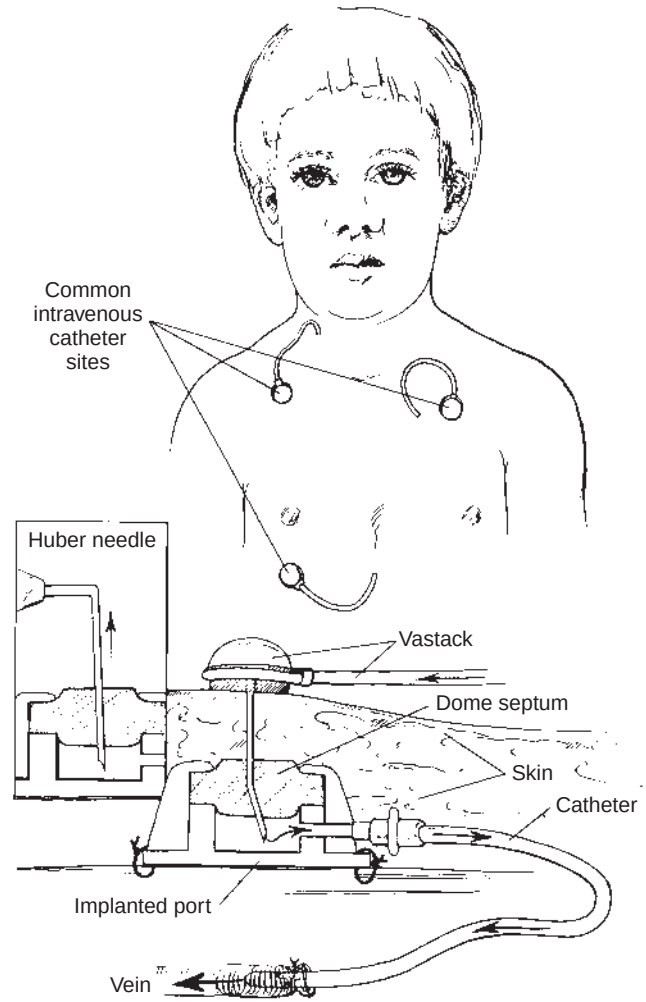
Sterile technique should be maintained at all times. Palpate the circular reservoir. Prepare the overlying skin with povidone–iodine solution. If have time, consider placement of topical anesthetic 30 to 40 minutes before access is desired. Connect the Huber needle to extension tubing at one end, and syringe with normal saline at other end. Tubing should be purged with normal saline and the clamp closed. Insert the Huber needle slowly through the skin into the septum of the circular reservoir until the back of the reservoir is reached. Unclamp and slowly inject saline. Watch for local infiltration, which may occur if the needle is not properly placed. Gently withdraw the plunger of the syringe to ensure placement. Lack of blood return is not an absolute contraindication for use. Blood drawing is accomplished through extension tubing after clearing the line of dead space solution. Medications or IV fluids may be attached. Remember that normal saline flush should be administered between medications. Flush with 5 mL of heparinized solution when medication or venous fluid administration is complete or blood drawing is accomplished. Remove the Huber needle.

Nonpatent Catheters—Use of Fibrinolytics

When central venous catheters or implantable catheters are not readily accessed, the most common reason is a clot being present. In the absence of central nervous system (CNS) or respiratory distress, the clinician should consider use of a fibrinolytic to assist in clot dissolution.

Urokinase (5,000 U per mL) or Streptokinase (10,000 U per 3 mL)

For 3F or 4F catheter, inject 0.5 mL into the catheter. Use 1 mL for larger size. The volume should approximate the catheter lumen priming volume. Allow to stand within the catheter for 20 minutes. Then, attempt to withdraw blood or dot with a 5- to 10-mL syringe. If this is unsuccessful, consider repeating one more time.



3.10

For more complex problems, including consideration of other precipitants, refer to the staff caring for the catheter or other texts. Because urokinase is biological, be sure to weigh the risk of its use in children at risk.

4.1. LUMBAR PUNCTURE

Indications

To obtain cerebrospinal fluid (CSF) for the diagnosis of meningitis, meningoencephalitis, subarachnoid hemorrhage, and other neurologic syndromes

Complications

1. Headache (uncommon in children younger than 10 years of age)
2. Apnea (central or obstructive)
3. Local back pain—occasionally with short-lived referred limp

4. Spinal cord bleeding—especially in the presence of bleeding diathesis
5. Infection
6. Subarachnoid epidermal cyst—secondary to foreign-body reaction
7. Ocular muscle palsy (transient)
8. Epidural CSF leak—asymptomatic to cauda equina syndrome
9. Brainstem herniation—in the presence of symptomatic intracranial hypertension

Equipment

Commercial trays; CSF manometers; spinal needle—22 gauge; 3.75 cm (1.5 in) for younger than 1 year old, 6.25 cm (2.5 in) for 1 year to middle childhood, and 8.75 cm (3.5 in) for older children and adolescents; povidone–iodine solution; consider EMLA® or Zylocaine® cream

Procedure

Lateral Decubitus Position

Restrain the patient in the lateral decubitus position. Maximally flex the spine without compromising the upper airway. Often, in infants younger than 3 months, the patient's hands can be held down between the flexed knees with one of the assistant's hands. The other hand can flex the neck at the appropriate time.

The spinal cord ends at approximately the level of the L1 and L2 vertebral bodies. Caudal to L2, only the filum terminale is present. The desired sites for LP are the interspaces between the posterior elements of L3 and L4 or L4 and L5. Locate these spaces by palpating the iliac crest (Fig. 4.1B, parts A and D). Follow an imaginary "plumb line" from the iliac crest to the spine. The interspace encountered is L4–L5. Use it or the one cephalad to it.

Use sterile technique for the LP. Cleanse the skin with povidone–iodine solution after donning sterile gloves. Using sponges, begin at the intended puncture site and sponge in widening circles until an area 10 cm in diameter has been cleansed. Repeat this three times. Drape the child beneath his/her flank and over the back with the spine accessible to view (as in Fig. 4.1A). Allow the solution to dry.

Use local anesthesia in children—this includes placement of EMLA® or ELA-Max® cream 45 to 60 minutes before LP when time is available. Alternatively, anesthetize the site by injecting 1% lidocaine intradermally to raise a wheal, then advance the needle into desired interspace, injecting anesthetic and being careful not to inject it into a blood vessel or spinal canal.

4.1A

Check the spinal needle and ensure the stylet is secure. Grasp the spinal needle firmly with the bevel facing "up" toward the ceiling, making the bevel parallel to the direction of the fibers of the ligamentum flavum. Recheck the patient's position to ensure the needle's trajectory is midsagittal to his/her back. Insert the needle into the skin over the selected interspace in the midline sagittal plane. Two methods of stabilizing and guiding the needle are shown (Fig. 4.1B, parts B and D). Insert the needle slowly, aiming slightly cephalad toward the umbilicus. When the ligamentum flavum and then the dura are punctured, a "pop" and decreased resistance are felt. Remove the stylet and check for flow of spinal fluid. If no fluid is obtained, reinsert the stylet, advance the needle slowly, and check frequently for the appearance of CSF. An alternative to keeping the stylet in during the procedure is to remove it after the needle is inserted into the skin. Introducing the needle without a stylet from the start increases the risk of a small bit of epidermis entering the spinal needle and either blocking it from CSF drainage or being unintentionally introduced into the CSF space, where a epidermoid cyst may be produced. When CSF flows, attach the manometer to the needle's hub if you are to obtain an opening pressure reading. Collect 1 mL of CSF in each of the three sterile tubes. Send the CSF for routine culture, glucose and protein determination, and cell count. Collect additional tubes as indicated. After collecting CSF, a closing pressure can be obtained. Reinsert the stylet and then remove the spinal needle with one quick motion. Cleanse the back and cover the puncture site.

Sitting Position

Restrain the infant in the seated position with maximal spinal flexion (Fig. 4.1B, part C). Have the assistant hold the infant's hands between his/her flexed legs with one hand and flex the infant's head with the other hand.

Place drapes underneath the child's buttocks and on the shoulders with an opening near the intended spinal puncture site. Choose the interspace as noted earlier and follow the procedure as outlined for the lateral position. Insert the needle so it runs parallel to the spinal cord (Fig. 4.1B, part D).

PROCEDURES

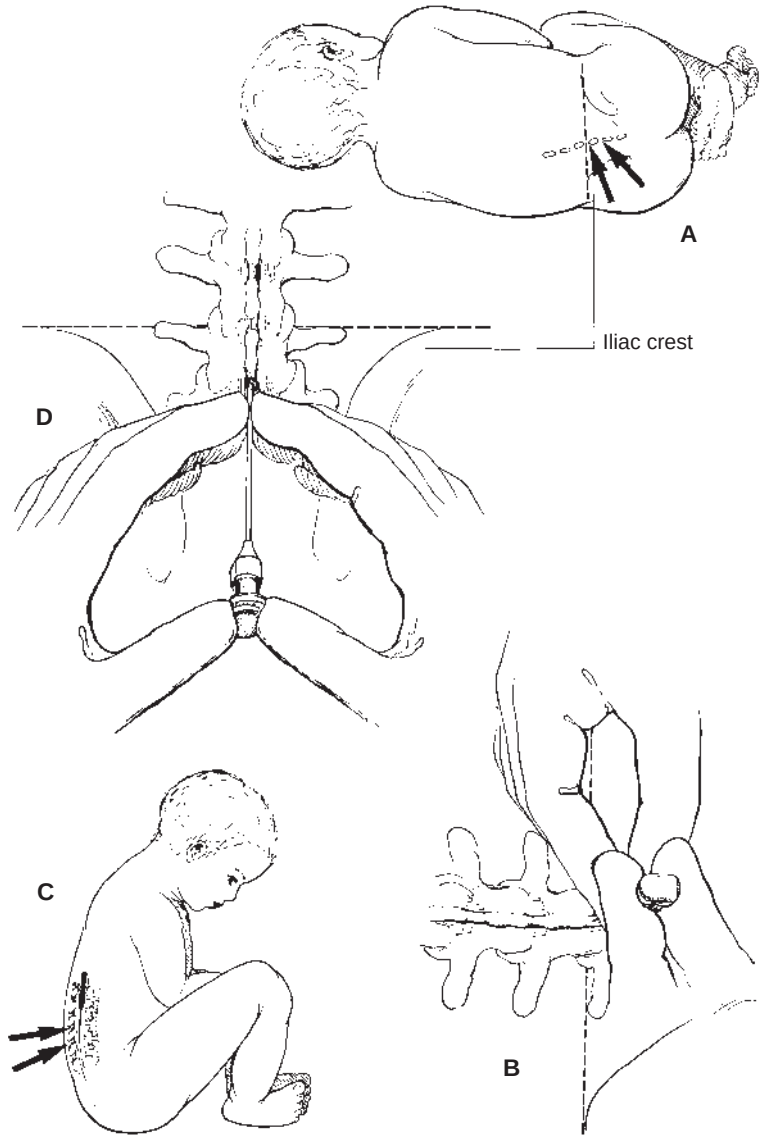
4.2. EVALUATION OF VENTRICULOPERITONEAL SHUNT

Indications

To evaluate the role of shunt malfunction as the cause of signs and symptoms, including vomiting, drowsiness, headache, seizures, bradycardia, coma, focal neurologic findings, or swelling around the shunt site

Complications

1. Proximal shunt dysfunction—Repetitive pumping of a functioning shunt may lead to blockage of the proximal



4.1B

shunt with tissue from the choroid plexus or blood from irritation of the ventricular wall.

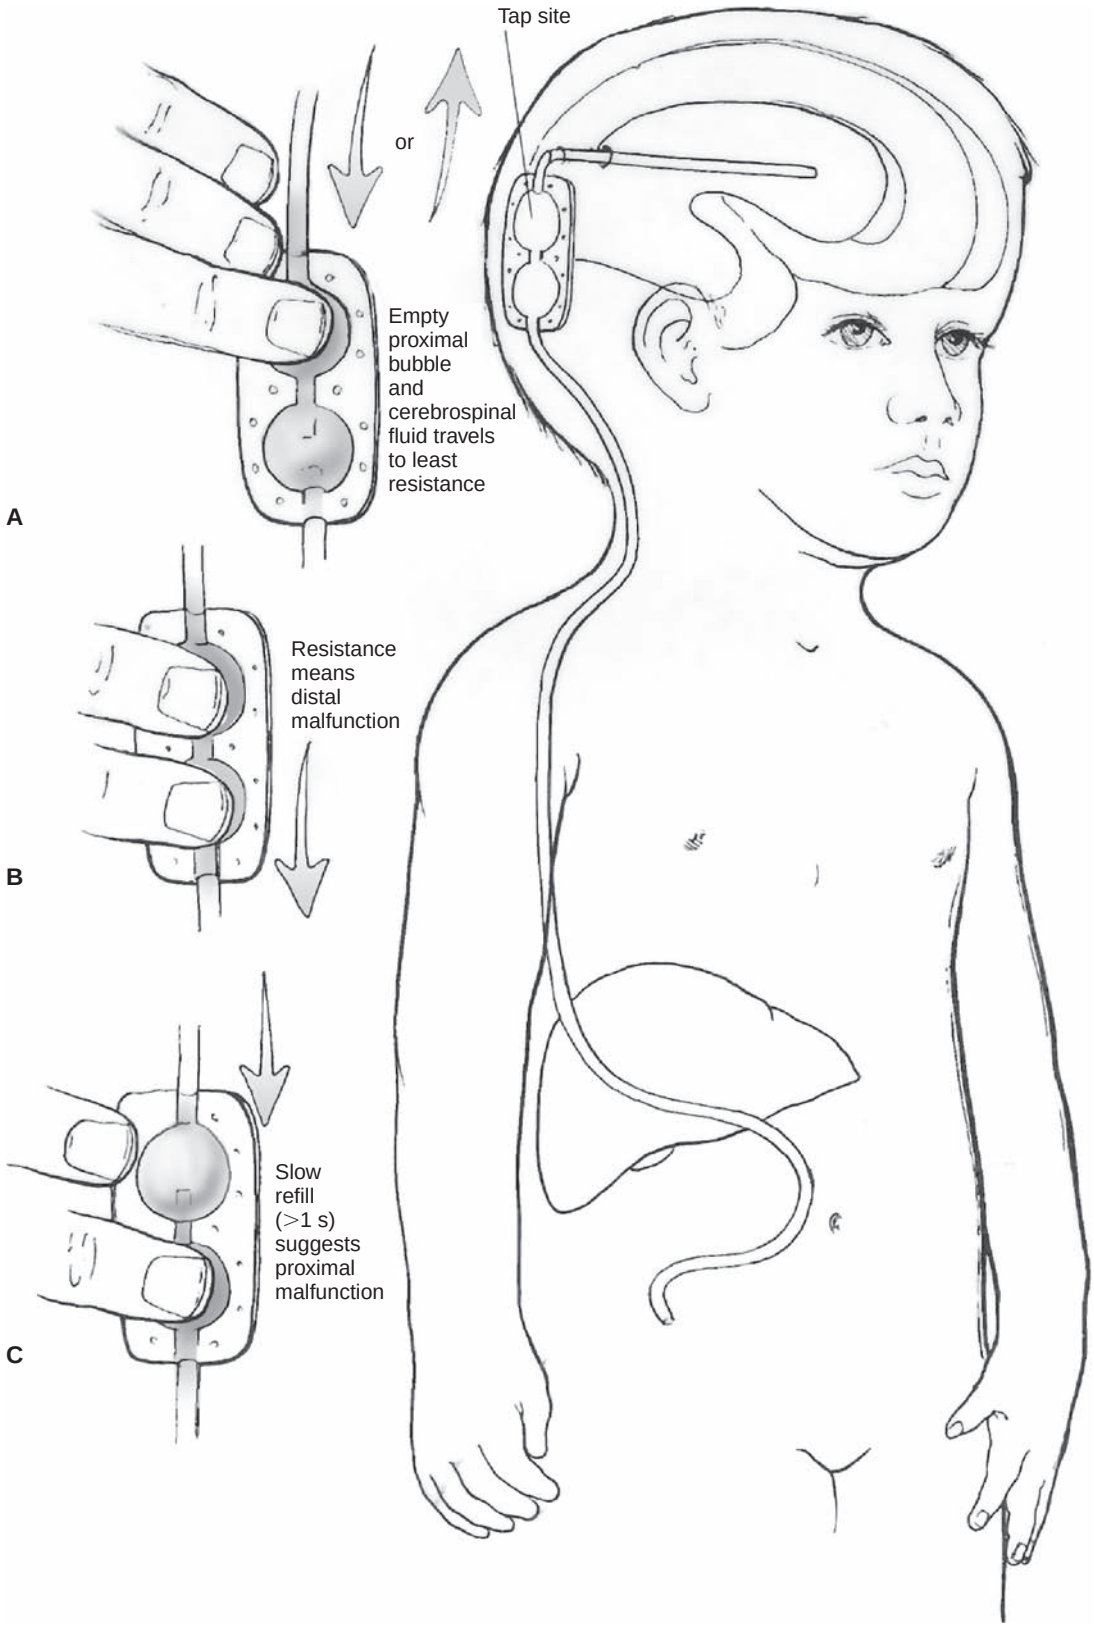
2. CSF leakage—If a complete blockage occurs distally, some patients develop a CSF collection in the subgaleal space that may be exacerbated by vigorous pumping.

Procedure

Figures 4.2 and 4.3 show two types of common permanent ventricular drainage systems. Figure 4.2 is a "double-bubble" ventriculoperitoneal shunt. Its distal end, located in the abdominal cavity, has a one-way valve. The shunt tubing travels from the lateral ventricle, through the skull, to the subcutaneous space of the scalp where a right angle is made. At this point, it connects to a double-bubble rubber reservoir that lies posterior and superior to the ear in the parietooccipital area of the skull. Finally, it continues subcutaneously, as shown, to the abdominal cavity, where the CSF drains, if the system functions properly, and is absorbed by the peritoneum.

To check the function and patency of the system, place the child in a comfortable position during the physical examination. Locate the tubing and trace its entire course to look for disconnections, fluid accumulations, or short tubing length at the distal end. This should not cause pain, as it involves only mild pressure on skin surface.

In Figure 4.2, three maneuvers to assess patency are shown. First, compress the proximal bubble as in Figure 4.2A. This ensures filling of the distal bubble for the next step and empties the chamber to test proximal blockage later. While still compressing proximally, place a finger over the distal bubble and compress it as in Figure 4.2B. Normally, there is no resistance to emptying of fluid through the valve into the abdominal cavity. Undue pressure suggests a distal tube blockage, disconnection, or insufficient tube length owing to the growth of the child. Finally, release the proximal bubble as in Figure 4.2C.



Tap site
or
Empty proximal bubble and cerebrospinal fluid travels to least resistance
A
Resistance means distal malfunction
B
Slow refill (>1 s) suggests proximal malfunction
C

4.2

Now the negative pressure in this bubble should suck fluid into it from the ventricular cavity, usually within 1 second. Any longer delay in filling often suggests a proximal blockage; however, if the shunt has been pumped several times in the previous hours, it may fill slowly because the proximal tip is sitting against the choroid plexus. Because there is no proximal valve, when the distal bubble is compressed, the proximal bubble can be repeatedly depressed to measure resistance to filling of the proximal shunt without draining excessive fluid from above.

Figure 4.3 shows the very common single-reservoir, single-pump shunt. When present, the circular chamber perpendicular to the shunt entering the skull is a reservoir for obtaining specimens. More distally a compressible rubber pump with a pressure valve is connected on each end to plastic tubing. In most, there is a valve often near the reservoir, which controls flow. It may be an in-line valve as part of the distal catheter. To pump this type, compress and release the distal soft tube, checking for refill. Each compression will test distal patency, whereas the release verifies proximal patency. Generally, the release is immediate in this shunt, so any delay of filling suggests blockage or choroid collapse. Because the connections of the pump to the shunt tubing are purse strings on either end, this system can disconnect and leak CSF subcutaneously.

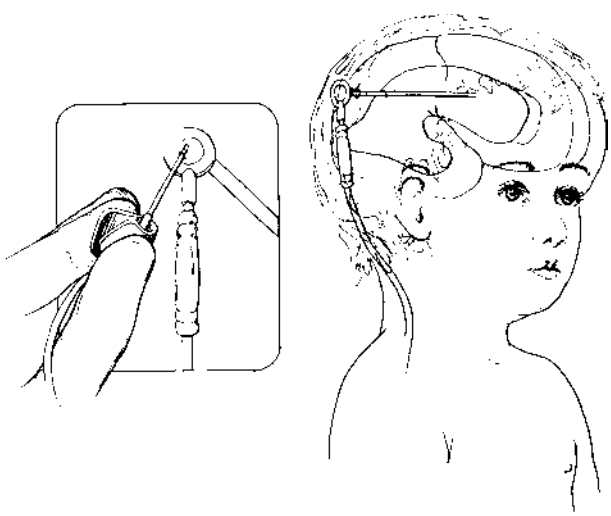
4.3. DIAGNOSTIC TAP OF VENTRICULOPERITONEAL SHUNT

Indications

1. Reduction of intracranial pressure in a child with acute symptomatic hydrocephalus typically from shunt obstruction
2. Diagnostic evaluation of possible ventricular or shunt infection

Complications

1. Infection
2. CSF leak
3. Local hematoma



4.3

Equipment

Butterfly infusion set, 23 or 25 gauge; 5- to 10-mL syringe; sterile collection tubes; manometer; sterile gloves, sterile gauze; povidone–iodine solution; 70% alcohol; razor blade; sterile drape; EMLA® or anesthetic cream; 1% lidocaine with needle and syringe

Procedure

Locate the reservoir and pump(s), and assess the function of the shunt if the symptoms are suggestive of blockage. When time permits 45 to 60 minutes to procedure, consider the application anesthetic cream to skin over the tap site. Restrain the patient in the supine position with the face turned toward the shoulder and the shunt reservoir facing up; shave the hair directly around the reservoir. Wash the site several times with povidone–iodine solution in a circumferential fashion; clean it off when dry with 70% alcohol and dry the area with sterile gauze. Don sterile gloves. Palpate the reservoir with one gloved finger (Figs. 4.2 and 4.3). Puncture the skin and quickly enter the reservoir. If distal obstruction is present, the fluid will be under considerable pressure and will flow readily. Attach the manometer immediately and standardize the zero mark on it at the level of the cerebral ventricles. Samples of CSF are collected aseptically into sterile tubes. Use slight negative pressure on the syringe to enhance flow if proximal obstruction or viscous infected fluid is evident. Drainage may be continued until the CSF pressure is between 10 to 20 mL (cm H_20). Refrain from applying suction on the syringe to minimize the chance of choroid plexus entering the shunt if the ventricle were to collapse around the proximal shunt.

Figure 4.3 shows a single reservoir system being tapped. In general, on the double-bubble setup, puncture the proximal bubble in a similar fashion as described earlier.

4.4. SUBDURAL TAP

Indications

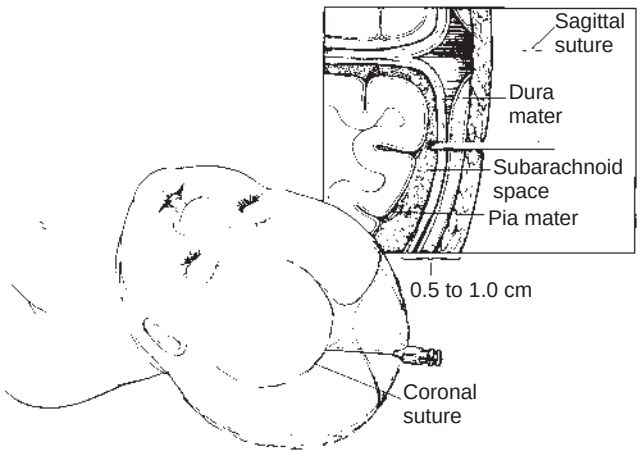
Evacuations of subdural blood or fluid in young infants, when such collections cause symptoms (i.e., seizures, unilateral paresis) from increased intracranial pressure

Complications

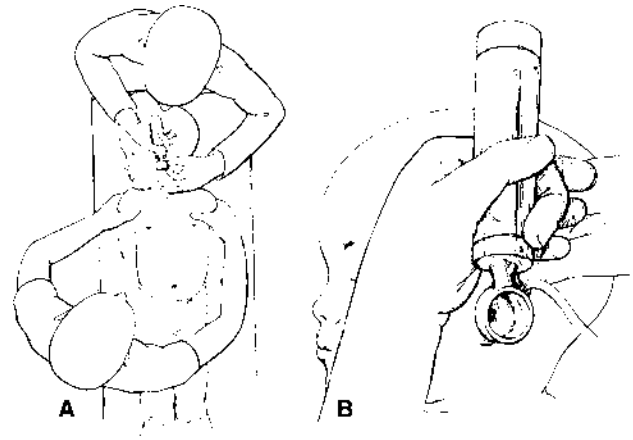
1. Intracranial hemorrhage
2. Contusion of the cerebral cortex
3. Subgaleal collection of fluid or blood
4. Infection

Equipment

Subdural or spinal needle (19 or 20 gauge); 10-mL syringe; razor blade; povidone–iodine solution; 70% alcohol; sterile gauze; 1% lidocaine with epinephrine; 22- and 25-gauge needles (Fig. 4.4); strongly consider pharmacologic sedation



4.4



5.1

Procedure

Prepare the infant for the procedure in the supine position after performing the appropriate measures for resuscitation and stabilization. Have an assistant restrain the patient in a mummy wrap or by leaning over the infant with his/her arms firmly pinned at the side. The head should be face up. Continuous monitoring of the cardiorespiratory status is essential.

Shave the scalp widely in an area around the lateral boundaries of the anterior fontanel (the anterior two thirds of the head). Prepare the site(s) with povidone–iodine solution and 70% alcohol, and then dry with sterile gauze. Wearing sterile gloves, palpate the coronal suture at the lateral aspect of the anterior fontanel. If the fontanel opening is extremely small, move several millimeters farther laterally in the coronal suture. Inject local anesthetic (i.e., 1% lidocaine with epinephrine) in the conscious child.

Grasp a 19- or 20-gauge subdural or spinal needle by the hub and check its patency. Hold it between the thumb and index finger, and rest the heel of the hand against the infant's scalp. Puncture the skin at a right angle to surface, stretching it slightly to obtain a Z-track. Advance the needle through the puncture site between the edges of the coronal suture until the feeling of resistance lessens. Then, remove the stylet to allow fluid or blood to drain; 10 to 15 mL can be safely evacuated from each side. Normally, the needle is not advanced more than 5 to 8 mm below the scalp's surface. Some infants may require bilateral taps.

5.1. PNEUMATIC OTOSCOPIC EXAMINATION

Indications

Evaluation of middle ear

Complications

Pain or bleeding from contusion or laceration of the external canal

Procedure

To safely and accurately evaluate the middle ear structures in infants, the lack of movement while performing the examination is critical. In many infants, this requires appropriate restraint. Many young children fear the approach of a physician, particularly to examine their ears. Usually a parent can provide proper immobilization. Place the infant supine on the examination table, and ask a parent to hold the arms firmly against the trunk (Fig. 5.1A) or against the head, grasping them just above the elbow. When assisting, the parent may hold his/her hand across the forehead against his/her own chest to minimize movement. Hold the otoscope as shown in Figure 5.1B, grasping it between the thumb and index finger of the dominant hand. The heel of the hand should rest against the anterior portion of the infant's head to maintain constant, firm pressure against the temporal skull while bringing the infant's head horizontal to the table. This assists the operator in ensuring the otoscope will move in conjunction with the child if he/she is not still during the procedure.

Once the infant is restrained, use the other hand to grasp the upper portion of the helix, stretching it superiorly and posteriorly in the child to straighten the external canal. In young infants, pull the helix inferiorly and posteriorly to best visualize the tympanic membrane. Simultaneously, observe the entrance to the auditory canal through the otoscope and flex the thumb to direct the speculum down the canal entrance. Then, straightening of the external canal is performed under direct visualization. The removal of cerumen obscuring the field may be necessary (see Procedure 5.3). Observe the tympanic membrane for color, contour, and presence of the bony and vascular landmarks (see the "Otitis Media" section in Chapter 54).

For evaluation of the compliance of the tympanic membrane, a tight seal is required between the auditory canal and the speculum. If the diameter of the speculum is found to be less than that of the canal, replace it with one of a larger size. Reenter the canal to one third to one half of its depth, establish a seal, and lightly squeeze the bulb while observing the tympanic membrane.

5.2. TYMPANOCENTESIS

Indications

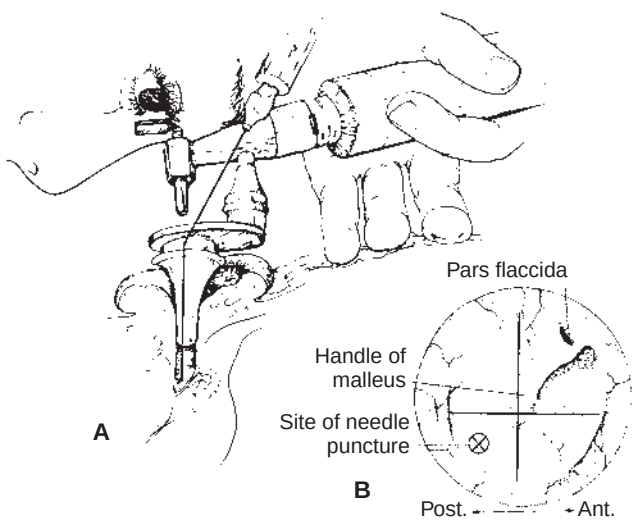
1. Otitis media unresponsive to conventional therapy in the neonate, in the immunosuppressed child, or with complications (with meningitis or brain abscess)
2. Relief of severe pain as a result of otitis media

Complications

1. Bleeding
2. Disarticulation of the ossicular chain
3. Laceration of the tympanic membrane or canal wall
4. Contamination of middle ear by bacteria in the external canal

Procedure

After full explanation of the procedure to the parents and patient, obtain consent including the use of pharmacologic sedation to reduce anxiety and movement. Prepare all equipment, include child life assistance if available and restrain the child securely in a supine position. Use the mummy or papoose restraint, or ask an assistant to restrain the trunk. Have the child's head held in the horizontal plane by an assistant. Visualize the external canal and clean any wax or debris from it. When available, use of operating head otoscope improves visualization of landmarks. Sterilize the ear canal by filling it with 70% alcohol or povidone–iodine solution for 60 seconds, and then drain out excess solution by placing the ear down. Again restrain the child's head in the horizontal plane, and visualize the tympanic membrane with an otoscope fitted with an operating head. Insert the aspiration set (a 22-gauge, 8- to 10-cm spinal needle bent 30 degrees 4 to 5 cm from the tip and attached to a 1-mL tuberculin syringe) into the otoscope, through the speculum as shown in Figure 5.2A. Pierce the eardrum as shown (Fig. 5.2B) in the inferoposterior quadrant. After entering the middle ear, aspirate with the syringe. Care should be taken not to contaminate the needle by touching the ear canal or otoscopic speculum. If only a small amount of fluid is obtained, flush the spinal needle with nonbacteriostatic normal saline.



5.2

5.3. REMOVAL OF A FOREIGN BODY FROM THE EAR

Indications

1. Foreign body
2. Obstruction of the external canal by cerumen

Complications

1. Laceration of the canal wall
2. Perforation of the tympanic membrane
3. Ossicular disruption

Procedure

Three methods are available for removal of a foreign body; all require cooperation from, or restraint of, the child. Other options include pharmacologic sedation to assist the operator. Because the material may not be emergent to remove and may be difficult in this setting, it is often ideal not to go to extreme measures where there may be local trauma or unnecessary anxiety/pain and to refer to an ear, nose, and throat specialist for more elective removal. Because a minor laceration of the ear canal is often unavoidable, the parents should be aware of this complication before the physician undertakes the use of a curette or forceps. After removal of foreign body or cerumen by any method, it is important to visualize the eardrum and document its condition.

Curette (Fig. 5.3A)

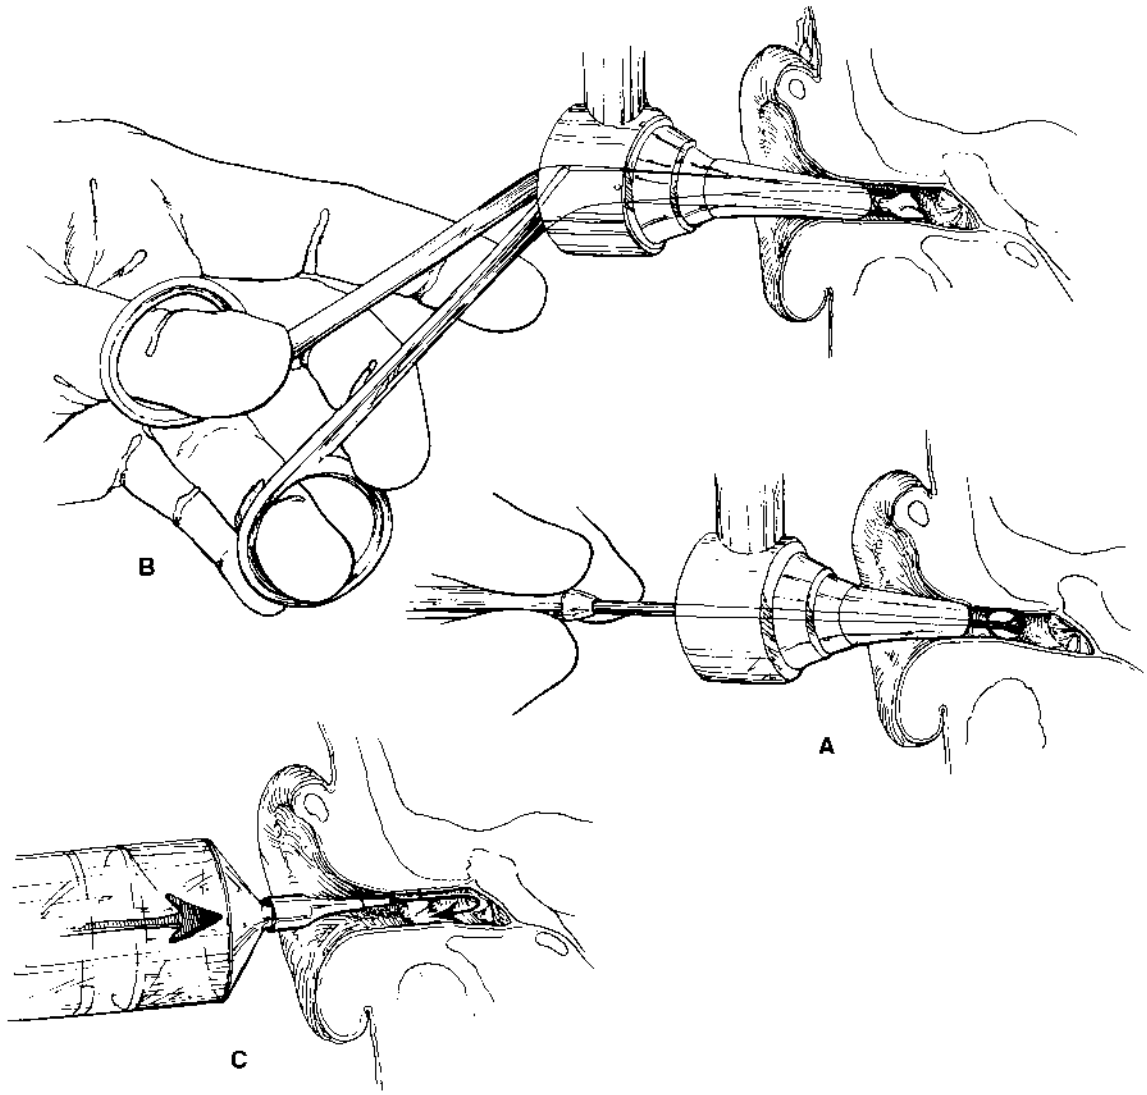
Visualize the foreign body with a speculum, preferably using an operating head otoscope. Then, slowly advance the curette just beyond the foreign body as shown. While applying pressure to the foreign body, slowly withdraw the curette until the foreign body is removed.

Forceps (Fig. 5.3B)

Visualize the foreign body with a speculum and look for a protruding edge of the foreign material. Carefully guide the forceps in the closed position under direct visualization through the speculum. Just a few millimeters from the edge of the foreign body, open the forceps and grasp the edge gently. Withdraw the forceps, visualizing the foreign body simultaneously to minimize the chance of a complication.

Irrigation (Fig. 5.3C)

Straighten the ear canal and visualize the foreign body directly with a speculum, ensuring the tympanic membrane is intact. If the foreign body is spongy or could be expansile when wet, such as a bean or other food material, do not use this method.



5.3

Do not attempt to remove a disc battery with irrigation. Remove the speculum and irrigate the ear canal by injecting a constant stream of water at body temperature. Use a 20- to 50-mL syringe attached to a flexible IV catheter tip (i.e., a cut section of tubing from a butterfly needle). Repeated irrigation may be necessary to provide complete emptying.

5.4. ASPIRATION OF AN AURICULAR HEMATOMA

Indications

Traumatic auricular hematoma or seroma

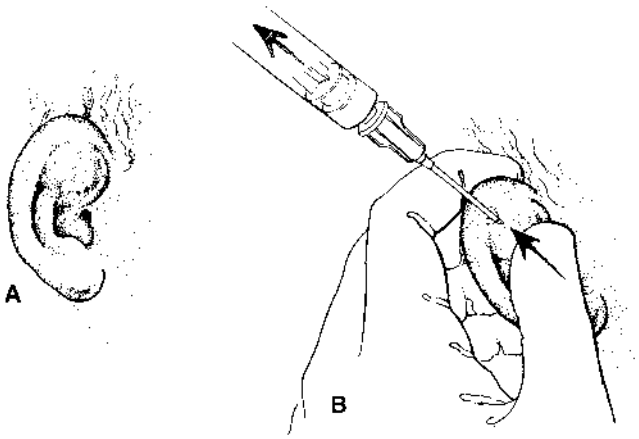
Complications

1. Recurrent hematoma or seroma
2. Infection (abscess)

Procedure

Restrain the child in a standard method. Palpate the hematoma to find the most fluctuant portion. Cleanse the skin over the hematoma with povidone–iodine solution and dry with sterile gauze. Topical anesthesia may be provided with EMLA® or topical lidocaine directly applied 30 to 45 minutes before aspiration on the hematoma. In very anxious children or those requiring longer procedure, consider the use of pharmacologic sedation prior to the procedure.

Use a 10- or 20-mL syringe with an 18-gauge straight needle. While stabilizing the syringe against the scalp with the nondominant gloved hand, puncture the most fluctuant portion of the hematoma with the needle (Figs. 5.4A and 5.4B). Maintain negative pressure on the syringe with one hand, while "milking" the hematoma with the thumb and index finger of the other. Withdraw the needle after emptying the hematoma, but continue to maintain pressure on the auricle between the thumb and the finger to tamponade any ongoing bleeding for 3 to 5 minutes. If blood clots are difficult to



5.4

remove, consider use of a curved hemostat to improve the evacuation. With wet cotton pledgets, reestablish the normal ear contours and apply a pressure dressing. Arrange for follow-up in 12 to 24 hours to have the dressing unwrapped, check the ear, and redress.

6.1. EVERSION OF THE EYELIDS

Indications

1. Identification of a foreign body or infection
2. Instillation of medications to the conjunctiva
3. Removal of a foreign body

Complications

Mild contusion or ecchymoses (rarely)

Procedure

Have an assistant restrain the infant on the examination table in the supine position with the arms wrapped around the head. Alternatively, small infants can sit on the lap of a parent who then holds the infant's head still. Older cooperative patients may sit up for the procedure.

Upper Lid

Upper lid eversion is the more difficult, normally requiring cooperation or restraint, because the examiner needs to use both hands. After restraint, grasp the eyelash and distal upper lid between the index finger and the thumb. Ask the child to look down at the floor if he/she will cooperate. Draw the eyelid downward as shown in Figure 6.1A. Place a clean cotton swab across the superior tarsal margin, as shown in Figure 6.1B. In one motion, move the swab slightly downward and pull the eyelid slightly upward. This maneuver should bend the eyelid slightly upward and backward and expose the palpebral surface, as shown in Figure 6.1C. To restore the lid to its usual position, lift the swab slightly while maintaining pressure along the upper lid margin, and turn the thumb and index finger downward.

Lower Lid

Place a thumb or finger at the base of the lower lid and gently retract it in a caudal and posterior direction while the child looks upward (Fig. 6.1D). While the eyelid is everted, removal of a foreign body can be accomplished. Use a clean cotton swab and apply it to the foreign body to flick it from the conjunctival surface.

6.2. IRRIGATION OF THE CONJUNCTIVA

Indications

Presence of a foreign body or caustic substance on the cornea or conjunctiva

Complications

1. Subconjunctival hemorrhage or corneal abrasion (rare) in a child who is not adequately restrained
2. Conjunctival erythema

Procedure

Place the child supine over a large sink or pail, as shown in Figure 6.2. To restrain an uncooperative child, two assistants are necessary. The person holding the head should wear a gown and may use gauze under each thumb to help keep the eyelids open. For foreign-body removal, where delay of a few minutes will not lead to further injury, place one to two drops of ophthalmic anesthetic on the conjunctiva. Allow bacteriostatic normal saline solution (between room and body temperature) to flow through a set of IV tubing. Drip the fluid rapidly into the conjunctival sac. Irrigate for a minimum of 5 minutes for acid using at least 1 liter. Irrigate for 20 minutes for alkali or unknown substances using at least 2 liters. Tap water at room temperature is an acceptable alternative for irrigation fluid, especially if it can be done immediately, such as in a home or office setting.

After irrigation, the eye should be carefully examined for corneal and conjunctival integrity, including staining with fluorescein dye.

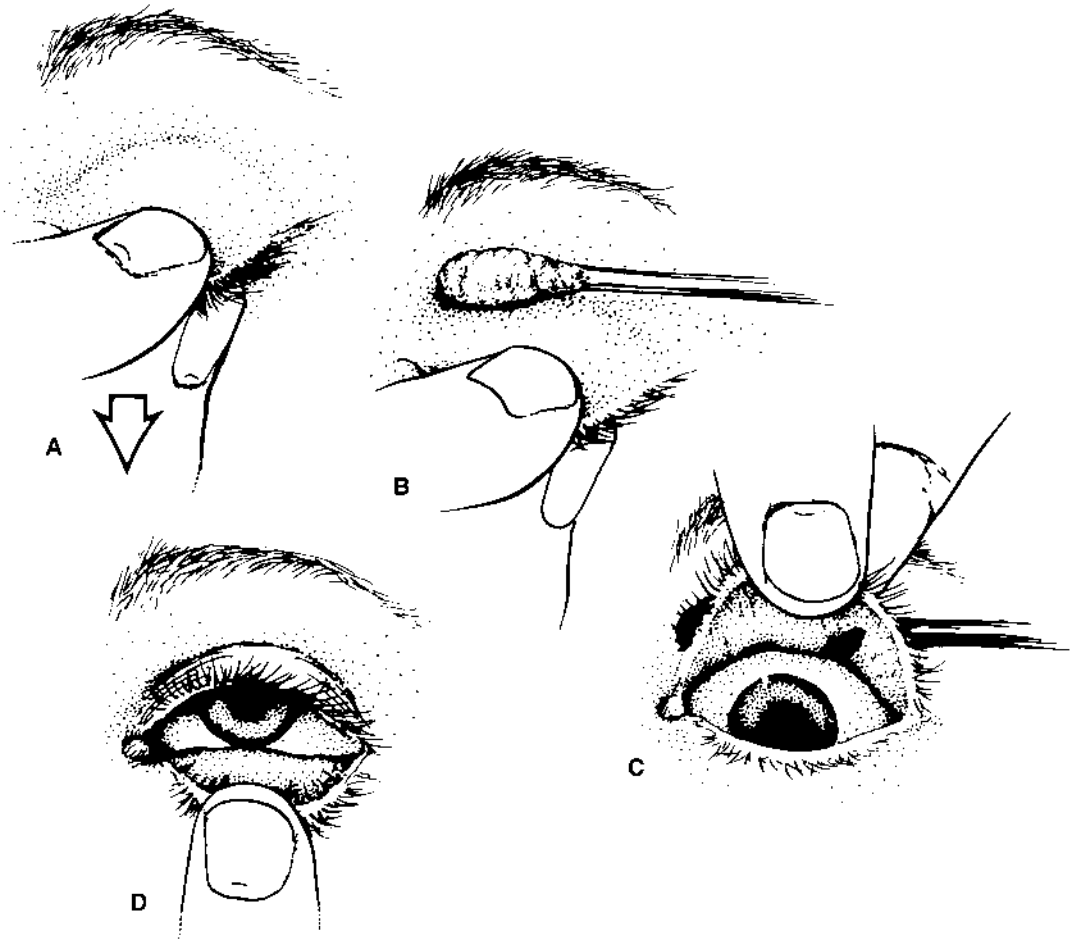
6.3. EYELID RETRACTION

Indications

1. Identification and removal of a foreign body
2. Enable examination of the anterior surface of the eye, cul de sac, and palpebral conjunctiva, especially in the uncooperative patient or when concern for traumatic rupture of the globe exists

Complications

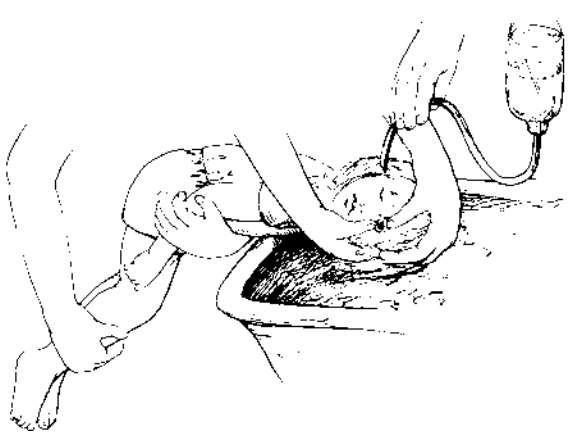
1. Contusion of lid/globe
2. Corneal abrasion



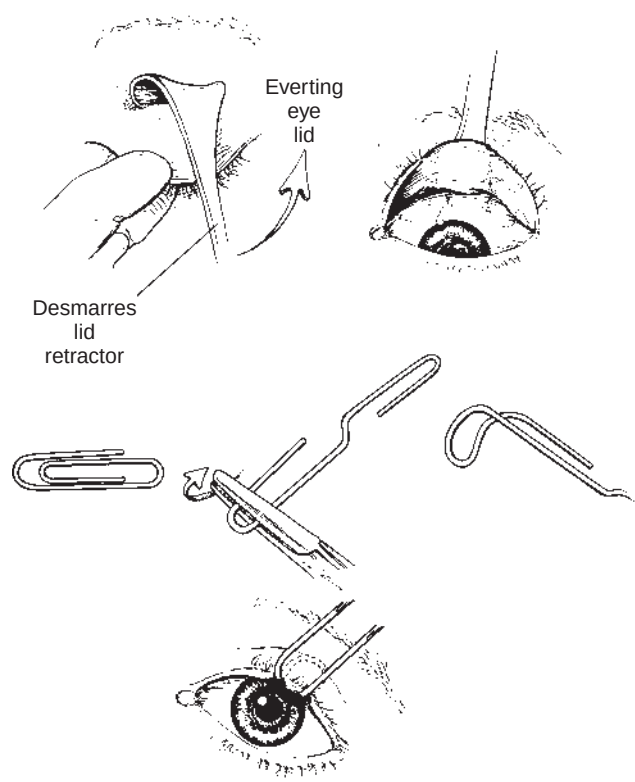
6.1

Procedure (Fig. 6.3)

As in all emergency procedures, universal blood and body fluid precautions (e.g., use of gloves) are a consideration. Place one finger on the orbital rim and gently but firmly roll the finger to gather the elastic tissue at the lid either upward (for the superior orbital rim) or downward (inferior rim). This maneuver



6.2



6.3

overcomes the orbicularis oculi muscle and makes complete forced eyelid closure extremely difficult for the uncooperative patient.

Several eye speculums are also available for use. The most useful for the emergency physician is the Desmarres retractor. Alternatives include the Eyegenie® eyelid retractor (Sigma Pharmaceuticals, LLC) which has advantage of having both ends of a speculum on a single instrument. Place a drop of topical anesthetic in the bulbar conjunctiva, and then slip the blade of the speculum under the lid margin and exert traction upward and/or downward as indicated, as well as away from the globe. The Desmarres retractor in Figure 6.3 is demonstrating eyelid eversion and not retraction. If only one retractor is to be used, it is most helpful to retract the upper eyelid, which often overhangs the lower lid when both are swollen.

Lid retraction is preferred over eversion with a cotton-tipped applicator when there is any concern about a traumatic rupture of the globe. This is because eversion tends to place some pressure on the eyeball and may lead to extrusion of intraorbital contents. When the clinician is unable to perform this easily as instructed or if there is concern of potential globe rupture, emergent ophthalmologic consultation is required.

6.4. CONTACT LENS REMOVAL

Indications

1. Contact lens wearer with altered state of consciousness
2. Eye trauma with lens in place
3. Inability of the patient to remove the contact lens

Contraindications

Possible corneal perforation—suction cup technique preferred in this instance

Complications

1. Corneal abrasion
2. Viral or bacterial contamination

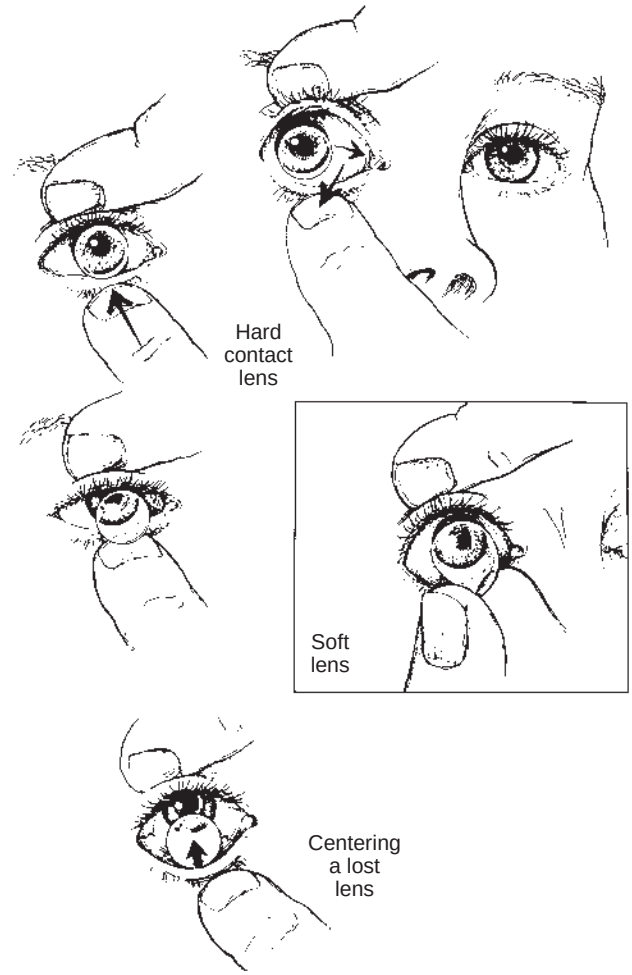
Procedure (Fig. 6.4)

Remember to assess visual acuity in each eye before contact lens removal and preferably use gloved hands when removing a lens. Unless contraindicated place a drop of ophthalmic anesthetic in the eye.

Hard Contact Lens

Lean the patient's face over a table or collecting cloth. Pull the lids from the lateral palpebral margin to lock the lids against the contact lens edges. Have the patient look toward his/her nose and then downward toward his/her chin. This movement works the lower eyelid under the lower lens edge and flips the lens off the eye. This technique requires a cooperative patient.

If the patient is unresponsive or must remain supine, place one thumb on the upper eyelid and the other thumb on the lower eyelid near the lid margins. With the lens centered over the cornea, open the eyelids until the lid margins are beyond the edges of the lens. Then press both eyelids gently but firmly on the globe and move the lids so they barely touch the edges of the lens. Press slightly harder on the lower lid to move it further under the bottom edge of the lens. As the lower lens edge begins to tip away from the eye, move the lids together and slide the lens out where it can be grasped.



6.4

You can also gently move the lens off the cornea with a cotton-tipped applicator. Instill a drop of topical anesthetic into the eye, then slide the lens laterally onto the sclera and lift the lens off the eye by getting the tip of the applicator under an edge of the lens. Try not to make contact with the cornea because this may induce an abrasion. Perhaps the easiest technique is to use a moistened suction-tip device (DMV Corporation; EyeSource.com) and simply lift the lens off the cornea. A drop of honey on a gloved fingertip can be used if a suction-tipped device is not available. The honey easily washes off a hard contact lens.

Soft Contact Lens

Pull the lower eyelid down with the middle finger. Place the index fingertip on the lower edge of the lens. Slide the lens

down onto the sclera and pinch the lens slightly between the thumb and index finger. This folds the lens and allows removal from the eye.

"Lost" Contact Lens

Patients may be uncertain whether their lens is hidden under a lid, remains on the cornea, or is truly off the eye. As with all other eye examinations, begin the evaluation with an assessment of visual acuity. Then inspect the eye for the contact lens. Although transparent, lenses are usually seen easily as a fine line on the sclera several millimeters peripheral to the limbus. If the lens is not evident on initial inspection, evert the eyelids as discussed in Procedure 6.1. If the lens is still not visible, place a drop of topical anesthetic in the eye. Then, with the patient looking toward his/her chin, sweep over the upper fornix gently with a moistened cotton-tipped applicator. If the lens remains elusive and the patient is insistent that it is still in the eye, a fluorescein examination may be performed after explaining that the dye will permanently stain a soft contact lens. If the contact lens is still not found, reassure the patient that a thorough examination has not located the missing lens. Be sure to check that the patient has not inadvertently placed one contact over the other in the same eye.

7.1. NASAL CAUTERIZATION

Indications

Epistaxis recalcitrant to conservative management with the application of a topical vasoconstrictor and manual pressure

Contraindications

Bleeding diathesis (e.g., hemophilia, thrombocytopenia)
Prior nasal cauterization within the past 4 to 6 weeks

Complications

1. Septal perforation
2. Staining of the external nose or upper lip with the use of silver nitrate
3. Thermal damage to the anterior nares or inferior turbinate with the use of electrocautery
4. Secondary bacterial infection of the cauterized area

Procedure

The patient should be sitting or lying in a supine position and, if necessary, manually restrained; distraction techniques, anxiolysis, or procedural sedation may be useful for the apprehensive patient. Care should be taken with patient positioning as well as with medication administration as brisk epistaxis may result in airway compromise in the supine or sedated patient. Topical anesthesia and vasoconstriction of the nasal mucosa can be achieved with the use of an atomizer or cotton pledgets soaked with the desired agents (Table 7.1). This will allow better visualization of the interior of the nose and may slow or even stop the bleeding. In addition, the topical anesthetic will aid in minimizing the pain associated with instrumentation of the nose. Prior to topical medication application, the patient should gently blow their nose to clear mucous, blood, and clot that may be present.

TABLE 7.1

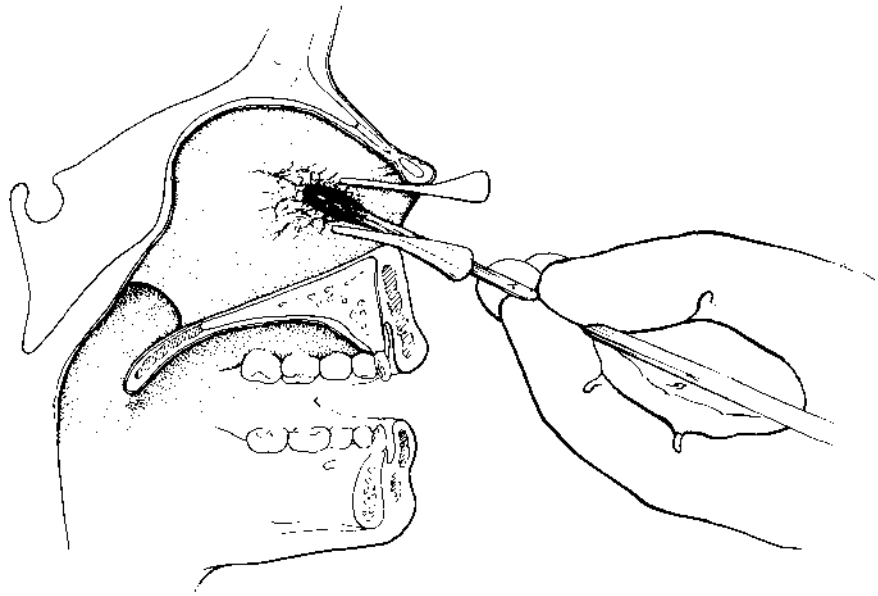
EQUIPMENT—OTORHINOLARYNGOLOGIC PROCEDURES

Directed light source (e.g., headlight, flashlight)
Frazier section tip
Nasal speculum
Bayonet forceps
Topical vasoconstrictor [phenylephrine (0.25%, 0.5%), epinephrine (1:1,000), cocaine (3% to 5% solution)]
Topical anesthestics [cocaine (3% to 5% solution), lidocaine (4%), ethyl chloride]
Absorbable gelatin sponge (Gelfoam)
Oxycel gauze (Surgicel)
Silver nitrate sticks
Expandable sponge nasal pack (Merocel, Rhino-Rocket)
Vaseline gauze (0.5 × 72 in)
Gauze (4 × 4) to make posterior pack
Suture (0-silk) 18 in length
Foley catheter (12 or 14 gauge with 30-mL balloon)
Red rubber catheters
Cuff (made of 1-in length of suction tubing)
Syringe (50 mL)
Sterile saline solution
Hoffman clamp (for Foley catheter)
Scalpel blade, no. 15
Alligator forceps

Insert the nasal speculum into the nose and open the blades widely, using a headlight or directed light source (i.e., flashlight or penlight) to illuminate the interior of the nose. Most epistaxis originates from Kiesselbach's plexus in Little's area (the anterior septum), and this area should be examined first. Suction any remaining clots or fresh blood gently with a Frazier suction tip on low-pressure wall suction to expose the source of hemorrhage. Once the site of bleeding is located, apply the tip of a silver nitrate stick to it and roll it over the bleeding area for 5 to 10 seconds (Fig. 7.1). Two or three sticks are often required to control an episode of epistaxis. Once the bleeding has stopped, petroleum jelly (Vaseline®) or oxidized cellulose gauze (Surgicel®) may be placed on the septum to stabilize the clot and protect the area from further trauma.

If electrocautery is available, it can be used in place of the silver nitrate sticks, but certain precautions must be taken. Although topical anesthesia is often effective for the application of silver nitrate sticks, injected local anesthesia with bilateral application is required before the use of electric current. If unilateral anesthesia is performed, the electric current may be transmitted through the septum causing significant discomfort to the non-anesthetized side. Also, the electrocautery must be properly grounded electrically and have a manual setting so that low voltage can be used. A conservative amount of cauterization is recommended to avoid septal perforation.

With either method of cauterization, refrain from cauterizing both sides of the nasal septum during the same treatment.



7.1

Vigorous bilateral cauterization may deprive the underlying septal cartilage of its blood supply leading to a septal perforation.

7.2. NASAL PACKING—ANTERIOR AND POSTERIOR

Indications

Epistaxis recalcitrant to or not amenable to medical management or cauterization

1. Bacterial rhinosinusitis
2. Toxic shock syndrome
3. Nasal alar or columellar necrosis
4. Septal ulceration or perforation
5. Synechiae formation
6. Hypoxemia or respiratory distress from sedation and nasal airway obstruction

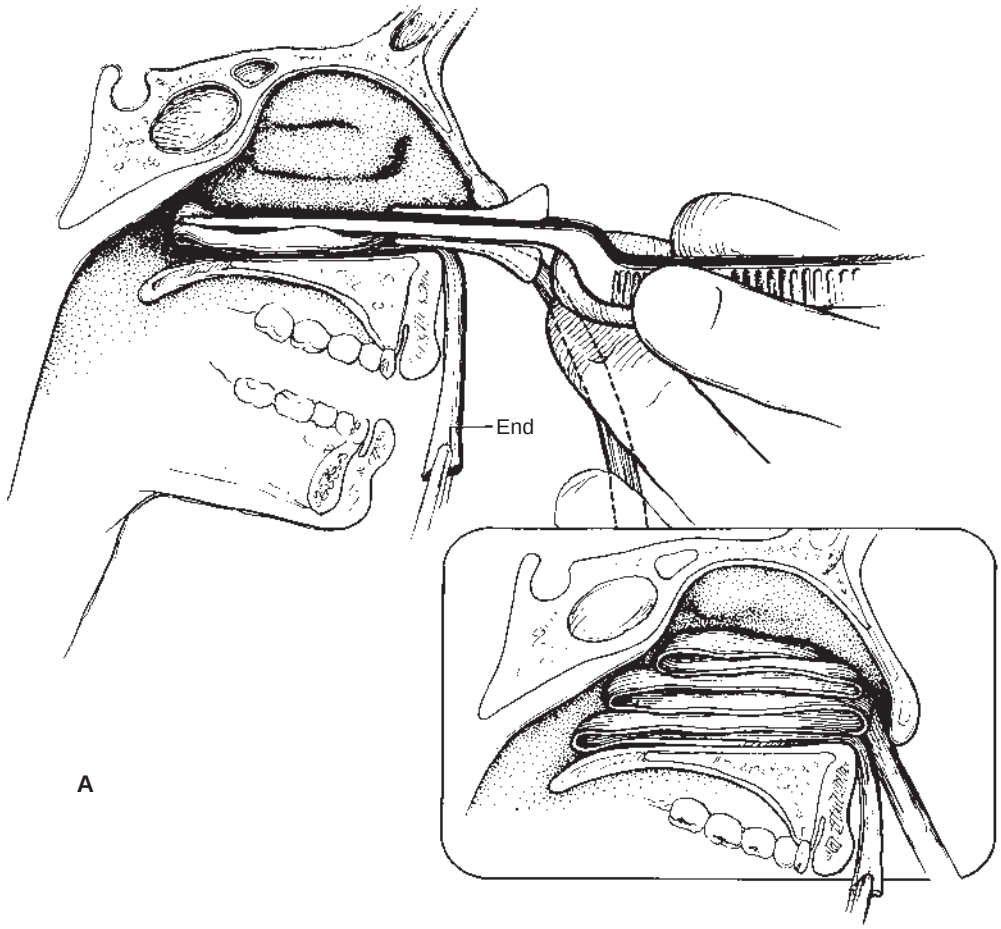
Procedure

Anterior Pack (Fig. 7.2A)

Anterior packing can be performed using a variety of commercially available nasal tampons or as classically described using petroleum jelly or antibiotic ointment impregnated gauze. Prior to insertion of packing, consider the use of an anxiolytic/amnestic or procedural sedation to minimize the pain and emotional trauma associated with the packing procedure in a pediatric patient. Prepare the patient in the same manner as for cauterization, including the careful visualization of the nasal cavity and suctioning of active bleeding. Mild anterior nasal bleeding can often be stopped with a small pack created out of absorbable (gelatin foam, oxidized cellulose, or thrombin-gelatin) material. Although this type of material does not apply a lot of pressure to a bleeding site, it facilitates clotting, protects the nasal mucosa, and does not require removal.

Nasal Tampons and Inflatable Devices. There are several commercially available products that all function by expansion when placed into the nasal cavity thereby tamponading the site of bleeding. A nasal tampon, such as Merocel®, is inserted in a dry, compressed state along the floor of the nasal cavity. When it contacts nasal secretions, blood, or added sterile saline, the tampon expands to fill the nasal cavity and applies direct pressure to the walls of the nasal cavity. The Rhino Rocket® represents a compressed foam polymer tampon made of polyvinyl alcohol and a delivery device to aid insertion. The nasal tampon comes loaded in a slim, syringe-like applicator, which is placed on the floor of the nose at the entrance or just inside the nose. The tampon is expelled into the nose from the applicator expanding as it contacts blood and nasal fluid. The retention strings should be secured to the side of the face. The Rapid Rhino® is a carboxymethylcellulose pack with an inflatable balloon that secures it in the nasal cavity after insertion. It facilitates platelet aggregation and also forms a gel-like lubricant over its surface easing insertion and removal.

Classic Anterior Pack with Ribbon Gauze. Using bayonet forceps, grasp a length of petroleum-jelly-impregnated gauze approximately 5 to 7 cm from its end, and insert it straight back along the floor of the nose for 3 to 4 cm. The end of the gauze should protrude from the nostril by 2 to 3 cm to prevent it from falling into the nasopharynx and causing the child to gag. Withdraw the bayonet forceps and grasp the gauze again approximately 7 cm from where it is now exiting the nose. This portion of the gauze should then be placed into the nose on top of the initial layer. Repeat the process until the nasal cavity is filled with layers of gauze from bottom to top. Any free end of gauze should be directed anteriorly so that it does not fall into



7.2A

the posterior nasopharynx and lead to gagging. A small piece of tape can be used to cover the nostril and prevent the child from disturbing the pack. Because the nasal pack causes stasis of the nasal secretions, oral antimicrobial drugs may be considered to prevent the occurrence of sinusitis. Nonresorbable anterior packs should be removed in 3 to 5 days.

Posterior Pack

If an anterior pack is not sufficient to stop an episode of epistaxis, a posterior pack may be required. The placement of posterior packs is extremely uncomfortable; therefore, procedural sedation is strongly recommended. Posterior packs can consist of a double-balloon catheter, 4″ × 4″ gauze, or a Foley catheter.

The double-balloon catheter has a distal, spherical, small balloon and a proximal, oblong, large balloon. The catheter should be lubricated and then inserted until the tip is in the pharynx beyond the choana. The distal, smaller balloon is then inflated with saline or water, and the catheter is pulled anteriorly to occlude the choana. The proximal, larger balloon is then inflated within the nasal cavity providing direct pressure. The portion of the catheter that is protruding from the nose should be padded with a gauze bolster to prevent pressure necrosis of the ala and columella as well as slippage of the catheter posteriorly.

To make the gauze pack, roll up a 4 × 4 gauze sponge until it is approximately 2 to 5 cm long and 2 cm in diameter; three no. 0 silk sutures (50 cm in length) are knotted around the middle of this roll. Next, thread a red rubber catheter into the nose and bring the end out the mouth by grasping it with a hemostat when it appears in the posterior oropharynx. Tie two of the silk sutures to the end of the catheter, as shown in Figure 7.2B, but hold the third with a hemostat. As the catheter is withdrawn from the nose, guide the pack into the mouth and then up into the nasopharynx (Figs. 7.2C and 7.2D). The pack is held in position by the two silk sutures, which pull the pack up against the vomer (posterior nasal septum). Tie these sutures together after placing an anterior gauze pack as previously described. The third silk suture, which is protruding from the child's mouth, is taped to the cheek to prevent aspiration of the pack if the nasal ties should loosen.

An alternative is to use two red rubber catheters and insert one through each nare. On completion, the sutures on each side can be loosely tied in front of the septum. An anterior pack is still used at the site of bleeding.

To place a posterior pack using a Foley catheter, make a plastic cuff by cutting a 2- to 3-cm length of clear plastic tubing (e.g., suction tubing) and pass it over a 12- or 14-gauge Foley catheter that has a 30-mL balloon. The cuff serves to hold the catheter in place outside the nose. Slide the cuff up to the bifurcation of the catheter; the distal tip of the Foley catheter beyond the balloon should be cut off. Test the inflation of the balloon by injecting saline. Place the catheter into

7.2B–D

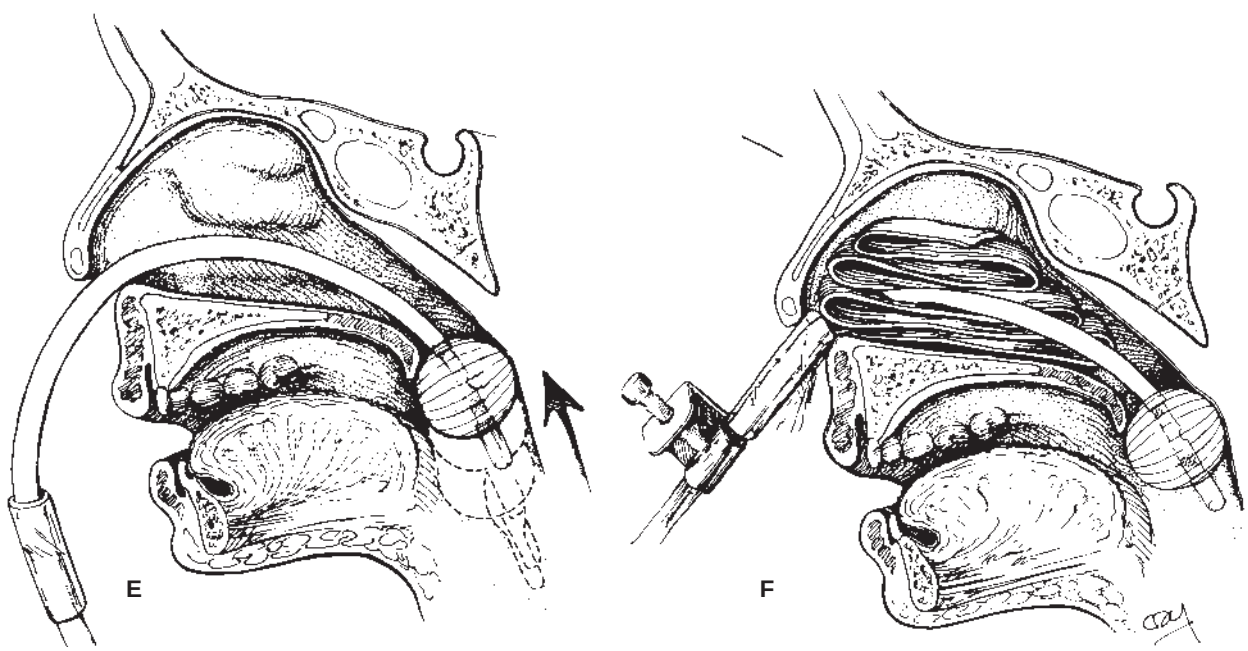
the nose and advance the end into the pharynx. After injecting 10 to 15 mL of saline into the balloon, pull the catheter back until the balloon is pressed tightly against the vomer (Fig. 7.2E). A standard anterior gauze pack is then placed in the nose. Slide the cuff of suction tubing down to contact the anterior gauze pack, making certain that the tubing is inside the nostril and not placing pressure on the nasal ala. A Hoffman clamp (or a hemostat, in an emergency) is then used to clamp the Foley catheter just distal to the cuff of tubing to keep the catheter from slipping posteriorly into the pharynx (Fig. 7.2F). Antimicrobial agents may be given to these children in an effort to prevent the occurrence of sinusitis.

Important Note. Toxic shock syndrome has been reported with nasal packing. If a nasal pack is left in place, it is recommended that an oral antibiotic, such as amoxicillin-clavulanate, be initiated and continued until packing removal. Posterior nasal packs are associated with hypoxia and hypercapnia. In addition, the sedation often required in these patients may decrease respiratory efforts and lead to significant respiratory embarrassment. For these reasons, any child with a posterior pack should be admitted to the hospital and observed in an intensive care setting.

7.3. REMOVAL OF A NASAL FOREIGN BODY

Indications

Presence of a nasal foreign body



7.2E–F

Complications

1. Rhinosinusitis
2. Mucosal laceration
3. Epistaxis
4. Aspiration
5. Incomplete removal of the foreign body

Procedure

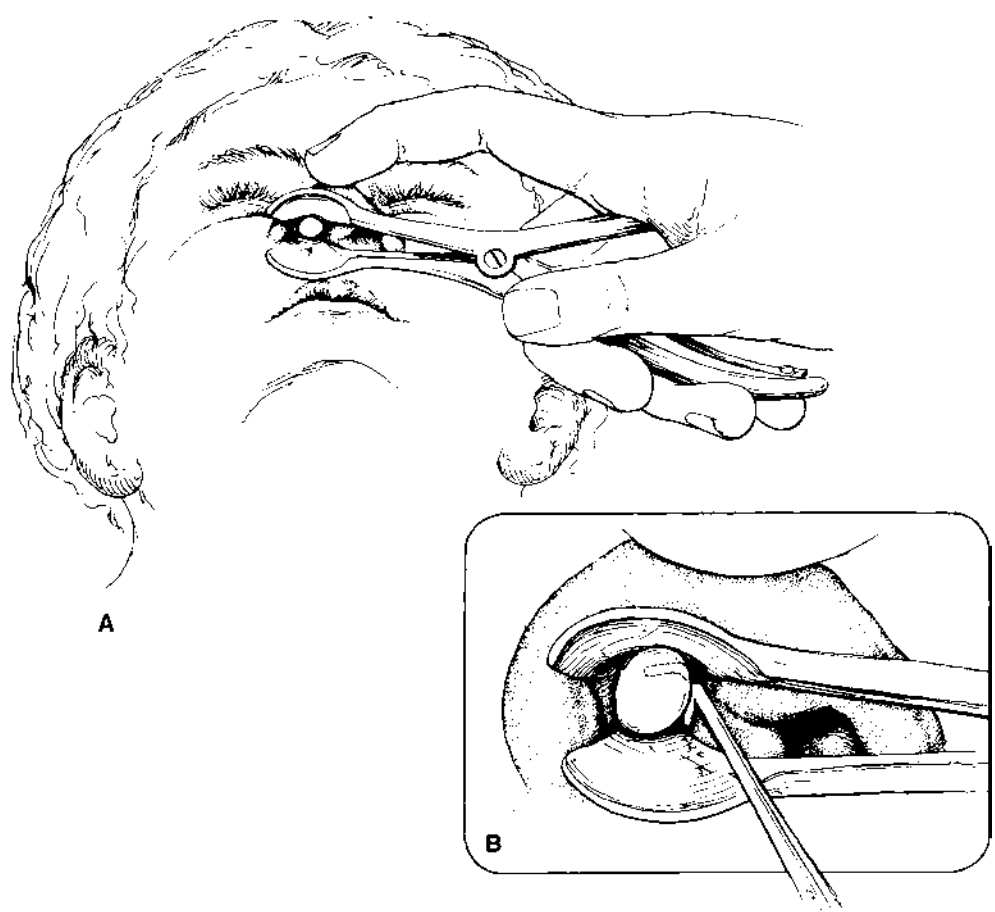
Preparation for the procedure to minimize the pain or anxiety and maximize visualization is the key to success. The patient must be still during instrumentation of the nose to prevent injury to the internal nasal structures. In most instances, it is useful to apply topical vasoconstrictor–anesthetic agent (neosynephrine 0.25%) to shrink the nasal membranes. The child should be supine and restrained. Then, visualize the interior of the nose with a nasal speculum and a headlight or directed light, as shown in Figure 7.3A. Purulent secretions should be gently removed by use of Frazier suction tip until the foreign body is clearly seen. The parent's kiss method of removal may be attempted and has demonstrated success in over 60% of children in some studies. The child is best held in another caregiver's lap and the parent explains that he/she is going to kiss the child. With one finger occluding the nares that is unaffected, the parent covers the child's mouth with his/hers and instills a short puff of air into the child's mouth to expel the foreign body.

If that fails or is felt to not be an option, attempt to extract the object with suction, a hook, or alligator forceps as determined by the size, nature, and position of the object. In some instances, procedural sedation may be necessary to enhance the removal of the foreign body. Figure 7.3B shows a hook being placed around a round foreign body. Do not push the foreign body into the posterior nasopharynx because it may be aspirated by the struggling child. The use of irrigation is *not recommended* because the foreign body may slip posteriorly and be aspirated, or hygroscopic foreign bodies (i.e., sponges) may swell and become lodged in the nose. The use of cyanoacrylate has been effective but requires the glue to directly be in contact with the foreign body for up to 30 seconds against a wooden stick; contact to the mucosa can adhere the stick with the intraluminal mucosa. After the foreign body has been removed, oral antimicrobial agents may be used to prevent an infection in the traumatized area.

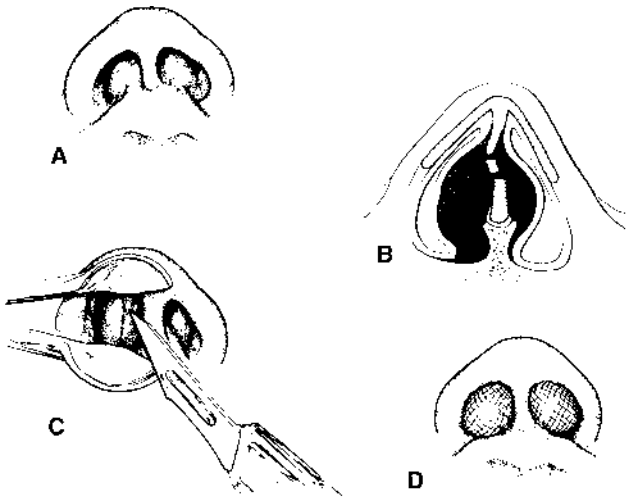
7.4. DRAINAGE OF SEPTAL HEMATOMA/ABSCESS

Indications

Presence of a nasal septal hematoma or abscess



7.3



7.4

Complications

1. Perichondritis
2. Septal abscess
3. Septal perforation
4. "Saddle nose" deformity

Procedure

Figures 7.4A and 7.4B show the external appearance and anatomy in a child with a septal hematoma. Because the drainage of a nasal septal hematoma/abscess is painful, this procedure is often performed on a child in the operating room under a general anesthetic. If drainage is to be performed in the ED, the child requires adequate sedation and restraint.

After visualization of the hematoma or abscess with a headlight or directed light and a nasal speculum, anesthetize the membrane with topical 3% to 5% cocaine or injectable 1% lidocaine. Sterile gloves should be worn. Incise the bulging membrane on the affected side (or sides, if a bilateral process is present) of the nasal septum with a no. 11 scalpel blade, as shown in Figure 7.4C. The material in the hematoma or abscess should be expressed manually and sent for microbiologic culture. Then a loose anterior nasal pack should be placed to tamponade the nasal membranes against the septum (Fig. 7.4D). The child should receive oral antibiotic therapy after the procedure, and the pack should be changed in 12 to 24 hours.

7.5. FLEXIBLE NASOPHARYNGOLARYNGOSCOPY

Indications

To evaluate the child's nasal cavity, nasopharynx, and larynx

Complications

1. Epistaxis
2. Edema of nasal airway
3. Laryngospasm
4. Aspiration

Procedure

The child is usually seated (on the parent's lap, if necessary). Consider an anxiolytic/amnestic, such as midazolam, in the apprehensive patient. The anterior nasal cavity is inspected to detect any nasal septal deformity or enlarged turbinate, and any blood or excess mucus is removed. Topical anesthesia is achieved by spraying 2% to 4% lidocaine solution into the more accessible of the two nasal cavities. Vasoconstriction with oxymetazoline nasal spray prior to the procedure may prevent bleeding and reduce edema optimizing the operator's view of the nasal cavity. If an atomizer is not available, a cotton pledget soaked with lidocaine and oxymetazoline is placed along the floor of the nose and left in place for 10 to 15 minutes.

The examiner sits opposite the child and inserts the tip of the flexible nasopharyngoscope with his/her left hand as the right hand controls the flex of the tip. The instrument is advanced along the floor of the nose through the inferior meatus until the nasopharynx is visualized (Fig. 7.5A). The eustachian tube opening can be identified along the lateral wall of the nasopharynx, and the adenoids (pharyngeal tonsils) can be visualized on the posterior wall. The tip is then deflected downward to view the soft palate and oropharynx. If the view becomes obstructed with mucus or the tip fogs up, the child is asked to swallow, which will clear the tip of the instrument. The palatine and lingual tonsils can be inspected as the scope is passed farther until the larynx is visualized (Fig. 7.5B). If the instrument causes gagging, the child is asked to open his/her mouth and "breathe like a puppy dog." This is often helpful in suppressing the gag reflex. After the laryngeal structures and vocal cord mobility have been evaluated, the instrument is withdrawn from the nose and the examination is complete.

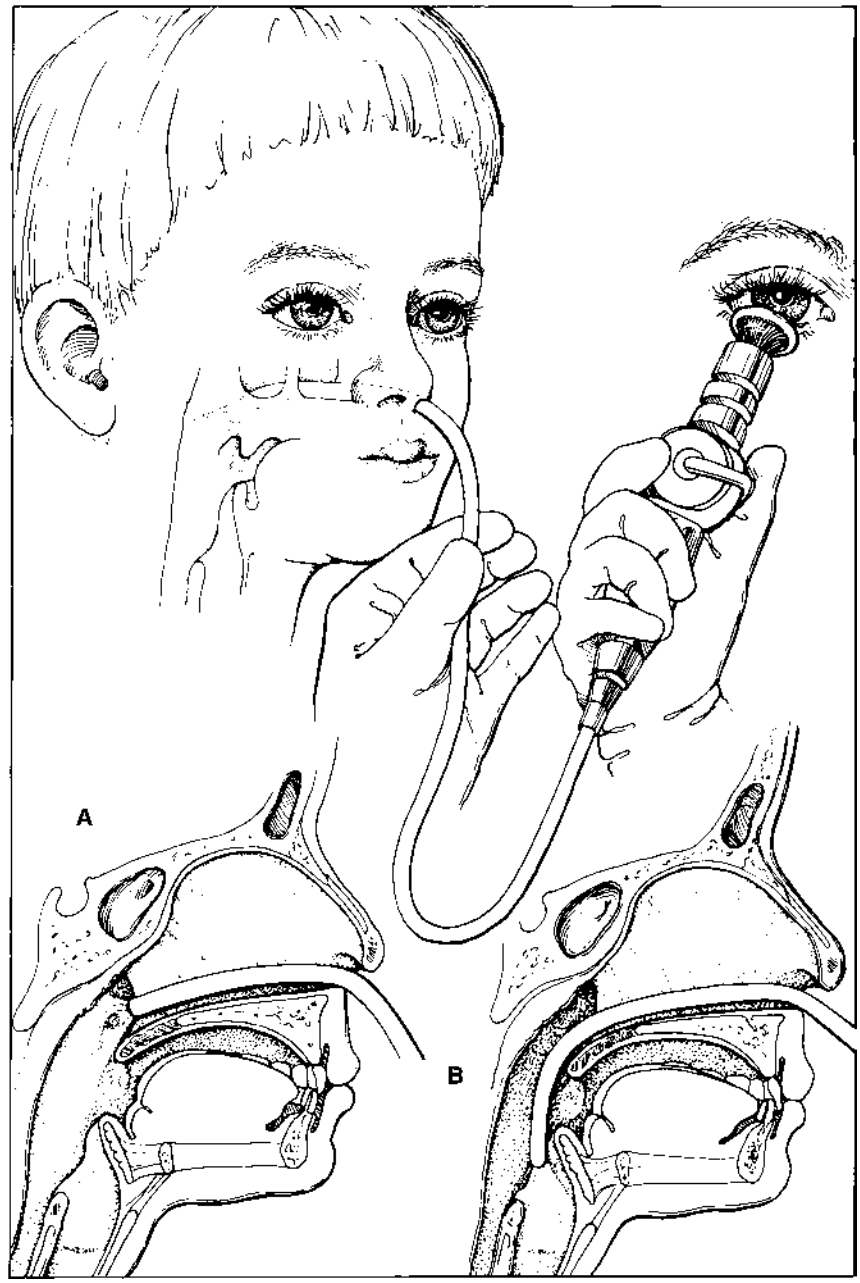
7.6. OROTRACHEAL INTUBATION

Indications

1. Cardiopulmonary resuscitation
2. Respiratory failure with hypoxemia or hypercarbia
3. Absent pharyngeal reflexes—coma, brainstem dysfunction
4. Unstable airway from facial trauma or an airway abnormality

Caution

Caution should be exercised in the intubation of the child with possible neck injury, a full stomach (see Chapters 1, 5, and 104),



7.5

temporomandibular ankylosis or a hypoplastic mandible (see Chapter 5), or a defect in blood coagulation.

Complications

1. Hypoxemia or cardiac arrest
2. Bronchial intubation with secondary contralateral atelectasis or ipsilateral pneumothorax
3. Vomiting and/or aspiration secondary to a full stomach
4. Dislodgment of teeth
5. Laceration of the lips and gums
6. Laryngeal trauma
7. Esophageal intubation

Equipment

Resuscitator with mask and oxygen source; oropharyngeal airways (Guedel 00, 0, 1, 2, 3, 4); uncuffed orotracheal tubes, 2.5- to 8-mm inner diameter (ID), cuffed tubes 3.5- to 8-mm ID (all with 15-mm male connector) (Table 7.6A); laryngoscope handle and several blades (Table 7.6B), extra batteries and bulbs; stylet—infant and adult, Teflon coated; Magill forceps—child and adult; suction equipment—central or portable suction source; Yankauer tonsil aspirator (replace tip by thick-walled rubber tubing); disposable sterile plastic suction catheters (5F, 8F, 10F, 14F)

TABLE 7.6A

ENDOTRACHEAL TUBE SIZES

Age	Size (ID, mm)—Uncuffed	Size (ID, mm)—Cuffed
Premature	2.5	—
Term to 3 mo	3.0	3.0
3–7 mo	3.5	
7–15 mo	4.0	3.5
15–24 mo	4.5	
2–15 yr	ID = [age (yr)/4] + 4	ID = [age (yr)/4] + 3.5

ID, inner diameter.

Procedure

Intubation is performed following preoxygenation—administer 100% oxygen at relatively high flows, that is, up to 10 L per minute in pediatric patients by a T-piece system or high oxygen concentration, self-inflating bag/mask for 3 minutes to a spontaneously ventilating patient. Prepare all equipment including ET tubes ½ size larger and smaller than calculated for age. Strongly consider use of a cuffed ET tube if using a 3.5 mm or larger tube. During resuscitations or in patients with inadequate ventilation, use assisted or controlled positive-pressure ventilation by bag-valve-mask before intubation for at least 1 minute or until cyanosis clears. If the child is being assisted in ventilation with a BVM, cricoid pressure may reduce the risk of gastrointestinal air increasing the risk of emesis during the procedure. However, the evidence is weak and is painful to the patient who is not sedated. Some operators find gentle cricoid pressure at time of intubation improves the visualization of the cords and airway.

Prepare the awake patient with an appropriate anesthetic (see Chapters 1, 4, and 5), and use proper restraint for any patient who should not receive temporary neuromuscular blockade. Then, with the patient supine and the head on a firm pad in the "sniffing" position (Fig. 7.6A), open the mouth with the right thumb and index finger by pulling the mandible open and forward. Insert the laryngoscope blade in the right corner of the mouth, and then pull the blade to the center, elevating the tongue and clearing the lower lip from between the teeth and the blade (Fig. 7.6B). Advance the blade under direct visualization into the hypopharynx (Fig. 7.6C). Elevate the mandibular tissue block by exerting force along the axis of the laryngoscope handle to expose the posterior pharyngeal wall and the proximal esophagus. Avoid any direct pressure of the laryngoscope blade on the dentoalveolar ridge. Slowly withdraw the blade with an assistant applying simultaneous cricoid pressure as needed (Fig. 7.6D); the larynx will ascend into view. If the epiglottis (Fig. 7.6B) obscures the glottic chink, further elevation of the blade usually reestablishes a good view. Advance the styletted endotracheal tube from the right side of the oropharynx to avoid blocking the view during tube passage. Pass it an appropriate distance (usually 2 to 3 cm) into the trachea or three times the inner diameter of the tube in centimeters from the mouth (Fig. 7.6E). For example, pass a 4F endotracheal tube so the 12-cm mark is at the lip at the corner of the mouth. Remove the stylet if used.

Ventilate the patient using the T-piece system or self-inflating bag; determine tube position above the carina by auscultation of equal breath sounds in both axillae.

Consider use of an oropharyngeal airway to protect the teeth and prevent biting of the orotracheal tube. Pick the airway that approximates the distance from the mouth to the angle of the jaw. Pass it into the larynx curved downward while keeping the mouth open with a tongue depressor. Secure the airway with tape to the orotracheal tube and child's skin.

Confirm proper position of the tip of the tube by portable anteroposterior chest radiograph to help avoid accidental extubation or endobronchial intubation. Aim for the tip to be superimposed over the body of the second thoracic vertebrae, corresponding to a distance of at least 2 cm above the carina (Fig. 7.6E).

TABLE 7.6B

LARYNGOSCOPE BLADES

Age	Name and size
Premature	Miller 0
Term to 1 yr	Wis-Hipple 1 or Miller 1
1 to 1.5 yr	Wis-Hipple 1½
1.5 to 12 yr	Miller or Flagg 2
13 yr +	Macintosh 3

7.7. CRICOTHYROIDOTOMY/ PERCUTANEOUS TRACHEOTOMY

Indications

1. Emergency airway access in a patient with an upper airway obstruction, resulting in progressive cyanosis, acidosis, and incipient cardiovascular collapse
2. To provide conduit for oxygenation and, ideally, ventilation, when the natural airway is not accessible for safe gas exchange and/or endotracheal intubation

Complications

1. Bleeding or hemorrhage
2. Subcutaneous and/or mediastinal emphysema
3. Perforation of the posterior wall of the trachea
4. Malposition of the catheter or cannula outside the trachea
5. Barotrauma—when complete proximal airway obstruction is present
6. Pneumothorax and/or pneumomediastinum
7. Infection—periosteal or mediastinal
8. Vocal cord injury and/or voice changes
9. Injury to great vessels, cricothyroid muscle or cricoid cartilage
10. Subglottic stenosis/edema
11. Specific complications with needle cricothyroidotomy:
    a. Kinking and obstruction of the soft IV cannula
    b. Ineffective ventilation with rapid development of severe respiratory acidosis

7.6

Absolute Contraindications

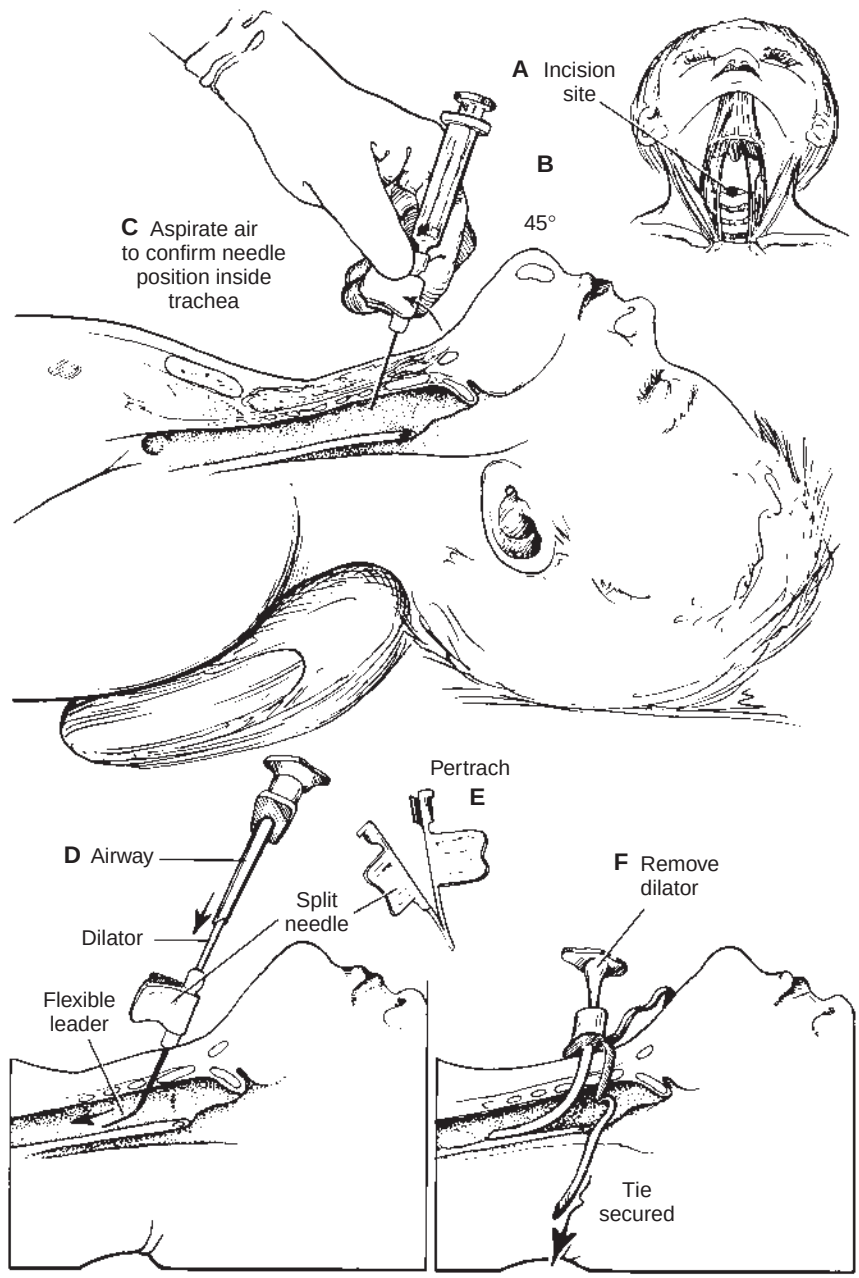
1. Prior major neck surgery that completely obscures anatomy

Equipment

1. Povidone–iodine solution or chlorhexidine
2. Sterile gloves and sterile gauze
3. Needle cricothyroidotomy—16- to 18-gauge, 8.5-cm over-the-needle catheter attached to a 5-mL syringe; 3-mm pediatric endotracheal tube adaptor; high pressure oxygen tubing with a Y-H–connector or three-way stopcock; high pressure oxygen source—50 psi (for adolescents), 25 to 35 psi set at 10 to 12 L per minute (for younger children)
4. Emergency percutaneous tracheotomy—11-blade scalpel, emergency percutaneous tracheotomy device (i.e., Pertrach® catheter) size 3, 3.5, and 4 mm, depending on age and size of patient

Procedure (Fig. 7.7)

Place the patient in a supine position with the neck slightly extended. A rolled towel may be necessary under the shoulders to extend the neck and improve exposure of the trachea. Rapidly prepare the area with povidone–iodine or chlorhexidine solution and don sterile gloves. Immobilize the larynx with one hand by grasping the upper poles of the thyroid cartilage. Palpate the cricothyroid membrane anteriorly between the thyroid cartilage (superiorly) and cricoid cartilage (inferiorly).



7.7

Needle Cricothyroidotomy

When performing a needle cricothyroidotomy, make a small puncture in the skin first with a 16- to 18-gauge needle (with attached syringe) over the center of the cricothyroid membrane. Then, at a 45-degree angle caudad, insert the IV cannula downward through the cricothyroid membrane until a pop is felt. As the cannula is advanced, aspirate continuously. When the pop is felt, there will be an immediate return of air in the syringe. Slide the IV plastic cannula off the needle and into the trachea. Take the syringe, attach it to the IV cannula, and aspirate to confirm successful aspiration of air. Remove syringe and attach the catheter needle hub to a 3-mm pediatric endotracheal tube adaptor. Then, connect this adaptor to high pressure oxygen tubing with a preprepared Y-connector. Set the oxygen flow meter at 50 psi (50 L per minute) for adolescents and at 25 to 35 psi (10 to 12 L per minute) for younger children. Apply intermittent occlusion of the open end of the Y-connector for 1 second, and then release the open end of the Y-connector for 4 seconds. Listen for breath sounds with each delivery of oxygen. Manually guard the plastic cannula to prevent it from kinking, and prepare for more definitive airway access from above, if possible.

Percutaneous Tracheotomy

When inserting an emergent pediatric percutaneous tracheotomy, make a 1-cm vertical and midline incision over the cricothyroid membrane using the 11-blade scalpel. Using an emergency pediatric percutaneous tracheotomy device, (i.e., Pertrach® device), insert the prepared splittable needle (already attached to a syringe), through the incision site at a 45-degree downward (caudal) angle. Within a few millimeters, the give of a "pop" will be felt as the needle bevel enters the trachea. Aspirate air, confirming the position within the tracheal lumen. Oscillate the tip of the intratracheal needle from side to side to confirm that it has not punctured the posterior wall of the trachea. Remove the syringe while stabilizing the splittable needle. Angle the splittable needle acutely toward the carina. Then, lubricate the leader and overlying endotracheal tube, and insert the leader through the needle beyond the needle bevel down toward the carina as far as possible. (If the needle bevel is outside the trachea, the leader will not thread.) Squeeze the flanges of the needle together and pull apart the flanges of the splittable needle. Keep the leader stable when performing this step. With steady pressure, advance the remainder of the leader, the dilator, and the tracheostomy tube directly into the trachea. Remove the leader and dilator, and attach the tracheostomy tube to a bag-valve-mask and ventilate the patient. Observe for chest wall excursion, auscultate for breath sounds, and then secure the tracheostomy tube in place with ties snugly fitted around the neck.

7.8. REPLACEMENT OF A TRACHEOSTOMY CANNULA

Indications

1. Relief of obstruction of a tracheostomy tube (i.e., secretions, mucous plug, or foreign body)
2. Accidental decannulation

Complications

1. Respiratory distress—hypoxemia and hypercarbia
2. Creation of a false tracheal passage, leading to pneumomediastinum and pneumothorax

Procedure

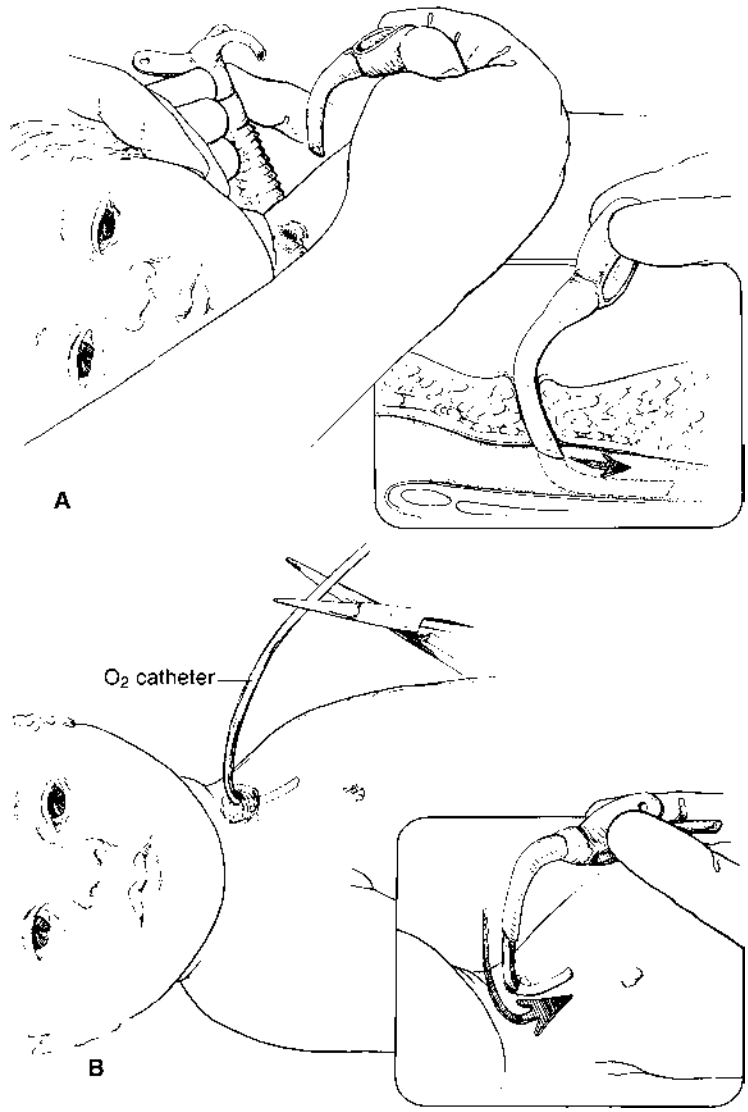
Replacement of an Obstructed Tracheostomy Cannula

The child with a tracheostomy who develops tachypnea, cyanosis, decreased breath sounds, or severe retractions should be assumed to have a mechanical obstruction of his/her cannula until proven otherwise. Have an assistant obtain a scissors, a new cannula (often available from the parents), or an endotracheal tube of the same diameter or one size smaller than the obstructed tube. Ventilate the child with 100% oxygen. Place a small, folded towel under the child's shoulder, and extend the head and neck. This maneuver exposes the tracheostomy site and eliminates redundancy or flaccidity of those tissues, which lie between the trachea and the anterior surface of the neck. The trachea is thereby forced closer to the plane of the skin. An attempt should be made to pass a suction catheter. If the catheter passes, apply suction at 80 to 120 cm of water and withdraw over 3 to 5 seconds. Immediately reventilate with 100% oxygen. *If the suction catheter will not pass through the tracheal cannula, the cannula must be changed immediately.* Carefully cut the strings that secure the cannula with bandage scissors so as not to lacerate the child's neck. Remove the tube, observe the tract of the tracheocutaneous fistula, and introduce the new cannula, preferably with internal obturator in place so the tip follows the course of the tracheocutaneous fistula (Fig. 7.8A). Press the flanges of the tracheostomy tube against the child's neck, and attach a swivel connector and resuscitator to the system. Remove the obturator if used, ventilate the child, and check for symmetric breath sounds by auscultation. Insert a hemostat through a flange hole on the lateral aspect of the cannula and pull the tracheostomy twill (cloth tape) through so two equal lengths of twill are left that are long enough to go around the neck to knot through the opposite flange hole. Before securing the knot, apply adhesive-backed foam, if available, to the string crossing the back of the neck. With the neck flexed, tie the string snugly. If the cannula is properly secured, an index finger should fit snugly under the strings while the head is flexed. Obtain a chest radiograph to ensure proper placement and to assess for pulmonary parenchymal change.

If a tracheostomy cannula is not immediately available, a standard endotracheal tube of the same diameter can be used instead. Care must be taken not to advance this longer tube beyond the carina by measuring it against the tracheostomy removed to estimate distance. The chest should be auscultated for equal breath sounds bilaterally and, in addition, position of the distal tip should be confirmed by a chest radiograph. Because this is temporary, obtain the correct size tracheostomy tube to change the endotracheal tube as soon as possible.

Replacement of a Dislodged Cannula

When a tracheal cannula is dislodged from the stoma of a child totally dependent on that cannula, it must be replaced



7.8

immediately. Time may not allow for acquiring a clean tube. Cut the strings and replace the dislodged cannula. Hold it firmly in place until it can be secured or until a clean cannula is made available. Occasionally, the tracheocutaneous stomal tract will constrict so the cannula cannot be replaced. Several options are then available. First, place a smaller tracheal cannula or endotracheal tube to allow oxygenation and ventilation. Second, electively dilate the stoma and replace the appropriate size tube. Alternatively, as in Figure 7.8B, pass a smaller oxygen catheter (10F or 14F). If the child is cyanotic, connect the catheter to an oxygen hose and run oxygen at a minimal flow rate of 1 L per minute (2 to 3 L per minute if older than 3 years of age.). If the child is not cyanotic, move directly toward passing a tracheostomy cannula over the oxygen catheter into the stoma. The oxygen catheter will serve as a stylet and guideline to keep the tracheostomy cannula from being forced into a false passage. If the cannula cannot be advanced, it may be necessary to oxygenate and ventilate the child with a resuscitator, and mask through the upper airway while an assistant covers the stoma with a gloved finger. If the upper airway is obstructed, place a small endotracheal tube (size 3.5 to 4.5) through the stoma, hold it in place, and use it to oxygenate the patient. Efforts to place a more appropriate size airway can then be reasonably made, using the surgical approach if other efforts fail.

Important Note

Remember that cardiopulmonary failure or respiratory distress often means obstruction of the tracheostomy. First, if unable to ventilate or suction, remove. Second, try to cannulate. Third, remember in some patients, an ET tube can be passed through the mouth or tracheostomy stoma. Last, remember to try the other procedures (e.g., oxygen catheter).

8.1. INSERTION OF A CHEST TUBE

Indications

1. Evacuation of a pneumothorax
2. Drainage of a hemopneumothorax, symptomatic empyema, or large pleural effusion
3. Esophageal rupture with gastric leakage into the pleural space

Complications

1. Bleeding (local and/or perforation of major vessels)
2. Pulmonary contusion
3. Pneumothorax or hemothorax
4. Infection (at insertion site, pneumonia, or empyema)
5. Bronchopleural fistula or pleurocutaneous air leak
6. Laceration or perforation of visceral organs (heart, lungs, diaphragm, spleen, liver, or other intraabdominal organs)
7. Subcutaneous emphysema
8. Reexpansion pulmonary edema
9. Intercostal neuralgia/neuritis

Contraindications

Absolute

1. Lung is completely adherent to chest wall throughout hemothorax

Relative

1. Risk of bleeding with patient treated with anticoagulants
2. Coagulopathies and platelet dysfunctions

Equipment

1. Povidone–iodine solution or chlorhexidine
2. Sterile gown, mask, hat, gloves, gauze and drapes
3. 11-blade scalpel; 5- to 10-mL syringe; needle (18- to 25-gauge) for anesthetic; 1% lidocaine
4. Needle driver; curved Kelly clamps or artery forceps; scissors; strong, non-absorbable suture
5. Age/size-appropriate thoracostomy tube (as designated in Table 8.1)
6. Pleural drainage system (e.g., Pleur-evac)

Procedure

Identify the side(s) with the hemothorax or pneumothorax by physical examination and chest radiograph, if time allows. Initiate treatment of cardiorespiratory disturbances before beginning the procedure. If abdominal distension is present, especially from a dilated stomach, pass a large-bore nasogastric tube to reduce diaphragmatic elevation.

Figure 8.1A shows the anatomy of a child with a right-sided pneumothorax from an anterior view, and the preferred sight of entry into the thorax between the anterior axillary and midaxillary lines at the level of the nipple (fifth intercostal space). Restrain the child, if necessary; minimize any respiratory compromise. Consider use of pharmacologic sedation. Generally, a young or seriously ill child should be supine, but an older, cooperative patient may sit. Locate the landmarks and cleanse the site with povidone–iodine or chlorhexidine solution. Prior to starting, mark the side affected and use your institution's "hold point" method to ensure correct side tube placement. Using aseptic technique with sterile gown, gloves and mask, create a sterile field. Infiltrate the skin, subcutaneous tissue, intercostal muscles and periosteum of the rib with a local anesthetic (1% lidocaine). Make a skin incision parallel to the rib and at least one intercostal space below the rib over which the catheter will pass. This spot provides an oblique trajectory for the chest tube, which helps maintain an airtight seal when the tube is in position and after its removal.

Figure 8.1B shows a 1.5- to 2-cm transverse skin incision made with a no. 15 scalpel blade. Using a curved hemostat or Kelly clamp, bluntly dissect through the muscle and fascial layers to the upper surface of the chosen rib. Determine the proper position by palpation of the rib with the tip of the instrument. Then, slide the tip over the superior rib margin, puncturing the intercostal muscles and pleura well below the neurovascular bundle of the adjacent cephalad rib, as shown in Figure 8.1C. Control the instrument so the tip does not enter more than 1 cm into the thoracic cavity. Spread the tips of the instrument widely to provide an opening through the intercostal muscles and pleura that is at least 1.5 to 2 cm in diameter. At this point, any fluid or air under pressure in the pleural space may surge out. Use your gloved finger to explore the tract and remove the curved hemostat, exploring the pleura to ensure lung falls away from pleural wall and to clear adhesions or clots.

As shown in Figure 8.1D, grasp the chest tube between the tips of the curved hemostat or clamp. In general, the smaller thoracic cavity in children as compared with that of adults makes the use of a trocar more risky. Then, advance the instrument through the incision and previously dissected tract to the pleural space. When the tube tip has entered this cavity, open the hemostat and advance the catheter posteriorly, in the apical direction, until it meets some resistance. The tip will most likely be at the apex of the hemithorax. Approximate the incision with several nylon sutures, some of which should encircle the tube to secure it in place. Sterile ointment and a sterile occlusive dressing should be applied to the wound. Further taping will help prevent dislodgment. After the tube has been attached to a drainage set (e.g., a Pleur-evac), obtain an upright or decubitus chest radiograph immediately.

TABLE 8.1

CHEST TUBE SIZES BY AGE

Age	Size (F)
Newborn	10–12
6 mo	10–12
1 yr	16–20
4 yr	20–28
10 yr	28–32
>14 yr	28–32

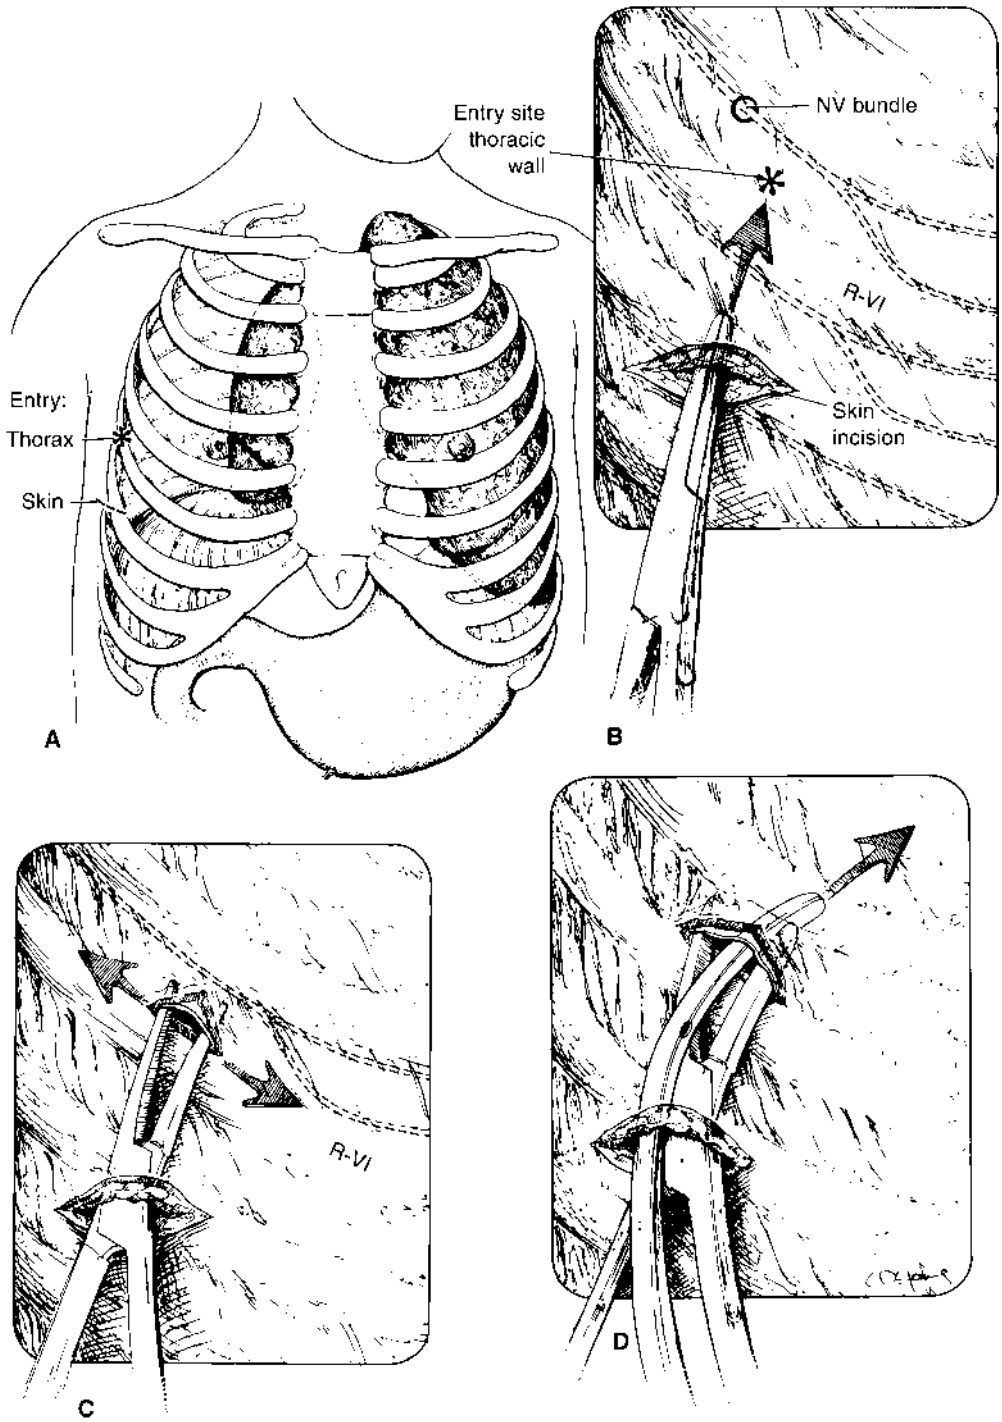
8.2. THORACENTESIS

Indications

Diagnostic or therapeutic drainage of a pleural effusion

Complications

1. Pneumothorax or hemothorax
2. Pulmonary contusion or lung laceration
3. Hepatic or splenic trauma



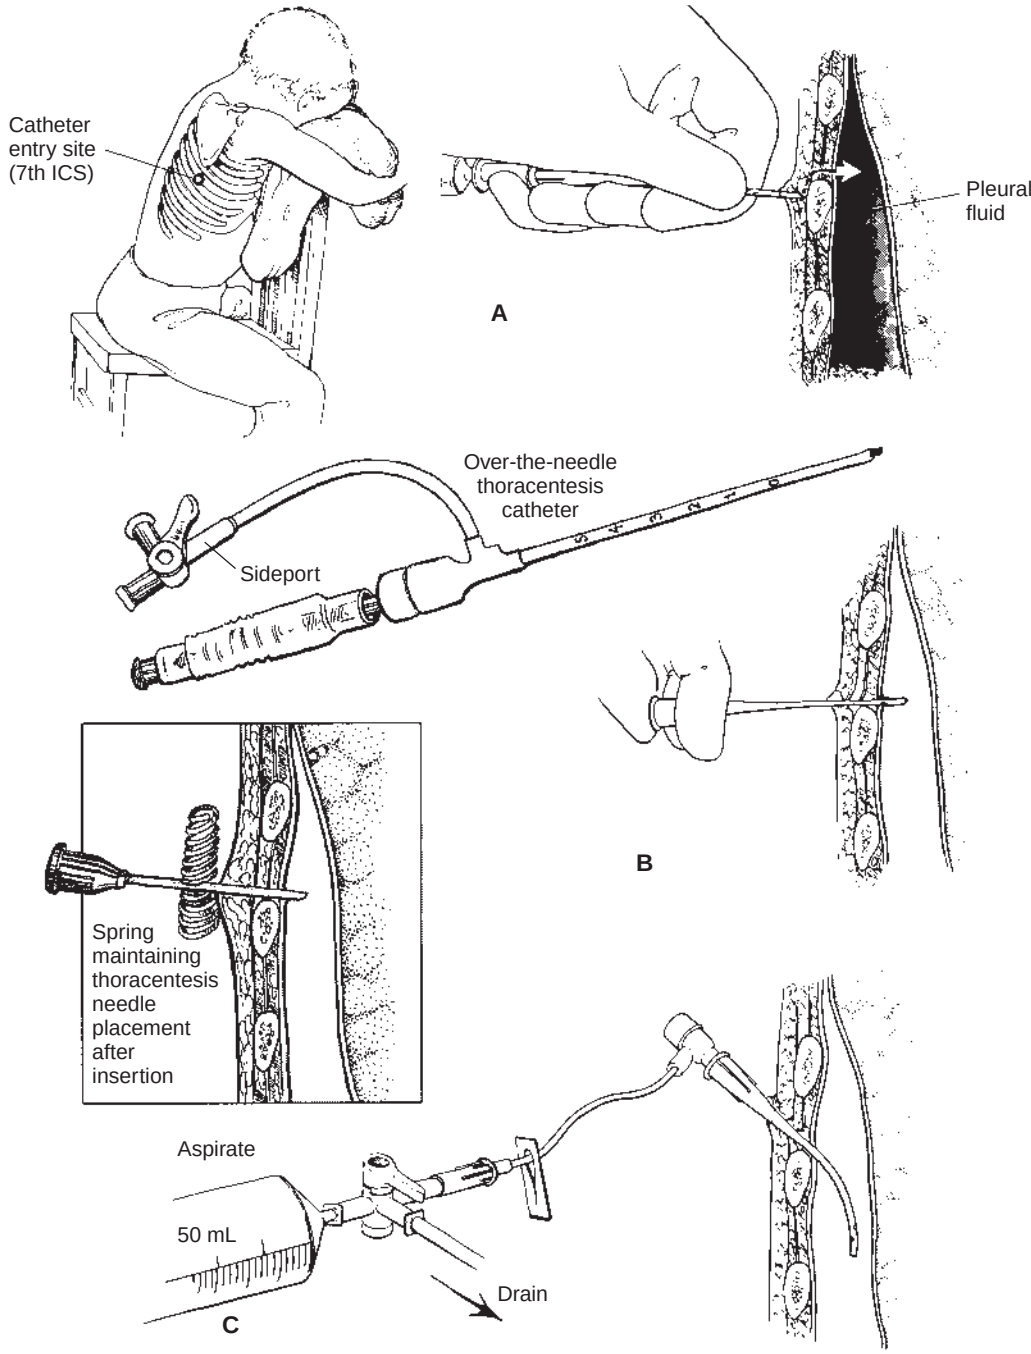
8.1

Equipment

1. Povidone–iodine solution or chlorhexidine
2. Sterile gown, mask, hat, gloves, and gauze
3. 5-mL syringe, 22-gauge needle, 1%. lidocaine
4. Over-the-needle catheter, no. 16 to 20, or 4-0 to 5-0 central line catheter tray, or pigtail thoracentesis catheter
5. Stopcock, T-connector, 20- to 50-mL syringe

Procedure

To confirm the presence of a free pleural effusion and the side involved, obtain erect and decubitus chest radiographs before the procedure. Prepare the equipment and the patient. Some children may do better with mild sedation if they are not having respiratory distress because restraint is difficult. Figure 8.2 shows the position useful in most toddlers and older children.



8.2

Place the child in the sitting position with the arms and head supported on a pillow. With the arm on the involved side elevated, the lower tip of the scapula lies just above the seventh intercostal space in the posterior axillary line. Significant amounts of free fluid in the thoracic cavity will usually be present at this point. Prior to starting the procedure, complete your institution's "hold point" procedure for the correct location/side. After donning sterile gloves, scrub the area of the intended puncture with antiseptic solution. Then, anesthetize the site with 1% lidocaine from the skin to the periosteum of the rib.

Figure 8.2A shows the use of an over-the-needle catheter device. Advance the needle through the skin at a right angle to the chest wall at the point marked in Figure 8.2. Direct the needle against the upper rib surface and then draw it back slightly. Next, lift up the catheter system gently and slowly advance it so the needle slides over the top surface of the rib. Maintain continuous suction on the syringe while entering the pleural cavity; a decrease in the resistance to advancement of the needle and flow of fluid signals penetration of the parietal pleura. Advance the catheter slightly further, holding the needle steady.

As shown in Figure 8.2B, remove the syringe and needle and cover the hub of the catheter with the thumb. Because the catheter is soft, it can be advanced further into the thoracic cavity with little risk of puncturing the lung. Aim caudally to achieve an optimal position for evacuation of fluid.

As shown in Figure 8.2C, quickly attach a syringe (20 to 50 mL), stopcock, and T-connector to the catheter tip to minimize any leakage of air into the thorax. Increments of up to 50 mL can be removed for diagnostic studies or to provide symptomatic relief. If suction becomes difficult, reposition the catheter to maximize drainage. If insufficient fluid is obtained using a large-bore catheter, insert a longer through-the-needle catheter deeper into the thorax to improve emptying. Alternatively, introduce a needle from the central catheter or other setup for the Seldinger technique. Introduce the wire through the needle after the pleural space is entered. Then, after removing the needle, advance the catheter into the pleural space over the wire. At the end of the procedure, quickly remove the catheter and apply a sterile occlusive dressing. An upright chest film should be obtained afterward to look for the presence of an iatrogenic pneumothorax.

8.3. RESUSCITATIVE THORACOTOMY

Indications

In penetrating chest and abdominal trauma, rarely blunt trauma or other cause of arrest in children and adolescents. Best outcome with penetrating from stabbing and not gunshot and in the patients with progressive loss of vital signs or cardiac arrest for but a few minutes.

1. To provide access to the pericardium and heart for relief of tamponade and to institute open cardiac massage
2. To obtain control of any active bleeding injuries from the lung, hilum, or heart
3. To provide direct compression or occlusion of the thoracic aorta to improve central circulation of the brain and heart
4. To provide placement of large-bore catheters directly into the right atrium

Complications

1. Bleeding
2. Intrathoracic or chest wall infection
3. Delayed pericardial effusion

Relative Contraindications

1. Any patient with absence of vital signs at the prehospital scene and on arrival to the ED, following cardiopulmonary resuscitation for more than five minutes
2. Any patient with no signs of life, or asystole, on arrival to the ED, following blunt thoracic trauma
3. Any patient with head or thoracic injury, as part of a severe multisystem trauma

Equipment

A complete thoracotomy tray with rib spreaders; large vascular clamps and an aortic clamp; toothed forceps and artery forceps; curved scissors; and a 10-blade scalpel and preprepared 3-0 cardiovascular suture with cardiovascular pledgets; internal defibrillator paddles; 4-0 and 3-0 silk suture on tapered needle; sterile IV connector tubing; an 8 Fr Foley catheter; povidone–iodine solution; gloves, sterile gowns, masks, and drapes

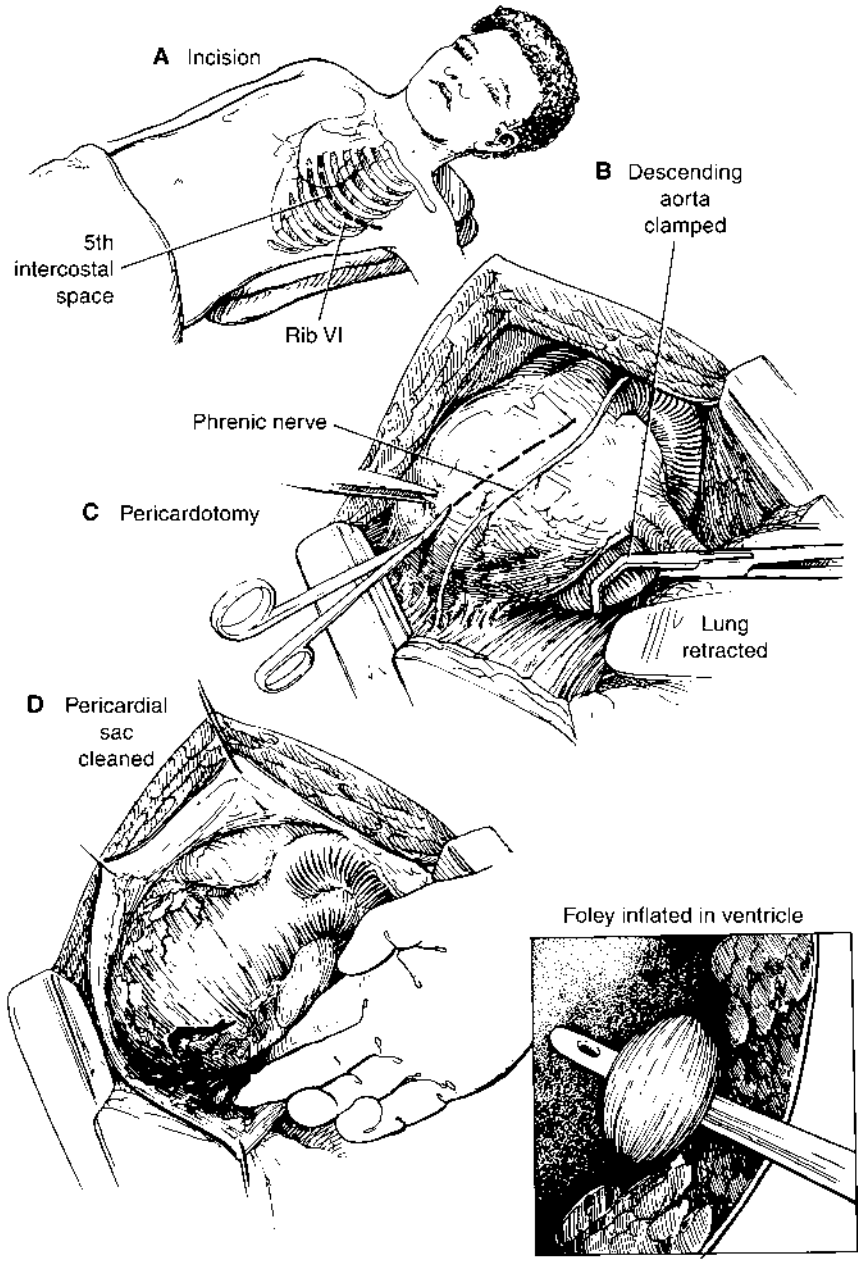
Procedure (Fig. 8.3)

The patient is positioned supine with side of operation elevated slightly with towels or wedge-shaped pillow. The entire chest from sheet to sheet and from neck to lower abdomen should be quickly prepared with povidone–iodine solution. A left anterolateral thoracotomy incision (most common incision site) should be made through the fourth or fifth intercostal space from anterior costochondral junction to midaxillary line cutting the intercostal muscle close to the top of the respective inferior rib. A chest wall retractor is inserted and opened, providing access to the pericardium and the descending aorta. If access remains limited, cut the sternum across to the opposite interspace using heavy scissors and spread the right anterior chest with another set of chest wall retractors.

Next is the inspection of the pericardium, followed by a pericardiotomy, if pericardial tamponade is present. Perform a pericardiotomy by making a longitudinal cut through the pericardium 1 cm anterior to the phrenic nerve. This is best done by catching one edge of the pericardium with the scissors and then grasping the pericardium with forceps so the longitudinal incision can be made superiorly and inferiorly. All blood and clots in the pericardial sac should be evacuated, and gentle digital pressure applied to any cardiac bleeding points. Next step is a thorough heart inspection, during which the heart should not be lifted if there is a left-sided cardiac perforation because of the risk of sudden, fatal coronary air embolism. The right atrium and right ventricle are the chambers most commonly injured by penetrating wounds. Use of a partially occluding vascular clamp is preferred for major vessels or atrial bleeds. For temporary control of hemorrhaging wounds, a Foley catheter can be inserted in the wound and the balloon inflated with tube clamped so as not to pull balloon out of the wound, thus increasing the size of the wound. In the case of a pulsatile cardiac activity, repair of the wounds should be delayed until adequate resuscitation; for a non-beating heart, sutures can be placed prior to resuscitation. Atrial and ventricular wounds can be temporarily controlled with 3.0 non absorbable mattress sutures or a stapling device.

After the heart has been repaired, or if perforation of the heart has not occurred, internal cardiac massage may be done using the palms and proximal fingers of two hands proceeding from the apex to base of the heart. Avoid compressions between the thumb and the hand because these may cause perforation. Internal defibrillation may be necessary in the event of ventricular tachycardia, ventricular fibrillation, or to restore adequate cardiac output. With defibrillation, internal paddles are used and energy settings are reduced.

If bleeding is occurring from a major portion of the lung or parenchyma, it may be tamponaded or clamped with a



8.3

Satinsky clamp. Likewise, if bleeding is occurring from the hilum of the lung, a large, curved vascular clamp should be placed across the hilum of the lung to secure hemostasis.

Cross-clamping of the descending thoracic aorta is an adjunctive measure to maintain proximal arterial pressure, thus increasing brain and heart perfusion, and decreasing subdiaphragmatic hemorrhage. In this case, the left lung is elevated anteriorly and superiorly by an assistant on the right of the patient. The operator on the left side of the patient should spread a DeBakey aortic clamp medial and lateral to the mid-descending aorta. The operator passes his/her finger around the descending aorta, and then applies the clamp to the descending aorta under direct visualization, with care to avoid avulsion to other aortic branches.

Once hemorrhage has been controlled and adequate resuscitative measures applied, the patient is moved to the operating room where definitive hemostasis is secured and all clots/debris are lavaged from the pericardial and pleural cavities. Finally, the chest will be closed after placement of appropriate chest and pericardial tubes.

9.1. PERICARDIOCENTESIS

Indications

1. Emergent removal of intrapericardial fluid in the treatment of cardiac tamponade

2. Elective removal of pericardial fluid in the presence of a chronic or recurrent pericardial accumulation leading to an impairment of cardiac output
3. As a diagnostic procedure for direct analysis of pericardial fluid

Complications

Acute

1. Myocardial penetration and aspiration of ventricular blood
2. Cardiac arrhythmias
3. New hemopericardium
4. Pneumothorax secondary to lung puncture
5. Coronary artery or vein laceration
6. Diaphragmatic perforation
7. Puncture of peritoneal cavity

Delayed

1. Pericardial leakage and development of a cutaneous fistula
2. Pericardioperitoneal fistula
3. Slowly developing pneumothorax
4. Pneumopericardium
5. Local infection
6. Hemorrhagic pericardial effusion leading to pericardial tamponade
7. Peritonitis from puncture of peritoneal cavity

Equipment

Povidone–iodine solution; sterile drapes, sterile gauze, gloves; 1% lidocaine, 3–5 mL syringe; 22-gauge needle; 20-gauge, 2.5-in or 3.5-in spinal needle or long (6 in) over-the-needle catheter; three-way stopcock; 20- and 50-mL syringes; sterile alligator clip; flexible sterile guidewire (0.018 in); soft infusion catheter (18 or 20 gauge); no. 15 scalpel blade and holder

Procedure

Position the child supine at a 30- to 45-degree angle to the horizontal plane. Sedation usually is required, and may necessitate capable airway management and ventilation to ensure the safety of the child. Attach the limb leads of an electrocardiogram (EKG) monitor. Clean and sterilize the precordium with povidone–iodine solution, and donning sterile gloves, drape the area with sterile towels. Infiltrate the area 1 to 2 cm below and to patient's left of the xiphoid process with 1% lidocaine; penetrate through the muscle layer to achieve satisfactory local anesthesia. Attach the spinal needle to a stopcock and a 20- to 50-mL syringe. Connect the "V" lead of the EKG to the hub of the needle with a sterile clip (alligator type) after checking that the lead is grounded. Turn the EKG recorder on to the "V" lead position.

Before inserting the needle, make a 2-mm incision 1 to 2 cm below and slightly to the patient's left of the xiphoid to facilitate penetration of the skin. Holding the needle perpendicular to the skin, advance it through this incision. Once below the skin, angle the needle at approximately 45 degrees up from the abdominal surface, pointing cephalad and toward the tip of the left scapula. Slowly advance, maintaining a slightly negative pressure on the syringe.

Monitor the EKG during this procedure. If an oscilloscope is not available, run a paper tracing continuously during the needle insertion. Close observation for a change in the EKG serves as a guide to the depth of the needle penetration. Advance the needle until pericardial fluid is obtained or evidence of myocardial contact is seen on EKG. The appearance of a widened and enlarged QRS complex or a "current of injury" pattern (ST segment changes and T-wave inversion) indicates penetration beyond the pericardium and into the myocardium. If this occurs as shown in Figure 9.1B, withdraw the needle and observe closely for the return of the baseline pattern of the EKG (Fig. 9.1A). Alternatively, a two-dimensional echocardiogram can be simultaneously done to localize the drainage site. Once in the pericardial space, the syringe fills with the pericardial fluid with some accompanying spontaneous relief of the negative pressure being applied to the plunger. If drainage of a large volume of fluid is anticipated, introduce a flexible wire through the indwelling needle, followed by an end-hole catheter passed over the wire into the pericardial space.

An alternative to using a spinal needle and the Seldinger technique for introduction of the catheter is to use a long over-the-needle catheter attached to the syringe and stopcock. When the tip of the needle has passed into the pericardial space, the catheter can be advanced and the needle withdrawn leaving the drainage catheter and stopcock assembly in place for future drainage needs.

After the procedure is complete, remove the needle (or catheter) and cover the puncture site with a sterile dressing. Observe the patient closely with frequent vital sign checks, until stable, in the intensive care unit. Obtain an upright chest radiograph to look for complications or a reaccumulation of pericardial fluid.

9.2. EMERGENCY TRANSVENOUS PACING

Indications

1. Persistent symptomatic bradycardia with inadequate cardiac output that is refractory to medical treatment. Examples include congenital complete atrioventricular block, acquired advanced second degree or third degree atrioventricular block, sinus bradycardia or sinus node dysfunction leading to symptomatic age-inappropriate bradycardia, and junctional or idioventricular rhythms.
2. Overdrive suppression of atrial or ventricular tachyarrhythmias refractory to other treatment modalities.

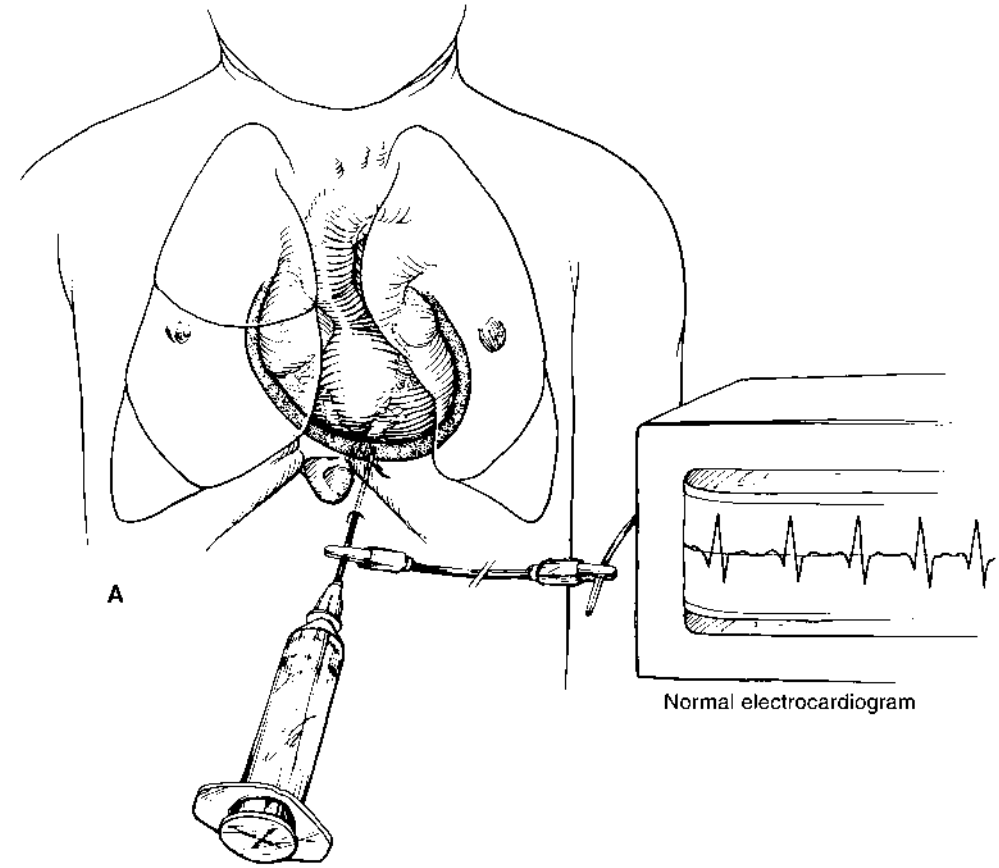
Contraindications

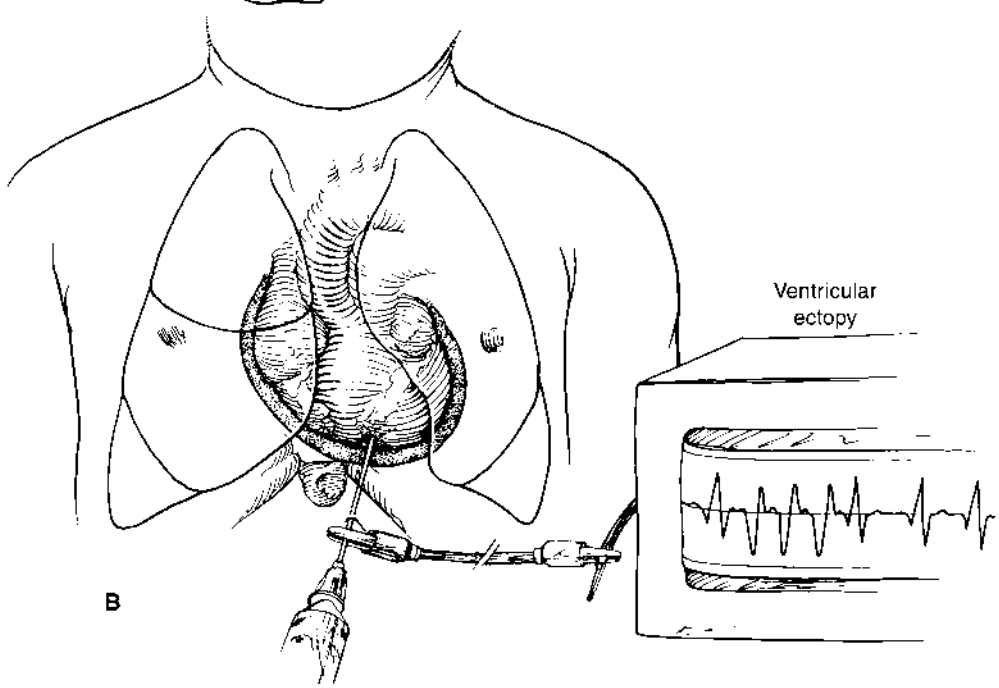
Congenital heart disease or surgery precluding transvenous access to the cardiac chambers

Complications

Acute

1. Perforation of vessel, heart, and/or contiguous structures (e.g., pneumothorax)





9.1

2. Hemopericardium
3. Failure to pace or sense normal cardiac electrical activity.
4. Arrhythmias related to catheter position in the heart (e.g., pacing catheter triggered ventricular tachycardia)
5. Venous occlusion by pacer lead

Subacute

1. Infection of cutaneous site or of catheter, if indwelling
2. Venous thrombosis related to catheter and embolic vascular events

Equipment

1. Needles for vessel entry and local anesthesia, scalpel blades, 1% lidocaine
2. Catheter introducer sheath (i.e., Hemaquet® with sideport), guidewire, suture material, povidone–iodine solution, sterile barrier, sponges, and sterile alligator clip
3. 3F to 5F pacing catheter—bipolar, with or without balloon tip
4. Single chamber external pacemaker with variable output current and sensitivity
5. Cardiac monitor and/or fluoroscope or ultrasound

Procedure

Temporary transvenous cardiac pacing entails insertion of a pacemaker catheter through a central vein into either the right atrium or right ventricle in order to deliver a current of electricity stimulating contraction of the heart to maintain circulatory integrity. Using the Seldinger technique (see Procedure 3.2) for venous access, insert an introducer sheath into the femoral, internal jugular, or subclavian vein under sterile conditions. In neonates, the pacing catheter can be inserted into the umbilical vein without a sheath.

After central venous access is attained, insert the pacing catheter through the introducer sheath and into the vein and *gently* advance it toward the heart. Guidance of catheter passage by fluoroscopy or ultrasound is desirable if available, but in an emergent situation the catheter can be advanced blindly or with EKG guidance. Position the distal end of the catheter in the atrium or ventricle, depending on the indication for pacing. An atrial catheter should be positioned laterally or in the atrial appendage, and a ventricular catheter should be positioned in the right ventricular apex. When advancing the catheter blindly, the cardiac monitor should be observed carefully for ectopy, which confirms atrial or ventricular contact. The pacemaker generator should be connected during manipulation, with proper capture of either the atrium or ventricle confirming the catheter position. If advancing under EKG guidance, the negative pole of the bipolar pacing electrode should be connected to a surface precordial lead with an alligator clip. The pacing electrode should be advanced and as the electrode traverses the right atrium and comes into contact with the right ventricle predictable EKG changes should be observed consistent with those expected on an intracardiac EKG (Table 9.1).

TABLE 9.1

EXPECTED CHANGES WITH CATHETER ADVANCEMENT ON INTRACARDIAC ELECTROCARDIOGRAM

Location	EKG changes
High right atrium	P wave and QRS complex inverted P wave usually with larger negative deflection than the QRS complex
Low right atrium	P wave develops a positive deflection
Crossing tricuspid valve	P wave biphasic
Right ventricle	P wave with small positive deflection Larger QRS complex deep and inverted
Right ventricular endocardium	Current of injury pattern—widened and enlarged QRS, ST segment changes

Connect the catheter to the pacemaker if not done already. Set the desired rate. Set the output current control to the maximum milliamperage and turn the pacemaker on. If electrical and mechanical capture are documented (pacer spike followed by either a P or QRS at the set rate along with a palpable pulse corresponding to the QRS), then progressively decrease the current until capture is lost. This is the *threshold current*. Set the milliamperage at 150% to 200% of the threshold current for a safety margin. Set the sensitivity control to the lowest setting (asynchronous) to pace all the time, regardless of the patient's own cardiac activity, or higher to allow suppression of the pacemaker by the patient's intrinsic cardiac activity. After insertion of the catheter, a chest x-ray should be obtained to confirm the catheter tip position radiographically.

Consider withdrawal of the sheath after the position of the catheter is confirmed, and it is functioning properly. Secure the catheter to the skin with a 4-0 silk suture. Place a sterile dressing, and secure the pacer to the arm or other location. If external transvenous pacing is to be of several days' duration, then prophylactic antibiotics and/or anticoagulation should be considered.

10.1. NASOGASTRIC TUBE PLACEMENT

Indications

1. Decompression of the stomach and proximal bowel for obstruction or trauma
2. Gastric lavage in the child with upper gastrointestinal (GI) bleeding or an ingestion/overdose
3. Administration of medication or nutrition

Complications

1. Tracheal intubation
2. Nasal, pharyngeal or esophageal trauma or laceration
3. Reflux or vomiting leading to aspiration
4. Direct airway instillation of tube contents—medications, food, etc.

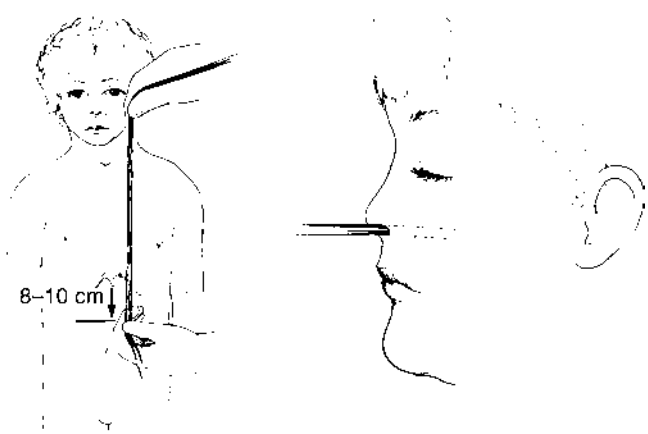
Procedure

Choose the largest size tube feasible to perform the indicated task, without causing undue discomfort to the child. In general, choose an 8F tube in the newborn, and around a 12F by the age of 1 year. A teenager will usually tolerate an 18F. In between, pick the size accordingly. In an adolescent overdose, the use of a 28F to 40F tube will assist in the efficient drainage of pill fragments from the GI tract, but its use has become very uncommon in the management of overdoses. Estimate the length of tubing to be passed by adding 8 to 10 cm to the distance from the nares to the xiphoid process (Fig. 10.1).

Prepare the child by explaining the procedure as fully as possible; sedation is rarely required. Older children who are alert can remain sitting. Infants and obtunded children require the supine position with their head turned to the side.

Straighten the curved tube out and check its patency with a syringe. If it is too pliable, stiffen it by immersion in ice water. Apply lubricant or lidocaine gel to facilitate atraumatic nasal passage. Grasp the tube 5 to 6 cm from the distal end and advance it posteriorly along the floor of the nose. If it is incorrectly directed up the nose, the tube may lacerate the inferior turbinate. Insert it with the natural curve of the tube pointing downward to pass the bend of the posterior pharynx. A cooperative child can be asked to flex his/her head slightly, as well as to swallow some water to assist in glottic closure and easy passage into the esophagus. An assistant should flex the infant's neck. If the child coughs and gags persistently or if the tube emerges from the mouth, temporarily discontinue the procedure and support the child until they recover from the episode.

When the tube is successfully passed to the measured length, check its position. Attach a syringe filled with air to the proximal end and, while depressing the plunger rapidly, listen with a stethoscope for gurgling over the stomach. Other confirmatory tests in high risk patients should be considered prior to using include pH testing of gastric contents (pH should be less than 4) or a frontal single view of the chest and part of the upper abdomen to confirm location. Tape the tube securely to the nose, using tincture of benzoin on the skin in the uncooperative or diaphoretic child.



10.1

10.2. PERITONEAL TAP

Indications

1. To obtain peritoneal fluid for diagnostic purposes
2. Relief of respiratory distress secondary to a large peritoneal fluid collection

Contraindications

1. Second or third trimester pregnancy (ultrasound guidance recommended)

Complications

1. Perforation of abdominal viscera or vessels
2. Local bleeding or soft tissue infection
3. Peritonitis
4. Ascitic fluid leak

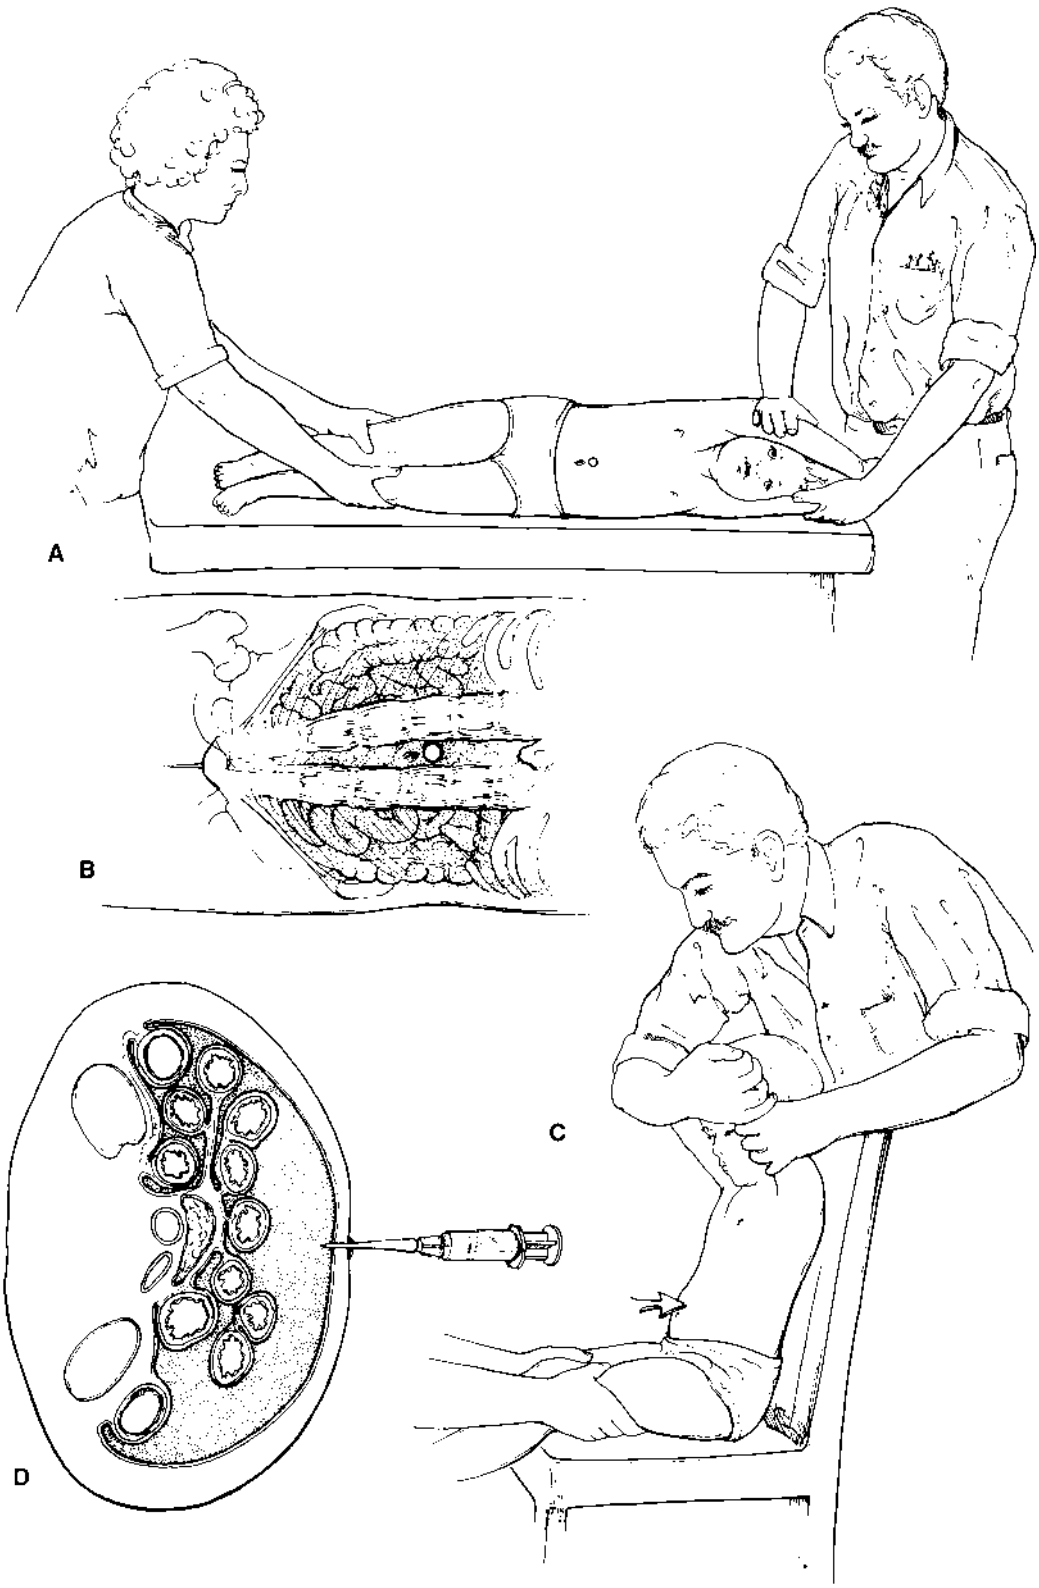
Procedure

The child undergoing a diagnostic peritoneal aspiration may require sedation to permit safe access to the peritoneal cavity. If a large amount of intraabdominal fluid has accumulated, it may elevate the diaphragm, causing respiratory compromise. This serves as a relative contraindication to the use of general anesthetic for sedation.

Before attempting this procedure, carefully evaluate the abdominal anatomy. Verify the presence of ascites by percussion, being certain to note shifting dullness after the child is turned. Place the patient in the position in which the procedure is to be done, either sitting (Fig. 10.2C) or lateral decubitus (Fig. 10.2A) with an adequate amount of restraint. If a large amount of fluid has collected, the child will have less respiratory embarrassment if allowed to be seated during the procedure. If concern remains regarding the location of viscera, adhesions, or a specific area to be entered for diagnostic studies, ultrasound can aid in localizing the best place to enter the abdominal cavity.

For a diagnostic tap, use an 18-, 20-, or 22-gauge metal needle or over-the-needle catheter. If a large amount of fluid must be evacuated, the plastic catheter, in contrast to a metal needle, allows repositioning of the patient and decreases the risk of bowel perforation during a prolonged procedure. There is a risk of kinking with a plastic catheter as well as a risk that the plastic catheter could be sheared off into the peritoneal cavity.

As shown in Figure 10.2B, a midline approach in either supraumbilical or infraumbilical location is probably the



10.2

safest. Position the child in either the sitting or decubitus position. Cleanse a large area around the planned site with povidone–iodine solution. Then, if in the decubitus position, drape the patient with towels under and over the back; whereas if in the sitting position, drape towels on the lap. Wearing sterile gloves, inject the skin with 1% lidocaine.

After local anesthesia is achieved, take the needle and catheter in hand. Stabilize the tip of the needle with the thumb and index finger, placing the heel of this hand against the abdominal wall. With the other hand, direct the needle perpendicular to the abdominal wall. Puncture the skin, and then move the needle tip caudad and parallel to the midline for a short distance to make a Z-track. Advance the needle with support until a "popping sensation" or decreased resistance is appreciated. Immediately verify penetration through the peritoneum by drawing fluid into the syringe. As shown schematically in Figure 10.2D, the abdominal viscera lie slightly away from the peritoneum if a moderate amount of fluid has collected.

Slowly advance the needle several millimeters while continuing to aspirate fluid with the syringe. Then remove the needle and syringe from the catheter and cover the opening with the thumb. After attaching a larger syringe and T-connector, observe for a brisk flow of fluid. The catheter tip can be repositioned once the needle has been removed, and the patient safely turned to facilitate the collection of fluid. When the procedure is completed, quickly pull the catheter straight out, and firmly apply sterile gauze and then a pressure dressing to the puncture wound.

10.3. PERITONEAL LAVAGE

Indications

Evaluation of a patient with blunt multiple trauma, and/or penetrating thoracoabdominal trauma, with cardiovascular instability or coma, to determine the need for immediate laparotomy. It is not sensitive for retroperitoneal bleeding.

Complications

1. Iatrogenic injury to abdominal viscera or vessels (may be enhanced by prior abdominal adhesions)
2. Hemorrhage or bleeding from the procedure with potential to be false positive test.
3. Wound infection and/or peritonitis
4 Evisceration

Contraindications

1. Existing indication for celiotomy
2. Relative contraindications are recent abdominal surgery, preexisting coagulopathy, and/or morbid obesity

Equipment

1. Povidone–iodine solution; sterile drapes; gloves; gauze; 1% lidocaine with epinephrine; peritoneal dialysis/lavage catheter; Ringer's lactate and/or normal saline solution; IV catheter; collecting bag; sample tubes; sutures (reabsorbable and superficial); Steri-strips
2. Open technique—no. 15 scalpel blade and handle, and two hemostats
3. Closed technique—18-gauge needle, guidewire, no. 11 scalpel blade

Procedure

The child should receive an overall trauma assessment, an IV infusion of saline through at least one large-bore catheter, and the appropriate laboratory and radiographic evaluation. Correction of any cardiorespiratory disturbances is essential for the procedure to be safely performed.

Pass a nasogastric tube to decompress the stomach and a urinary catheter to empty the bladder. Select a site for the incision, either supraumbilical or infraumbilical, in the midline. A supraumbilical location is preferable in younger children in whom the bladder extends into the abdomen (Fig. 10.3A) and/or in pregnant patients (above the uterine fundus). Using aseptic technique, including sterile gown, gloves, and mask, prepare the anterior abdominal wall with povidone–iodine solution. Inject 1% lidocaine with epinephrine (to lessen bleeding) into the skin and subcutaneous tissue for local anesthesia.

Open Technique

When performing the open technique, make a 1.5- to 2-cm transverse incision in the skin with a no. 15 scalpel blade 1 to 2 cm above the umbilicus (Fig. 10.3A). The subcutaneous tissue should be divided and the linea alba exposed by blunt dissection. Make a transverse or vertical incision through the linea alba as shown in Figure 10.3B, with care not to penetrate deeper than this fascial plane.

Using two hemostats, grasp the peritoneum at the center of the fascial opening, as shown in Figure 10.3C. The field should be maintained free of blood to prevent a false-positive result. Between the hemostats, make a small incision through the peritoneum with the scalpel to provide access to the abdominal cavity. An immediate return of frankly bloody material constitutes a positive result.

If frankly bloody fluid is not obtained on opening the peritoneum, gently introduce a peritoneal dialysis catheter, without a trocar, through the peritoneal opening. Pass it caudally just inside the peritoneal lining into the pelvis to minimize the chance of perforating a viscus, as shown in cross-section in Figure 10.3D. If aspiration through the catheter yields frankly bloody fluid, significant intraabdominal bleeding has occurred.

Closed Technique

When performing the closed technique, insert an 18-gauge beveled needle attached to syringe through the skin, subcutaneous tissue, fascia, and into the peritoneum. (Light resistance may be noted when penetrating the fascia and the peritoneum.) Using Seldinger technique, pass a guidewire through the needle until resistance is met, or 3 cm of guidewire remains outside needle hub. Then remove the needle over the guidewire, with caution not to displace current guidewire location. Using an 11-blade scalpel, incise a small area of skin directly next to the guidewire (entrance site of the catheter).

A
Incision across linea alba
B
Site of peritoneal incision
C
D
E

10.3

Next, pass peritoneal lavage catheter over the guidewire into the peritoneal cavity and withdraw the guidewire. Connect catheter to syringe and aspirate. If gross blood is obtained, significant intraabdominal bleeding has occurred.

Lavage (Open and Closed Techniques)

If no blood is obtained, quickly infuse 10 to 20 mL per kg of Ringer's lactate or normal saline solution into the abdominal cavity through the catheter, as shown in Figure 10.3E. After the fluid has been instilled, turn the patient from side to side to promote its distribution throughout the peritoneal cavity. Then, allow the fluid to run back out under gravity into a sterile collecting bag connected to IV tubing. Return of at least 200 ml of lavage represents adequate sample (at the rate 30% to 50% of fluid volume instilled). Effluent samples should be sent for determination of red blood cell (RBC) count, white blood cell (WBC) count, amylase level, Gram stain, and examination for stool or food particles. At the completion of the lavage, whether the result is positive or negative, carefully remove the catheter. Use chromic sutures to close the peritoneum, and 2-0 or 3-0 absorbable sutures for the fascia and subcutaneous tissue. Place Steri-strips across the skin.

Positive results include gross blood; more than 100,000 RBCs or 500 WBCs per high-power field in blunt trauma; greater than 10,000 RBCs in penetrating trauma; particulate matter or positive Gram stain for food fibers or bacteria; elevated lavage amylase or alkaline phosphatase. A negative diagnostic peritoneal lavage does not exclude retroperitoneal bleeding or diaphragmatic tears.

10.4. REPLACEMENT OF A GASTROSTOMY TUBE

Indications

Obstruction or dislodgment of a gastrostomy tube

Contraindications

1. Evidence of peritonitis
2. Freshly placed tube in first weeks after placement (relative)
3. Tubes out more than 4 to 6 hours (often require dilation)

Complications

1. Bleeding at the mucosal site
2. Separation of the stomach from the abdominal wall
3. Gastric outlet obstruction from an improperly positioned tube

Equipment

1. Replacement tube—Button, Bard, Mallincott, MIC KEY, PeeWee, or Foley catheter
2. Lubricant
3. Normal saline
4. Syringes (5 to 10 mL, 30 to 50 mL)
5. Absorbent dressing
6. Tape

Procedure

When a child with a gastrostomy appears in the ED after dislodgment of the tube, it should be replaced as soon as possible. The opening quickly narrows, making passage of a replacement difficult.

Perform a history and physical examination to rule out an intraabdominal obstruction, and examine the gastrostomy site for bleeding or tears. Pass a blunt-tipped stylet or lubricated cotton-tipped swab through the opening to assess the patency and direction of the tract.

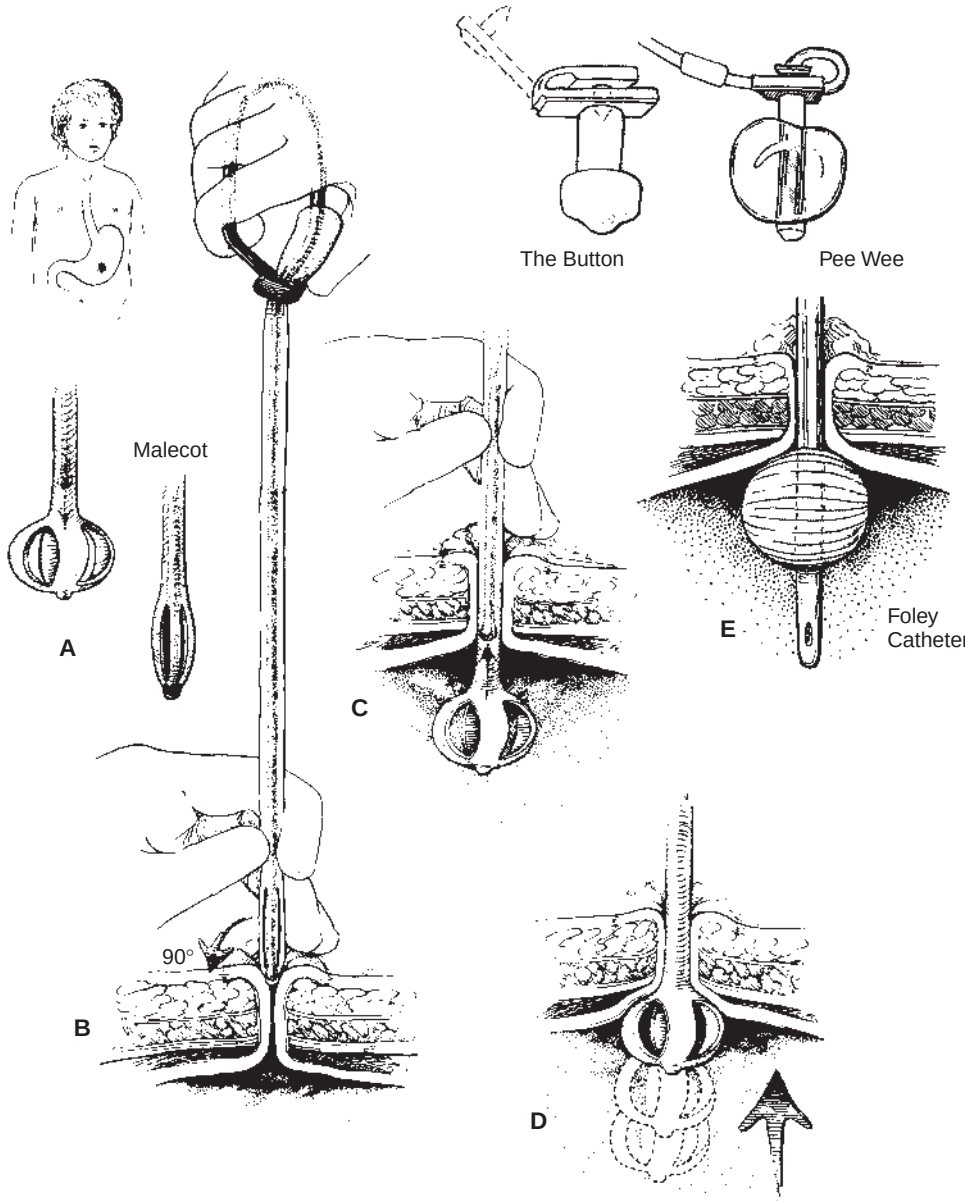
Prepare the equipment. Fill the balloon with saline to ensure it works. When using "mushroom" or "ball" tubes, slide the tube over the stylet after lubricating the distal end, as in Figure 10.4A. When no replacement is available, an alternative is to use a Foley catheter of similar diameter. Hook the end of the tube and the handle of the stylet, and generously apply lubricant to the distal portion.

Restrain the child in the supine position. Holding the system perpendicular to the abdominal wall, as in Figure 10.4B, aim it in the direction of the stoma tract as determined by the previous probing. Grasp the distal end of the tube between the index finger and thumb of one hand and stabilize it by placing the heel of this hand against the abdominal wall to prevent slippage. When using a styletted tube, the other hand holds the handle of the stylet and the proximal portion of the tube.

Pass the tip of the catheter into the opening to the gastrostomy site and, with steady, firm pressure, push it down in the direction of the stomach, perpendicular to the abdominal wall. It may take 30 to 45 seconds of this steady pressure to stretch the site enough to permit entry. Avoid sudden jerking of the tip because this increases the chance of mucosal damage or separation.

When the stomach is entered, resistance suddenly lessons. As shown in Figure 10.4C, the tube must be inserted far enough so the entire tube or whole "mushroom" tip (balloon) is in the gastric cavity. For buttons, advance completely. Instill the saline to inflate the balloon. Remove the syringe. For a styletted tube, advance several centimeters if little resistance, detach the handle of the stylet from the catheter, and pass the catheter 4 to 5 cm farther. The balloon will spontaneously open on withdrawal of the stylet. Then fully withdraw the stylet and pull the tube gently out to appreciate the "clunk" on reaching the surface. If the tube is in the stomach, it will move freely and spontaneously drain gastric contents. If gastric contents do not spontaneously drain and the tube appears to be in, install 30 to 60 mL of normal saline and withdraw it to check for gastric contents. If still in doubt or with difficult placements, consider instilling barium or gastrograffin and obtaining a radiograph. Recent literature suggests that ultrasound with color Doppler can accurately define the location of the tube as can air insufflation as a contrast medium. Cover the distal end with clean gauze.

Occasionally, the catheter may not be advanced far enough, leaving the balloon in the wall of the stomach. If this is the case, remove the saline with the syringe or reinsert the stylet, stretch the tube, and with constant pressure, advance the catheter into the stomach. Similarly, if a child with a gastrostomy tube in place appears to be uncomfortable or have an obstructed tube,



10.4

the tube may have been incorrectly placed or may have slipped out so the balloon is inflated in the gastric wall.

If the procedure causes mucosal trauma, the local application of lubricant gel or a neutralizing agent, such as an antacid, may decrease inflammation of the stoma.

10.5. REDUCTION OF AN INCARCERATED INGUINAL HERNIA

Indications

1. To prevent strangulation of incarcerated bowel, ovary, or other organs
2. To allow for edema to resolve, permitting a less hazardous, semi-elective repair of the hernia

Complications

1. Compression damage of the bowel or other incarcerated organ or tissue (may be related to the incarceration and not reduction).
2. Increased edema and pain

Procedure (Fig. 10.5)

Be careful to ascertain if the patient has a hernia and not the acute presentation of a hydrocele. Place the patient supine in a

10.5

mild Trendelenburg position to decrease edema in the incarcerated tissue. The primary principle of reduction is to reduce the contents of the bowel first, after which the edematous bowel itself may then be coaxed back into the abdominal cavity. Consider pharmacologic sedation and pain control to reduce discomfort and the infant's rising intraabdominal pressure. This is done by applying bimanual pressure along the entire inguinal canal so uniform pressure is placed on the incarcerated bowel. Begin to apply pressure gently with slightly increased pressure in the distal canal compared with the proximal canal to encourage reduction of intestinal contents into the bowel within the abdomen. Apply a sustained, moderate pressure for up to 5 minutes or until reduction is achieved.

If reduction has not occurred at this point, it may be due to patient discomfort and tensing of the abdominal wall. Reassess the pain control or sedation used. When ready, reposition the patient gently in a Trendelenburg position and apply the same maneuver of sustained pressure along the inguinal canal. Use one of the ipsilateral hand having thumb and index finger compressing at the ring while the other hand is leading/pushing the hernia towards the ring will often be successful. If sustained pressure is successful, a gurgling sensation will

first be felt as the intestinal contents move back into the intraabdominal bowel, after which the bowel loop itself may begin to move and finally slide up the inguinal canal and in through the internal ring into the abdomen. When manual reduction, even with sedation, is not successful, usually the situation is one in which the incarcerated bowel and/or ovary is outside the external ring. Another mass within the inguinal canal that does not lend itself to ready reduction is a hydrocele, which simulates incarcerated bowel. On occasion an ultrasound will help distinguish between the two when unclear on physical examination. After reduction, the rate of complications is similar to operative issues, with the exception of recurrent incarceration being common. If reduction is not successful after an effort of 5 or 10 minutes with the benefit of sedation, prepare the patient for surgery and consult to have the infant assessed immediately.

10.6. RECTAL PROLAPSE

Indications

Manual reduction of rectal prolapse is necessary when it is prolonged, fails to reduce spontaneously, or is associated with passive congestion and/or hemorrhage.

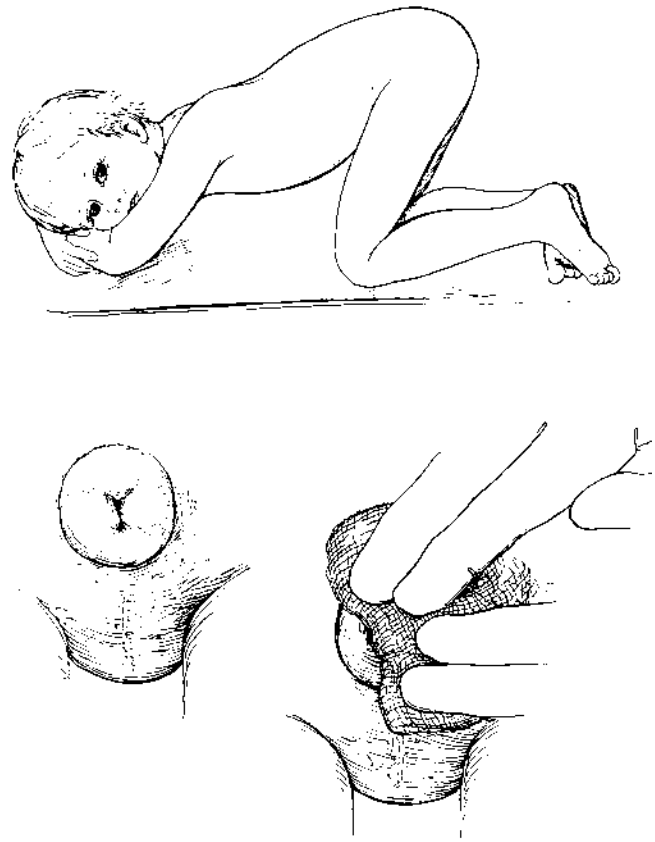
Complications

Extremely rare but occasionally bleeding occurs

Procedure

In the anxious child (peak age, 1 to 3 years), consider administration of sedative before attempting. Don gloves. Have the child lie prone on his/her knees. Lubricate your gloves with petrolatum (Vaseline) and hold the prolapsed edges with 4 × 4 in^2 gauze. Then bimanually apply pressure on alternate sides to reduce the prolapse (Fig. 10.6). Application of a pressure dressing with Vaseline/gauze, dry gauze and tape across the buttocks is recommended.

Have the patient lie on his/her side afterward. Be sure to address the primary problem (see Chapters 13, 99, and 121). Causes include cystic fibrosis, diarrhea, chronic constipation and neurologic conditions. Surgery is uncommonly required in young children.



10.6

11.1. CATHETERIZATION OF THE BLADDER

Indications

1. Multiple trauma, especially for evaluation of the urinary tract in the unconscious child
2. Monitoring of urine output in conditions such as shock or severe head injury
3. Relief of acute urinary retention
4. To obtain a urine specimen for diagnosis in a young child or other when they cannot give a clean catch specimen

Contraindications

Urethral trauma

Complications

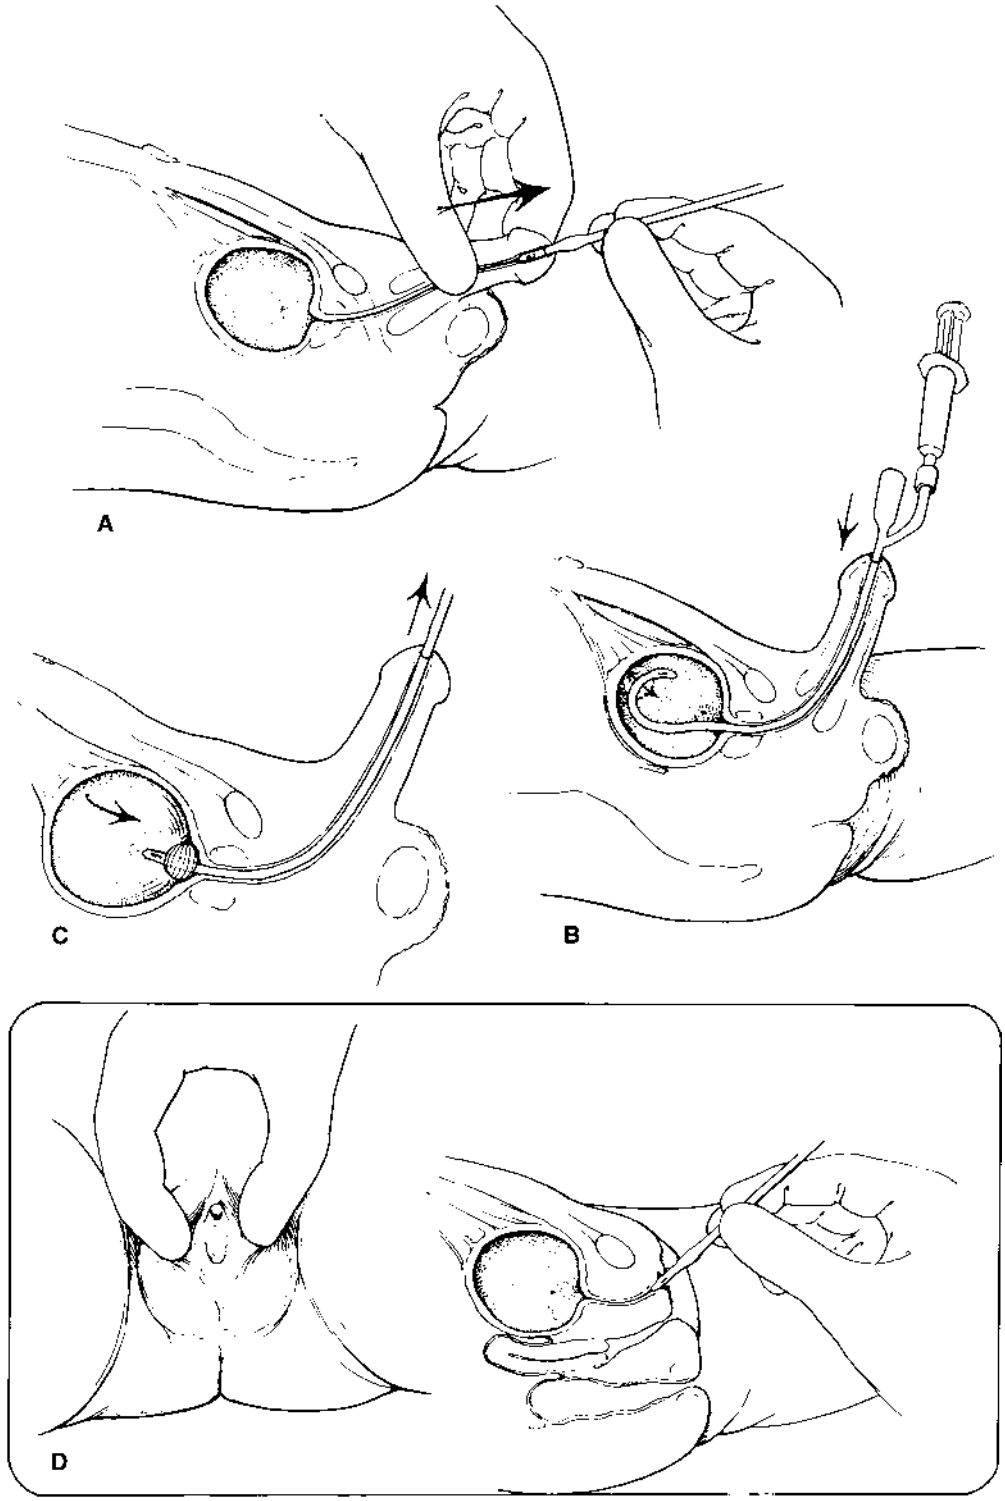
1. Urethral, bladder trauma
2. Vaginal catheterization
3. Urinary tract infection
4. Intravesical knot (rare)

Procedure

Restrain the patient as necessary, using the method shown for suprapubic bladder aspiration in infants (Fig. 11.1A). The older child may require additional restraint if he/she is uncooperative. Prepare the urethral meatus and penis or the perineal area thoroughly by scrubbing with a povidone–iodine solution; select a Foley catheter of the appropriate size (8F in newborns, 10F in most children, and 12F in older children). Inflate the balloon on the catheter with normal saline to test its competence. The catheter tip should be well lubricated with sterile lubricant to minimize local trauma.

Male

As shown in Figure 11.1A, gently grasp and extend the penile shaft to straighten out the urethral pathway. Hold the catheter



11.1

near the distal tip and advance it up the urethra unless resistance or an obstruction is encountered. If this occurs, select a smaller catheter. Generally, if an 8F is too large, a 5F, 15-cm length feeding tube is a satisfactory alternative, but it is more difficult to maintain in the bladder.

When the catheter reaches the junction of the penile shaft and the perineum, it may help to position the penis more vertically, as shown in Figure 11.1B. The catheter should be passed into the bladder all the way to the Y-connection; this is important because urine may begin to flow while the catheter

is in the proximal urethra, and inflation of the balloon in the urethra may lead to complications.

Figure 11.1C shows withdrawal of the catheter after inflation of the balloon. When the balloon strikes the wall, a "clunking" sensation is appreciated; this indicates that the balloon is resting on the trigone. The catheter should then be taped to the child's leg, leaving a lax portion to prevent injury to the trigone if the catheter is accidentally pulled.

Female

In the female, the principles of catheterization are similar to those in the male. Have an assistant carefully spread the labia, as shown in Figure 11.1D, if it is difficult to visualize the urethra. Then, introduce a well-lubricated, pretested Foley catheter into the bladder. Again, advance the catheter its entire length before inflating the balloon. A catheter that is passed in its entirety will avoid the problem of inadvertently catheterizing the vagina of a young girl. After withdrawing the catheter until a "clunking" sensation is appreciated, secure it with tape to the child's leg.

11.2. SUPRAPUBIC BLADDER ASPIRATION

Indications

To obtain a sterile urine specimen for culture in infants and children younger than 2 years of age or children who are incontinent when urethral contamination is to be avoided or anatomic abnormalities are encountered. In general, urethral catheterization has become the preferred technique.

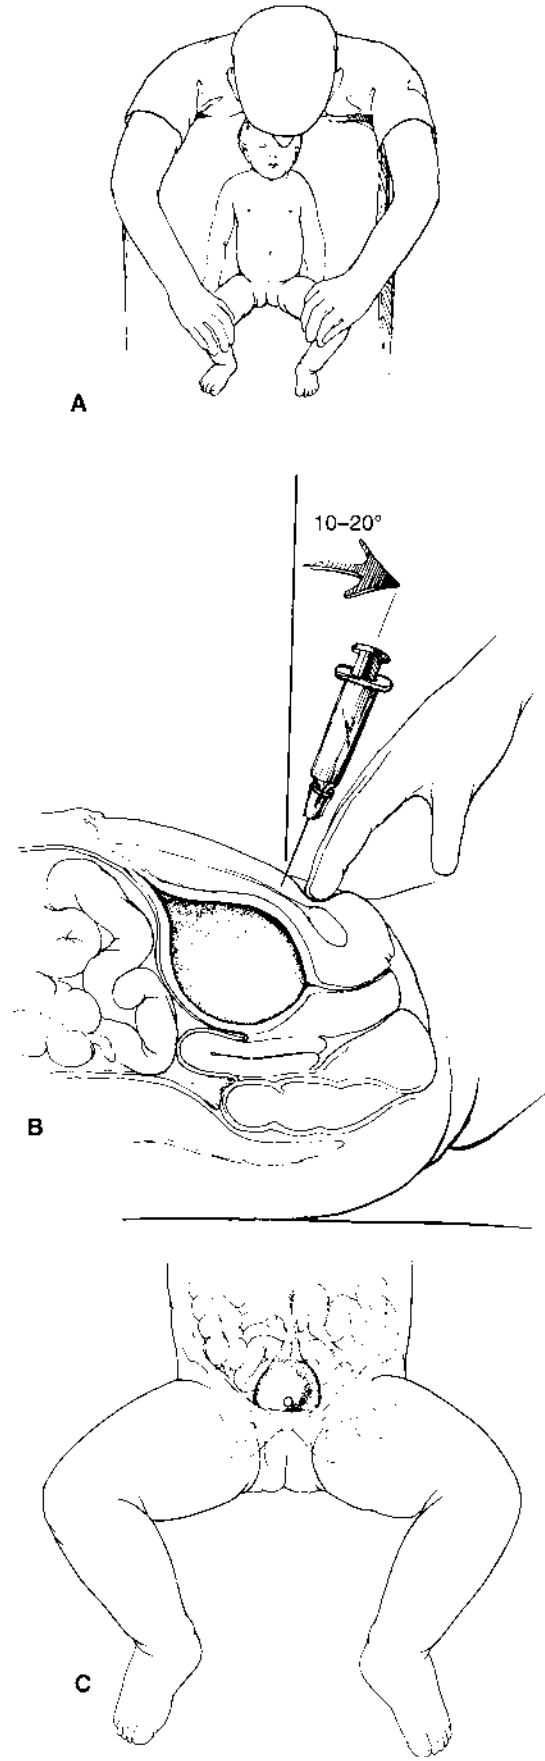
Complications

1. Hematuria—microscopic hematuria virtually always occurs. Gross hematuria is uncommon.
2. Intestinal perforation
3. Infection of the abdominal wall

Procedure

Consider use of ultrasound as shown in Figure 13.3 to assess for urine in the bladders prior to the procedure. Position the infant supine. Holding the legs in the frog-leg position as shown in Figure 11.2A, restrain the child firmly. Have a gloved assistant occlude the penile urethra in a male infant to prevent urination while preparations are made. It is wise to wait at least 1 hour before doing this procedure if the infant has just voided.

Select a puncture site in the midline of the abdomen, approximately 1 to 2 cm cephalad to the superior edge of the pubic bone (Figs. 11.2B and 11.2C). Prepare the skin by cleansing with povidone–iodine solution. After three applications of the antiseptic solution, wipe the dry area with 70% alcohol. Position a 1.5-in 22-gauge needle (with 3-mL syringe attached) at the planned puncture site perpendicular to the plane of the abdominal wall, which is generally 10 to 20 degrees from the true vertical (Fig. 11.2C). Pierce the skin and then, with a second quick stabbing



11.2

motion, enter the bladder. Withdraw the needle slowly while aspirating with the syringe. If urine is not obtained, do not remove the needle from below the surface of the abdomen. Instead, change the angle of the needle, and reinsert it as previously described. Attempt the procedure at two different angles; first, about 20 degrees caudad to the perpendicular, and second, above 20 degrees cephalad to the perpendicular. If urine is not obtained after the third attempt, further trials are unlikely to be successful. Either perform urethral catheterization or wait 1 to 2 hours and try the suprapubic bladder tap again. Alternatively, use simple ultrasound to know when the bladder is fuller to be able to better guarantee collection of urine specimen.

12.1. INCISION AND DRAINAGE OF AN ABSCESS

Indications

Diagnostic and therapeutic drainage of fluctuant adenitis or superficial soft tissue abscess. Community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is commonly the etiologic agent.

Complications

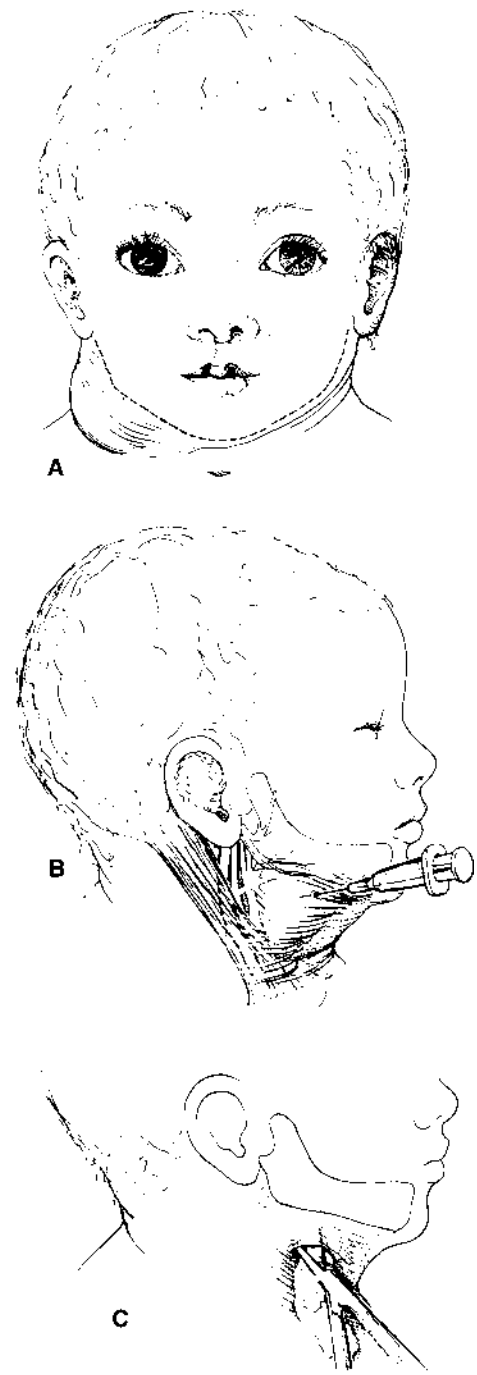
1. Scar formation
2. Injury to local structures surrounding or underlying the abscess (arteries, veins, nerves, tendons)
3. Fistula formation—usually only with mycobacterial neck mass (scrofula)

Contraindications

1. Relative contraindications would include herpetic whitlow, which may increase spread of infection and atypical tubercular abscesses where fistula risk increases.
2. Consider surgical consultation with deep perianal or central facial abscesses.

Procedure

Preparation of the pediatric patient for abscess drainage is critical and includes pharmacologic anxiolysis and pain management in most instances. This may necessitate attention to the NPO status of the patient. Of less risk, is consideration of oral anxiolysis and amnesia with medication such as midazolam in dosing up to 0.5 mg per kg (maximum 20 mg). Parenteral use of ketamine for procedural sedation is much more satisfactory in children with a complex or large abscess. The application of EMLA® or other anesthetic cream may be of value anesthetizing the superficial epidermis when the procedure is not being performed immediately. Distraction techniques and the use of child life may also help to reduce anxiety and pain. Immediately prior to beginning the procedure, position the child to maximize the access to the abscess, and complete the preprocedural time out as required by your institution. For example, in case of a cervical neck mass, place the child supine with head turned 90 degrees away from the midline to expose the neck. Have an assistant stabilize the patient at the site of the procedure, Figures 12.1A and 12.1B shows a neck abscess, and restrain as necessary. Local anesthetic (xylocaine 1%) injection in a field block 360 degrees surrounding the abscess will reduce pain. This should be followed by xylocaine injection linearly along the abscess where the incision is to be made. In very small ones, occasionally the topical anesthetic is sufficient if appropriate pain relief has been achieved with adjuvant medication.



12.1

Incision and Drainage

Preparation of the site includes cleansing of the skin with povidone–iodine solution. With a no. 11 scalpel blade, incise the skin over the abscess parallel to the natural creases of the skin to the depth of the superficial fascia. Then, bluntly open the abscess with a hemostat for at least 1 cm, as shown in Figure 12.1C. Insert a gloved little finger into the abscess to break up any septae. The abscess cavity may be irrigated with normal saline to enhance removal of debris and purulence. Pack the wound lightly with a packing strip leaving 2 to 3 cm of the strip outside of the cavity. This will function to physically keep the wound open to promote further drainage and also will provide hemostasis. Dress the wound with an absorbent dressing, such as Mepilex® Border, that will draw additional purulence and drainage away from the skin surface. Remove the packing in 1 to 2 days. The utility of antibiotics in addition to incision and drainage is unclear with studies demonstrating equal efficacy. Some recommend use when there is surrounding cellulitis, systemic symptoms such as fever or difficult to completely drain early abscesses (see Chapter 92).

12.2. CLOSED REDUCTION OF DISLOCATIONS

12.2A. Finger/Toe Joint Dislocation

Indications

Interphalangeal and metacarpophalangeal/metatarsophalangeal dislocations

Complications

Fractures secondary to attempted reduction

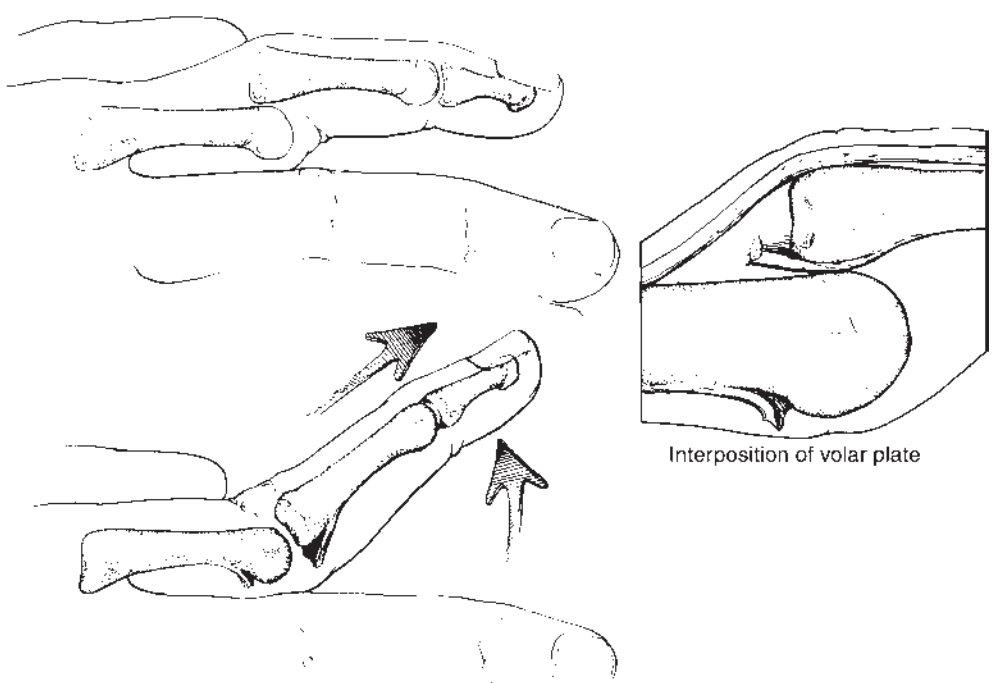
Procedure

Check the neurovascular status in the affected phalanx. Splint the deformed phalanx for comfort if necessary. Radiographs of at least two views are usually taken to ascertain the presence of obvious fractures or interposition of the volar plate of the distal phalanx. It is important to note that closed reduction of a dislocation may not be possible when there is dorsal dislocation with interposition of the volar plate or entrapment of the metacarpal/metatarsal head (Fig. 12.2A).

Consider the use of procedural sedation, a digital block, or both. If necessary, have an assistant restrain the child. Grasp the extremity proximal to the dislocation to stabilize the joint. Grasp the tip of the distal phalanx and apply traction longitudinally. The joint will usually slide into proper position. If this method is unsuccessful, apply pressure distally to accentuate the deformity a few degrees, mild hyperextension, while applying traction to the phalanx longitudinally.

After reduction, obtain radiographs to ensure proper position of the joints and to evaluate for fractures. Immobilize the joint in slight flexion for 2 to 3 weeks in total, usually with a foam padded splint. Distal interphalangeal joints are immobilized in full extension and proximal interphalangeal joints with 20 to 30 degrees of flexion. If a small avulsion of the volar lip of the distal phalanx is evident, apply a dorsal splint to prevent hyperextension of the affected joint.

In cases in which the reduction is unsuccessful, the volar plate is interposed, or the second metacarpal bone is trapped, consult an orthopedic surgeon immediately to assess the need of open reduction. Volar dislocations are more complicated and often require open reduction.



12.2A

12.2B. Shoulder (Glenohumeral) Joint Dislocation

Indications

Anterior shoulder dislocations in adolescents and young adults. For posterior shoulder dislocations, orthopedic consultation is recommended.

Complications

1. Nerve injury to the axillary nerve, brachial plexus, radial, ulnar, or distal nerves
2. Tear or detachment of the rotator cuff
3. Fractures of humeral head
4. Vascular injury
5. Recurrent dislocation

Procedure

There are multiple methods to reduce an anterior dislocation of the shoulder. Most pediatric emergency medicine physicians prefer techniques that require minimal force such as the external rotation techniques, the Stimson technique, or the scapular manipulation technique. The traditional traction–countertraction technique is still used in many circumstances but it requires more force and several assistants. Reduction of glenohumeral dislocation often requires administration of both intravenous narcotic analgesics and muscle relaxants (i.e., fentanyl and midazolam). However with some of the less forceful techniques, little to no medications are required.

1. The External Rotation Technique

   The patient is sitting upright or lying supine and has the elbow on the affected side adducted and flexed at 90 degrees. The clinician usually grasps the wrist and very slowly (over 5 to 10 minutes) externally rotates the shoulder while maintaining the arm adducted. The shoulder usually relocates when the arm is externally rotated between 70 to 110 degrees. A variation of this technique is called the Hennipen technique.

   Occasionally, the Milch technique is added to the external rotation technique to achieve reduction. After the arm is fully externally rotated, abduct the arm at the shoulder over the head while maintaining external rotation. Then apply traction in line with the humerus and apply posterior pressure over the humeral head—either with direct force over the anterior head of the axilla or pressure to the humeral head in the axilla using the clinician's thumb.
2. The Stimson Technique

   The patient lies prone with the affected arm hanging over the edge of the stretcher with 4–7 kg (10-15 lb) pounds of weight attached to the wrist. Muscular relaxation by use of benzodiazepine may facilitate reduction. Reduction usually takes approximately 20 to 30 minutes (Fig. 12.2B, part A)
3. Scapular Manipulation Technique

   The patient usually lies prone with the affected arm hanging off the edge of the stretcher. To facilitate reduction, apply downward traction using either an assistant or 10 to 15 pounds of weight attached to the wrist. The clinician will then pushes the inferior tip of the scapula medially while pulling the superior aspect laterally (Fig. 12.2B, part B). Muscular relaxation is a good adjunct for this procedure.
4. Traction and Countertraction

   Have an assistant apply countertraction with a folded sheet wrapped around the chest. Simultaneously, as the operator, exert traction to the arm as shown in Figure 12.2B, part C. After the linear traction frees the humeral head, apply slight lateral traction to reduce the proximal humerus.

Postreduction

Following successful reduction, splint the shoulder either using a sling and swath or shoulder immobilizer. Traditionally the shoulder has been immobilized in internal rotation and reduction, however some recent studies suggest that the incidence of redislocation is less with 10 degrees of external rotation. Most clinicians obtain a postreduction radiograph of the shoulder yet new findings are rarely found on postreduction films. The patient should be referred for orthopedic follow-up and rehabilitation.

12.2C. Patella Dislocation

Indications

Closed patellar dislocations, particularly laterally displaced

Complications

1. Intraarticular hematoma
2. Bony or ligamentous trauma

Procedure

Assess the joint and extremity for ligamentous stability and neurovascular integrity. Most practitioners will obtain a radiograph to evaluate for associated osteochondral fractures, which can be close to 25%. For an obvious patella dislocation that occurred without significant associated trauma, radiographs may not be necessary. The benefits of the radiograph must be weighed against the increased pain, swelling and resultant neurovascular compromise pain that occurs with delays by obtaining radiographs. Sedation/muscle relaxation and analgesia with administration of a benzodiazepine and narcotic may ease the reduction. In many instances, the reduction may be spontaneous after administration of benzodiazepine alone.

When laterally dislocated, the knee joint is usually held in mild flexion (20 to 30 degrees). Have an assistant stabilize the distal thigh, as shown in Figure 12.2C, part A. Then, while extending the knee joint, simultaneously apply gentle pressure on the lateral aspect of the patella to medially reposition it (Fig. 12.2C, part B). Knee mobility should be restored immediately on successful reduction. If radiographs were not initially obtained, they should be obtained after reduction. The use of an extended knee brace with crutches for a brief time provides appropriate restriction of activity with orthopedic follow-up in around a week. Some patients are at risk of recurrence and may benefit from evaluation.

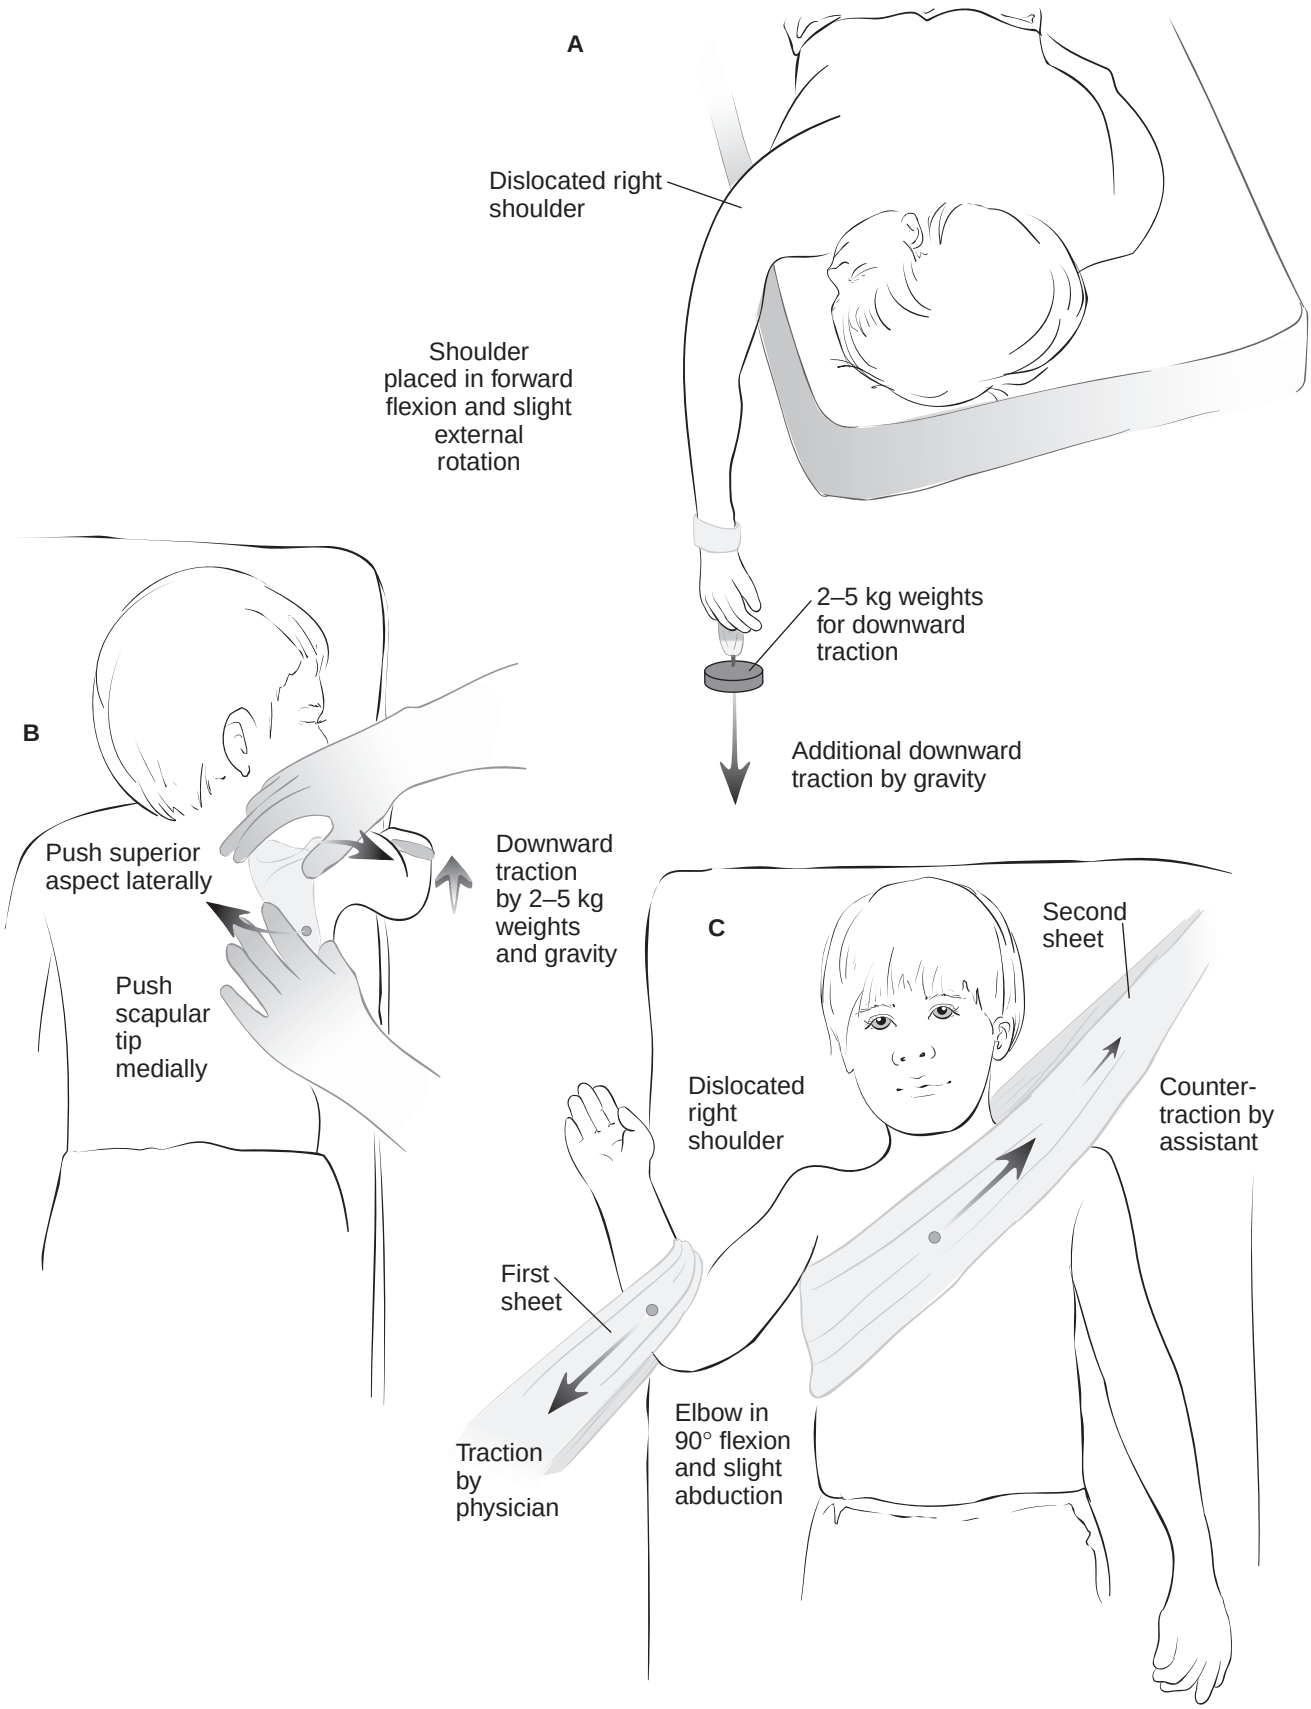
12.2D. Hip Dislocation

Indications

For traumatic dislocations of the hip

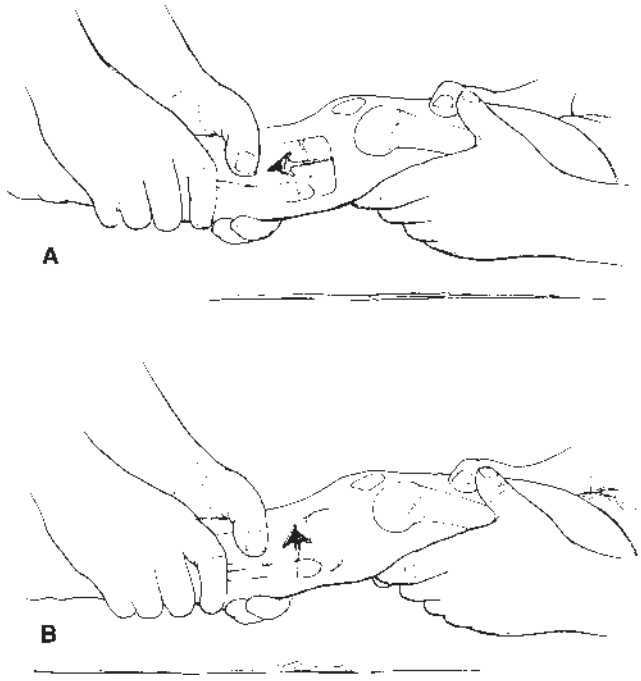
Complications

1. Associated fractures
2. Avascular necrosis of the femoral head
3. Sciatic nerve injury (mainly with posterior dislocation)
4. Deep venous thrombosis

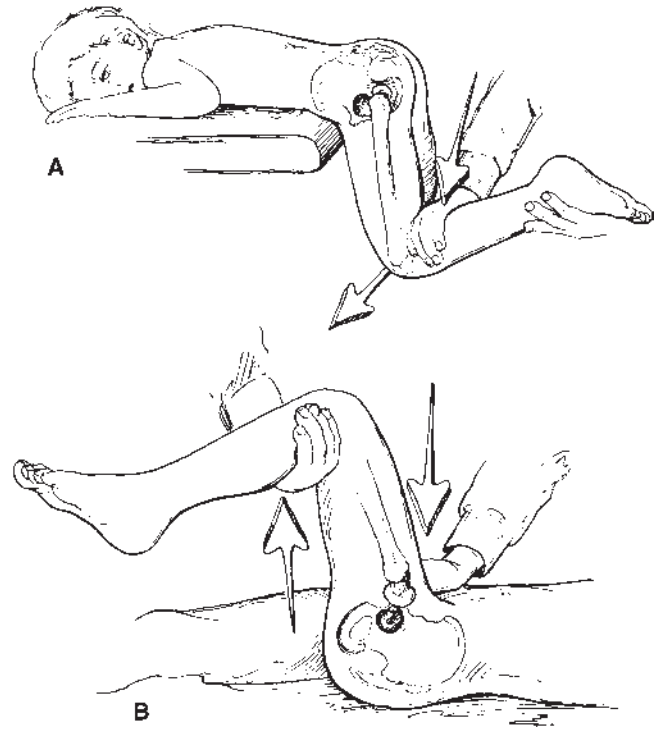


A
Dislocated right shoulder
Shoulder placed in forward flexion and slight external rotation
2–5 kg weights for downward traction
Additional downward traction by gravity
B
Push superior aspect laterally
Push scapular tip medially
Downward traction by 2–5 kg weights and gravity
C
Second sheet
Dislocated right shoulder
Counter-traction by assistant
First sheet
Elbow in 90° flexion and slight abduction
Traction by physician

12.2B



12.2C



12.2D

Procedure

Assess the neurovascular status of the affected limb. Associated fractures are common due to the magnitude of force required to produce a hip injury, thus radiographs with at least two different views—anteroposterior and oblique should always be obtained. When the diagnosis is confirmed and there are no contraindications to proceed, attempt at reduction may be initiated in the ED. Given the high incidence of complications, as well as the need for traction, non—weight-bearing management, hospital admission and close follow-up, emergent orthopedic consultation prior to reduction with the goal to reduce the hip within 4 to 6 hours of injury. Failure to reduce after 2 to 3 attempts mandates open reduction.

Placement of an IV and administration of narcotic and/or benzodiazepine or other procedural sedation is usually necessary for optimal analgesia and relaxation to facilitate reduction. Sedation must be carefully monitored, especially if other injuries are present.

Posterior Dislocations. Posterior dislocations are more common. The mechanism of injury is often a flexed knee having a posterior-directed force applied (i.e., dashboard injury in motor vehicle accident). The femoral head in the dislocation lies posterior to the acetabulum (Fig. 12.2D, part A and B). Characteristically, the hip is flexed and the leg is adducted, internally rotated, and shortened. The preferred method of reduction is called the Stinson method (Fig. 12.2D, part A). Place the patient prone on the examination table. The affected extremity needs to be flexed 90 degrees at the hip. The physician must apply downward traction on the calf. Have an assistant press over the greater trochanter to slide the femoral head into position. Common practice is to place the patient in Buck's traction following the procedure and after obtaining postreduction films.

Anterior Dislocations. Anterior dislocations are much less common but may occur with anterior-directed force in a motor vehicle crash or a fall associated with forced abduction. The femoral head may come to lie in the obturator canal or anterior to the symphysis pubis. On examination, the hip is extended and the leg is abducted and externally rotated with no obvious shortening.

Place the patient supine and apply strong downward pressure on both anterosuperior iliac crests to keep the trunk on the bed. Have an assistant grasp the affected limb flexing the hip and knee to 90 degrees (Fig. 12.2D, part B). Then, rotate the leg to a neutral position. This will make it a posterior slip. The assistant then must maintain steady forceful traction in the calf at 90 degrees to lift the femoral head into the acetabulum. While continuing the force, extend the knee and hip to bring the leg to the extended position. Obtain a radiograph before traction is applied.

12.2E. Elbow Joint Dislocation

Indications

Posterior elbow dislocations

Complications

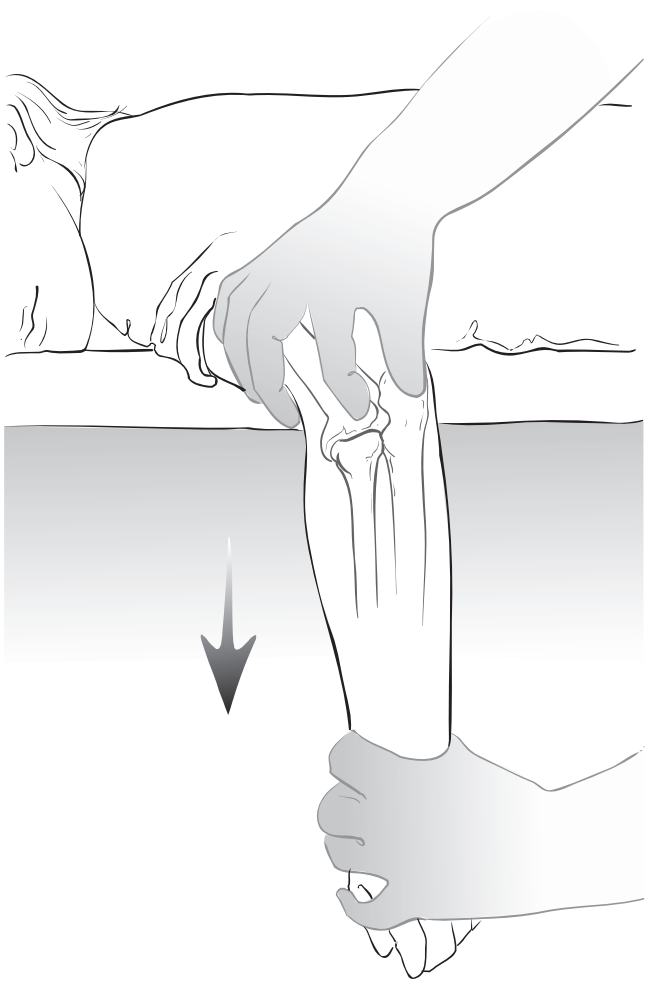
1. Brachial artery injury (especially with open elbow dislocations)
2. Median and ulnar nerve injury as a result of stretching, entrapment, or severance.

3. Periarticular fractures of the radial head and/or coronoid process of the ulna are especially common.
4. Development of vascular compromise due to hematoma formation or soft tissue swelling.

Procedure

Once the diagnosis of posterior elbow dislocation has been made, prepare the patient with IV narcotics and muscle relaxants or other procedural sedation agents.

Prone Approach. Place the patient in the prone position on an examination table or stretcher, with the injured arm flexed about 90 degrees over the edge. Then, correct any medial or lateral translation of the proximal ulna. Grasp the wrist of the patient's injured arm, and apply traction and slight supination to the forearm to distract the coronoid process from the olecranon fossa. If an assistant is available, they may help by applying countertraction. (Fig. 12.2E) Using your other hand, apply pressure to the posterior aspect of the olecranon while pronating the arm. When a "clunk," along with the restoration of normal joint contour is appreciated, the reduction is complete.



12.2E

Supine Approach. Place the patient in the supine position on the examination table or stretcher. Have an assistant stabilize the humerus against the stretcher with both hands. Grasp the wrist, and apply slow, steady, inline traction. Ensure that the elbow is slightly flexed, and the wrist is supinated. If not successful after approximately 10 minutes, gently flex the forearm or apply traction to the proximal volar surface of the forearm. Reduction is complete after hearing or feeling the characteristic "clunk," coupled with restoration of the normal joint contour.

Postreduction

Following successful reduction, place the elbow through gentle range-of-motion testing. It is important to note that extending the elbow beyond 20 degrees from full extension may cause the elbow to redislocate, and therefore is not recommended. Inability to move the elbow smoothly through range of motion exercises following reduction raises the concern of a trapped medial epicondyle fracture. Repeat neurovascular examination should take place postreduction, as should follow-up radiographs of the elbow to assess for fracture.

If near-full range of motion is present in the affected elbow, a posterior splint should be applied, with the forearm in neutral or slight pronation and the elbow flexed at 90 degrees. As delayed vascular compromise is an important consideration, all patients should be observed for 2 to 3 hours postreduction. If at the end of the observation period there is no evidence of vascular compromise, the patient may be discharged home with orthopedic referral for follow-up. Typically, after 5 to 10 days, range of motion exercises are initiated with interval splinting or with use of a sling for comfort and support. Immobilization for prolonged periods has been associated with a poorer ultimate range of motion of the elbow.

12.3. DRAINAGE OF A SUBUNGUAL HEMATOMA

Indications

Blood under pressure beneath a nail bed, either proximally or distally

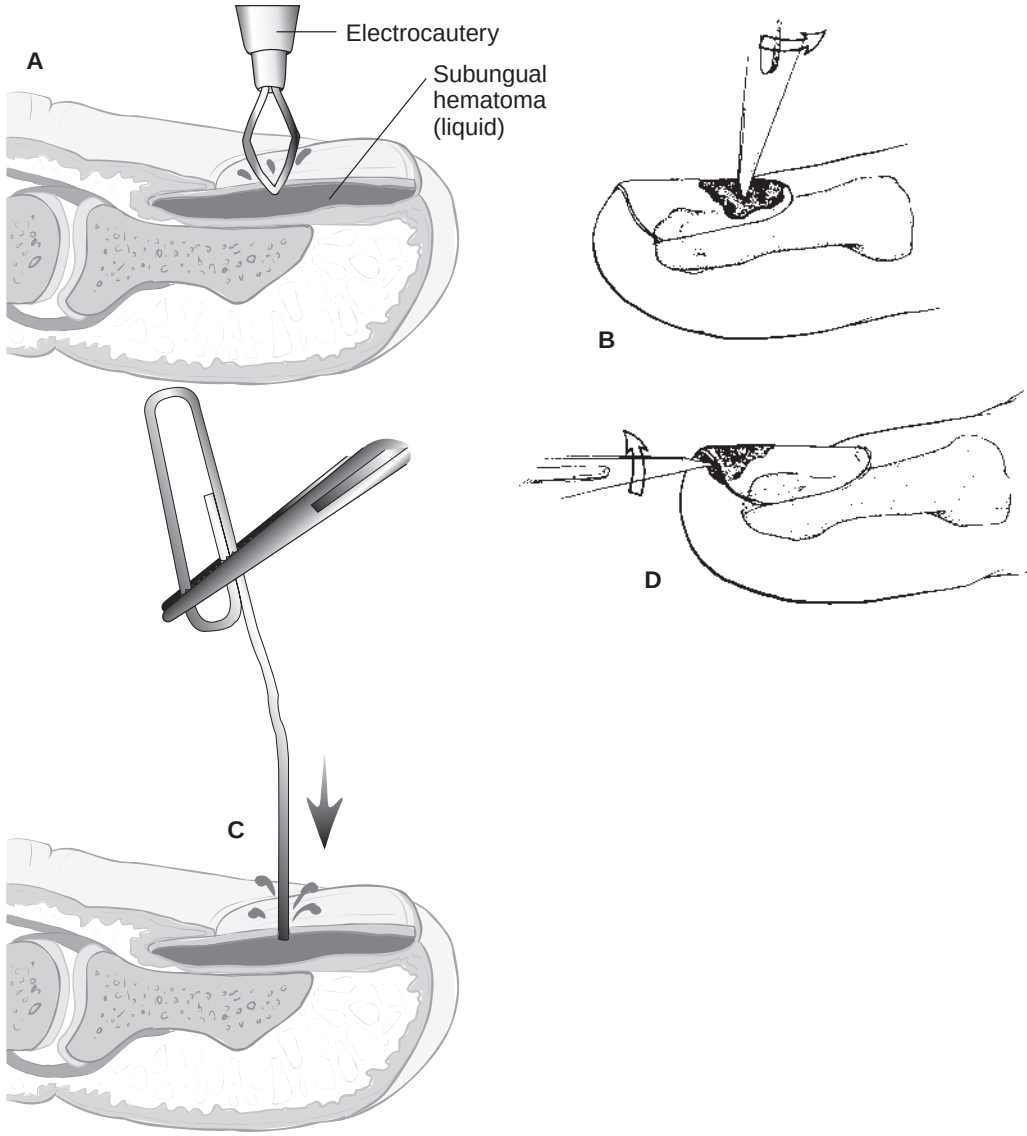
Complications

1. Bleeding
2. Infection

Procedure

Subungual hematomas occur from trauma in the proximal or distal nail bed, as shown in Figure 12.3. Consider a radiograph to evaluate for a tuft fracture of the distal phalanx. Generally, the hematoma causes pain that is immediately relieved with drainage. A digital nerve block may be used for anesthesia but is useful in anxious children or those with an already painful injury.

A hematoma of the proximal nail bed is relieved by making a hole in the nail (trephination). Restrain the child and digit on a table. Soak the fingertip in povidone–iodine



12.3A–D

solution for several minutes. A high temperature surgical one-use electrocautery pen can be used to puncture the nail and this technique is more rapid and less painful than making a hole with a scalpel (Fig. 12.3A). In the setting where electrocautery is not readily available, options include heating of a paper clip on a hemostat or the use of an 11 blade. Enter perpendicular to the nail in the center of the hematoma. Puncture the nail by simultaneously applying downward and rotary pressure, as shown in Figure 12.3B (blade) and Figure 12.3C (heated paper clip). Apply pressure sterile gauze to drain the blood for several minutes, and then cover with a sterile dressing.

A distal hematoma is shown in Figure 12.3D. Restrain the child and finger on a firm surface. Cleanse the nail with povidone–iodine solution. Take a scalpel with a no. 11 blade and lance the hematoma by inserting the blade directly under the nail parallel to its course. Keep the blade against the undersurface of the nail. Cover with a sterile gauze while blood is draining and apply a sterile dressing.

12.4. INCISION AND DRAINAGE OF A FELON

Indications

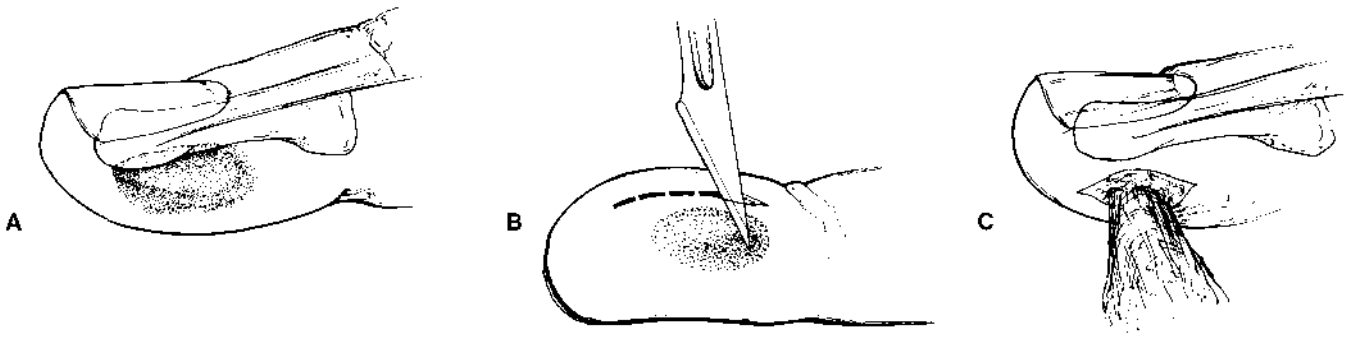
A felon, or digital pulp space abscess, requires drainage to relieve severe pain and to decrease the spread of infection.

Complications

1. Scar formation
2. Bleeding

Procedure

The use of procedural sedation may be a useful adjunct to digital block in an anxious child. Have an assistant hold the hand



12.4

supinated on a table top. Locate the felon in the pulp space (Fig. 12.4A) between the volar soft tissues and the periosteum of the distal phalanx. The incision should be made at the site of maximal tenderness.

Anesthetize the distal finger with a digital nerve block, as described in Procedure 12.13A. After obtaining anesthesia, scrub the fingertip with povidone–iodine solution. Don sterile gloves. Make a longitudinal incision (Fig. 12.4B) over the previously selected site using a no. 11 scalpel blade. A felon is an abscess and should be drained where it points, just like any other abscess. When pus is encountered, enlarge the incision to the proximal and distal limits of the abscess. Do not divide the septa.

Previously described techniques, such as the "fishmouth" and lateral incisions, are associated with iatrogenic complications. These include skin slough, permanent anesthesia, unstable fat pad, pain, and an unsightly scar.

After drainage, place a small gauze wick in the opening (Fig. 12.4C) to keep the wound edges separated. Place a bulky dressing and immobilize the hand with a short forearm splint. In 24 to 48 hours, remove the dressing and inspect the wound. Subsequent dressing changes may be done every 3 days. Systemic antibiotics are recommended.

Complications

1. Bleeding
2. Scar formation

Procedure

Consider mild anxiolysis with midazolam in anxious children. In most instances perform a digital block with 1% lidocaine as in Procedure 12.13A. In older cooperative patients, occasionally the use of ethyl chloride spray over the site to be lanced is sufficient for anesthesia. Prepare the site (Fig. 12.5A) for the surgical procedure with povidone–iodine solution and cover with sterile disposable drapes. Using a no. 11 surgical blade, incise the skin at its junction with the nail. As indicated in Figure 12.5B, extend the incision along the base of the nail to permit adequate drainage. If the paronychia is only on one side of the nail bed, make the incision along the lateral margin of the nail bed distal to the cuticle. To keep the wound open, placement of a gauze wick is often useful at the lateral margin of the nail. Dress the wound and instruct the patient to use warm compresses.

12.5. INCISION AND DRAINAGE OF A PARONYCHIA

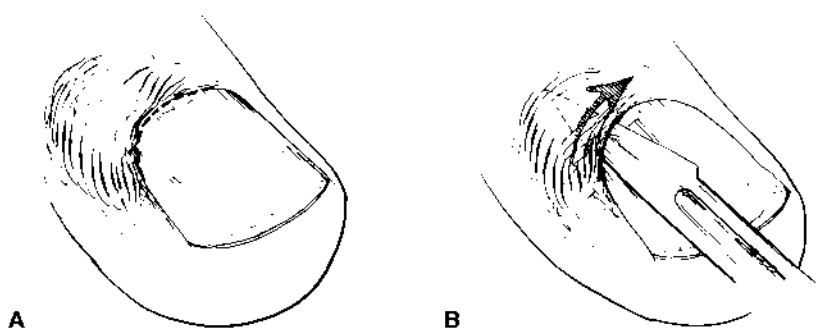
Indications

Failure of a superficial infection of the soft tissue along the edges of the nail to respond to medical treatment or the development of pus beneath the surface.

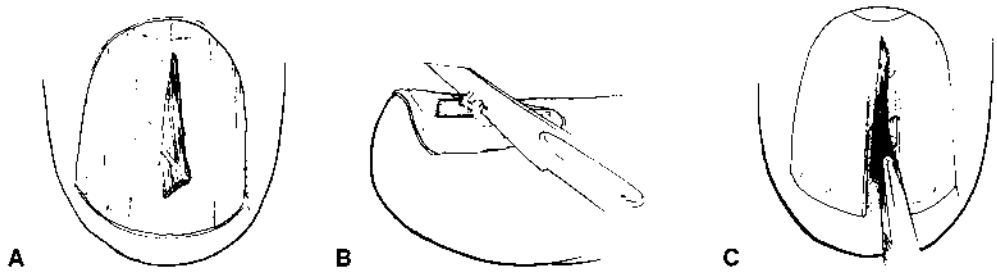
12.6. REMOVAL OF A SUBUNGUAL SPLINTER OR FOREIGN BODY

Indications

1. Painful subungual splinter
2. To prevent infection or a foreign-body reaction to a splinter in the nail bed



12.5



12.6

Complications

1. Bleeding
2. Infection

Procedure

Restrain the child's hand with the fingers extended (Fig. 12.6A). If the splinter end is visible, it may be possible to pull it out directly with tweezers or a hemostat. Consider use of a digital block if it is painful. An alternative is to use a no. 11 blade to scrape the nail down to the nail bed for the splinter to uncover enough splinter to remove it. Hold the blade perpendicular to the direction of the splinter and at 90 degrees from the horizontal, as in Figure 12.6B. Scrape the nail off in a proximal to distal fashion, applying pressure gently to minimize discomfort from squeezing the nail onto the splinter. The shape of the nail removed is similar to that of a "U." With a small tweezers or forceps, grasp the splinter once it is exposed and tug it gently to remove it from the nail bed (Fig. 12.6C). Soak the finger in a warm povidone–iodine and water solution several times per day to decrease the chance of infection.

Large splinters or those embedded deeply under the nail require prolonged scraping and are best removed by excision of a large portion of nail after a digital block.

12.7. REMOVAL OF RINGS

Indications

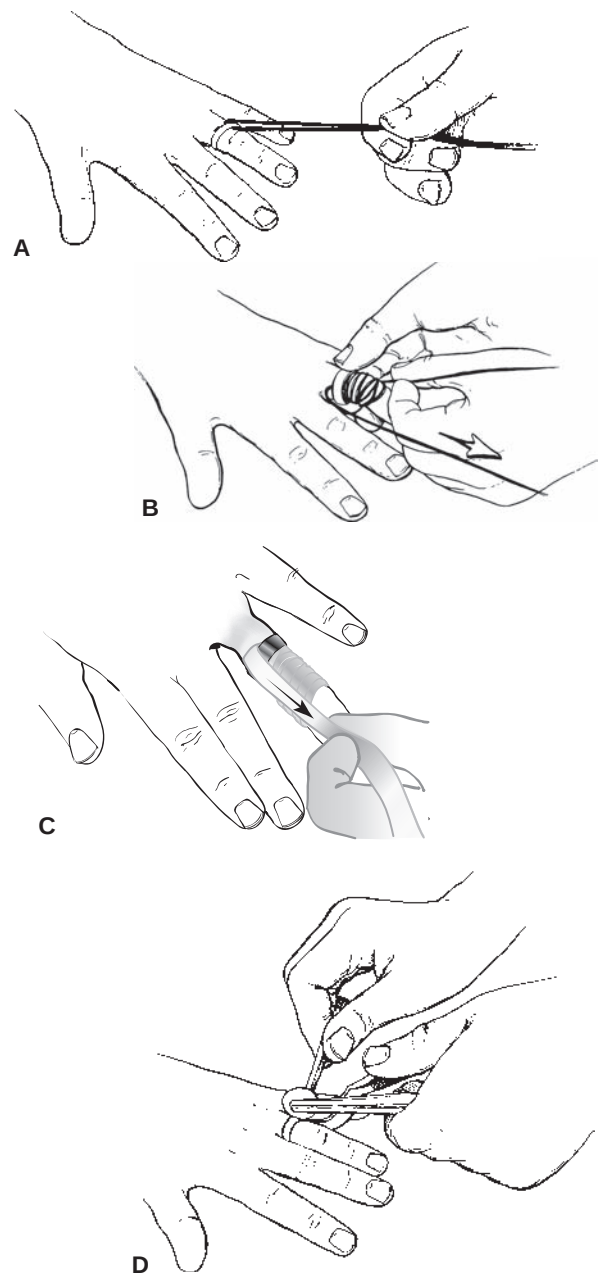
Strangulating ring on a digit

Complications

1. Vascular compromise
2. Trauma to digit

Procedure

1. String pull (Fig. 12.7A)—Explain the procedure and position the patient comfortably. Cleanse the area and consider a digital block. Use a string or heavy suture. Place one end of the string under the ring and pull it through. Place a small



12.7

amount of lubricating ointment at the distal end of the ring. Grasp both ends of the suture 5 to 10 cm from the ring. Pull the suture in a circular motion. Continue slipping the suture around the ring as it gradually moves along the finger.

After the ring is removed, cleanse the digit and apply sterile dressing as needed.

2. String compression of skin (Fig. 12.7B)—Explain the procedure and position the patient comfortably. Cleanse the area and consider a digital block to reduce pain and ease getting the string under the ring. Use string or 3-0 silk suture. Alternatively, use ribbon gauze in the same way. The string at the proximal end should be placed under the ring. Then wrap the suture on the distal side around the finger. Continue to wrap the string tightly to compress the soft-tissue swelling on the finger until it covers the proximal interphalangeal joint. Grasp the ring, and while exerting a back-and-forth twisting movement, pull the ring over the suture and off the finger. If this cannot be done, pull on the string that is under the proximal end in a circular unwrapping fashion to assist in pulling the ring off the finger. Pull the string around and off the finger at the proximal end to draw the ring off the finger distally. Thin ribbon-like gauze or umbilical tape has been used for this also (Fig. 12.7C).

After the ring is off, remove the remaining suture from encircling the finger. Cleanse the digit and apply sterile dressing as needed.

3. Ring cutting (Fig. 12.7D)—Often, it is preferable to try technique no. 2 or 3, if edema distal to ring is minimal, in an attempt to avoid cutting the ring. Explain the procedure as appropriate to the child and the parent or guardian. Position the patient supine or sitting. Cleanse the area with povidone–iodine solution or substitute. When there is considerable pain or swelling, it is best to inject a digital block prior to starting.

Insert the ring-cutter guard between the ring and the finger. Place the blade on the ring. Grasp the handle of the ring cutter and apply pressure while rotating the blade. If the ring is made of hard metal, cutting may be difficult and friction will cause the ring to heat up. If this occurs, stop until the metal cools.

After the ring is completely cut through, pull the ring apart manually or with a hemostat and remove from the digit. Even when the ring is easily cut off, this part of the procedure can be painful. Cleanse the digit and apply sterile dressing as necessary.

12.8. REMOVAL OF FISH HOOKS

Indications

Presence of a barbed fish hook through the epidermis. Fish hooks embedded in or around the eye should be removed with the direct involvement of ophthalmology to avoid or not further injure the globe.

Complications

1. Infection
2. Direct damage to tissue

Equipment

1. Povidone–iodine solution
2. 5-mL syringe, 25- or 27-gauge needle
3. Lidocaine 1%
4. Needle holders

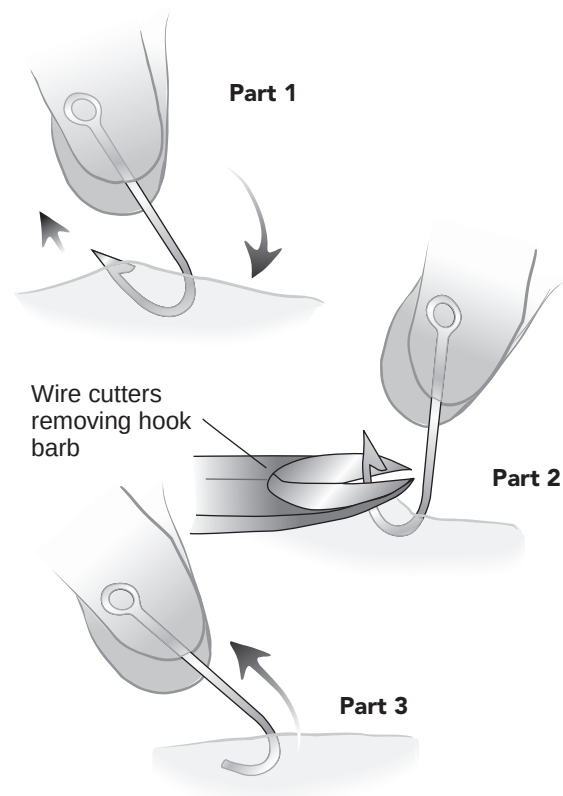
Procedure (Fig. 12.8)

1. Barb cut. Explain the procedure as appropriate to the child and the parent or guardian. Position and restrain the child to have easy access to the fish hook. Cleanse the area with povidone–iodine solution or substitute. Inject 1% lidocaine with a 25- or 27-gauge needle into the surrounding skin or when appropriate do a digital block.

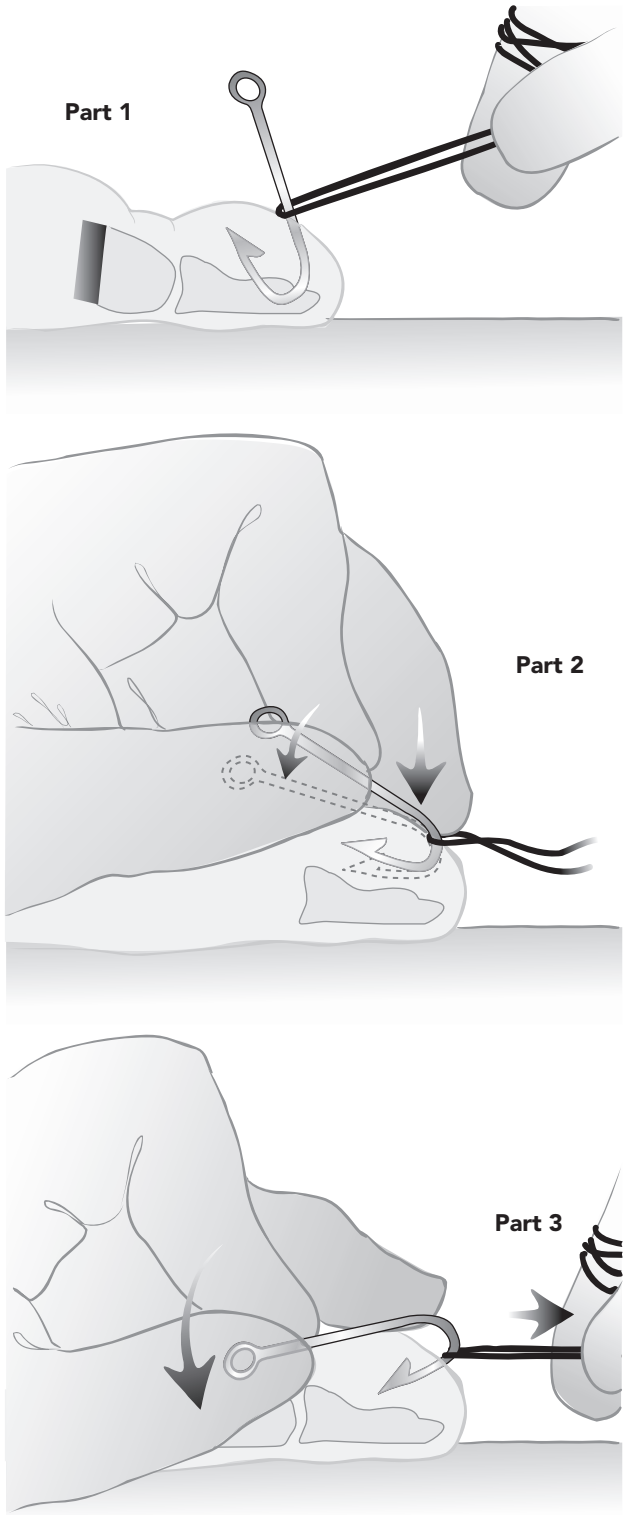
Wearing sterile gloves, grasp the fish hook with needle holders. Apply downward pressure along the curve of the fish hook (proximal to distal), forcing the barb end of the hook out through the skin (Fig. 12.8A, part 1). After the barb has been pushed through the skin, sever the barb with a wire cutter (Fig. 12.8A, part 2). The remainder of the hook can then be extracted by withdrawing it along its original path of entry (Fig. 12.8A, part 3).

2. String removal (Fig. 12.8B). When the fish hook lies too deep to force through a second wound, an alternate method can be used.

Explain the procedure and restrain the child as necessary. Cleanse the area with povidone–iodine solution or



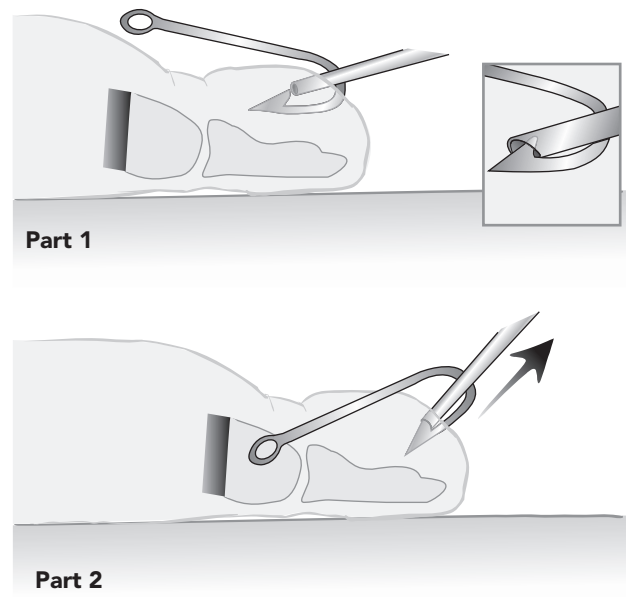
12.8A



12.8B

substitute. Inject 1% lidocaine with a 25- or 27-gauge needle into the surrounding skin.

Loop a piece of string around the hook (part 1). With the nondominant hand, depress the shaft of the hook against the skin (part 2). Grasp the end of the string with the dominant hand and pull sharply (part 3). This action should disengage the barb, and the hook can be removed through the entry wound.



12.8C

3. Needle technique (Fig. 12.8C). This uses the principle that a needle such as an 18 gauge may be large enough to cover the barb and allow the withdrawal of the fishhook without fear that the barb will continue to catch the hook. Prepare the site as before with the injection of 1% lidocaine. Enter the opening through the skin along the needle and then the needle can catch on the barb. It may be necessary to push the fishhook slightly in to more easily access the barb with the needle. Then pull the fishhook out the opening with the needle engaged.

   Following removal, cleanse the area and apply sterile dressing. Give active or passive tetanus immunization as indicated. Consider antibiotic prophylaxis only in high risk patients with issues of immunity.

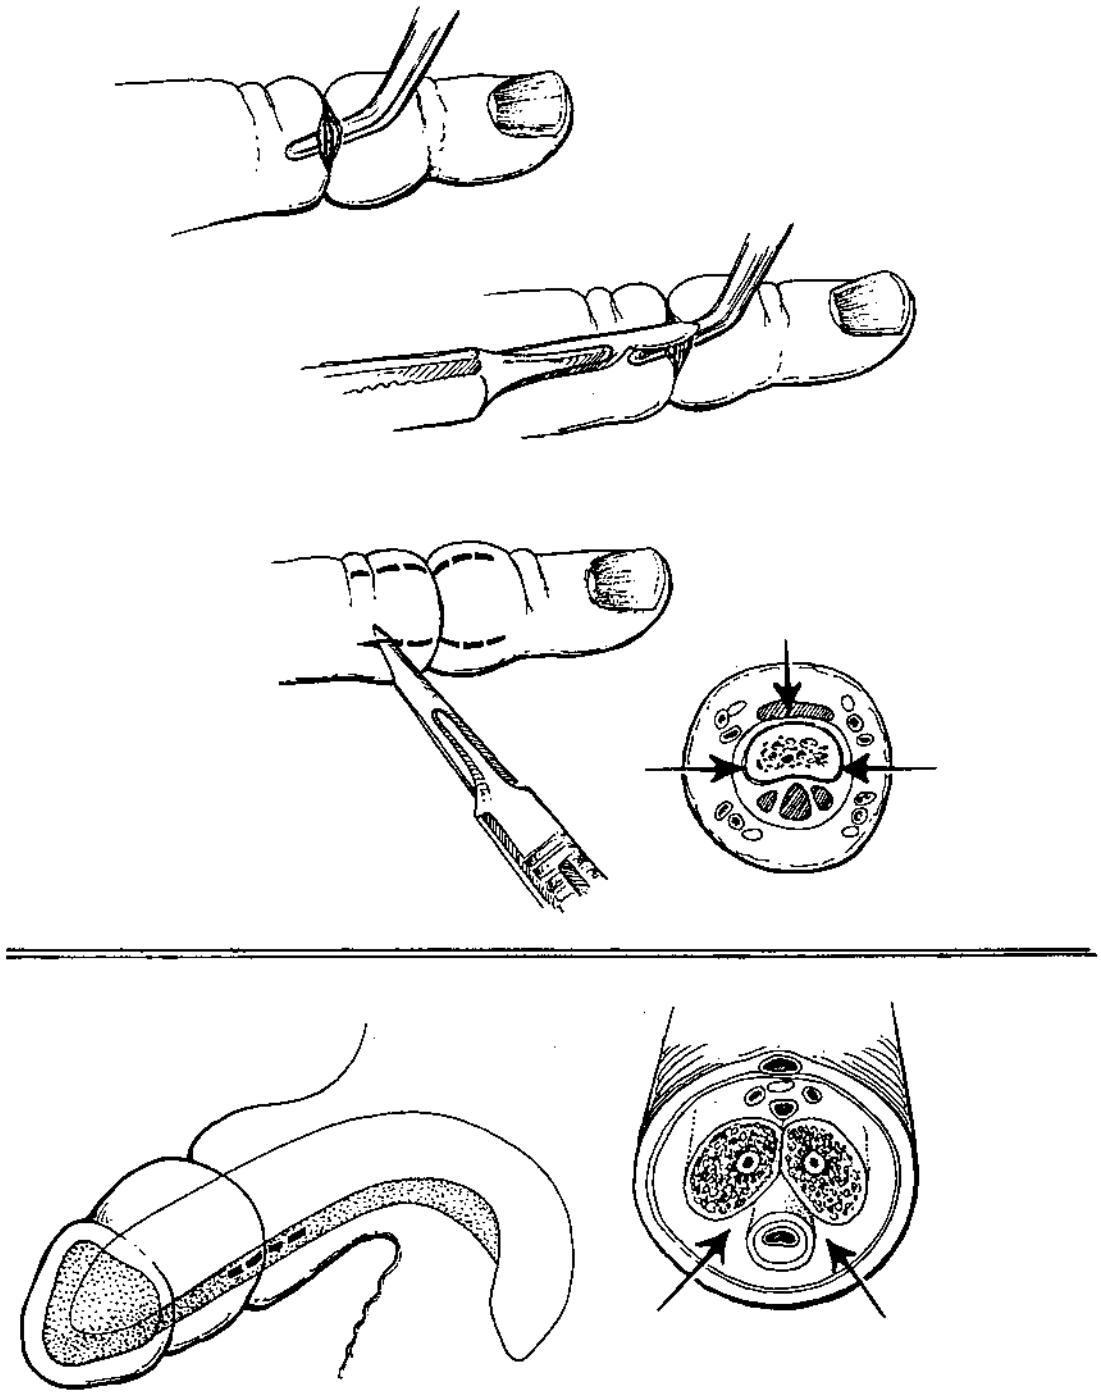
12.9. HAIR TOURNIQUET REMOVAL (FIG. 12.9)

Indications

To remove apparent constricting bands of hair or thread from finger, toe, penis, or clitoris

Complications

1. Damage to nerves or arterial supply (may be caused by prolonged ischemia from the tourniquet or incision)
2. Damage to tendons
3. Damage to corpus cavernosum, corpus spongiosum, clitoris or urethra



12.9

Equipment

1. Topical, local or regional anesthesia materials
2. Scalpel blade with handle—no. 11 blade
3. Povidone–iodine solution
4. Fine-tip forceps
5. Blunt probe
6. Fine-tip scissors

Procedure

Constriction by hair or thread of a digit or penis and occasionally the clitoris occurs most often in the first few months of life but can be seen in older children on occasion. On physical examination, a sharp circumferential demarcation is usually apparent. Hair tourniquets on digits have been confused with a felon or paronychia. Hair tourniquets on a penis have been

confused with paraphimosis or balanitis. The application of EMLA® or other anesthetic cream to the site 45 minutes before the procedure will often make removal much less painful.

1. Isolating the band—If the hair or thread is not deeply embedded, a blunt metal probe may be used to isolate the constricting band. The band is best isolated by placing the probe under the hair or thread on the dorsal aspect of the finger or toe. Digital or penile block will assist in those where they can not be helped with topical anesthetic. Once the band is isolated, it may be cut with a fine-tip scissors or by placing a scalpel blade against the probe to protect the underlying skin. Improvement of the swelling and release of the constriction must be noted before discharging the patient.
2. Hair remover—Application of hair remover can dissolve a hair and provide relief. This method will not work with synthetic fibers. Hair remover should not be used if marked inflammation or swelling to the tissue is evident. This method is also not recommended for removing a constricting band from the penis. Improvement of the swelling and release of the constriction must be noted before discharging the patient.
3. Surgical removal—If the hair or fiber cannot be isolated by the aforementioned methods, then direct incision of the band is indicated.
   a. Digit—A digital block should be performed and the area should be cleansed and draped in a sterile fashion. To avoid the neurovascular bundles, an incision should be made at the 3-o'clock or the 9-o'clock position. The incision should be made longitudinally along the digit, perpendicular to the band. The incision should be extended to the bone to ensure removal. After improvement in the constriction is noted, a dressing may be applied.

      An incision on the dorsal aspect is an alternative, since the tourniquet may be less deeply embedded on the dorsal surface. This approach will probably result in a longitudinal incision into the extensor tendon. With splinting and general wound care, this incision should heal without complications.
   b. Penis—Urologic consultation is advisable before undertaking this procedure, unless ischemic damage might worsen because of a delay. A penile nerve block should be performed, and the area should be cleansed and draped in a sterile fashion. The incision should be made at the 4-o'clock or 8-o'clock position. This is the junction of the corpus cavernosum and corpus spongiosum. The goal is to release the constricting band without penetrating the lumen of the corpus. Reperfusion normally occurs within several minutes after relief of the constricting band; however, some swelling may persist for several days. A loose dressing should be applied.
   c. Clitoris—Although an uncommon occurrence, the procedure for such a situation has been described. Topical anesthetic such as EMLA® should be applied. If difficult to release the constricting band as previously described, immediate urologic or gynecologic consultation should be undertaken.

      Neurovascular status and tendon function should be documented after the procedure. Tetanus prophylaxis should be given as indicated, and reevaluation is suggested in 24 hours when the swelling should have mostly resolved.

12.10. ARTHROCENTESIS—GENERAL CONSIDERATIONS

Indications

1. Removal of a joint effusion causing severe pain and distension that limits function
2. Suspected septic arthritis
3. To obtain joint fluid for the diagnosis of systemic illness (i.e., collagen vascular disease)

Complications

1. Bleeding
2. Infection—joint space or bone

Contraindications (relative)

1. Bleeding diathesis—Patients with bleeding diatheses (i.e., hemophilia) as the cause of the joint effusion usually require only immobilization and replacement of coagulation factors.
2. Presence of a fracture around the joint space—Aspiration may increase the chance of infection when a fracture is present.

Equipment

1. Marking pen, povidone-iodine solution, gauze, bacteriostatic saline solution, adhesive bandage
2. Local anesthetic—1% lidocaine, topical anesthetic such as EMLA®
3. 23- or 25-gauge needles, 3-mL syringes, 18- or 20-gauge syringe, and 5- to 10-mL syringe, specimen collection tubes

12.10A. Knee Joint

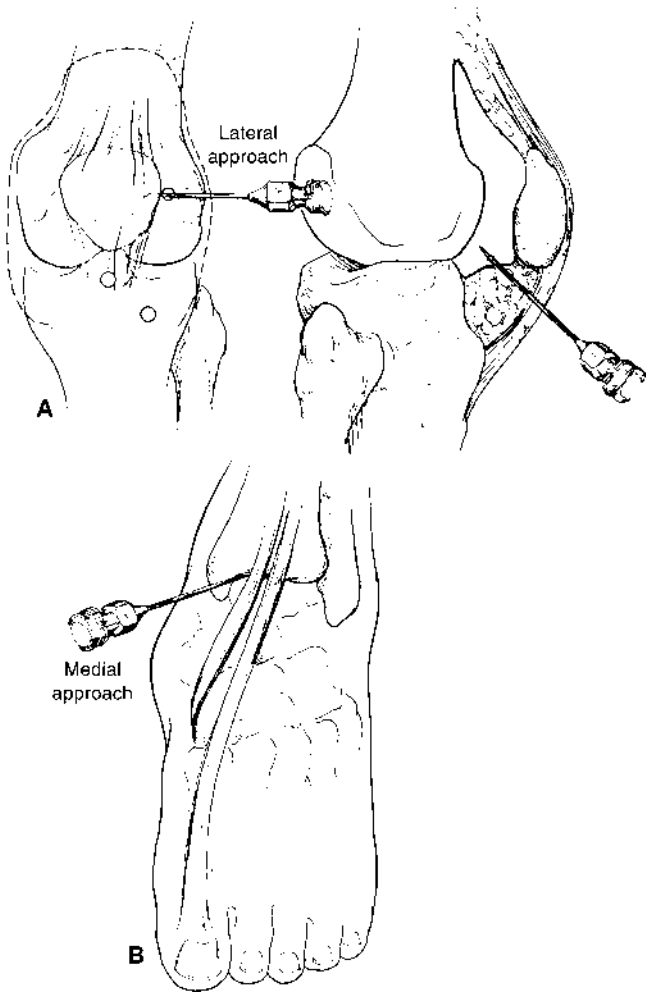
Remember to use your institution's "hold point" procedure before starting.

Procedure

The knee is the joint that most commonly requires aspiration in children, primarily to evaluate possible bacterial infection or to drain large traumatic effusion. Radiographs should usually be obtained before tapping the joint. Ultrasound guided arthrocentesis has been tried but may not improve success rate in the knee joint.

Place the child supine on the examination table, with the knee actively extended as far as comfortable. A towel under the slightly flexed joint will usually be helpful for comfort and for positioning. Restrain the child as necessary. Have an assistant hold both the thigh and calf of the leg to be tapped. Consider pharmacologic sedation as necessary. When time allows, consider lidocaine-prilocaine paste (EMLA®) or other noninjectable anesthetic.

The lateral approach to the knee is preferred because it avoids passage through the vastus medialis muscle. Pick a



12.10A–B

puncture point at the midpatellar level in the anteroposterior view and at the posterior margin of the patella in the lateral view (Fig. 12.10A).

Cleanse the area to be punctured circumferentially with povidone–iodine solution. Use a 23- or 25-gauge needle attached to a 3-mL syringe to inject 1% lidocaine into the skin and subcutaneous tissues for anesthesia or, alternatively, spray ethyl chloride locally. Avoid injecting into the joint space prior to obtaining fluid for testing and culture.

Wearing sterile gloves, attach an 18-gauge needle to a 10-mL syringe. Hold the syringe in one hand while palpating the lateral margin of the patella with the other. Puncture the skin with syringe 10 to 20 degrees above the horizontal at the anesthetized site. Advance the needle, applying suction on the plunger of the syringe, until it passes into the joint space near the margin of the patella. When the joint space is entered, the syringe will fill the joint fluid. Stabilize the syringe against the patient's leg with the heel of the hand during the aspiration. Move the needle slightly in varied directions to effectively evacuate the joint and minimize the risk of injury to the synovium.

At completion, remove the syringe and apply a sterile gauze pad over the puncture site. Send the aspirate for appropriate studies. Immobilize the knee joint with a supportive dressing and avoid weight bearing during the treatment phase acutely.

12.10B. Ankle Joint

Procedure

Restrain the patient in the supine position on the examining table. Have an assistant hold the foot in slight plantar flexion (approximately 110 degrees). Place a soft brace under the plantar surface of the foot to provide further immobilization.

Identify two landmarks, the medial malleolus of the distal tibia and the thick halluces longus extensor tendon. The latter structure is found approximately 1 cm anterolateral to the medial malleolus, as shown in Figure 12.10B.

Pick a puncture site between these landmarks. Cleanse it circumferentially with povidone–iodine solution. Wear sterile gloves and inject 1% lidocaine locally to anesthetize the skin. Use either an 18- or 20-gauge plain or spinal needle attached to a 10-mL syringe.

Puncture the skin aiming the needle slightly inferiorly toward the tibial–talar articulation as shown. Apply suction to the syringe. Aspirate the fluid from the joint and remove the needle when satisfied that an adequate specimen has been obtained (often only a small amount). Apply sterile gauze to the puncture site and immobilize the joint.

12.10C. Elbow Joint

Procedure

Rest the child prone or seated, with his/her arm extended and elbow flexed 90 degrees to maximally open the joint space. Restrain the patient, maintaining the arm and forearm in this flexed position.

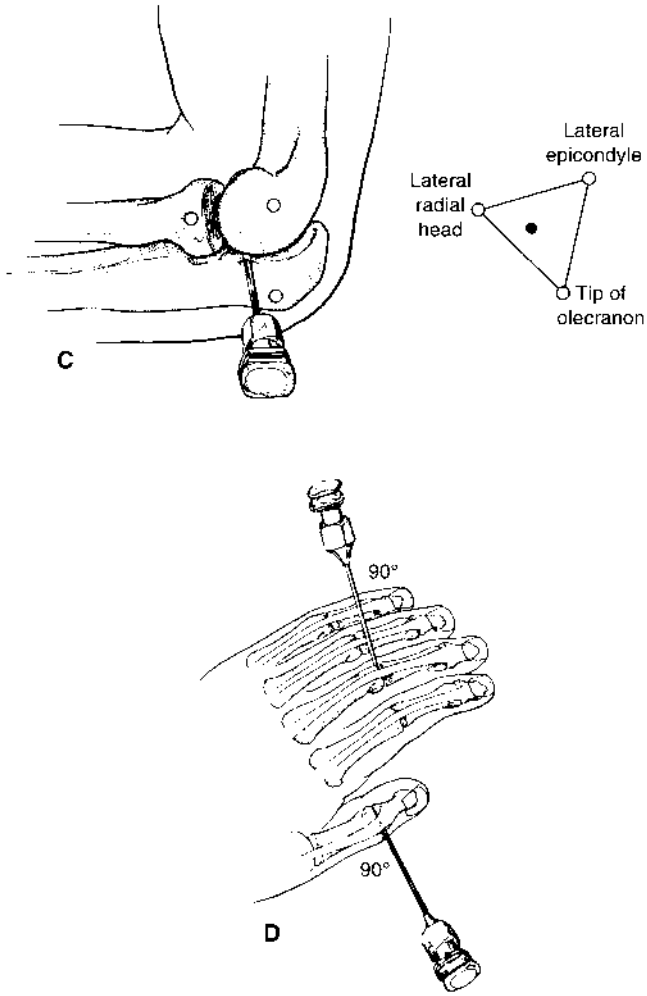
The needle puncture site should lie in the center of the triangle formed by the head of the radius, the lateral humeral epicondyle, and the olecranon, as demonstrated in Figure 12.10C. Sterilize the site with povidone–iodine solution. Wearing sterile gloves, inject the skin with 1% lidocaine or spray with ethyl chloride for anesthesia. Use a large-bore, 18- or 20-gauge needle on a 10-mL syringe.

Puncture the skin perpendicularly to the surface of the arm (Fig. 12.10C). Hold the syringe in one hand and guide the needle tip with the thumb and index finger of the other, leaning against the patient's arm. Advance the syringe while applying suction to the plunger, until the needle enters the elbow joint. If difficulty is encountered on entering the joint space, pull the needle back and reassess the location of the landmarks. Readvance it in a new line. Continue to stabilize the syringe while aspirating fluid. Remove the needle and press sterile gauze over the puncture site. Immobilize the joint.

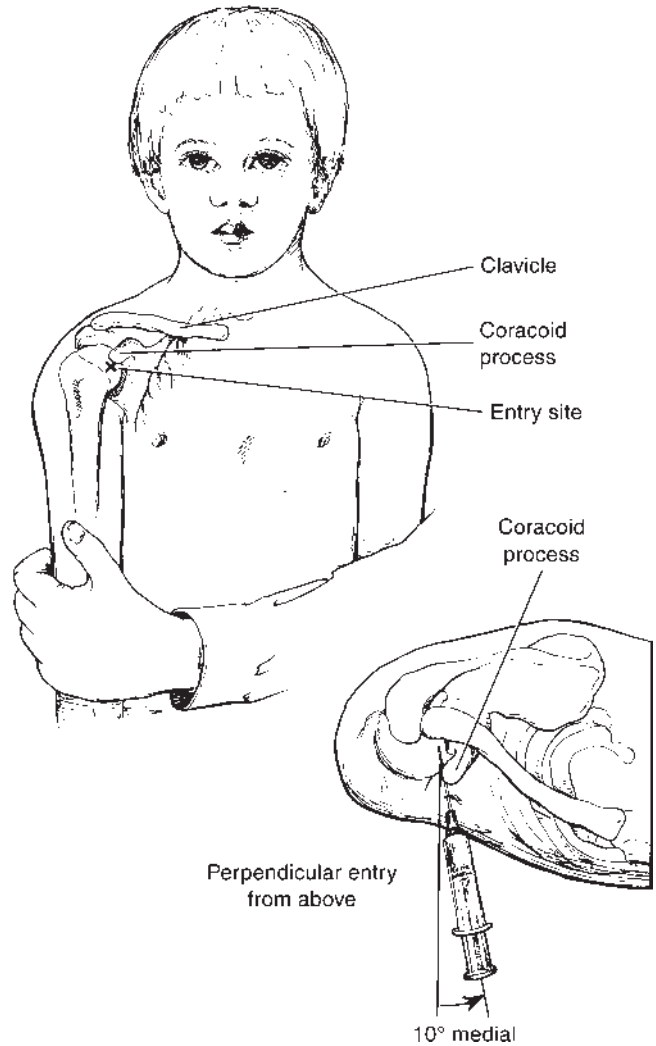
12.10D. Interphalangeal Joint

Procedure

Have the child sit with the forearm extended over the examination table or place him/her prone with the arms extended over the head. Restrain, if necessary. Have an assistant immobilize the finger proximally and distally. Locate the joint to be aspirated, using the radiograph as necessary. Choose a puncture site on the dorsal surface because the skin of the palm is



12.10C–D



12.10E

tougher and because slight flexion opens the joint space, facilitating a dorsal approach (Fig. 12.10D).

Cleanse the surface with povidone–iodine solution and allow to dry. If using lidocaine, avoid preparations with epinephrine. A digital block may be considered. Using a 22-gauge needle attached to a 5-mL syringe, puncture the skin perpendicularly to the long axis of the finger and advance the needle to the joint space. Be sure to puncture the skin and joint in the middle of the finger to avoid the digital vessels, which run peripherally. Aspirate fluid with suction on the syringe. Remove the needle and press sterile gauze over the puncture. Immobilize the joint.

12.10E. Shoulder Joint

Procedure (Fig. 12.10E)

Rest the child supine or seated with his/her shoulder flexed (arm at the side). Restrain the patient as necessary. Have an assistant hold the arm next to the chest.

Use the anterior approach for joint aspiration. Identify the coracoid process found just below the distal end of the clavicle and immediately medial to the humeral head.

The puncture site is just below and immediately lateral to the tip of the coracoid process. Cleanse the area circumferentially with povidone–iodine solution. Wear sterile gloves and inject 1% lidocaine into the skin and subcutaneous tissue with a 25- to 27-gauge needle. For aspiration, use an 18- or 20-gauge needle attached to a 10-mL syringe.

Direct the needle perpendicular (neither caudal or cephalad) to the entry site, angling 10 degrees medially to enter the joint space. Apply suction to the syringe during entry. Aspirate the fluid and withdraw from the joint when adequate specimen has been obtained. Place sterile gauze over the puncture site and immobilize the joint in a sling or harness.

12.11. TOPICAL ANESTHESIA AND DIRECT WOUND INFILTRATION

Indications

Anesthesia for laceration repair, removal of foreign body, or other simple procedures of the skin

Complications

1. Infection
2. Bleeding
3. Intravascular injection

Equipment

1. Povidone–iodine solution, bacteriostatic normal saline
2. 3-, 5-, or 10-mL syringe
3. Local anesthetic
   a. LET solution (1% lidocaine, 1:2,000 epinephrine, 0.5% tetracaine) usually made up to 2-mL unit dose. TAC has been removed from most institutions due to cost and the risk of abuse due to cocaine in the combination.
   b. EMLA® (eutectic mixture of local anesthetics) or ELA-Max® (4% lidocaine)
   c. Lidocaine 1% or 2%
      i. Maximum dose of 5 mg per kg or 0.5 mL per kg of 1% solution
      ii. May alkalinize with $NaHCO_3$ to raise pH and decrease pain of injection [8.4% $NaHCO_3$: lidocaine (1:10) mixed and bottle labeled with additive, date, and time; expires in 7 days]
4. Lidocaine 1% with epinephrine (may alkalinize)
   a. Maximum dose of 7 mg per kg or 0.7 mL per kg of 1% solution
   b. Use on highly vascular regions to minimize bleeding
   c. Do not use end-arterial locations (fingers, toes, penis, nose, and earlobes)
5. 26-, 27-, or 30-gauge needles
6. Cotton balls, occlusive dressing (i.e., Tegaderm®)

Procedure

Check the region for blood supply, sensation, and motor nerve function before injecting the anesthetic. Prepare materials before the child enters the treatment room or out of view of the child. Have all equipment ready to use before beginning the procedure. Consider procedural sedation for complex or painful procedures even unless topical anesthetic is all required.

Topical Anesthetic

1. The placement of LET (less expensive and a noncontrolled substance) is particularly useful in locations with excellent vascularization and away from end arteries. Prepare the anesthetic wound with removal of debris and blood clots. Draw the solution into a 3-mL syringe. It is useful to place a few drops into the wound initially either directly or from a cotton swab. The remainder of the solution is then placed on a cotton ball and firmly pressed onto the wound for about 20 minutes. Where possible, covering with an occlusive clear dressing, such as Tegaderm®, can reduce the risk of the anesthetic contacting other nearby surfaces on the patient. Avoid placing the cotton ball near mucous membranes where systemic absorption of the cocaine can place the child at risk of seizure. The wound is ready for closure or other procedures when blanching of skin appears in the area that was covered, usually in 30–45 minutes. The duration of anesthesia is around 1 hour.
2. EMLA® or ELA-Max® are effective topical anesthetics that continues to gain popularity in use. They are applied for intact skin under which procedures are to be done, such as venipuncture, LP, simple local procedure, or needle aspiration. The cream is placed on the skin in a white layer and then covered with an occlusive dressing. The time to anesthetic effectiveness is a minimum of 45 to 60 minutes.

Direct Wound Infiltration

Immobilize the young child by wrapping him/her in a sheet, using a papoose restraint, or having an assistant restrain the child. Use developmentally sensitive methods. A calm, reassuring approach that engages the child in conversation or distraction may avoid the need for sedation. Strongly consider topical anesthetic first if time permits.

Cleanse the area well with povidone–iodine solution. Dry with sterile gauze. Instill a few drops of the anesthetic directly into the wound.

Begin injection proximally on the side of the wound closest to the spinal efferent nerve. If the proximal portion of the wound is anesthetized first, then through blockage of nerve conduction, the distal portion may become partially anesthetized.

When anesthetizing a possible moving target, the operator should hold both sides of the wound with the nondominant hand. The syringe containing lidocaine can be pressed firmly against the operator's nondominant thumb. This allows the patient, operator, and syringe to move in a unified fashion if the child struggles.

Insert a 26-, 27-, or 30-gauge needle through the subcutaneous tissue exposed by the laceration. The subdermis of the wound is used because it is less painful than either direct injection through intact skin or into the dermis (Fig. 12.11A). Slowly inject a small bolus of the lidocaine solution (Fig. 12.11B). Continue to advance, aspirating continuously while in the vicinity of large vessels. Otherwise, aspiration before injection is rarely necessary.

Remove the needle and reinsert subcutaneously into adjacent tissue that has already been anesthetized. Slowly inject another bolus of anesthetic and advance the needle while injecting (Fig. 12.11C).

Continue this process of injection, withdrawal, and reinsertion in a sequential fashion around the entire perimeter of the wound. Wait 5 minutes for anesthetic effect.

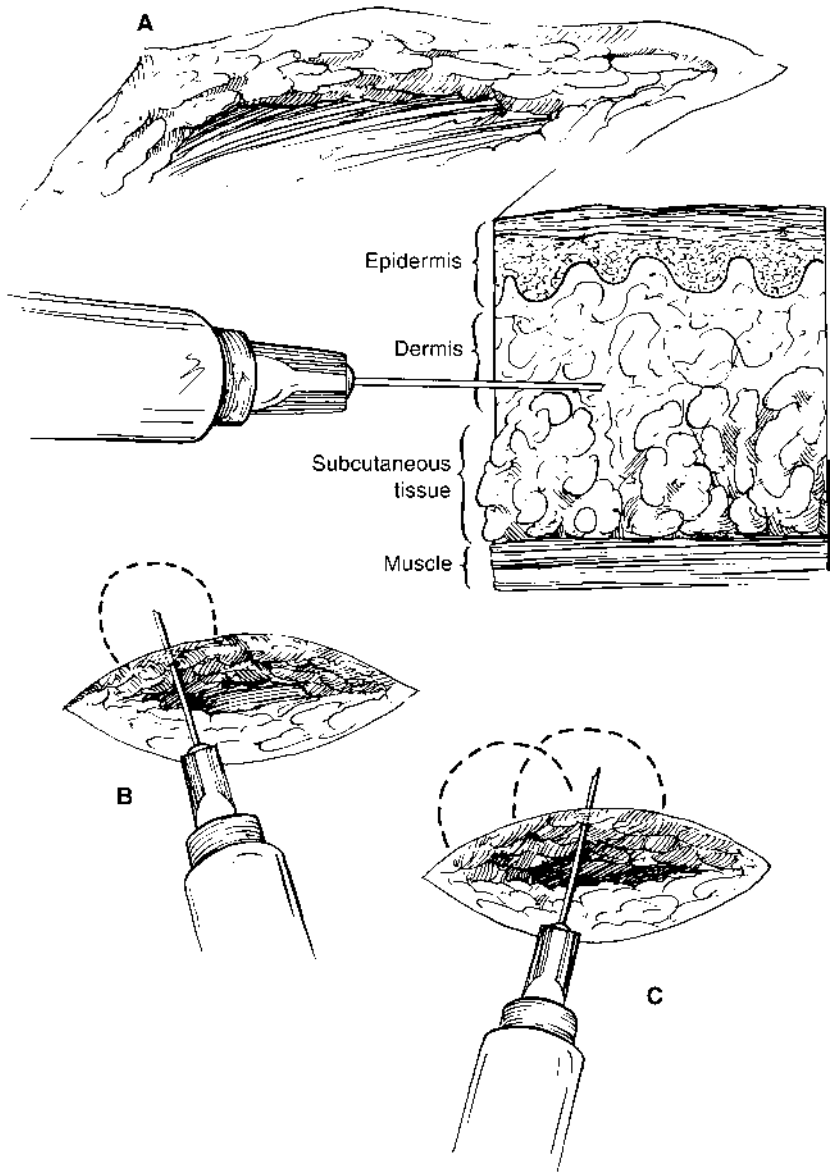
12.12. FIELD BLOCK

Indications

Local anesthesia for surgical procedures to be performed in areas of inflammation or infection (i.e., grossly contaminated lacerations, incision, and drainage of an abscess) or for local anesthesia with preservation of the wound architecture.

Complications

1. Infection
2. Bleeding



12.11

Equipment

1. Povidone–iodine solution
2. 3-, 5-, or 10-mL syringe
3. Local anesthetic
   a. Lidocaine 1% or 2% (may alkalinize with $NaHCO_3$)
   b. Lidocaine 1% with epinephrine (may alkalinize) (not for use on fingers, toes, penis, nose, and earlobes)
4. 25-, 27-, or 30-gauge needles

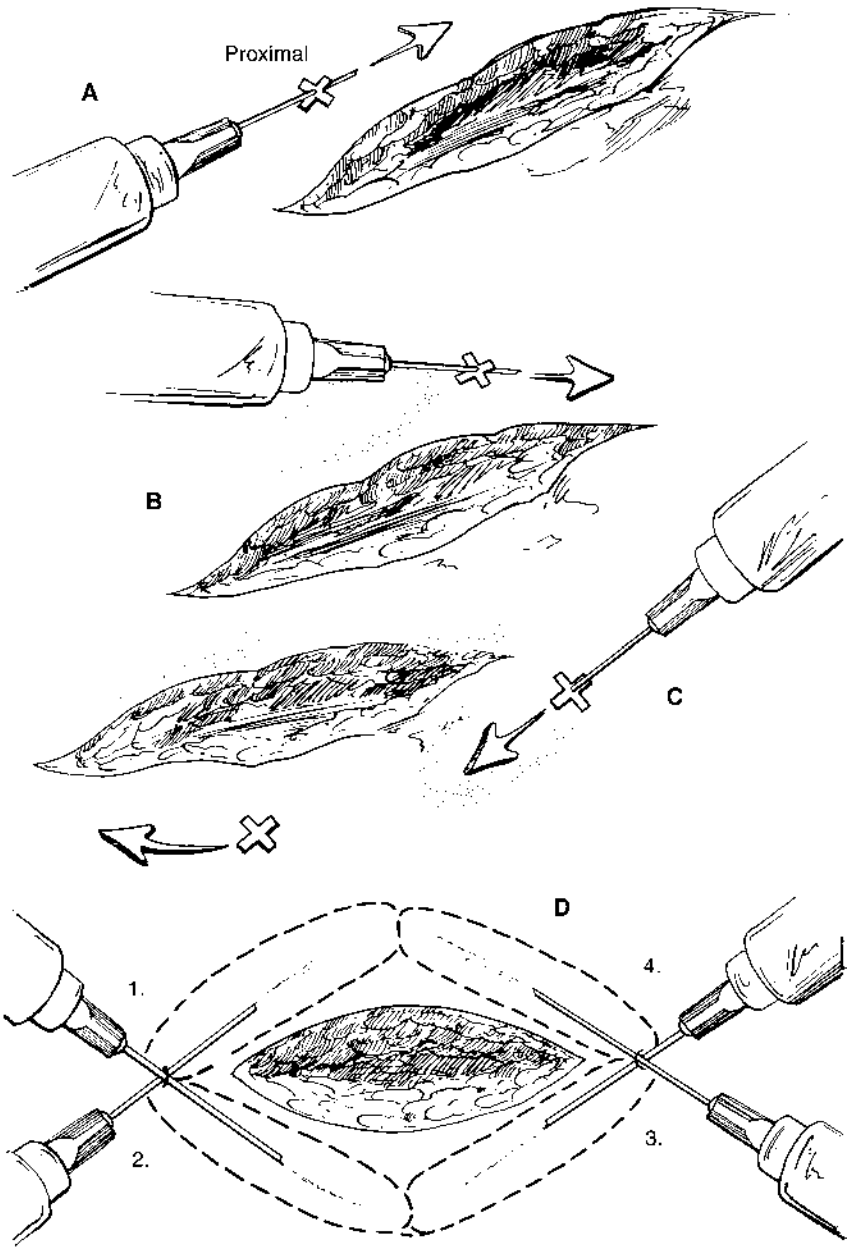
Procedure

Check the area for blood supply, sensation, and motor nerve function before injecting the anesthetic agent. Cleanse the area well with povidone–iodine solution. Dry with sterile gauze.

Field blocks use the same plane of injection as direct wound infiltration, but the subdermis is entered through intact skin to prevent carrying debris or bacteria into uncontaminated tissues.

Insert the needle through the skin into the superficial fascia at the proximal aspect of the laceration (Fig. 12.12A). Aspirate before injection in the vicinity of a large major vessel. Inject the lidocaine slowly in small amounts as the needle is advanced to approximately two-thirds the length of the needle. Continue to inject slowly as the needle is withdrawn from the insertion site. Reinsert the needle at the end of the first wheal, where the skin is becoming anesthetized. Repeat injections (Fig. 12.12B) in this fashion. Continue injections until complete infiltration of the circumference of the wound has been achieved (Fig. 12.12C). Allow 5 minutes for anesthesia.

If the field block is used to prevent distortion of the wound margins, then anesthetic is infiltrated in a diamond-shaped fashion around the wound. The needle is inserted at the



12.12

proximal end of the wound, and lidocaine is injected slowly as the needle is advanced. The needle is then withdrawn and redirected approximately 90 degrees, and infiltration is continued. The needle is then reinserted at the other end of the wound and the process repeated until the diamond-shaped ring of lidocaine is complete (Fig. 12.12D). This region should be anesthetized after 5 minutes.

12.13. PERIPHERAL NERVE BLOCKS—GENERAL PRINCIPLES

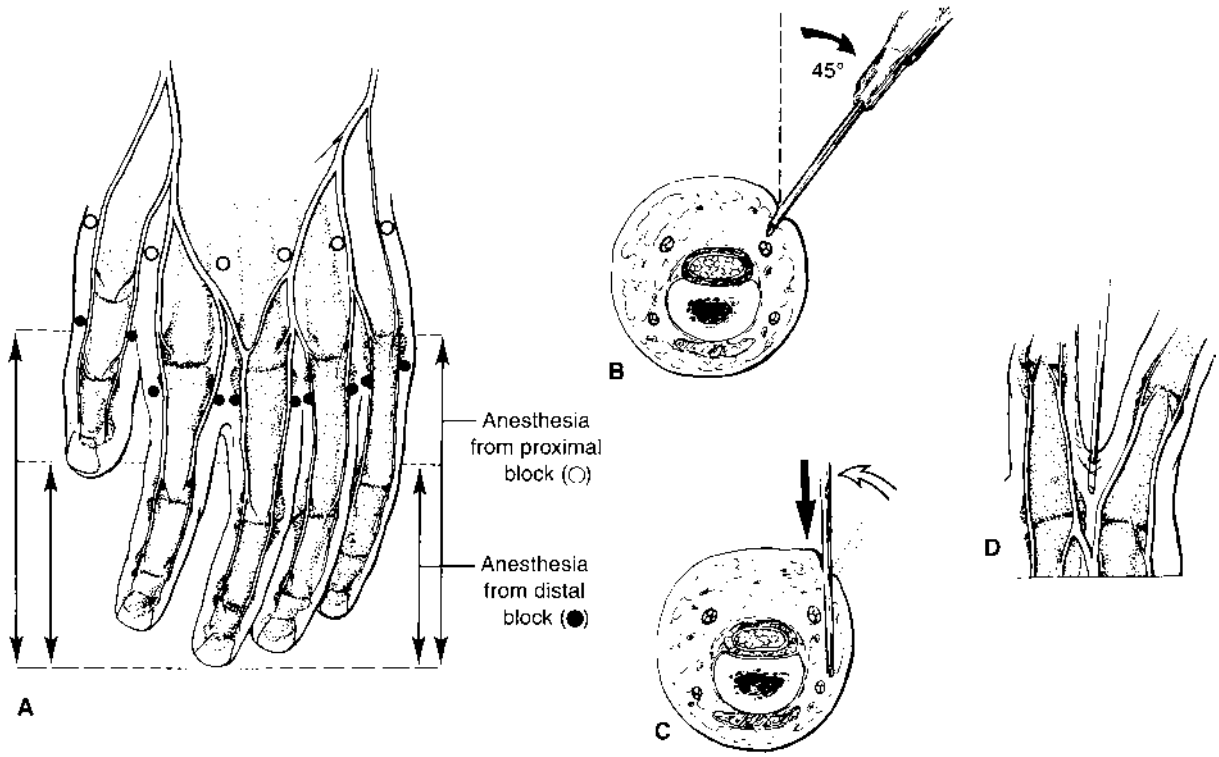
Following are the peripheral blocks, which are most commonly required in the emergency setting. As a summary, the lists of complications and equipment are as follows.

Complications

1. Infection
2. Bleeding
3. Intravascular, intraneural injections
4. Contracture if prolonged splint or not in position of function

Equipment

1. Povidone–iodine solution
2. 3- to 5-mL syringe
3. 1% lidocaine (may be alkalinized with 1 mL $NaHCO_3$ to 10 mL lidocaine)
4. 25- to 27-gauge 1- to 1.5-in needle



12.13A

12.13A. Digital and Metacarpal Nerve Block

Indications

Anesthesia of fingers and toes for surgical procedures (i.e., drainage of a felon or paronychia, removal of a foreign body, or laceration repair) including the proximal digit

Caution

Do not use a vasoconstrictor such as epinephrine with the anesthetic agent.

Procedure

Carefully identify the area that requires the anesthetic. If it includes more than the distal two-thirds to three-fourths of the fingers or toes, use the metacarpal nerve block. For more proximal procedures consider other options. Check the digit for blood supply, sensation, and motor nerve function before injecting the anesthetic agent. The site of puncture on the digits for each is shown in Figure 12.13A.

Consider procedural sedation, child life techniques, and restraint if required. Have an assistant grasp the extremity proximal to the digit to prevent movement.

The digital nerves, as shown in Figure 12.13A, part B, are both dorsal and volar in the body of the digit, and anesthesia must be injected at both levels (see closed circles, Fig. 12.13A).

Scrub the planned puncture sites on the medial and lateral aspect(s) of the finger thoroughly with povidone–iodine solution. Dry with sterile gauze and don gloves. Use a 22-gauge needle attached to a 5-mL syringe and 1% lidocaine (without epinephrine). Inject the site at a 45-degree angle from vertical until the needle hits the periosteum. Release the tension on the needle and gently rotate the syringe to the vertical as shown in Figure 12.13A, part C. Then, advance the needle to the volar surface while injecting anesthetic until at least three-fourths through the digit. Remove the needle from the tissue, and then repeat the procedure on the other side of the digit in a similar manner. The digit should be anesthetized after several minutes.

An alternative approach to the digital nerve block is to block the nerve at the level of the metacarpophalangeal joint. This method may be less painful and may have fewer complications than a more distal block.

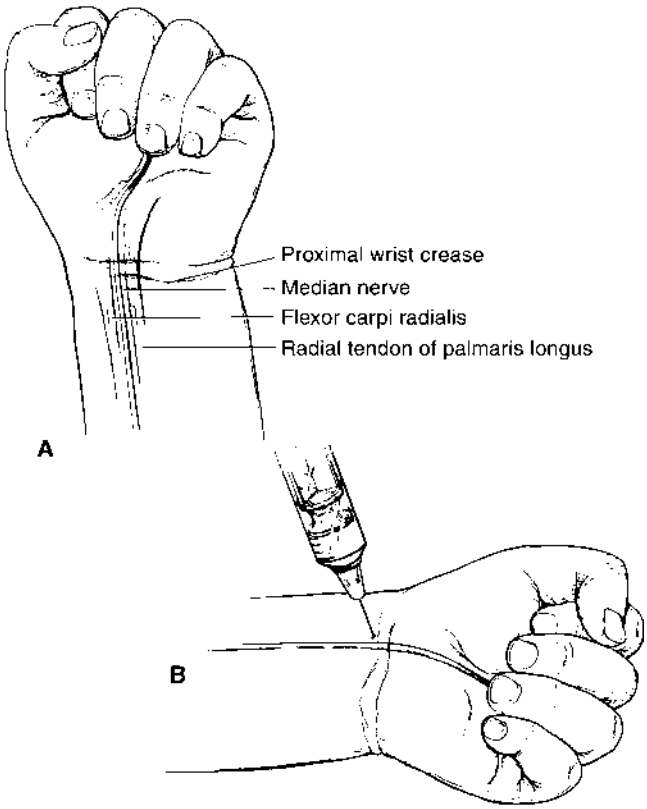
Achieve the block by inserting a 25-gauge, 5/8-in needle along each side of the finger at the intradigital fold in line with web space. Insert the needle into the web space until the tip is at the level of the metacarpal phalangeal joint (1 to 2 cm) and inject 1 to 2 mL of 1% lidocaine. For the index finger, place a half-ring wheal of lidocaine along the radial side of the proximal aspect of the finger. For the fifth digit, inject a similar wheal along the ulnar border to anesthetize the lateral aspect.

Proximal Digital Nerve Block. Figure 12.13A shows the location of more proximal block (see the open circles). Inject these areas when the entire finger, including the proximal phalanx, must be anesthetized. The nerve is closer to the palmar surface here, making it best to inject the anesthetic closer to the palmar surface.

12.13B. Median Nerve Block

Indications

1. Lacerations distal to the nerve's sensory distribution
2. Removal of a foreign body



12.13B

Procedure (Fig. 12.13B)

The median nerve at the level of the proximal wrist crease courses superficially to lie between the more medial tendon of the flexor carpi radialis and the immediately radial tendon of the palmaris longus. Locate the two tendons by having the patient make a fist and flex the wrist. Cleanse the area with povidone–iodine solution. Insert a 25-gauge, 5/8-in needle at the level of the proximal skin crease on the distal forearm and at a right angle to the tendon. Depending on the size of the child, insert the needle 0.5 to 1 cm and inject 2 to 3 mL of 1% lidocaine. In the older child or adolescent, attempt to demonstrate paresthesia of the hand to ensure the nerve is touched by the needle point before injecting the lidocaine. If a paresthesia is elicited when entering the retinaculum, withdraw slightly prior to injection to avoid directly injecting the nerve. The effect will be best in 10 to 20 minutes.

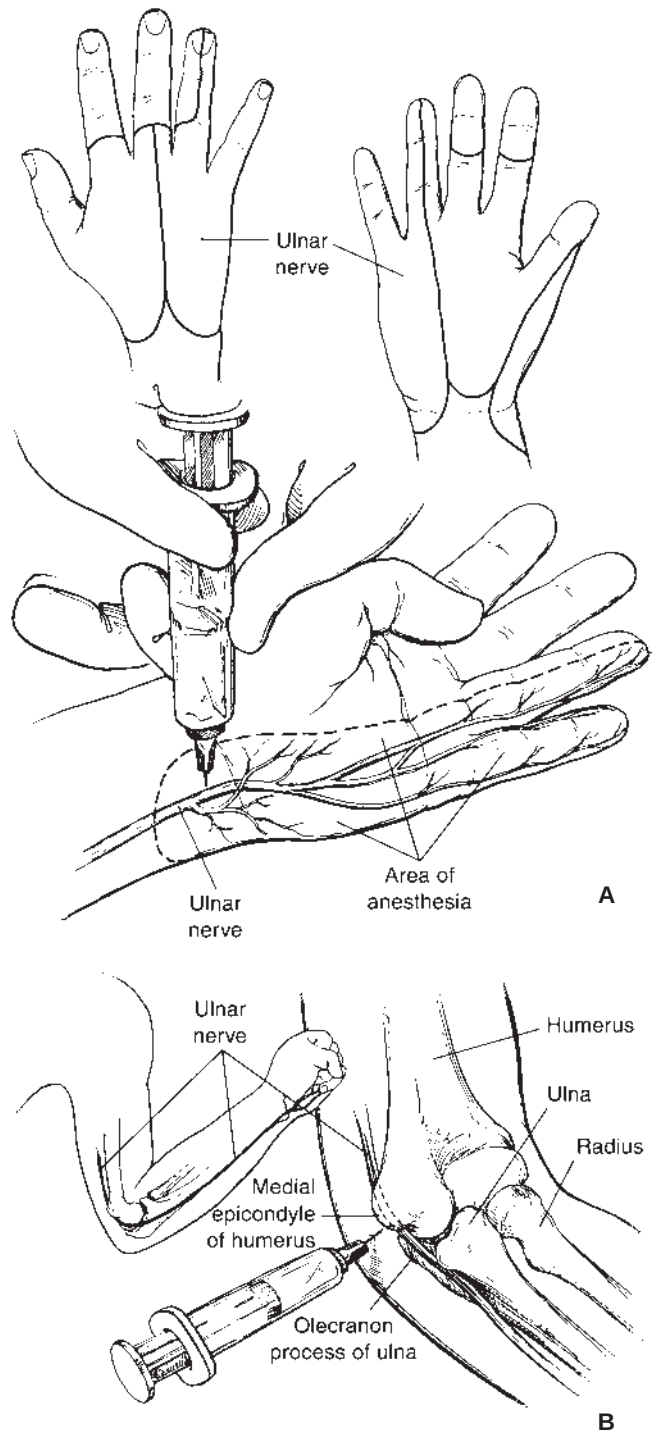
12.13C. Ulnar Nerve Block

Indications

To provide anesthesia to the dorsal and palmar aspects of the hand, fifth finger, and ulnar side of the fourth finger to perform surgical procedures (i.e., laceration repair, debridement of hand burns or abrasions, reduction of hand fractures, or foreign-body removal)

Procedure

Carefully identify the area requiring anesthesia (Fig. 12.13C, part A). Check the hand and digits for blood supply, sensation, and motor nerve function before injecting lidocaine.



12.13C

The ulnar nerve divides into two branches at the wrist. The palmar branch is located at the proximal wrist crease between the ulnar artery and the flexor carpi ulnaris tendon. The dorsal branch divides from the palmar branch 3 to 4 cm proximal to the wrist and courses under the flexor carpi ulnaris tendon.

The ulnar nerve can be blocked at the wrist or elbow. Ulnar nerve blocks at the wrist are not always successful because

they require that both branches receive anesthetic. However, the risk of discomfort and of intraneural injection is slightly greater with blocks at the elbow.

1. Ulnar nerve block at the wrist—Cleanse the ventral surface of the wrist area well with povidone—iodine solution. Dry with sterile gauze.

   Using a 25-gauge needle, inject an intradermal skin wheal of lidocaine over the ulnar nerve at the proximal wrist crease at the level of the ulnar styloid. Insert the needle perpendicular to the skin on the ulnar side of the ulnar artery (Fig. 12.13C, Part A). At a depth of about 5 mm, paresthesia usually occurs. Aspirate to prevent intravascular injection, and then infuse 3 mL of lidocaine. If no paresthesia is elicited, inject an additional 2 mL of anesthetic. If the dorsal sensory branch of the ulnar nerve is not adequately anesthetized, inject approximately 3 mL of lidocaine subcutaneously on the dorsal surface of the wrist just distal to the ulnar styloid. Wait 10 to 15 minutes for anesthesia to take effect.
2. Ulnar nerve block at the elbow—Palpate the cordlike ulnar nerve between the medial epicondyle and olecranon by flexing the elbow. Cleanse the overlying skin with povidone–iodine solution. Dry with sterile gauze.

   With a 25-gauge needle, raise an intradermal skin wheal over the nerve. Through the skin wheal, inject 3 to 5 mL of 1% lidocaine on either side of the ulnar nerve (Fig. 12.19C, Part B). Do not inject directly into the nerve sheath. If paresthesias occur, remove the needle approximately 2 mm to avoid intraneural injection because this may result in postoperative paresthesias. Wait 15 minutes for anesthesia to take effect.

12.13D. Radial Nerve Block

Indications

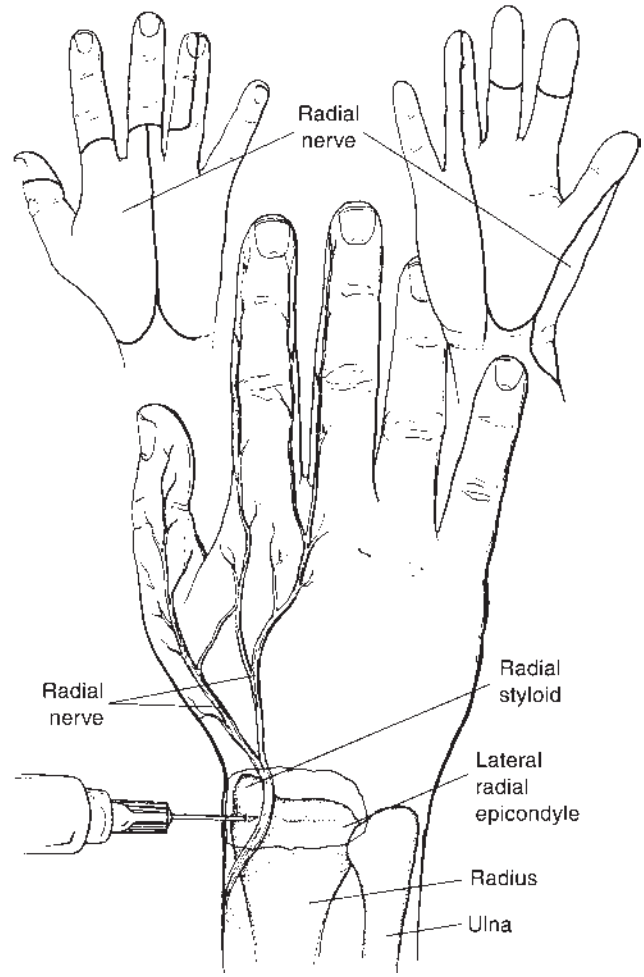
1. Anesthesia of the dorsum of the thumb, index, and middle fingers, and radial portion of the dorsum of the hand for surgical procedures (i.e., laceration repair, debridement of hand burns or abrasions, or foreign-body removal)
2. A radial nerve block may be combined with median and ulnar nerve blocks for reduction of hand fractures

Procedure

Carefully identify the area requiring anesthesia (Fig. 12.13D). If it includes more than the dorsum and radial aspect of the hand, alternative methods must be performed to achieve adequate anesthesia.

Proximal to the wrist, a superficial cutaneous branch exits the main radial nerve. At the level of the wrist, this branch subdivides into several rami, which lie subcutaneously and provide sensory innervation to the dorsal–radial aspect of the wrist and hand.

Scrub the dorsal–radial aspect of the wrist thoroughly with povidone–iodine solution. Dry with sterile gauze. Identify the radial styloid. Insert a 25-gauge needle into the subcutaneous tissue 2 to 4 cm proximal to the prominence of the radial styloid. Slowly inject a small bolus of lidocaine (2 to 4 mL). To anesthetize the dorsal branches, lay down a continuous subcutaneous tract of lidocaine from the radial styloid to the lateral



12.13D

radial epicondyle of up to 5 to 10 mL. Allow 10 to 15 minutes for a complete block.

12.13E. Supraorbital Nerve Block

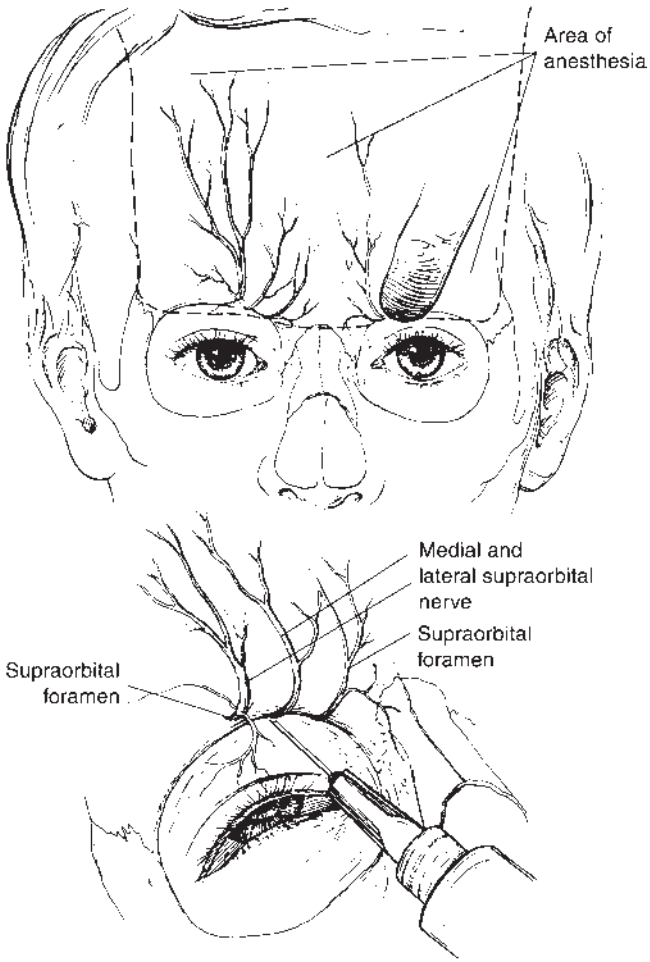
Indications

1. Lacerations within sensory distribution of the nerve (Fig. 12.13E)
2. Removal of a foreign body

Procedure

The supraorbital nerve exits the skull at the foramen just above the supraorbital ridge. The supratrochlear nerve exits just medial to the supraorbital nerve. Locate the foramen by palpating over the medial aspect of the supraorbital ridge (Fig. 12.13E).

Cleanse the area with povidone–iodine solution. Insert a 25-gauge, 5/8-in needle just medial to the foramen, directed toward the foramen (Fig. 12.13E). Depending on the size of the child, insert the needle 0.5 to 1 cm and inject 1 to 3 mL of 1% lidocaine with epinephrine. In the older child or adolescent, attempt to demonstrate paresthesia of the forehead to ensure the nerve is touched by the needle point before injecting the lidocaine.



12.13E

12.13F. Infraorbital Nerve Block (Intraoral Approach)

Indications

1. Lacerations within sensory distribution of the nerve (Fig. 12.13F)—midface (skin of the upper lip, nose, and lower eyelid)
2. Removal of a foreign body

Procedure

The infraorbital nerve exits its foramen just below the infraorbital ridge. Locate the foramen by palpating over the cheek just below the infraorbital ridge.

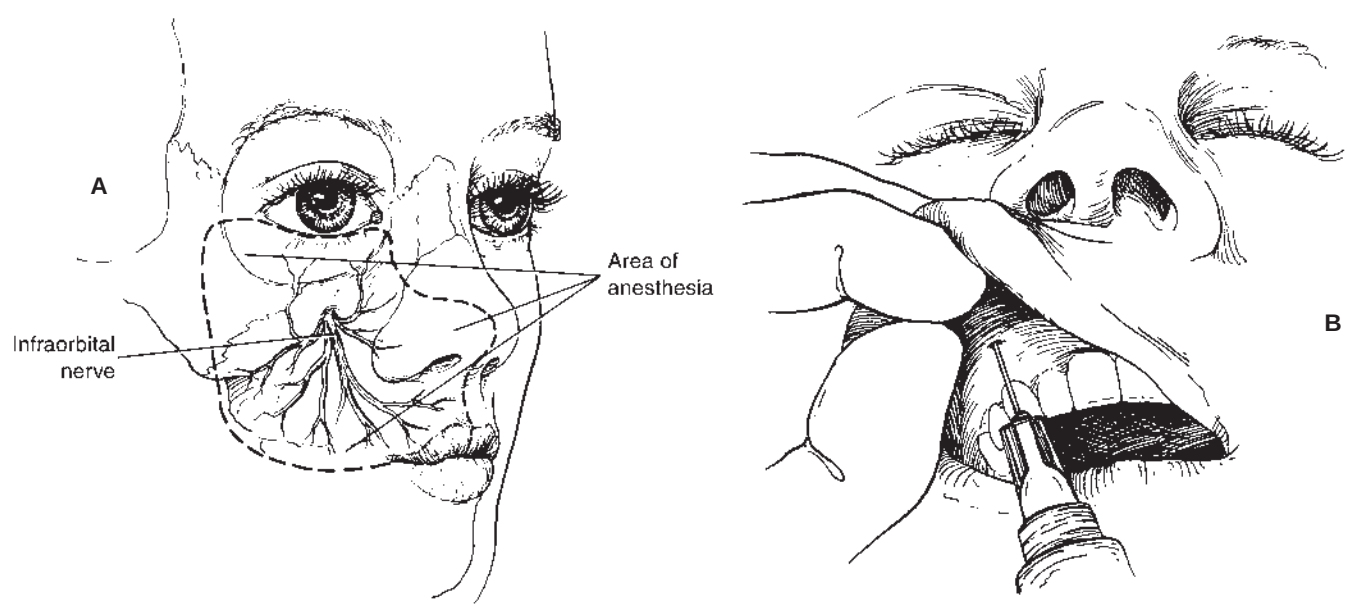
Don gloves and place a finger over the infraorbital ridge while using the index finger to hold up the upper lip. Numb the upper gum near the second bicuspid with a topical anesthetic. Insert a 25-gauge, 1.5-in needle on a syringe with 1% lidocaine. Puncture the gum line along the long axis of the second upper bicuspid and advance until the needle is palpated at the foramen where the infraorbital nerve exits. The needle is inserted to about a depth of 2 cm in a full-grown teenager. Inject 1 to 2 mL of 1% lidocaine.

When tissue injury is sufficient to make palpation of the infraorbital ridge difficult, a field block may be used infiltrating 4 to 5 mL in a fanlike distribution along the upper buccal fold. Wait 5 minutes for anesthesia to occur.

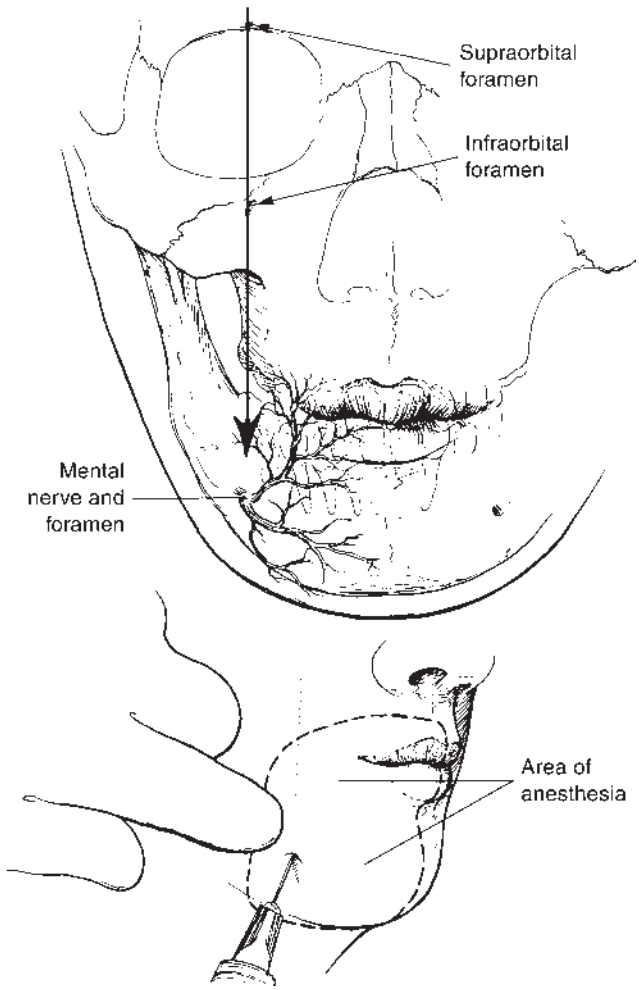
12.13G. Mental (Infraoral) Nerve Block

Indications

1. Lacerations of the lower lip and chin
2. Removal of a foreign body



12.13F



12.13G

Procedure

The mental nerve is a branch of the alveolar nerve with sensory distribution of the lower lip and chin (Fig. 12.13G). It exits its foramen in the mandible at the level of the premolar. Locate the foramen by palpating over the mandible in line with the supraorbital and infraorbital foramen (Fig. 12.13G).

Cleanse the area with topical anesthetic. Insert a 25-gauge, 5/8-in needle just medial to the foramen directed toward the foramen. Depending on the size of the child, insert the needle approximately 0.5 cm and inject 1 to 2 mL of 1% lidocaine with epinephrine. In the older child or adolescent, attempt to demonstrate paresthesia of the lower lip to ensure the nerve is touched by the needle point before injecting lidocaine.

12.14. SPLINTING OF MUSCULOSKELETAL INJURIES

General Splinting

Indications

To provide short-term stabilization and/or protection of musculoskeletal injuries (fractures, tendon injuries, lacerations, or tenosynovitis)

Complications

1. Neurovascular compromise
2. Pressure sores
3. Contact dermatitis

Equipment

1. Cotton bandage (Webril®)
2. Plaster slabs or rolls (2-, 3-, 4-, and 6-in widths) or prepadded material (OCL™ and Orthoglass®) of same widths
3. Room temperature tap water
4. Elastic (Ace™) bandage
5. Adhesive tape

Procedure

Determine the style of splint needed from the anatomic considerations of the injury. Remember that the injured extremity should be splinted in a position of function to minimize contractures. Skin lesions and wounds should be cleansed, repaired, and dressed in the usual manner before the application of plaster. Open fractures should be evaluated emergently by an orthopedic surgeon. Neurovascular status should be documented before and after the splint is applied.

Before applying the splint, it is important to completely expose the extremity to be splinted and anticipate the child's ability to remove his/her clothing once the splint is applied.

Plaster Splint

Measure and cut the appropriate length of plaster. It is better to cut the length slightly longer than necessary to account for any shrinkage of material. If the cut length is too long, the end can always be rolled on itself. The upper extremity requires 8 to 10 layers; the lower, 12 to 14 layers to withstand some weight bearing. In general, the slab should be wide enough to cover approximately one-half of the circumference of the extremity but should never be so wide that it overlaps itself.

Next, prepare the padding. If toes or fingers are to be incorporated within the splint, place padding between the digits to prevent maceration. Roll Webril® bandage around the injured extremity in a distal to proximal manner, making sure to overlap each turn by 50%. Extend the padding 2 to 3 cm distally and proximally beyond the area to be splinted. Wrinkles of the Webril can create pressure points and are best avoided by stretching and partially tearing the bandage during application. Bony prominences require additional padding with orthopedic felt or Webril to minimize pressure injury. Stockinette may be used under the Webril, if desired.

Immerse the plaster slab in room temperature water until bubbling stops. Because setting plaster elaborates heat, room temperature water is recommended to minimize risk of heat injury to the patient's skin. Remove the slab from the water and on an absorbent surface such as a towel; smooth the plaster to remove excess moisture and wrinkles and to laminate the layers. The setting time of the plaster is determined by the temperature of the water and the overall moisture content of the plaster, with warmer water and drier plaster shortening the set time. Properly position the splint onto the extremity. Using your palms, smooth and contour the splint to the extremity, taking care not to leave indentations. Indentations create pressure points that will be uncomfortable and cause skin breakdown. Fold the exposed Webril back over the ends of the splint.

Next, an optional layer of gauze or a single layer of Webril may be placed over the splint to prevent the Ace™ wrap from being incorporated into the plaster. Then, roll the Ace wrap over the splint in a distal to proximal manner and secure with tape. The extremity should be maintained in the desired position until the splint is sufficiently hard.

Fiberglass Splint

A good option is to use one of the commercially available splinting preparations (OCL™ or Orthoglass™), which incorporate the padding and a fiberglass splint material into a single preparation. These preparations are designed to provide a sufficient amount of padding by themselves and do not require the use of additional padding under the splint. However, some practitioners prefer to pad bony prominences, such as the malleoli, heel, or elbow, particularly when the splints may be kept on longer before follow-up. The advantages of these materials are their ease and neatness of application. The fiberglass products also appear to be more durable than the plaster splints. A relative disadvantage is that these commercially available products are not as moldable to the bends of an extremity as well as plaster seems to be.

It is important to follow the specific manufacturer's instructions when using these products to ensure appropriate application. In general, these products are cut to length; moistened with water; stretched, smoothed, and molded to the injured extremity; and then covered with an Ace bandage. Once the material is applied and secured, maintain the extremity in the proper position until the splint becomes sufficiently rigid. This takes place usually much quicker than plaster, as short as 10 minutes from application. It is helpful to cut the material slightly longer than necessary and to fold the excess length back on itself to make a smooth comfortable end to the splint. This technique is especially helpful at natural flexion areas, such as the palm or toes. *Remember* also that the cut ends of the fiberglass material become sharp when dry and require either taping of the exposed ends or a stretching of the padding material on its application to cover the exposed end and prevent skin laceration.

Other Issues

Dispense crutches or slings as appropriate to prevent weight bearing or usage that may enhance edema, pain, or cause the splint to break. Children in general are not capable of using crutches if they are 6 years of age or younger. Discharge instructions include appropriate recommendations for rest, ice, and elevation. Discuss signs and symptoms of neurovascular compromise, and recommend that the patient loosen the splint and return to the ED if neurovascular insufficiency is suspected. Assist in arrangement of appropriate referral and follow-up specific to each injury. For nonangulated and nondisplaced fractures, this visit is generally acceptable within 7 days of injury, although some orthopedic surgeons may desire to have follow-up sooner, in 2 to 3 days. It is important to work within the recommendations of the specialists for specific follow-up.

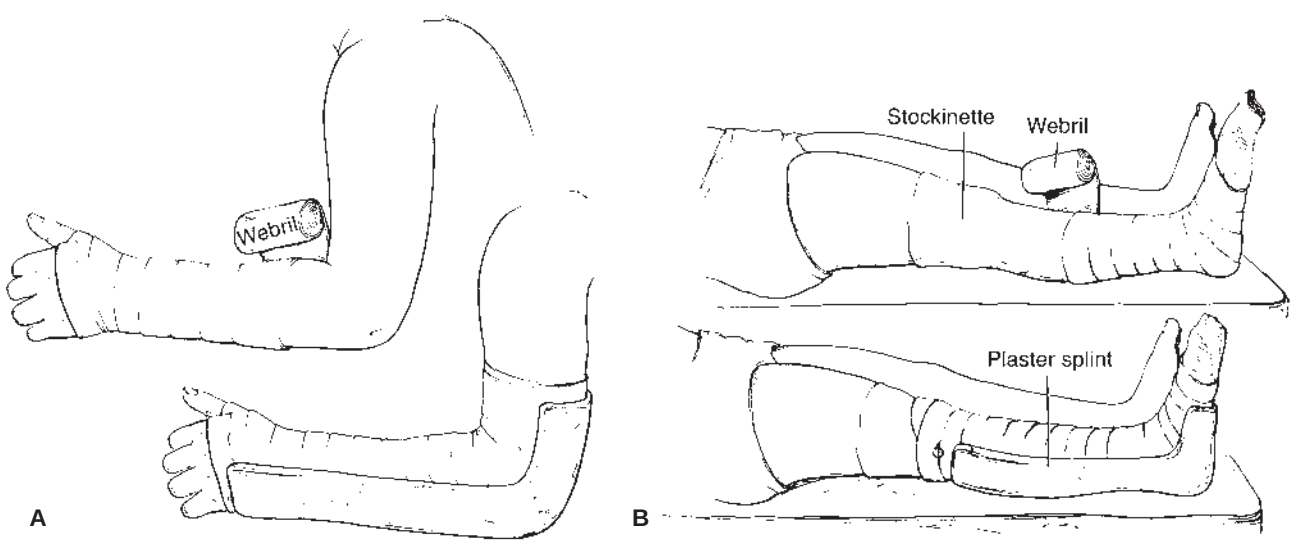
12.14A. Long Arm Posterior Splint

Immobilization of elbow and forearm injuries

Procedure

Ascertain that the injury will be adequately immobilized by a long arm splint (Fig. 12.14A). Prepare the child by carefully exposing the upper arm, elbow, and forearm. The appropriate position for splinting will have the child flexed to 90 degrees at the elbow, the forearm in neutral position, and slight dorsiflexion at the wrist. When applying a splint for a supracondylar fracture, position the forearm with slight pronation. Do not move the injured arm passively around swollen or disfigured areas.

The length of this splint will extend from the palmar crease of the hand to mid-arm being the length up the arm from the elbow. It will run along the ulnar side of the forearm and the posterior aspect of the humerus. Take care so the splint does not impinge on the axilla. The width should extend semicircularly



12.14A–B

halfway around the arm. Prepare and apply the splint material as described in the "General Splinting" section. This splint requires the use of a sling.

Supracondylar fractures may require more urgent follow-up and should be discussed with an orthopedic surgeon.

12.14B. Posterior Ankle Splint

Indications

Immobilization of ankle sprains and fractures of the foot, ankle, and distal fibula

Procedure

This splint extends from the foot, including the ball of the foot, to proximal lower leg at the level of the fibular head. Ensure it does not impinge on the popliteal fossa when the leg is flexed. For metatarsal fractures, the splint is sometimes extended to include the toes. The material should be wide enough to support the entire width of the foot. The splint will maintain the foot at 90 degrees of flexion and is most easily applied with the child in the prone position with the leg flexed. Prepare and apply the splint materials as described in the "General Splinting" section. Consider additional padding at the malleoli and calcaneus. Once the splint is applied, it is often necessary to have someone maintain the foot at 90 degrees while the material hardens.

Discharge the patient with crutches and warn that this splint does not tolerate weight bearing well, particularly in school-age children or teens.

12.14C. Ankle Stirrup (Sugar Tong) Splint

Indications

Immobilization of injuries to the ankle, especially in adolescents

Procedure

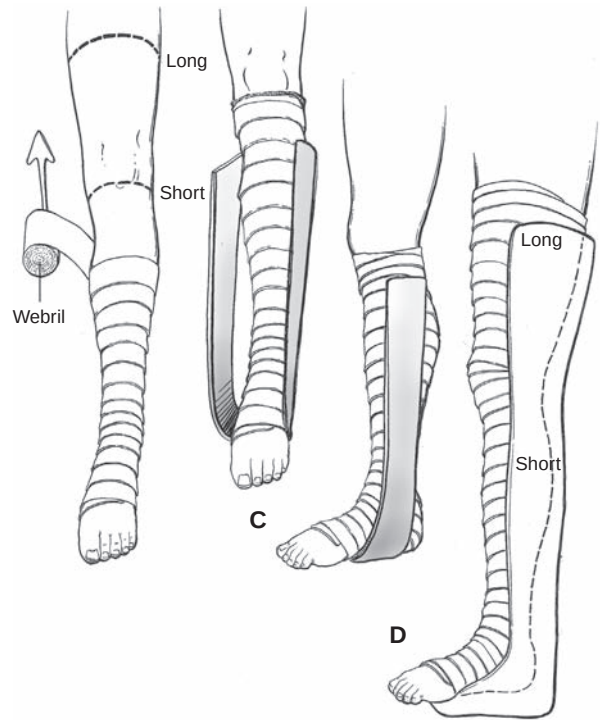
This splint may be used alone or together with a posterior splint. It provides lateral and medial support to injured ankles. This splint extends in a U-shaped fashion from the fibular head around the ankle to just below the knee. The width of the material should be approximately one-half of the circumference of the narrowest portion of the lower leg. The material, however, should not overlap. Application occurs more easily with the patient in the prone position and the foot at 90 degrees. Consider padding the malleoli with felt or Webril™ to decrease the incidence of pressure sores. Prepare and apply the splint materials as described in the "General Splinting" section. When using the posterior and stirrup splint together, place the posterior splint on first closest to the leg.

Discharge the patient with crutches and discourage weight bearing.

12.14D. Long Leg Posterior Splint

Indications

Immobilization of knee injuries and fractures of the midshaft and proximal tibia and fibula



12.14C–D

Procedure

The injuries immobilized by this splint often require early orthopedic consultation. When used, the splint extends from just behind the toes to the area below the gluteal fold (Fig. 12.14C, D). The splint material must be sufficiently wide to support the proximal thigh and the knee. The final position will maintain the ankle at 90 degrees and the knee in slight flexion. The help of an assistant or two is necessary to support and elevate the leg during the procedure. Prepare and apply the splint materials as described in the "General Splinting" section. Discharge the patient with crutches and discourage weight bearing.

12.14E. Ulnar Gutter Splint

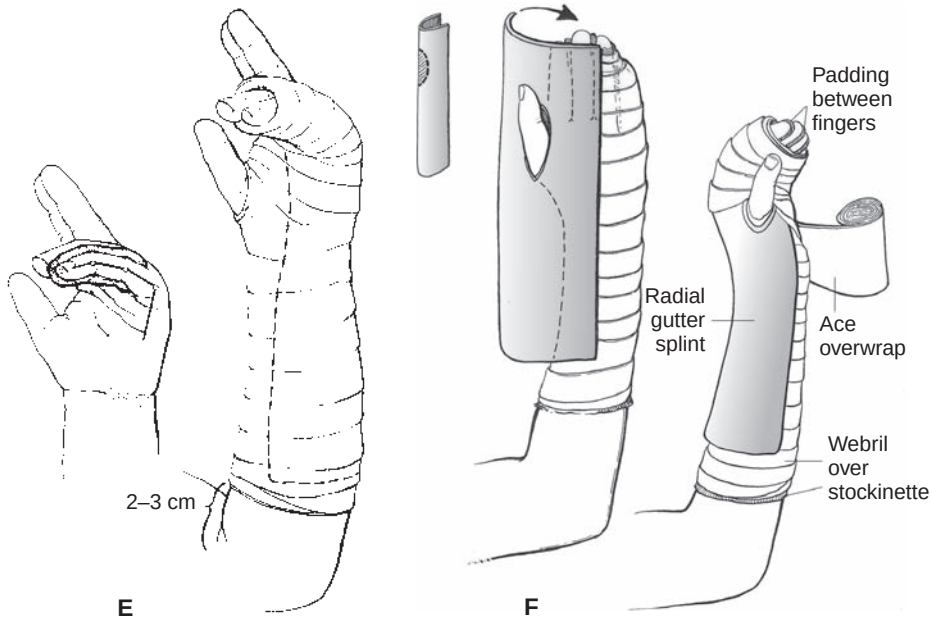
Indications

1. Boxer's fractures (up to 20 degrees angulation without rotation)
2. Uncomplicated fourth and fifth phalangeal fractures

Procedure (Fig. 12.14E)

This splint is U-shaped, incorporates the fourth and fifth phalanges, and extends along the ulnar side of the forearm. The final splint extends from the distal fingers to the proximal forearm. The proper splinting position maintains slight dorsiflexion of the wrist, 60 to 90 degrees of flexion of the metacarpophalangeal joint, and 20 degrees of flexion of the interphalangeal joints.

To determine the appropriate length of splint material, measure from the patient's fingertip to 2 to 3 cm shy of the volar crease at the elbow. The plaster material should be wide enough to enclose the fourth and fifth phalanges and overlie both the



12.14E–F

volar and dorsal surfaces of the fourth and fifth metacarpals. Place the patient's elbow in a neutral position so no pronation or supination of the forearm is possible. Prepare and apply the splint materials as described in the "General Splinting" section. Remember to place padding between the digits. For metacarpal fractures, it is desirable to approach 90 degrees of flexion at the metacarpal phalangeal joint. This position tightens the collateral ligaments and helps maintain reduction.

Inform the patient that the knuckle contour at the fracture site may be less noticeable after this injury heals.

12.14F. Radial Gutter Splint

Indications

1. Second and third metacarpal fractures
2. Second and third phalangeal fractures

Procedure

This splint is U-shaped and lies along the radial side of the arm. It extends from the tips of the second and third phalanges to the proximal forearm a few inches shy of the flexural crease at the elbow. The width of the material will cover the second and third metacarpals on the volar and dorsal surfaces. The final position maintains the forearm in neutral position with the wrist in slight dorsiflexion, the metacarpal joint at 60 to 90 degrees of flexion, and up to slight flexion of the interphalangeal joints.

Prepare and apply the materials as described in the "General Splinting" section. A hole must be made in the splinting material to allow for the thumb. Accomplish this by locating the position of the thumb on the splint material, folding the material in half, and cutting a semicircle of material from the folded edge. If fiberglass is used, this cut edge is sharp so the padding must be stretched well or additional padding placed around the thumb to keep fiberglass from direct contact with the skin. Remember also to place padding between the fingers.

A sling is not necessary but can be dispensed for comfort.

12.14G. Sugar Tong Splint—Forearm

Indications

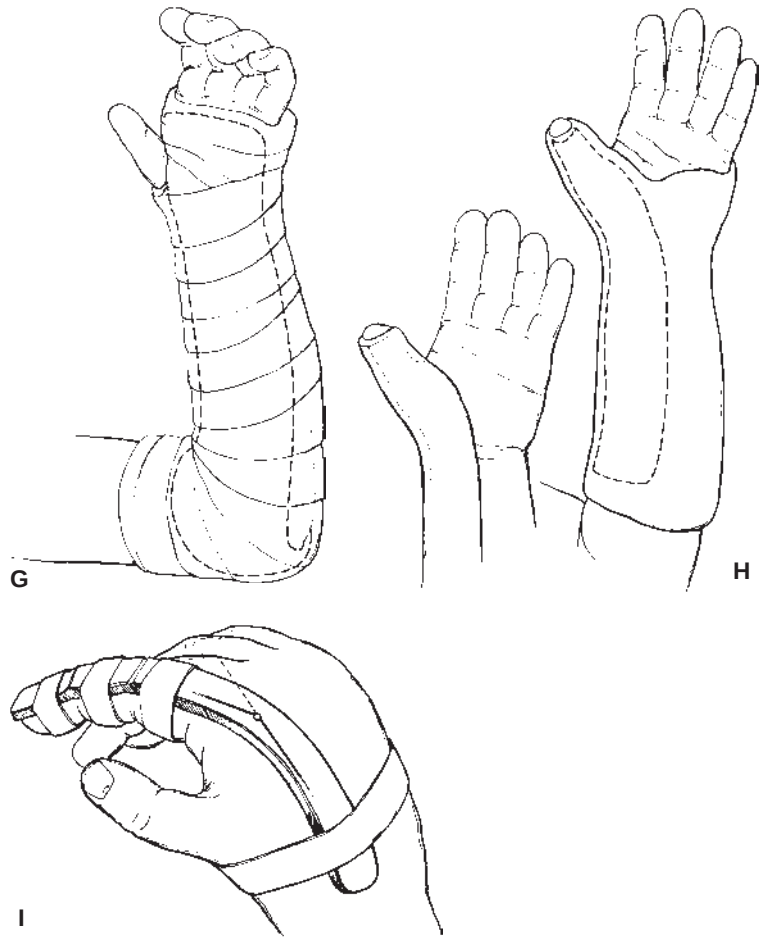
Distal radius and wrist fractures in which pronation and supination are minimized and the elbow is immobilized.

Procedure

As shown in Figure 12.14G, the splint extends along the volar surface from the flexural crease of the palm, around the elbow, and dorsally to the metacarpal heads. The fingers and thumb remain free. As shown in the figure, the arm should be flexed 90 degrees at the elbow with no rotation of the forearm. The hand is dorsiflexed minimally (have the patient hold a small roll of tape or Webril™).

With the arm positioned as just described, measure from the midpalm around the elbow to the knuckles dorsally (add 1 to 2 in to allow for shrinkage). The splinting material should be wide enough to support the arm volarly and dorsally but not so wide as to overlap. Prepare and apply the materials as described in the "General Splinting" section. Ensure sufficient padding is placed over the elbow if simple plaster is used. A properly measured splint allows 90 degrees of flexion of the fingers and approaches, but does not cover, the knuckles dorsally. An assistant is helpful when applying this splint. Ensure the thumb is free to move in all directions.

Discharge the patient with a sling with the hand slightly above the level of the elbow.



12.14G–I

12.14H. Thumb Spica Splint

Indications

1. Nonrotated, nonangulated, nonarticular fractures of the thumb metacarpal or phalanx
2. Ulnar collateral ligament injuries (gamekeeper's thumb)
3. Suspected or documented scaphoid (navicular) fracture

Procedure (Fig. 12.14H)

The splint extends in a U-shaped manner along the radial side of the thumb and forearm from the thumbnail to the midforearm. The proper splinting position maintains the wrist in slight dorsiflexion, the thumb in some flexion and abduction, and the interphalangeal joint in slight flexion. The final position is as though the patient were holding a glass or catching a ball, and will allow apposition of the index finger and thumb.

Determine the appropriate length of splint material by measuring from the patient's thumbnail to the midforearm. The splint should be wide enough to completely encircle the thumb. Prepare and apply the splint materials as described in the "General Splinting" section. The Webril should cover the thumb, hand, and forearm. Mold the splint so the thumb is maintained in the position previously described.

A sling is usually unnecessary.

12.14I. Dorsal Extension Block (Finger Splint)

Indications

1. Nonrotated, nonangulated fractures of the phalanges, not involving greater than 10% of the joint line
2. Immobilization after laceration or tendon repair
3. Sprains of the phalangeal ligaments
4. Note: Mallet and boutonniere fingers require an alternative splinting method

Equipment

1. Commercially available foam splints with aluminum backing
2. 1/2- and 1-in adhesive tape

Procedure

A dorsal splint is preferred to a volar splint because tactile sensation is maintained, it is more comfortable for the patient, and it is more protective of the injury as the splint lies between the patient and outside surfaces during ambulation.

The splint extends from the dorsum of the wrist to the end of the finger (Fig. 12.14I). The appropriate width will be equal to the diameter of the finger. Cut the splint to the proper length and place tape on the sharp edges. Tape the splint with 1-in

tape to the dorsum of the hand and wrist. Bend the splint to obtain 50 to 90 degrees of flexion at the metacarpophalangeal joint and 15 to 20 degrees of flexion at the interphalangeal joints. Secure the splint of the finger with 1/2-in tape, making sure not to cover the joint lines. Do not place tape over the distal phalanx.

12.15. REDUCTION OF NURSEMAID'S ELBOW

Indications

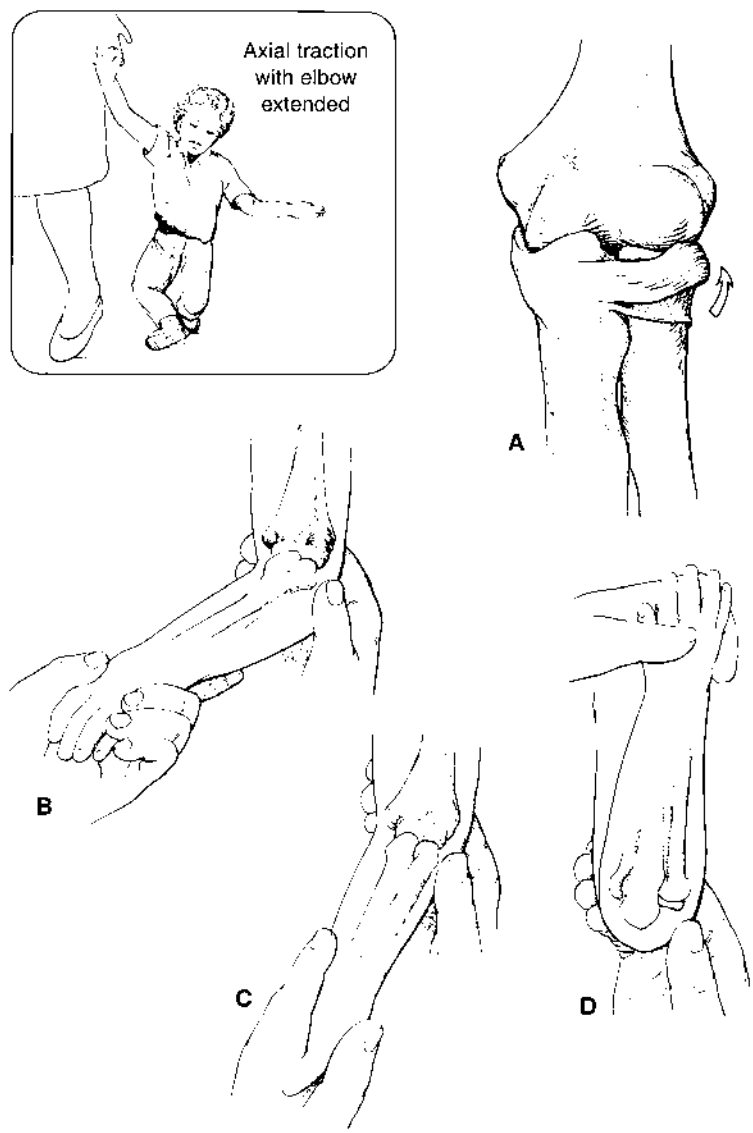
Radial head subluxation (nursemaid's elbow), which is an injury that probably represents interposition of the annular ligament between the radial head and the capitellum (Fig. 12.15A).

Complications

Vascular or musculoskeletal damage if the maneuver is performed on a child with a fracture (i.e., supracondylar fracture of humerus).

Procedure

Radiographs are not necessary if the suspicion for radial head subluxation is high, but are helpful to be certain that no bony injury exists when the history and examination are equivocal. Suspicion for radial head subluxation is based on (i) A history that is suggestive of a mechanism that would lead to radial head subluxation, such as excessive axial traction placed across the elbow joint during a fall while holding hands with an adult (Fig. 12.15); (ii) Observation of the affected arm,



12.15

which is generally held at the child's side, slightly flexed at the elbow in pronation; and (iii) Absence of point tenderness along the length of the arm and shoulder during examination of the affected arm. An adequate examination requires that the child be comfortable and may entail some distraction. Oral analgesia with acetaminophen or ibuprofen may be useful.

Generally, it takes less than 10 to 15 minutes after the reduction before the child uses the arm normally. Rarely, when a prolonged period has elapsed before reduction, it will take somewhat longer for the child to regain normal function after the maneuver is performed. Repeat or try an alternative approach if unsatisfied with the child's use of the arm.

Supination and Flexion Approach

After explaining the procedure to the parent, have the parent or assistant gently restrain the child in the sitting position. As shown in Figure 12.15B, grasp the palm of the child's hand as if to shake it. Encircle the elbow with the other hand with the thumb over the annular ligament of the radius and position the elbow in some flexion. Gently distract the elbow joint and then supinate the palm of the hand (Fig. 12.15C), and in a continuous motion, flex the elbow to the shoulder (Fig. 12.15D). During the flexion maneuver, the physician feels a "pop" with the thumb that lies over the radial head.

Hyperpronation

In more recent years, an alternative approach utilizes hyperpronation with flexion to achieve reduction. Some clinicians use this method as their primary means of reduction, whereas others employ it after the supination-flexion technique fails. This approach may be less painful. As shown in Figure 12.15B, gently grasp the patient's hand on the affected side as if to shake it, stabilize the elbow joint in some flexion, and place pressure with a finger on the radial head. Gently distract the elbow joint and hyperpronate by rotating the hand on the affected side medially. As before, the physician will feel a "pop" with the hand placed over the radial head.

12.16. APPLICATION OF A FIGURE-OF-EIGHT HARNESS

Indications

An alternative to use of a sling for immobilizing of midshaft clavicle fractures

Complications

1. Pressure sores (tight application)
2. Pain (loose application)

Procedure

Obtain radiographs in two views to confirm the presence and location of the fracture. Then choose a figure-of-eight dressing by measuring the child's chest circumference and picking the closest available size (Table 12.16).

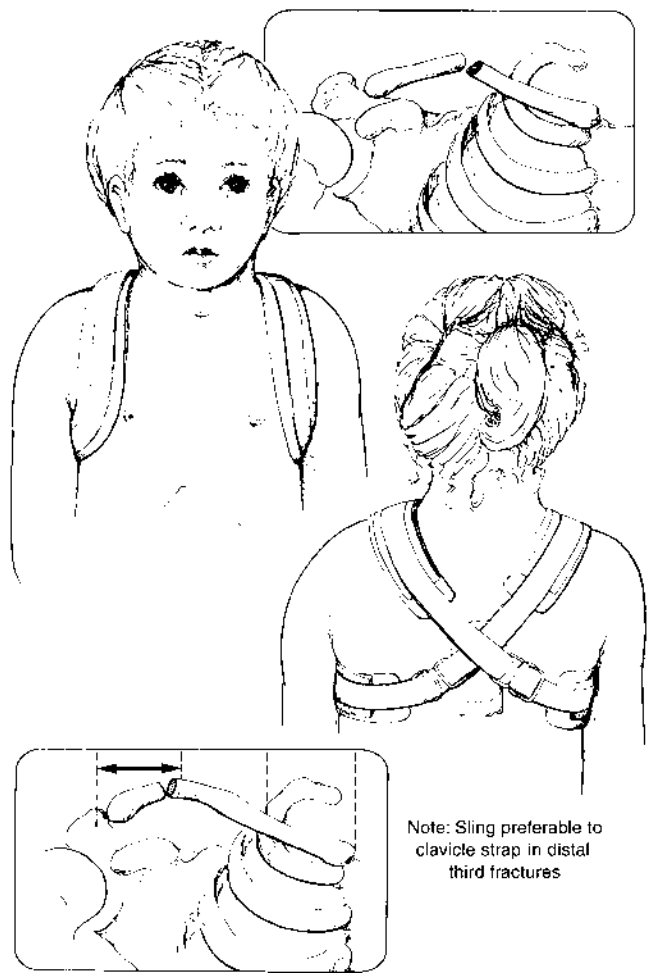
TABLE 12.16

FIGURE-OF-EIGHT HARNESS SIZES

Size	Chest circumference (cm)
Extra extra small	<20
Extra small	20–25
Small	25–30
Medium	30–35
Medium long	33–39

Stand the child up and loosely drape the harness over his/her shoulders to assess how much to tighten the straps. Remove the harness and manually adjust the straps by sliding the cloth through the metal clips. Make it slightly tighter than estimated during the fitting to pull the shoulders slightly back from their usual forward, rounded position.

Reapply the harness around the shoulders from the front to the back with the soft padding against the skin of the axillae. Approximate the buckles in the midline of the back and clip them. The harness should fit snugly, and the shoulders should be straight (Fig. 12.16). Tighten the straps as necessary.



12.16

Have the patient wear the harness except during bathing for 3 weeks. The parent should demonstrate the successful reapplication of the harness before leaving the ED.

Alternative—Sling

The use of a figure of 8 harness versus a sling for conservative treatment of uncomplicated clavicle fracture has not clearly demonstrate strong evidence for better outcomes. Midshaft and greatly displaced fractures have been treated effectively with surgical intervention in older adolescents and adults. A number of experts have chosen the use of a sling for 3 weeks as equal therapy. An alternative to uncomplicated clavicle fractures is the use of an arm sling at close to 90 degrees.

13.1 ULTRASOUND GUIDANCE FOR CENTRAL VEIN CATHETERIZATION

Indications

In patients who require central venous access, ultrasound facilitates central vein catheterization by providing direct visualization and localization of vessels, as well as real-time guidance of the venipuncture needle.

Complications

Complications are the same as for standard central vein catheterization procedures using landmark techniques. Ultrasound guidance reduces the rate of these complications. There are no reported harmful effects resulting from the use of ultrasound at energy levels necessary for this procedure. Placement of a probe within a sterile field may increase the risk of bacterial contamination.

Equipment

1. Portable ultrasound unit
2. 7.5 to 10 MHz standoff transducer probe
3. Sterile ultrasound gel
4. Sterile transducer probe sheath
5. Sterile needle guide (optional)
6. Standard equipment for central venous line placement

Procedure

Internal Jugular

The use of ultrasound guidance when placing a central venous catheter is most easily performed as a two-person procedure. Place the child in the supine position with the table tilted to 15 degrees Trendelenburg and the head rotated away from the intended side of cannulation. A towel roll under the shoulders may improve visualization of the field. Prepare and drape the neck in sterile fashion. Instill a generous amount of ultrasound gel into the sterile sheath. Place the sterile sheath over the probe head and proximal length of cable. Ensure all air is removed from between the probe head sheath. Apply an additional layer of sterile ultrasound gel to the sheath overlying the probe head. Attach the needle guide to the transducer probe. Position the probe on the skin surface above the clavicle and between the two heads of the sternocleidomastoid muscle. Hold the probe perpendicular to the path of the internal jugular vein with the needle guide facing the patient's head. Vessels appear as dark (anechoic) circular objects on the ultrasound screen. Maneuver the probe to produce a cross-sectional image of the jugular vein and carotid artery on the screen. An ultrasound unit with Doppler capabilities will facilitate identification of patent vessels. The jugular vein ordinarily lies superficial and lateral to the carotid artery. Pressure on the probe assists in distinguishing veins from arteries. The thinner-walled vein will collapse under pressure while the artery will not. A Valsalva maneuver in a cooperative patient will increase the diameter of the vein. Rotate the patient's head while transducing the vessels to find the optimal position in which the vessels lie side by side. Align the vein so it is centered beneath the probe and the electronic dot markers on the screen intersect it. Anesthetize the skin surface at the puncture site. Place the needle in the needle guide with the bevel facing the probe and advance through the skin. Observe the needle on the screen as it enters the vessel. The needle indents the vein as it comes in contact with the surface. The vein returns to its normal shape once it is punctured. Confirm placement through aspiration of blood into the syringe. Disengage the needle from the holder and remove the probe from the skin surface. Complete the placement of the central line as when using the landmark technique.

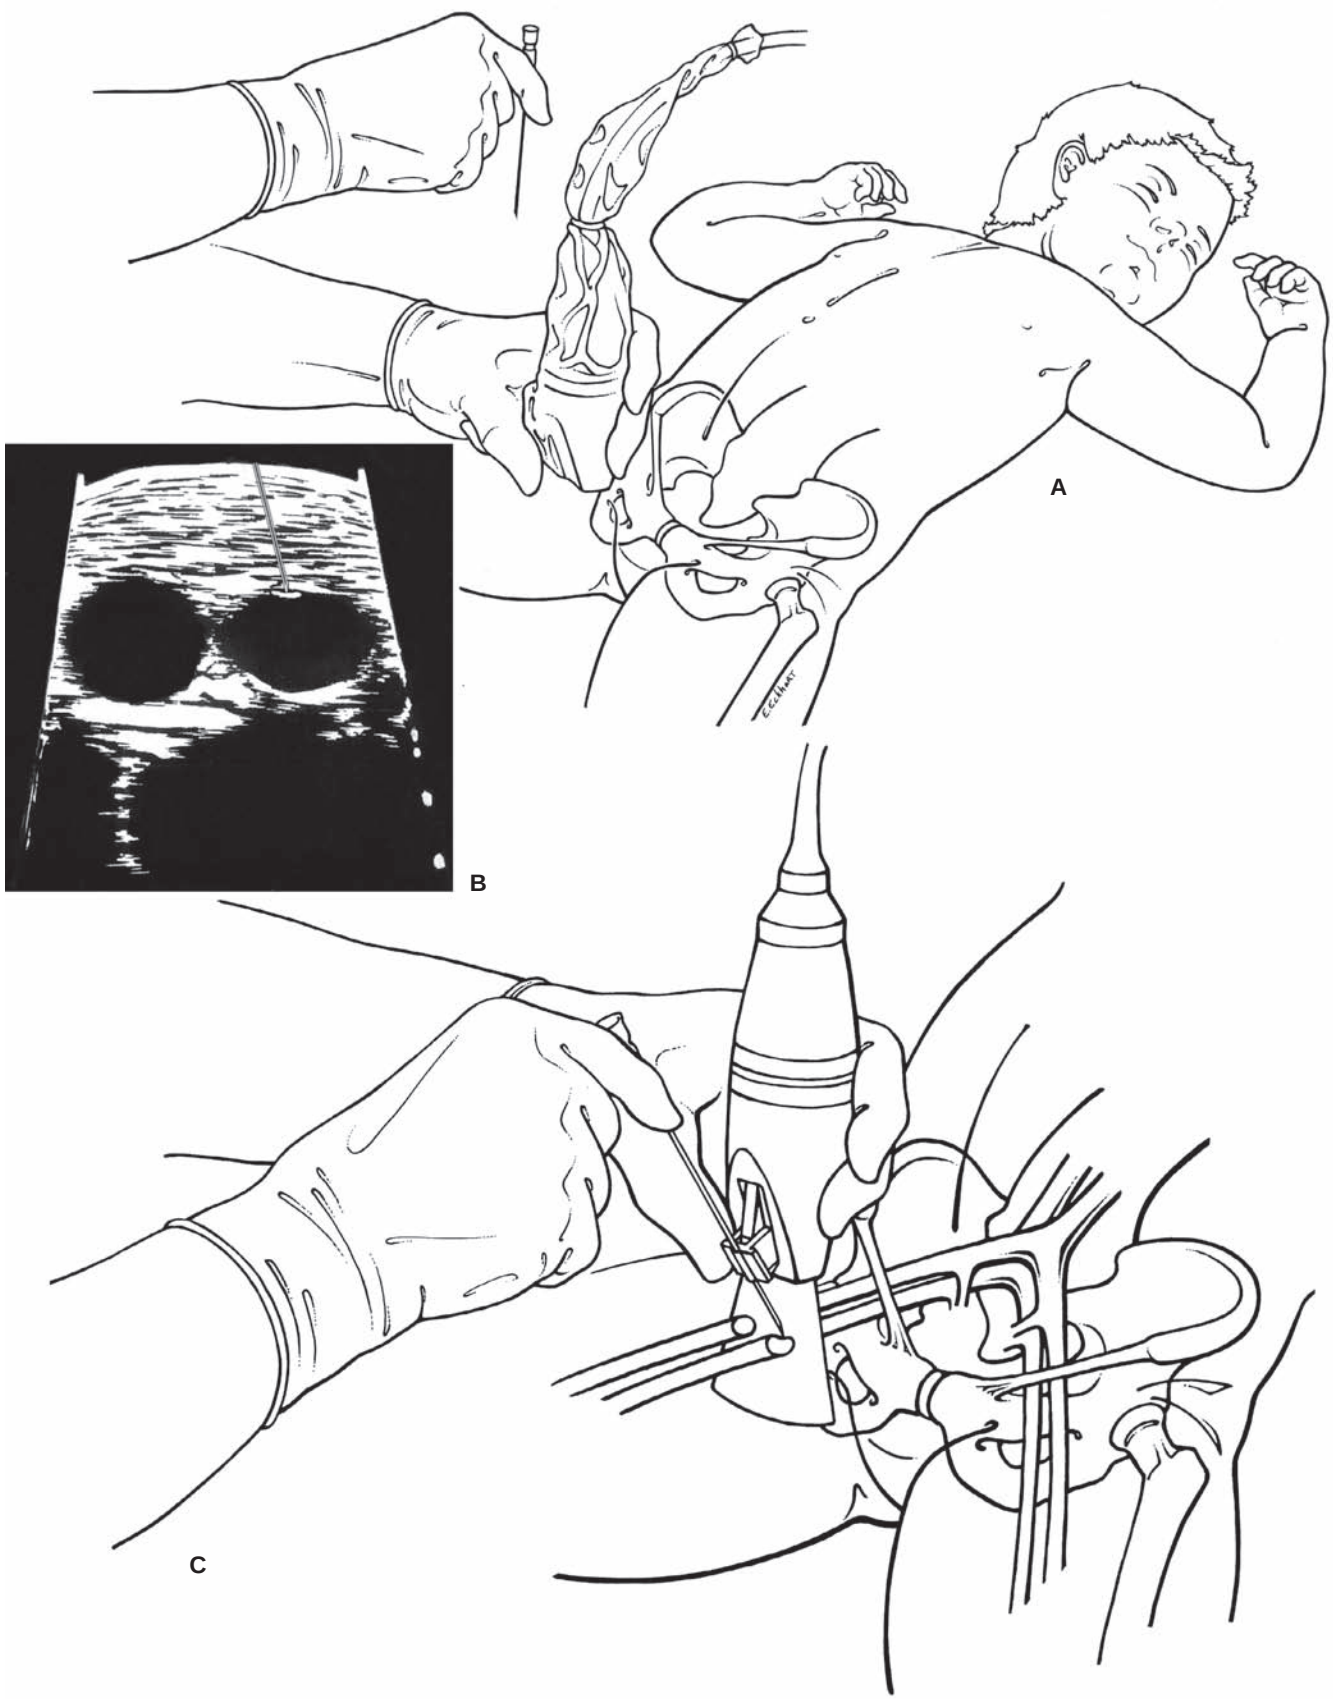
Femoral Vein

Position the child supine with the leg abducted and externally rotated. Prepare and drape the skin surface using sterile technique. Prepare the transducer probe as described previously. Place the probe on the skin surface just below the inguinal ligament at the point of the femoral artery pulsation (Fig. 13.1A). In the setting of a difficult-to-palpate pulse or cardiac arrest, place the probe midway between the anterior superior iliac crest and the pubic symphysis. Position the probe perpendicular to the direction of the femoral vein with the needle guide facing the feet. Identify the femoral vein and artery on the ultrasound screen (Fig. 13.1B). The vein lies medial to the artery. Use the previously mentioned techniques to distinguish the vein from the artery. Anesthetize the skin at the puncture site using sterile technique. Insert the needle through the needle guide with the bevel facing the probe (Fig. 13.1C), and advance through the skin surface until cannulation is visualized on the screen and confirmed through aspiration of blood into the syringe. Remove the needle from the guide and the probe from the skin surface. Complete femoral vein catheterization using standard Seldinger technique.

13.2. FOCUSED ABDOMINAL SONOGRAPHY FOR TRAUMA

Indications

Focused abdominal sonography for trauma (FAST) is a limited ultrasound examination performed in the setting of pediatric



13.1

blunt abdominal trauma to screen for the presence of free fluid (i.e., blood) within the peritoneum. The FAST examination is performed simultaneously with the secondary trauma survey.

Complications

There are no harmful effects from the ultrasound itself.

Limitations

1. The FAST examination is unable to detect solid organ or intestinal injuries that are not associated with free intraperitoneal fluid.
2. Limited utility with inexperienced operator.
3. Fluid in the pelvis may be missed in the setting of an empty bladder.

Equipment

1. Portable ultrasound unit
2. Sector or curved transducer with 2.5- to 5-MHz frequency
3. Ultrasound gel

Procedure

The FAST examination consists of ultrasound scans in four separate locations on the abdomen: the right upper quadrant, the subxiphoid space, the left upper quadrant, and the suprapubic area. Choose the transducer based on the size and body habitus of the patient. Children with more adipose tissue will require a transducer with a lower frequency to increase ultrasound penetration.

First, place the child in the supine position on the examination table with the examiner on the patient's right side. Apply ultrasound gel to the skin surface at each site to improve transmission of the sound waves and minimize artifact. Orient the transducer to obtain a sagittal view. Holding the transducer in the right hand, place it along the midaxillary line between the eleventh and twelfth ribs (Fig. 13.2A). Angle the transducer until the liver edge, diaphragm, and surface of the right kidney are identified. Presence of fluid in Morrison's pouch produces a dark (hypoechoic) shadow between the liver and kidney.

Second, image the heart by placing the probe in the subxiphoid space (Fig. 13.2B), oriented for sagittal sections and angled toward the tip of the left scapula. Identify the bright stripe of the diaphragm and the pulsating heart. Fluid within the pericardial sac appears as a dark layer between the bright (hyperechoic) lines of the pericardium and the myocardium.

Third, place the probe along the left posterior axillary line between the tenth and eleventh ribs (Fig. 13.2C). Angle it toward the patient's umbilicus until the capsule of the spleen and the surface of the left kidney are identified. Free intraperitoneal fluid appears as a dark shadow between these two structures or posterior to the spleen.

Fourth, place the probe 2 to 3 cm above the symphysis pubis and direct the probe 30 degrees caudally (Fig. 13.2D). Orient the probe to obtain a sagittal view. Angle the transducer toward the patient's left and right to scan the retrovesical space or pouch of Douglas. Rotate the probe 90 degrees to obtain a transverse image of the bladder. Free fluid appears as a dark shadow behind the bladder or uterus and may compress the posterior surface of the bladder. The optimal view is obtained in the presence of a full bladder. If the bladder is empty, place a Foley catheter and infuse with normal saline.

The presence of intraperitoneal fluid in the setting of abdominal trauma suggests intraabdominal injury with hemorrhage.

13.3. URINARY BLADDER ULTRASOUND

Indications

1. To facilitate urethral catheterization or suprapubic bladder aspiration (SBA)
2. To document bladder volume in order to distinguish dehydration from bladder outlet obstruction

Complications

Complications are the same as for standard urethral catheterization or SBA but should be less frequent. Ultrasound measurement of bladder volume to confirm the presence of urine should decrease the number of attempts needed for successful urine collection. When used as an adjunct to SBA, ultrasound should reduce the complication rate. There are no reported harmful effects resulting from the use of ultrasound at energy levels necessary for this procedure.

Equipment

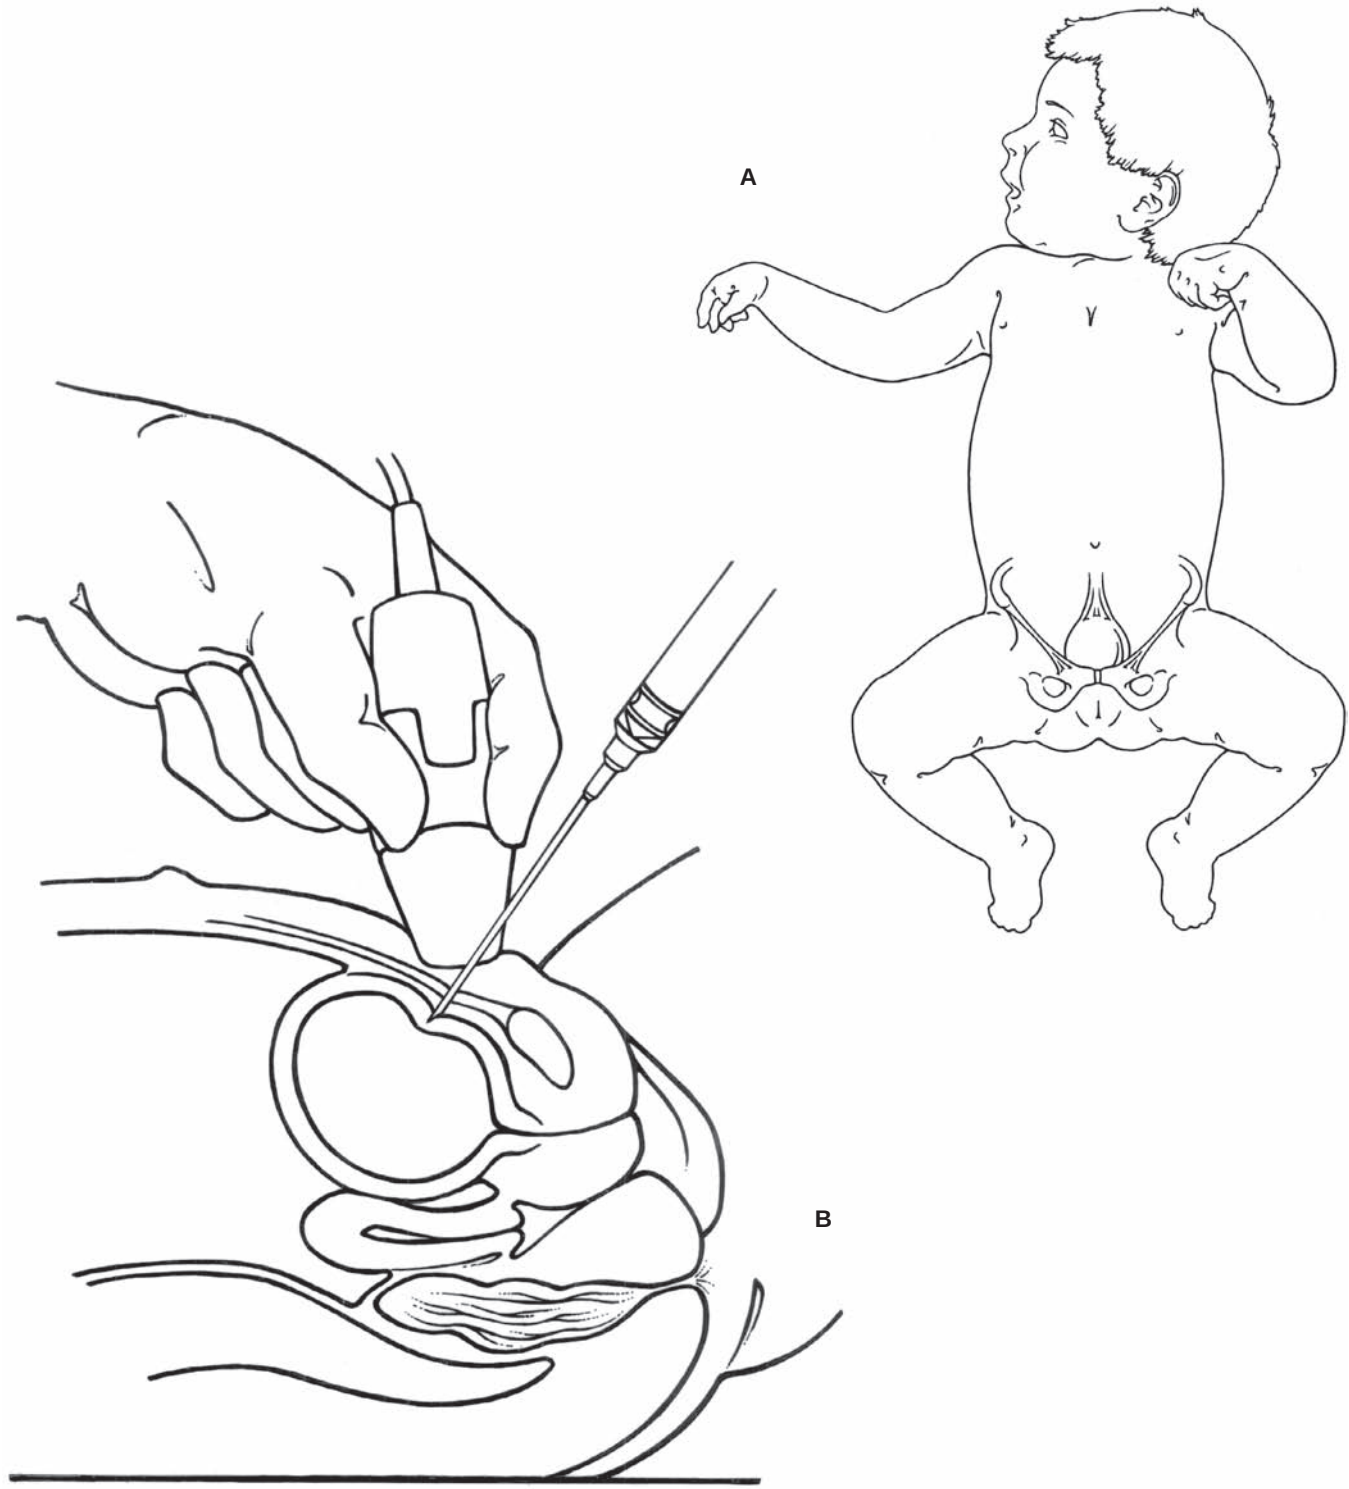
1. Portable ultrasound unit with volumetric calculation capability
2. 3.5- to 7.5-MHz probe
3. Ultrasound gel (sterile for SBA)
4. Sterile transducer sheath for SBA
5. Standard equipment for SBA or urethral catheterization.
6. Sterile marking pen (optional)

Procedure

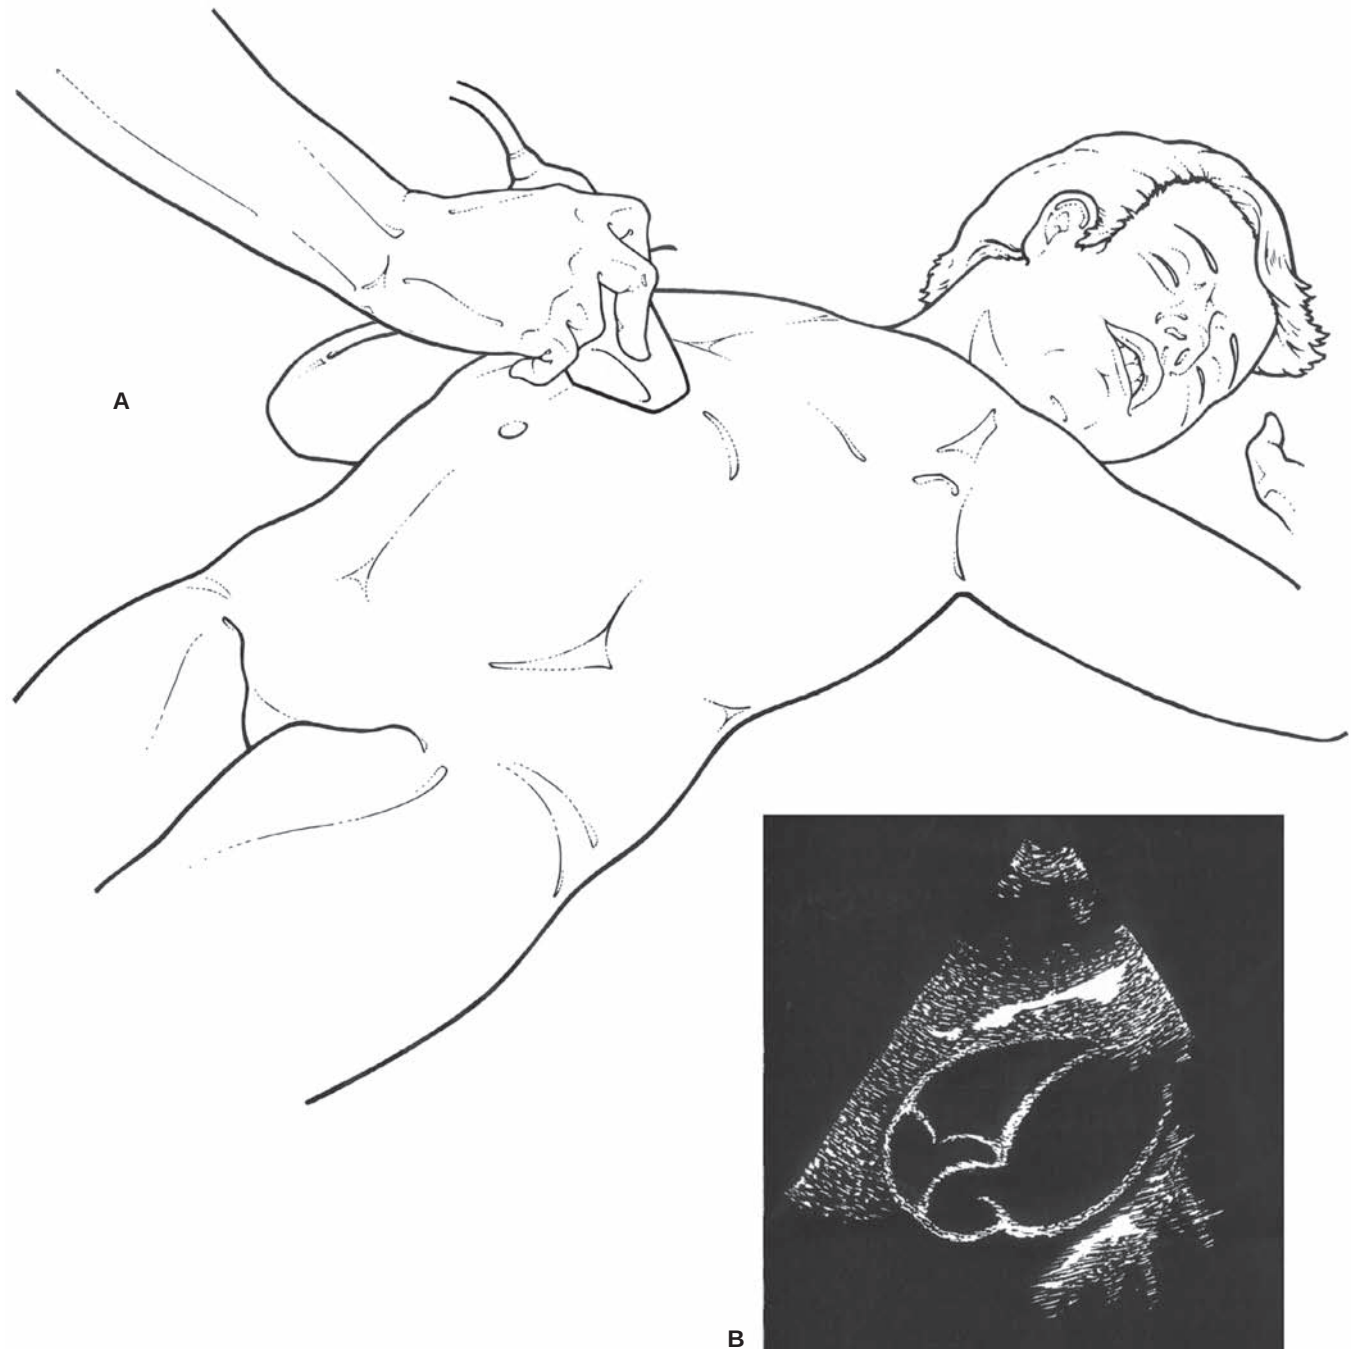
Bladder Volume Measurement

An assistant should secure the patient supine in a frog-leg position (Fig. 13.3A). Apply ultrasound gel just above the symphysis pubis. Hold the probe on the midline of the abdomen angled in a slight caudad direction. In males, apply gentle pressure at the base of the penis against the symphysis pubis to prevent early voiding when the probe is pressed against the bladder. The bladder appears as an anechoic (black) structure. In the transverse view, the bladder has a characteristically rhomboid shape. Angle the probe in order to obtain the largest diameter. Freeze the image on the screen when the maximum bladder size is visualized. Measure the anterioposterior and transverse diameters. Turn the probe 90 degrees for a longitudinal view. Freeze the maximum diameter view and

13.2



13.3



13.4

measure the bladder depth. Measurements exceeding 2 cm in all dimensions ensure a volume greater than 5 mL. Complete the standard technique for bladder catheterization as soon as ultrasound imaging is complete.

Suprapubic Aspiration

An assistant immobilizes the infant or young child in the supine position. Prepare the lower abdomen with povidone–iodine solution to produce a sterile field. Instill a generous amount of ultrasound gel into the sterile sheath. Place the sterile sheath over the probe head and proximal length of cable. Apply a second layer of sterile ultrasound gel to the sheath overlying the probe head. Place sterile ultrasound gel on the midline just above the symphysis pubis. Image the bladder in the transverse and longitudinal planes as described previously. Puncture the skin in the midline of the abdomen at the point where the bladder wall comes closest to the probe (Fig. 13.3B). The puncture site can be marked with a sterile pen or with pressure applied with a sterile needle cap. Alternatively, the puncture can be visualized in real time by maintaining the probe in place. Perform the aspiration as described previously.

13.4. ULTRASOUND ASSESSMENT OF CARDIAC ACTIVITY AND PERICARDIAL EFFUSION

Indications

1. To view cardiac activity during cardiac resuscitation
2. To diagnose pericardial effusion that may contribute to failed resuscitation or hypotension of unknown etiology

Complications

There are no complications of echocardiography.

Equipment

1. Portable ultrasound unit
2. 3.5 to 5 MHz transducer with a small footprint to allow imaging between the ribs
3. Ultrasound gel

Procedure

The subxiphoid view is the easiest to obtain and most commonly used. With the patient in the supine position, place ultrasound gel over the left costal margin at the xiphoid process. Place the probe in the transverse orientation on the ultrasound gel and pointing at the left shoulder (Fig. 13.4A). Adjust the angle and position of the probe until the bright (hyperechoic) stripe of the diaphragm, the dark (anechoic) pericardial space, and the hyperechoic wall of the right ventricle appear on one image (Fig. 13.4B). These structures appear in this order from the top down on the display screen.

The presence of cardiac contractions as visualized by real-time ultrasonography suggests cardiac response to inotropes and further measures should proceed accordingly to pediatric advanced life-support algorithms. No visible cardiac motion confirms cardiac standstill. An anechoic (dark) layer appearing between the hyperechoic (white) stripes of the pericardium and the wall of the right ventricle suggests the presence of fluid within the pericardial sac.

  2.15.1 Uncuffed sizes 2.5–8.5 (2 of each)
  2.15.2 Cuffed sizes 3.5, 4.0, 4.5, 5.0, 6.0, 7.0, 8.0 (2 of each)
2.16 Laryngeal mask airways
2.17 Stylets (1 adult, 1 infant)
2.18 Easycap ($ETCO_2$ analyzer), 2 sizes
2.19 Disposable Manometer, 15 mm, 22 mm

3. Circulation

3.1 Stat IV tray
3.2 Central venous pressure tray, 5, 10, 11 (2 of each)
3.3 Cutdown tray (2)
3.4 Umbilical catheterization tray
3.5 Intraosseous needles—16, 18 (2 of each); EZ-IO (3 sizes)
3.6 Radial artery tray (2.5F, 5 cm; 2.5F, 2.5 cm)
3.7 Drugs, prepackaged
  3.7.1 Epinephrine 1:1,000; 1:10,000
  3.7.2 Dextrose (D 25%) (D 10%)
  3.7.3 Atropine
  3.7.4 Sodium bicarbonate
  3.7.5 Calcium chloride
  3.7.6 Lidocaine 2%
3.8 Drugs
  3.8.1 Acyclovir
  3.8.2 Adenosine
  3.8.3 Afrin® nasal spray
  3.8.4 Amiodarone
  3.8.5 Ampicillin
  3.8.6 Benadryl®
  3.8.7 Bretylium
  3.8.8 Calcium gluconate
  3.8.9 Cefotaxime
  3.8.10 Ceftriaxone
  3.8.11 Charcoal
  3.8.12 Clindamycin
  3.8.13 Cyanide kit (Hydroxocobalamin)
  3.8.14 Dexamethasone
  3.8.15 Diazepam
  3.8.16 Diazoxide
  3.8.17 Digoxin
  3.8.18 Dilantin
  3.8.19 Diphenhydramine
  3.8.20 Dobutamine
  3.8.21 Dopamine
  3.8.22 Fentanyl
  3.8.23 Flumazenil
  3.8.24 Furosemide
  3.8.25 Gastrografin
  3.8.26 Gentamicin
  3.8.27 Glucagon
  3.8.28 Haloperidol
  3.8.29 Heparin vial

- 3.8.30 Hydralazine
- 3.8.31 Hydrocortisone
- 3.8.32 Insulin
- 3.8.33 Isoproterenol
- 3.8.34 Ketamine
- 3.8.35 Ketorolac
- 3.8.36 Lidocaine 1%
- 3.8.37 Lidocaine 2%
- 3.8.38 Magnesium sulfate
- 3.8.39 Mannitol
- 3.8.40 Midazolam
- 3.8.41 Milrinone
- 3.8.42 Morphine
- 3.8.43 Meperidine
- 3.8.44 Methylprednisolone
- 3.8.45 Naloxone (1 mg per mL)
- 3.8.46 Neostigmine
- 3.8.47 Nifedipine
- 3.8.48 Nitroprusside
- 3.8.49 Norepinephrine (Levophed®)
- 3.8.50 Oxacillin
- 3.8.51 Pentobarbital
- 3.8.52 Phenobarbital
- 3.8.53 Procainamide
- 3.8.54 Prostaglandin
- 3.8.55 Risperidone
- 3.8.56 Solu-Medrol®
- 3.8.57 Terbutaline
- 3.8.58 Thiopental
- 3.8.59 3% Saline
- 3.8.60 Vasopressin
- 3.8.61 Vancomycin
- 3.8.62 Vecuronium
- 3.8.63 Verapamil

3.9 IV fluids
- 3.9.1 Tubing
- 3.9.2 Stopcocks
- 3.9.3 Normal saline solution, 1 L (10 bags)
- 3.9.4 Lactated Ringer's solution, 1 L (10 bags)
- 3.9.5 Albumin 5%, 25%

3.10 Syringes
3.11 Alcohol pads
3.12 Needles (all sizes)
3.13 Broselow Tape™ or dosage wall chart
3.14 Infusion pumps (3)
3.15 Cardiac board
3.16 Arm boards
3.17 Tape
3.18 Tincture of benzoin
3.19 Tegaderm

4. Monitoring

4.1 Sphygmomanometer Doppler and aneroid
4.2 Blood pressure cuffs (neonate, child, adult, large adult, thigh)
4.3 EKG/leads
4.4 Pulse oximeter
4.5 End-tidal CO_2 monitor
4.6 Doppler (handheld)
4.7 Defibrillator/defibrillator paste
4.8 Temperature probe
4.9 Hypothermia thermometer
4.10 Blood pressure-monitoring lines
4.11 Intracranial pressure-monitoring lines

5. Laboratory Testing

5.1 Syringes
5.2 Needles
5.3 Alcohol pads
5.4 Betadine
5.5 Tubes including culture media
5.6 Blood gas kit
5.7 Point-of-care testing (i-STAT)
5.8 Glucometer, test strips
5.9 Hemoccult cards
5.10 Sterile basins, bedpans, urinals
5.11 Evidence bags
5.12 Shroud, autopsy permits, related supplies

6. Trauma Care

6.1 Cervical collars: Stifneck® Baby no-neck or Pediatric no-neck, short, regular
6.2 Nasogastric tubes, 10, 16 (2 of each)
6.3 Feeding tubes, 3.5F–8F (2 of each)
6.4 Foley catheters, catheterization tray
6.5 Tracheostomy tray (2)
6.6 Thoracentesis tray
6.7 Chest tube insertion (2)
6.8 Chest tubes, 12F, 16F, 20F, 24F, 28F, 32F, 34F, 40F (2 of each)
6.9 Pleurovac
6.10 Thoracotomy tray
6.11 Minor procedure tray (3)
6.12 Peritoneal tray (11F dialysis set)
6.13 Obstetric pack
6.14 Blood administration sets
6.15 Blood warmer
6.16 Pressure bags
6.17 Garder-Walls tongs
6.18 Hare traction splint
6.19 Scalpels no. 10, 11, 15
6.20 Suture material (1 box of each):
- 2.0 Silk ties
- 3.0 Silk
- 4.0 Vicryl
- Tevdek cardiovascular, 2.0, 4.0, 5.0
- TFE polymer pledgets (8677-01)
- TFE polymer pledgets (8675-01)

7. Other

7.1 Protective supplies
- 7.1.1 Gloves, nonlatex (small, medium, large) (5 each)

- 7.1.2 Gowns
- 7.1.3 Masks
- 7.1.4 Shoe covers
- 7.1.5 Protective eye goggles/Fluidshield mask
- 7.1.6 Needle receptacles
- 7.1.7 Caps

7.2 Stat worksheet on clipboard
7.3 Key phone numbers
7.4 Drug formulary
7.5 Drug labels
7.6 Scissors, heavy gauge
7.7 Flashlight
7.8 Ophthalmoscope
7.9 Otoscope
7.10 Overbed warmers
7.11 Blankets
7.12 Bair hugger
7.13 Hand print kit

8. Transport Equipment

8.1 Portable suction
8.2 Portable monitors
8.3 Infusion pump
8.4 Airway box
8.5 Drug box

A-2 OFFICE OR CLINIC

1. Airway Equipment

1.1 Oxygen tank with flow meter
1.2 Face masks
1.3 Oxygen reservoir masks
1.4 Nasal cannula
1.5 Oxygen tubing
1.6 Oropharyngeal airways (all sizes)
1.7 Nasopharyngeal airways (all sizes)
1.8 Suction machine, portable
1.9 Suction catheters
1.10 Yankauer suction tips (4)
1.11 Magill forceps (small, medium, large)

2. Breathing Equipment

2.1 Bag-valve-mask with O_2 reservoir (adult, pediatric)
2.2 Masks (infant to adult sizes)
2.3 Pulse oximeter

3. Circulation Equipment

3.1 Cardiac board
3.2 IV catheter—25, 23, 21 (3 of each)
3.3 IV catheter—22, 20, 16 (3 of each)
3.4 Intraosseous needles (4)
3.5 Normal saline 5% dextrose, 500 mL (2)
3.6 Normal saline solution, 500 mL (2)
3.7 Solusets (2)
3.8 Sphygmomanometers—cuffs (4 sizes)
3.9 Drug box—prepackaged syringes

- 3.9.1 Epinephrine 1:10,000
- 3.9.2 Sodium bicarbonate, full strength
- 3.9.3 Sodium bicarbonate, half strength
- 3.9.4 Dextrose, 25%
- 3.9.5 Atropine, 0.4 mg per 0.5 mL
- 3.9.6 Naloxone
- 3.9.7 Diazepam/lorazepam
- 3.9.8 Phenobarbital
- 3.9.9 Activated charcoal
- 3.9.10 Tourniquets
- 3.9.11 Betadine swabs
- 3.9.12 Alcohol swabs
- 3.9.13 Tape
- 3.9.14 Syringes
- 3.9.15 Arm boards

4. Other Equipment

4.1 Resuscitation cart checklist
4.2 Semirigid cervical collars (adult, pediatric)
4.3 Sandbags (3)
4.4 Splints, inflatable
4.5 Nasogastric tubes
4.6 Rubber gloves
4.7 Protective eyewear
4.8 Broselow Tape™ or wall chart

APPENDIX B ■ EMERGENCY DRUG COMPENDIUM

SHANNON F. MANZI, PHARMD

Appendix B provides an easily accessible resource for dosages and side effects of medications included in the main text. The dosages included here are based on literature available at the time the text was prepared. For medications that are relatively new to pediatrics (e.g., dexmedetomidine), further refinement in drug dosage recommendations will undoubtedly occur. Other frequently updated drug information resources, such as the online Lexi-Comp's Pediatric Dosing Handbook (updated continuously), American Hospital Formulary Service (updated quarterly), or Facts and Comparisons (updated monthly) may provide additional information. Finally, for added safety, prescribers should check the package insert and/or one or two additional resources for dosage information whenever prescribing an unfamiliar drug. Some medications only have the commonly used dosage forms listed.

A list of the abbreviations used and their definitions is presented at the end of this appendix. Please note that all drugs listed are to be given IV may also be given via an IO line.

RESUSCITATION DRUG LIST

Drug: ADENOSINE (ADENOCARD®)
Route of Administration: IV
Dose: *SVT; Initial:* 0.1 mg per kg per dose (max 6 mg per dose)
Subsequent: neonates: Increase by increments of 0.05 mg per kg to a maximum of 0.25 mg per kg per dose; *children:* Increase by increments of 0.1 mg per kg per dose (max 12 mg per dose) to a maximum of 0.3 mg per kg. Allow 2 minutes between incremental increases.
Precautions: Administer by rapid bolus IV injection over 1-2 seconds simultaneously with a rapid saline flush of 5-10 mL; use 3- or 4-way stopcock, if necessary. Continuous EKG and BP monitoring is mandatory. Theophylline and caffeine may antagonize the effect of adenosine; therefore, patients receiving these drugs may require higher dosages of adenosine.
Adverse Effects: Sinus bradycardia, ventricular ectopy
Availability: Injection: 3 mg per mL

Drug: ALPROSTADIL (PROSTIN VR Pediatric®)
Synonyms: Prostaglandin, PGE_1
Route of Administration: IV
Dose: *Initial*: *neonates and infants:* 0.05 to 0.1 mcg per kg per minute; *maintenance*: 0.01 to 0.4 mcg per kg per minute
Precautions: Dose should be titrated to lowest rate that produces desired side effects. Apnea occurs in approximately 10% of neonates with congenital heart defects within first hour of infusion.
Adverse Effects: Severe hypotension, apnea, bradycardia
Availability: Injection: 500 mcg per mL

Drug: AMIODARONE (CORDARONE®)
Use caution, sound-alike drugs include: Amrinone (Inocor®)
Route of Administration: IV
Dose: *VF/VT arrest:* 5 mg per kg IV rapid push (max 300 mg per dose)
Dysrhythmia (unstable): 5 mg per kg IV over 20 to 60 minutes (max 300 mg per dose)
Continuous infusion for tachyarrhythmias: 5 to 15 mcg per kg per minute
Precautions: Dilute with D5W only for continuous infusion. Up to 75% of patients will experience adverse effects. Many drug–drug interactions due to cytochrome P450 inhibition.
Adverse Effects: Arrhythmias, cardiogenic shock, hypotension, hepatotoxicity, headache, pulmonary fibrosis and interstitial pneumonitis, skin discoloration
Availability: Injection: 50 mg per mL

Drug: ATROPINE
Route of Administration: IV, ETT
Dose: *Initial:* 0.02 mg per kg (min single dose: 0.1 mg; max single dose: 1 mg adolescent, 2 mg adult). For ETT use, dose is 2 to 10 times the IV dose. Dilute with normal saline (NS) to a volume of 3 to 5 mL and follow with several positive-pressure breaths.
Subsequent: The initial dose may be repeated every 5 to 10 minutes to a maximum cumulative dose of 2 mg.
Note: Much higher doses are necessary in organophosphate/nerve agent toxicity.
Precautions: A minimum dose of 0.1 mg should be administered to avoid the paradoxical bradycardia that may occur with lower dosages.

Adverse Effects: Tachycardia, excessive drying of secretions, mydriasis
Availability: Injection: many strengths available; most common concentrations are 0.4, 0.5, and 1 mg per mL

Drug: CALCIUM CHLORIDE
Use caution, sound-alike drugs include: Calcium gluconate
Route of Administration: IV
Dose: *Initial:* Calcium chloride: 20 mg per kg (max 1,000 mg per dose)
Subsequent: The initial dose may be repeated once, 10 minutes following initial dose. Total maximum dose 2,000 mg.
Precautions: Calcium chloride must be diluted and should be given through a central IV line whenever possible. Scalp, hand, and foot veins should not be used for administration unless in life-threatening situation. Calcium in any form should be infused slowly while monitoring the patient for bradycardia. Do not admix calcium with any solution containing sodium bicarbonate or phosphate salts (a fatal precipitation can occur). Calcium is contraindicated in digitalis toxicity. Calcium may antagonize the effects of verapamil.
Adverse Effects: Hypercalcemia, cardiac arrest, venous irritation.
Note: Extravasation may cause severe necrosis and sloughing.
Availability: Injection: 1 g in 10 mL (13.5 mEq calcium per g)

Drug: CALCIUM GLUCONATE
Use caution, sound-alike drugs include: Calcium chloride
Route of Administration: IV
Dose: *Initial:* Calcium gluconate: 100 mg per kg (max 3,000 mg per dose)
Subsequent: The initial dose may be repeated once, 10 minutes following initial dose. Total maximum dose 3,000 mg.
Precautions: Calcium gluconate should be diluted and ideally be given only through a central IV line; however, a large peripheral line may be used, if necessary. Calcium in any form should be infused slowly while monitoring the patient for bradycardia. Do not admix calcium with any solution containing sodium bicarbonate or phosphate salts (a fatal precipitation can occur). Calcium is contraindicated in digitalis toxicity. Calcium may antagonize the effects of verapamil.
Adverse Effects: Hypercalcemia, cardiac arrest, venous irritation.
Note: Extravasation may cause severe necrosis and sloughing.
Availability: Injection: 1 g in 10 mL (4.5 mEq of calcium per g)

Drug: DEXTROSE
Route of Administration: IV
Dose: *Initial:* 0.5 to 1 g per kg administered slowly (2 to 4 mL per kg of a 25% dextrose or 5 to 10 mL per kg of a 10% dextrose solution). If 25% dextrose is not available, dilute 50% dextrose 1:1 with sterile water or NS for injection to yield a 25% solution. Concentrations of continuous infusions greater than 12.5% should be infused via a central line when possible. For neonates with hypoglycemia, a dose of 0.25 to 0.5 g per kg (2.5 to 5 mL per kg) of a 10% dextrose solution should be used.
Subsequent: Subsequent doses and infusions should be based on the serum glucose concentration.
Adverse Effects: Hyperglycemia, hyperosmolarity
Availability: Injection: 0.1 g per mL (10% dextrose/water), 0.25 g per mL (25% dextrose/water), 0.5 g per mL (50% dextrose/water)

Drug: DOBUTAMINE (DOBUTREX®)
Use caution, sound-alike drugs include: Dopamine
Route of Administration: IV
Dose: 2 to 20 mcg per kg per minute (titrate to desired cardiovascular effect)
Precautions: Unstable in alkaline solutions. Solutions containing sodium bicarbonate should not be admixed with dobutamine. May begin administration via a peripheral line, changing to central access as soon as possible.
Adverse Effects: Tachycardia, exaggerated hypertensive response, ventricular ectopy
Availability: Injection: concentrate for IV infusion (must be further diluted): 12.5 mg per mL

Drug: DOPAMINE (INTROPIN®)
Use caution, sound-alike drugs include: Dobutamine
Route of Administration: IV
Dose: 2 to 20 mcg per kg per minute (titrate to desired renal or cardiovascular effect). If low perfusion state persists following adequate volume replacement, begin infusion at 10 mcg per kg per minute. Titrate as needed.
Precautions: Dopamine is unstable in alkaline solutions. Solutions containing sodium bicarbonate should not be admixed with dopamine (inactivation of dopamine may occur). May begin administration via a peripheral line, changing to central access as soon as possible.
Adverse Effects: Hypertension, tachycardia, and vasoconstriction may be seen with high infusion rates.
Availability: Injection (must be further diluted): 40 mg per mL

Drug: EPINEPHRINE
Route of Administration: IM, IV, ETT, SC
Dose: *Initial:* 10 mcg per kg (0.1 mL per kg of 1:10,000 solution) IV (max initial dose: 5 mL)
Subsequent: All subsequent doses should be the same as the initial dose. Beta-blocker overdose may require high dose (1:1,000) at 0.1 mL per kg if no response.

Intramuscular: 0.01 mL per kg (1:1,000 solution) max 0.5 mg per dose
Continuous infusion: 0.1 to 1 mcg per kg per minute.
Endotracheal: 0.1 mg per kg (0.1 mL of 1:1,000 solution) diluted in 3 to 5 mL of saline followed by several positive-pressure breaths.
Precautions: Epinephrine is inactivated in the presence of bicarbonate. Extravasations should be treated immediately with phentolamine.
Adverse Effects: Hypotension, hypertension, tachycardia, vasoconstriction
Availability: Injection: 100 mcg per mL (1:10,000); 1 mg per mL (1:1,000): Autoinjector: 0.15 mg, 0.3 mg

---

Drug: ETOMIDATE (AMIDATE®)
Route of Administration: IV
Dose: *RSI:* 0.3 mg per kg IV × 1 dose
Procedural Sedation: 0.15 mg per kg per dose IV PRN sedation × 2 doses
Precautions: May result in adrenal suppression if multiple doses or continuous infusion used. May cause pain on injection.
Adverse Effects: Injection site pain, involuntary skeletal muscle movement, nausea, and vomiting
Availability: Injection: 2 mg per mL

Drug: FLUMAZENIL (ROMAZICON®)
Route of Administration: IV
Dose: *Benzodiazepine reversal:* 0.01 mg per kg IV × 1 dose (max 0.2 mg per dose); may repeat as needed to a max of 0.05 mg per kg or 1 mg total, whichever is less.
Precautions: Use caution if patient is dependent on benzodiazepines. May result in abrupt withdrawal precipitating hypertension, myocardial infarction, and seizures.
Adverse Effects: Arrhythmias, hyper/hypotension, acute withdrawal symptoms
Availability: Injection: 0.1 mg per mL

Drug: KETAMINE (KETALAR®)
Use caution, sound-alike drugs include: Ketorolac (Toradol®)
Route of Administration: IV, IM
Dose: *Rapid sequence intubation:* 1 to 2 mg per kg IV or 3 to 7 mg per kg IM (1 dose)
See general medication section for procedural sedation dosing.
Precautions: Avoid use in patients with suspected head trauma or seizures of unknown origin, may increase ICP.
Adverse Effects: Laryngospasms, emergence reactions, tachycardia, hypertension
Availability: Injection: 10, 50, and 100 mg per mL

Drug: ISOPROTERENOL (ISUPREL®)
Route of Administration: IV infusion
Dose: 0.1 to 1 mcg per kg per minute
Precautions: Isoproterenol may aggravate arrhythmias associated with digitalis toxicity. In the dehydrated or hypovolemic patient, the vasodilatory properties of isoproterenol may produce exaggerated hypotension. Commercially available products contain sulfites and should be used with caution in patients known to be sensitive to sulfiting agents.
Adverse Effects: Tachyarrhythmias, myocardial ischemia, hypotension, hypertension, tremor, agitation
Availability: Injection: 0.02, 0.2 mg per mL

Drug: LIDOCAINE (XYLOCAINE®)
Route of Administration: IV, ETT
Dose: *Initial:* 1 mg per kg (max 100 mg per dose) IV over 2 to 4 minutes (maximum rate 0.7 mg per kg per minute or 50 mg per minute, whichever is less)
Note: If using via ETT, dose is two to four times the IV dose diluted in 3 to 5 mL of saline and followed by several positive-pressure breaths.
Subsequent: Initial dose may be repeated up to two to three times at 5- to 10-minute intervals (maximum dose during a 1-hour period: 200 to 300 mg). Once the initial bolus has been given, a continuous infusion of lidocaine at 20 to 50 mcg per kg per minute should be initiated. Lidocaine serum concentrations should be monitored.
Precautions: Dosage must be modified in children with CHF, shock, or liver disease.
Adverse Effects: *Early*: nausea, vomiting, altered CNS status, paresthesias
Later: seizures, cardiac toxicity (myocardial depression, arrhythmias)
Availability: Injection: various concentrations ranging from 10 to 200 mg per mL (dilute to a concentration of 10 to 20 mg per mL for IV push and 8 mg per mL for continuous infusion before use)

Drug: LORAZEPAM (ATIVAN®)
Route of Administration: IV, IM
Dose: *Status epilepticus:* 0.1 mg per kg per dose (max 4 mg per dose) IV/IM q5min × 2 to 3 doses
Continuous infusion: 0.05 to 0.1 mg per kg per hour
Precautions: Contains large amounts of propylene glycol, may result in metabolic acidosis, do NOT use in neonates as a continuous infusion. Precipitation may occur if final concentration is less than 1 mg per mL.
Adverse Effects: CNS depression, hypotension, bradycardia, respiratory depression
Availability: Injection: 2, 4 mg per mL

Drug: METHYLPREDNISOLONE SODIUM SUCCINATE (SOLU-MEDROL®)
Route of Administration: IV, IM
Dose: *Initial shock, acute SLE, multiple sclerosis, transverse mylelitis*: 30 mg per kg by IV infusion over 15 to

30 minutes, max 1,500 mg per dose; *acute asthma and allergic reactions*: 1 to 2 mg per kg by slow IV push over 5 to 10 minutes (usual max 80 mg per dose).

Precautions: Use of high-dose methylprednisolone in treatment of shock and spinal cord injury remains controversial.

Adverse Effects: Hypotension and vasodilation may occur with rapid IV injection. Electrolyte abnormalities, mood disturbances, infection.

Availability: Injection: 40, 125, 500 mg; 1 or 2 g (powder for reconstitution).

Drug: NALOXONE (NARCAN®)

Route of Administration: IV, IM, SC, ETT

Dose: *Dose depends on degree of reversal needed.

Initial: age birth to 5 years (weight <20 kg): 0.1 mg per kg per dose; *age older than 5 years:* 2 mg per dose (max initial dose: 2 mg). Higher doses may be needed in refractory adults. If giving via ETT, dose is 2 to 10 times the IV dose diluted in 3 to 5 mL of saline followed by several positive-pressure breaths.

Subsequent: The initial dose may be repeated every 3 to 5 minutes up to a maximum of five doses.

*Graded reversal: 0.001 to 0.01 mg per kg (1 to 10 mcg per kg) IV q3–5min as needed for respiratory depression secondary to PCA/epidural or chronic opiate use.

Adverse Effects: May precipitate withdrawal symptoms in narcotic-dependent patients.

Availability: Injection: 0.4, 1 mg per mL

Drug: NICARDIPINE (CARDENE®)

Route of Administration: IV

Dose: *Hypertensive emergencies: initial:* 1 to 3 mcg per kg per minute as a continuous infusion, titrate as needed to maintain BP in desired range. Max of 5 mcg per kg per minute.

Note: Do not use in patients at risk for increased intracranial pressure.

Adverse Effects: Hypotension, reflex tachycardia, phlebitis, increased ICP

Availability: Injection: 2.5 mg per mL

Drug: NITROPRUSSIDE, SODIUM (NITROPRESS®, NIPRIDE®)

Route of Administration: IV

Dose: *Hypertensive emergencies: initial:* 0.5 to 1 mcg per kg per minute as a continuous infusion, titrate as needed to maintain BP in desired range. Average 3 mcg per kg per minute, max of 10 mcg per kg per minute. At doses higher than 4 mcg per kg per minute, thiocyanate levels need to be monitored.

Note: Sodium nitroprusside is only compatible with D5W and must be protected from light. Nitroprusside has an immediate onset of action. Careful hemodynamic monitoring is essential. Infusion should be administered by infusion pump. Freshly prepared solutions may appear brownish; any solution discolored blue, green, orange, or red should be discarded. Other medications should not be admixed or run through the same line with nitroprusside.

Adverse Effects: Usually associated with excessive or rapid lowering of BP. Cyanide intoxication may occur in patients with renal dysfunction and prolonged duration of infusion. Cyanide and thiocyanate levels should be checked in patients receiving nitroprusside for more than 3 days or rates higher than 4 mcg per kg per minute. Other effects may include increased ICP, disorientation, nausea, and vomiting.

Availability: Injection: 10, 25 mg per mL

Drug: NOREPINEPHRINE (LEVOPHED®)

Route of Administration: IV

Dose: 0.05 to 1 mcg per kg per minute as a continuous infusion. Titrate as needed to maintain BP.

Precautions: May begin administration via a peripheral line, changing to central access as soon as possible. Must be further diluted for infusion.

Adverse Effects: Hypertension, organ ischemia, decreased peripheral perfusion

Availability: Injection: 1 mg per mL

Drug: ROCURONIUM (ZEMURON®)

Route of Administration: IV, IM

Dose: *RSI:* 0.6 to 1.2 mg per kg IV. For IM, use higher end of dosing range (up to 1.8 mg per kg per dose) if giving IM.

Precautions: Use only in the presence of personnel skilled in the management of an artificial airway.

Adverse Effects: Respiratory arrest, hyper/hypotension, arrhythmias (rare)

Availability: Injection: 10 mg per mL

Drug: SODIUM BICARBONATE

Route of Administration: IV

Dose: *Initial: age younger than 1 month or weight less than 5 kg:* 1 mEq per kg (2 mL per kg) of 0.5 mEq per mL (4.2%) solution. If only 7.5% or 8.4% solution (1 mEq per mL) is available, dilute 1:1 with D5W before administration; *age older than 1 month or >5 kg:* 1 mEq per kg (1 mL per kg) of 1 mEq per mL (8.4%) solution.

Subsequent: Corrective NaHCO dose (mEq) = 0.3 body weight (kg) × base deficit (mEq per L) OR 0.5 × body weight (kg) × (24 − serum HCO_3).

Note: Give one-half of this calculated estimate.

Continuous infusion: Up to 1 mEq per kg per hour

Tumor-lysis syndrome: D5W with sodium bicarbonate 75 mEq per L at 125 mL per m^2 per hour to maintain urine pH 7 to 8 and SG less than or equal to 1.010. Do not use bicarbonate hydration if also using rasburicase (Elitek®).

Precautions: Sodium bicarbonate should be given by direct IV administration slowly (max rate for infants 10 mEq per minute) and followed by NS flush to avoid precipitation in the IV line with other drugs such as calcium. Sodium bicarbonate should not be given via the ETT because it irritates the upper respiratory tract and lung parenchyma.
Adverse Effects: Hypernatremia (contains 11.9 mEq of sodium per 1 g), alkalosis, hyperosmolarity
Availability: Injection: most common concentrations are 0.5 mEq per mL (4.2%) and 1 mEq per mL (8.4%)

Drug: SUCCINYLCHOLINE (ANECTINE®)
Route of Administration: IV, IM
Dose: *Intubation:* 1 to 2 mg per kg IV or 2 to 4 mg per kg deep IM (max dose: 150 mg)
Use 2 mg per kg IV if younger than 2 years of age.
Precautions: Use only in the presence of personnel skilled in the management of an artificial airway. Avoid using in patients with personal or familial history of malignant hyperthermia, hyperkalemia, burns, renal failure, or myopathy associated with elevated CPK values.
Adverse Effects: Muscle fasciculations, respiratory depression, malignant hyperthermia, bradycardia, hypotension, cardiac arrhythmias (hyperkalemia)
Availability: Injection: 20, 50, 100 mg per mL

Drug: THIOPENTAL (PENTOTHAL®)
Route of Administration: IV
Dose: *RSI:* 3 to 6 mg per kg IV
Reduction of ICP: 1.5 to 5 mg per kg per dose IV
Precautions: Extravascular injection may cause pain, swelling, ulceration, and necrosis. Do not use in patients with hypotension.
Adverse Effects: Pronounced hypotension, respiratory depression, apnea, emergence delirium, nausea, vomiting, laryngospasm
Availability: Injection: 250 mg, 500 mg, 1 g, 2.5 g, 5 g

Drug: VASOPRESSIN (PITRESSIN®)
Route of Administration: IV
Dose: *VF or VT:* Adults: 40 units × 1 dose
GI hemorrhage: 0.002 to 0.005 units per kg per minute IV titrated up to a max of 0.01 unit per kg per minute
Diabetes Insipidus: 0.5 milliunits per kg per hour (0.005 units/kg/hr) IV to a max of 10 milliunits/kg/hr (0.01 units/kg/hr).
Precautions: Infiltration of the IV site can result in severe necrosis.
Adverse Effects: Pronounced hypertension, cardiac arrhythmias, vasoconstriction, abdominal cramping, nausea, vomiting, water intoxication
Availability: Injection: 20 units per mL

MEDICATIONS

Drug: ACETAMINOPHEN (FEVERALL®, LIQUIPRIN®, TEMPRA®, TYLENOL®)
Route of Administration: PO, PR
Dose: 10 to 15 mg per kg per dose in four to six divided doses (max daily dose: 90 mg per kg per day or 4 g, whichever is less); *loading dose:* 30 to 40 mg per kg PR × 1 dose
Precautions: Use cautiously in patients with liver disease and those who have not eaten in several days. Watch for duplicate therapy, especially with concurrent Percocet® or Vicodin® orders.
Availability (advise parents/patients that many strengths are available):
Chewable tablets: 80, 160 mg
Tablets: 325, 500 mg
Drops: 100 mg per mL
Oral suspension: 32 mg per mL
Capsules with powder for oral solution: 80, 160 mg (Feverall®)
Suppositories: 80, 120, 325, 650 mg

Drug: ACETAZOLAMIDE (DIAMOX®)
Route of Administration: IV, PO
Dose: 20 mg per kg per day IV/PO divided q6h, increase by 25 mg per kg per day (max 100 mg per kg per day)
Precautions: Do not use extended-release preparations for pseudotumor cerebri, diuresis, or epilepsy. Dosage adjustment required with renal dysfunction.
Adverse Effects: Electrolyte abnormalities, bone marrow suppression, headache, vertigo, GI upset
Availability: Injection: 500 mg
Tablets: 125 mg, 250 mg
Extended release capsule: 500 mg

Drug: ACETYLCYSTEINE (MUCOMYST®, ACETADOTE)
Route of Administration: PO, PR, IV
Dose: *Acetaminophen poisoning*: 150 mg per kg IV over 1 hour, then 50 mg per kg over 4 hours, then 100 mg per kg over 16 hours OR 140 mg per kg × 1 loading dose IV/PO, followed by 70 mg per kg per dose IV/PO q4h × 12 to 17 doses
Meconium ileus equivalent: 5 to 30 mL of 10% solution PO or PR three to six times per day
Prevention of contrast-induced nephrotoxicity: 10 mg per kg per dose PO BID (max 600 mg per dose) on day prior to and day of procedure
Precautions: Many regimens exist. Consult toxicologist. Higher rates of anaphylactoid reactions occur with IV administration. Consider late administration (more than 48 hours postingestion) as acetylcysteine

may provide benefit in acetaminophen toxicity. Acetylcysteine therapy may be discontinued prior to reaching 17 doses if acetaminophen levels are undetectable and LFTs return to baseline.

Adverse Effects: Nausea, vomiting, GI distress, anaphylactoid reactions, rash

Availability: Injection: 20% (200 mg per mL) solution

Oral: 20% (200 mg per mL) solution

Drug: ACYCLOVIR (ZOVIRAX®)

Route of Administration: IV, PO, topical

Dose: *Neonatal herpes simplex:* 30 to 60 mg per kg per day IV divided q8h. *Children and adults: mucocutaneous herpes simplex:* 750 mg per m^2 per day or 15 mg per kg per day IV divided q8h. *Varicella-zoster:* 1,500 mg per m^2 per day or 30 mg per kg per day IV divided q8h. *Herpes simplex encephalitis:* 60 mg per kg per day IV divided q8h. *Varicella (immunocompetent child only):* 80 mg per kg per day PO in four divided doses for 5 days (max 3,200 mg per day). *Genital herpes (initial treatment): adults:* 1 g per day PO in five divided doses or 1,200 mg per day PO in three divided doses for 7 to 10 days; *children:* 80 mg per kg per day PO in three to five divided doses (max 3,200 mg per day). *Topical:* Apply to cover each lesion six times daily for 7 days. A finger cot or glove should be used to apply ointment to prevent viral transmission.

Precautions: Patients should be adequately hydrated to prevent precipitation of acyclovir crystals in the renal tubules. Dosage adjustment required with renal dysfunction. Dose for obese patients should be based on ideal body weight.

Adverse Effects: Nephrotoxicity, headache, vertigo, GI upset, thrombophlebitis

Availability: Injection: 500 mg, 1 g

Capsules: 200 mg

Tablets: 400 mg, 800 mg

Oral suspension: 40 mg per mL

Topical ointment: 5%

Drug: ADENOSINE (see Resuscitation List)

Drug: ALBUTEROL (PROVENTIL®, VENTOLIN®)

Route of Administration: PO, inhalation

Dose: *Oral therapy generally not recommended. PO: children (age 2 to 6 years):* Initial dose 0.1 mg per kg per dose given TID (do not exceed 2 mg TID initially). May increase dose gradually to 0.2 mg per kg per dose given TID (not to exceed 12 mg per day); *children (6 to 14 years):* initial dose 2 mg given TID to QID. May cautiously increase to a maximum daily dose of 24 mg per day; *inhalation: MDI (90 mcg per puff): children younger than 12 years:* one to two inhalations four times per day; *children older than 12 years:* one to two inhalations given four to six times daily. *PO Rotahaler: older than 4 years:* 200 mcg every 4 to 6 hours; may increase to 400 mcg per dose. *Nebulizer:* 0.15 mg per kg (0.03 mL per kg of 0.5% solution) (maximum single dose: 5 mg or 1 mL of 0.5% solution) every 20 minutes for three doses (may use standard doses of 0.5 mL <30 kg and 1 mL for >30 kg), then q1–6h. Continuous nebulization 0.5 mg per kg per hour (suggested β_2-agonist total max 20 mg per hour). May be combined with ipratropium for nebulization.

Adverse Effects: Tachycardia, nervousness, tremor, palpitations, alterations in blood glucose, hypokalemia

Availability: Tablets: 2, 4 mg

Extended-release tablets: 4, 8 mg

Oral syrup: 0.4 mg per mL

Metered-dose aerosol: each actuation delivers 90 mcg of albuterol

Capsules containing powder for oral inhalation: 200 mcg

Solution for nebulization: 0.5% (5 mg per mL) concentrate, 0.083% (0.83 mg per mL) prediluted bullets

---

Drug: ALLOPURINOL (ZYLOPRIM®)

Route of Administration: IV. PO

Dose: *Tumor lysis syndrome:* 10 mg per kg per day divided BID (max 300 mg per dose)

Adverse Effects: Allergic reactions, hepatotoxicity, bone marrow suppression, rash

Availability: Injection: 100-mg vials. Tablets 100 mg, 300 mg

---

Drug: ALPROSTADIL (see Resuscitation List)

Drug: ALTEPLASE (tPA, ACTIVASE®)

Route of Administration: IV

Dose: *Catheter clearance:* Volume of catheter + 10%: max 2 mg in 2 mL in clogged port for 20 minutes to 2 hours, then withdraw

Catheter-directed thrombolysis: 0.01 to 0.2 mg per kg per hour at the site of the thrombus; Involvement of service managing the catheter recommended.

Systemic thrombotic therapy: 0.1 to 0.6 mg per kg per hour IV × 6 hours; Consider pediatric hematology consult.

Precautions: Recent major surgery, trauma, history of AVM or aneurysm, and uncontrolled hypertension are contraindications for use.

Adverse Effects: Hemorrhage, hypotension, fever, rash

Availability: Injection: 2-, 50-, 100-mg vials

Drug: AMINOCAPROIC ACID (AMICAR®)

Route of Administration: PO, IV

Dose: *Initial:* 50 to 100 mg per kg IV × 1 dose (infuse over 1 hour)

Subsequent: 30 mg per kg per hour IV as continuous infusion or 100 mg per kg per dose IV/PO q6h to achieve plasma concentration greater than or equal to 130 mg per L for inhibition of systemic hyperfibrinolysis (max 30 g per day)
Precautions: Rapid injection may result in arrhythmia and hypotension.
Availability: Injection: 250 mg per mL
Tablet: 500 mg
Oral syrup: 250 mg per mL

Drug: AMINOPHYLLINE (see THEOPHYLLINE®)

Drug: AMOXICILLIN (AMOXIL®, LAROTID®, POLYMOX®)
Route of Administration: PO
Dose: 20 to 120 mg per kg per day in two to three divided doses (max 3 g per day). If high-dose amoxicillin (80 mg per kg per day) is not required, may dose as follows: patients weighing less than 10 kg may receive 125 mg TID and patients weighing 10 to 50 kg may receive 250 mg TID, those greater than 50 kg may receive 500 mg TID.
Adverse Effects: Diarrhea, rash, hypersensitivity reactions
Availability: Capsules: 250, 500 mg
Tablets: 500, 875 mg
Chewable tablets: 125, 200, 250, 400 mg
Oral suspension: 125 mg per 5 mL, 200 mg per 5 mL, 250 mg per 5 mL, 400 mg per 5 mL

Drug: AMOXICILLIN/CLAVULANIC ACID (AUGMENTIN®)
Route of Administration: PO
Dose: 20 to 120 mg per kg per day of amoxicillin component in two to three divided doses (max 3 g per day of amoxicillin)
Precautions: PO suspension and chewable tablets contain a 4:1 ratio of amoxicillin to clavulanic acid. Film-coated tablets contain a 2:1 or 4:1 ratio of the drugs. Note that two 250-mg film-coated tablets should not be substituted for one 500-mg film-coated tablet to avoid GI side effects from excessive clavulanic acid. The BID formulation contains a 7:1 ratio of amoxicillin to clavulanic acid.
Adverse Effects: Similar to amoxicillin alone. Diarrhea or loose stools has been reported in 9% of patients, although is reportedly higher in practice. Limit dosage to 40 mg per kg per day of amoxicillin component and administer doses with food to minimize GI side effects. Nausea and vomiting appear related to the dose of clavulanic acid.
Availability: Powder for oral suspension:
200: Amoxicillin 200 mg and clavulanic acid 28.5 mg per 5 mL (100 mL)
400: Amoxicillin 400 mg and clavulanic acid 57 mg per 5 mL (100 mL)
125: Amoxicillin 125 mg and clavulanic acid 31.25 mg per 5 mL (75, 100, 150 mL)
250: Amoxicillin 250 mg and clavulanic acid 62.5 mg per 5 mL (75, 100, 150 mL)
ES-600: Amoxicillin 600 mg and clavulanic acid 42.9 mg per 5 mL (75, 125, 200 mL)
Tablet:
250: Amoxicillin 250 mg and clavulanic acid 125 mg
500: Amoxicillin 500 mg and clavulanic acid 125 mg
875: Amoxicillin 875 mg and clavulanic acid 125 mg
Tablet, chewable:
125: Amoxicillin 125 mg and clavulanic acid 31.25 mg
200: Amoxicillin 200 mg and clavulanic acid 28.5 mg
250: Amoxicillin 250 mg and clavulanic acid 62.5 mg
400: Amoxicillin 400 mg and clavulanic acid 57 mg
Tablet, extended release (Augmentin XR™):
Amoxicillin 1,000 mg and clavulanic acid 62.5 mg

Drug: AMPICILLIN (GENERIC)
Route of Administration: PO, IM, IV
Dose: *Injection: younger than 7 days of age:* 100 to 300 mg per kg per day divided every 12 hours; *older than 7 days of age:* 100 to 400 mg per kg per day in four to six divided doses. Use maximum doses for treatment of meningitis; *PO: older than 1 month of age:* 50 to 100 mg per kg per day in four divided doses (max 3 g per day).
Precautions: When given orally, ampicillin should be administered on an empty stomach.
Adverse Effects: See Amoxicillin. Diarrhea occurs with greater frequency as compared with amoxicillin.
Availability: Injection: 125-, 250-, 500-mg vials; 1-g vials
Oral suspension: 25, 50 mg per mL
Capsules: 250, 500 mg

Drug: AMPICILLIN/SULBACTAM (UNASYN®)
Route of Administration: IV
Dose: Dose based on ampicillin component: 200 mg per kg per day IV divided q6h
Precautions: Infuse over at least 30 minutes.
Adverse Effects: See Ampicillin.
Availability: Injection: 500-mg vials; 1-g vials (2-1 ration of amoxicillin to sulfbactam)

Drug: ASPIRIN (ACETYLSALICYLIC ACID, ASA)
Route of Administration: PO, PR
Dose: *Fever/analgesia:* 10 to 15 mg per kg per dose every 4 to 6 hours, max 4 g per day.
Rheumatoid arthritis: 60 to 90 mg per kg per day initial dose in four divided doses (max dose 4 g per day). Administer with food.
Kawasaki disease: 80 to 100 mg per kg per day divided every 6 hours until fever resolves, then 3 to 5 mg per kg per day.

Precautions: Avoid use in patients with varicella or influenza and during presumed outbreaks of influenza because of a possible associated risk of Reye's syndrome. Use with caution in bleeding disorders or when using concomitantly with other medications that carry a risk of bleeding. Serum concentrations should be monitored in patients receiving long-term therapy. Small changes in dose may result in disproportionate increases in serum concentration.
Adverse Effects: GI upset, GI bleeding, tinnitus, reduced platelet function, bronchospasm
Availability (many strengths are available):
Tablets: 75, 81, 165, 325, 500 mg
Suppositories: 300, 600 mg

Drug: ATENOLOL (TENORMIN®)
Route of Administration: PO
Dose: *Initial:* 0.8 to 1 mg per kg per day PO daily; *maintenance*: 0.8 to 2 mg per kg per day PO daily
Precautions: IV preparation not used in children.
Adverse Effects: Hypotension, heart block, headache, wheezing
Availability: Tablets: 25, 50, 100 mg
Injection: 0.5 mg per mL

Drug: ATROPINE (see Resuscitation Drug List)

Drug: AZATHIOPRINE (IMURAN®)
Route of Administration: PO, IV
Dose: *Initial*: 2 to 5 mg per kg per dose; *maintenance:* 1 to 3 mg per kg per day in one to two divided doses
Precautions: Reduce dosage to 25% to 30% of usual when allopurinol is also being administered. Concurrent use of ACE inhibitors may result in severe anemia.
Adverse Effects: Bone marrow suppression, nausea, vomiting, stomatitis
Availability: Injection: 5 mg per mL
Tablet: 50 mg

Drug: AZITHROMYCIN (ZITHROMAX®)
Route of Administration: PO, IV
Dose: *Otitis media (age older than 6 months):* 30 mg per kg PO as a single dose (max dose: 1,500 mg); alternatively, 10 mg per kg PO as a single dose (max dose: 500 mg) followed by 5 mg per kg per day PO (max daily dose: 250 mg) on days 2 to 5.
Streptococcal pharyngitis: 12 mg per kg PO single daily dose for 5 days (max dose: 500 mg per day); alternatively, 10 mg per kg PO as a single dose (max dose: 500 mg) followed by 5 mg per kg per day PO (max daily dose: 250 mg) on days 2 to 5.
Community-acquired pneumonia: 10 mg per kg PO/IV as a single dose (max dose: 500 mg) followed by 5 mg per kg per day PO/IV (max daily dose: 250 mg) on days 2 to 5.
Uncomplicated chlamydial infections, chancroid (adolescents and adults): 1 g PO as a single dose.
Note: Although effective against gonorrhea, the 2-g oral dose is poorly tolerated and therefore not recommended as first-line therapy.
Adverse Effects: Nausea, vomiting, metallic taste, rash
Availability: Oral capsules: 250 mg
Tablets: 250, 500 mg
Oral suspension: 20, 40 mg per mL
Single-dose packets: 1 g per packet
Injection: 500 mg per vial

Drug: BARLEY MALT SOUP EXTRACT (MALTSUPEX®)
Route of Administration: PO
Dose: 5 to 30 mL per day or 4 to 32 g per day, usual 4 to 8 g per day; dilute per manufacturer instructions
Adverse Effects: diarrhea, allergic reactions
Availability: Liquid 16 g per 15 mL, powder 16 g per tbsp

Drug: BECLOMETHASONE (BECLOVENT®, VANCERIL®)
Route of Administration: Inhalation
Dose: *Asthma: age 6 to 12 years:* 1 to 2 puffs TID to QID by PO inhalation (max dose: 10 puffs per day). Each puff delivers 42 mcg.
Rhinitis (seasonal or perennial): age 6 to 12 years: spray (42 mcg) in each nostril BID to TID.
Precautions: Caution should be used in converting asthmatic patients from oral steroids to inhaled steroids. Monitor such patients for steroid withdrawal symptoms (muscle and joint pain, malaise, anorexia, nausea, hypotension, and other symptoms of acute adrenal insufficiency). Not recommended for "prn" use.
Adverse Effects: Hoarseness, oral candidiasis or aspergillosis, dry mouth, bronchospasm
Availability: Aerosol for oral inhalation: 42 mcg per metered spray
Aerosol for nasal insufflation: 42 mcg per metered spray

Drug: BENZTROPINE (COGENTIN®)
Route of Administration: PO, IM, IV
Dose: *Age older than 3 years:* 0.02 to 0.05 mg per kg per dose once or twice daily (max dose: 6 mg per day)
Precautions: Not for use in children younger than 3 years of age, unless life-threatening emergency. Use cautiously in older children.
Adverse Effects: Anticholinergic symptoms—dry mouth, tachyarrhythmias, nausea, vomiting, hallucinations, coma
Availability: Tablets: 0.5, 1, 2 mg
Injection: 1 mg per mL

Drug: BUPIVACAINE (MARCAINE, SENSORCAINE®)
Route of Administration: Infiltration
Dose: Depending on type of block, 5 to 50 mL is instilled
Precautions: Never inject intravenously. Intralipids should be immediately available in case of inadvertent intravenous or intra-arterial injection.
Adverse Effects: Respiratory arrest, seizures
Availability: Injection: 0.25%, 0.5%, 0.75%

Drug: C-1 INHIBITOR (CINRYZE®)
Route of Administration: IV
Dose: *Hereditary angioedema:* 10 to 20 units per kg acute; 1,000 units every 3 to 4 days for prophylaxis
Precautions: Should be given at room temperature at a rate of 1 mL per minute.
Adverse Effects: Severe hypersensitivity reactions, thrombosis, muscle pain
Availability: Injection 500 units

Drug: CALCIUM (see Resuscitation List)

Drug: CAPTOPRIL (CAPOTEN®)
Route of Administration: PO
Dose: *Hypertension: neonate:* 0.01 to 0.1 mg per kg per dose; *older infants and children:* 0.15 to 0.5 mg per kg per dose (max 12.5 mg initial dose). Twofold increments in the dosage can be made after an observation period of 1 to 2 hours if the initial doses are ineffective. Maintenance doses may be given every 8 to 12 hours.
CHF (or other patients who may be salt/volume depleted): An initial dose of 25% to 50% of the usual antihypertensive doses should be used. Max 6 mg per kg per day in two to three divided doses.
Precautions: Pronounced hypotension may be observed when captopril is administered in conjunction with diuretics or other antihypertensive drugs. Hyperkalemia may occur when used with potassium-sparing diuretics or potassium supplementation. Dosages should be reduced in patients with impaired renal function. Do not use in patients with bilateral renal artery stenosis or unilateral renal artery stenosis with a solitary kidney as renal blood flow may be severely impaired.
Adverse Effects: Excessive lowering of BP, cough, proteinuria, neutropenia, rash, altered taste perception, angioedema
Availability: Tablets: 12.5, 25, 50, 100 mg
Note: Several recipes for compounding captopril suspension have been published. Due to the relative instability in aqueous solutions, captopril suspensions have a relatively short stability of 7 to 10 days.

Drug: CARBAMAZEPINE (TEGRETOL®, CARBATROL®)
Route of Administration: PO
Dose: *Initial:* 5 to 10 mg per kg per day in three to four divided doses, increasing every 5 to 7 days as needed. *Usual maintenance*: 15 to 35 mg per kg per day in three to four divided doses for immediate-release products and in two divided doses for extended-release products (max 1,200 mg per day).
Adverse Effects: Transient leukopenia, aplastic anemia (rare), ataxia and other CNS disturbances, GI upset, constipation, rash, Stevens-Johnson syndrome, nystagmus, hepatotoxicity
Precautions: Major drug interactions may occur with other medications metabolized via the 3A3/4 and 2C19 enzyme pathways. Carbamazepine induces its own metabolism approximately 14 days after starting therapy; therefore, a dose increase may be required at this time. Serum trough concentrations of carbamazepine (therapeutic 4 to 12 mg per dL) and any other concomitant anticonvulsants should be monitored.
Availability: Tablets: 100 mg (chewable), 200-mg tablets, extended-release: 100, 200, 400 mg capsules, extended-release: 200, 300 mg
Oral suspension: 20 mg per mL
Note: May use suspension rectally as a temporary alternative to oral route.

Drug: CARNITINE (CARNITOR®)
Route of Administration: PO, IV
Dose: *Primary carnitine deficiency or prophylaxis of valproic acid-induced hepatotoxicity:* 50 to 100 mg per kg per day PO divided BID-TID, usual max 3 g per day; *severe cases:* 50 mg per kg IV load, then 50 to 300 mg per kg per day IV divided q4–6h
Adverse Effects: Nausea, vomiting, diarrhea, body odor
Availability: Oral solution: 100 mg per mL
Tablets: 330 mg
Injection: 200 mg per mL

Drug: CEFADROXIL (DURICEF®)
Route of Administration: PO
Dose: 30 mg per kg per day as a single dose or two equally divided doses, max 4 g per day
Adverse Effects: Rash, GI upset, transient leukopenia
Availability: Capsules: 500 mg
Tablets: 1 g
Oral suspension: 25, 50, 100 mg per mL

Drug: CEFAZOLIN (ANCEF®, KEFZOL®)
Route of Administration: IM, IV
Dose: 50 to 100 mg per kg per day in three divided doses, *osteomyelitis*: 150 mg per kg per day IV divided q8h (max 12 g per day)
Adverse Effects: Other than allergic reactions, adverse effects are rarely observed. Rare adverse effects include

elevations in serum transaminase values, positive Coombs' test, and hemolytic anemia.
Availability: Injection: 250-, 500-mg vials; 1-, 5-g vials

Drug: CEFDINIR (OMNICEF®)
Route of Administration: PO
Dose: *Age older than 6 months:* 14 mg per kg per day in two divided doses (max dose: 600 mg per day)
Adverse Effects: Nausea, vomiting, diarrhea
Availability: Oral suspension: mg per mL
Tablets: 300, 600 mg
Oral Suspension: 25 mg per mL

Drug: CEFIXIME (SUPRAX®)
Route of Administration: PO
Dose: *Age older than 6 months:* 8 mg per kg per day in one to two divided doses (max 400 mg per day); *gonorrhea*: 400 mg PO as a single dose
Adverse Effects: Nausea, vomiting, diarrhea
Availability: Oral suspension: 20 mg per mL
Tablets: 200, 400 mg

Drug: CEFOTAXIME (CLAFORAN®)
Route of Administration: IV, IM
Dose: *Age younger than 1 week*: 100 mg per kg per day in two divided doses; *age 1 to 4 weeks:* 150 mg per kg per day in three divided doses; *age 1 month to 12 years:* 50 to 200 mg per kg per day in four to six equally divided doses (max 12 g per day). *Penicillin intermediate or resistant pneumococcal meningitis*: 300 mg per kg per day in four divided doses.
Adverse Effects: See Cefazolin.
Availability: Injection: 1-, 2-g vials

Drug: CEFPROZIL (CEFZIL®)
Route of Administration: PO
Dose: 15 to 30 mg per kg per day in two divided doses (max 1 g per day)
Adverse Effects: Rash, diarrhea, nausea, vomiting
Availability: Tablets: 250, 500 mg
Oral suspension: 25, 50 mg per mL

Drug: CEFTAZIDIME (FORTAZ®, TAZIDIME®)
Route of Administration: IV, IM
Dose: *Age 0 to 4 weeks*: 100 to 150 mg per kg per day in two to three divided doses; *age 1 month to 12 years*: 100 to 150 mg per kg per day in three divided doses (max 6 g per day). *Cystic fibrosis*: 150 to 200 mg per kg per day IV divided q8h.
Adverse Effects: See Cefazolin. Transient neutropenia with positive Coombs.
Availability: Injection: 500-mg vials; 1-, 2-g vials

Drug: CEFTRIAXONE (ROCEPHIN®)
Route of Administration: IV, IM
Dose: *Usual dose:* 50 to 100 mg per kg per day in one or two divided doses. *Bacterial meningitis:* Initial dosage should be 100 mg per kg as a single dose followed by 100 mg per kg per day in two divided doses (max 2,000 mg per dose). *Uncomplicated gonorrhea:* 125 mg IM single dose; use 250 mg IM single dose if concomitant PID (max 4 g per day). *Chancroid:* 250 mg IM single dose.
Adverse Effects: See Cefazolin; also, biliary sludging/cholelithiasis; avoid use in neonates with hyperbilirubinemia because ceftriaxone has been shown to displace bilirubin from albumin-binding sites, possibly leading to kernicterus.
Availability: Injection: 250-, 500-mg vials; 1-, 2-g vials

Drug: CEFUROXIME (CEFTIN®, ZINACEF®)
Route of Administration: IV, PO
Dose: *Injection: Neonates:* 50 to 100 mg per kg per day divided q12h. *Age older than 3 months: usual dose:* 50 to 150 mg per kg per day in three or four divided doses. Because of limited penetration into cerebrospinal fluid, avoid use in patients with possible meningitis (max dose: 9 g per day).
Oral suspension: 20 to 30 mg per kg per day in two divided doses.
Oral tablets: 250 to 500 mg per day (total dose) in two divided doses.
Note: Tablets and oral suspension are NOT bioequivalent and are NOT substitutable on a mg-per-kg basis.
Adverse Effects: See Cefazolin. Rash, GI distress.
Availability: Injection: 750-, 1,500-mg vials per premixed infusions
Oral tablets: 125, 250, 500 mg
Oral suspension: 25 mg per mL

Drug: CEPHALEXIN (KEFLEX®)
Route of Administration: PO
Dose: 50 to 100 mg per kg per day given in four divided doses (max 4 g per day)
Adverse Effects: Nausea, vomiting, diarrhea; possible cross-hypersensitivity with penicillins
Availability: Capsules: 125, 250, 500 mg
Oral suspension: 25, 50 mg per mL

Drug: CETIRIZINE (ZYRTEC®)
Route of Administration: PO
Dose: *2 to 5 years*: 2 .5 to 5 mg per day in one to two divided doses. *Older than 5 years:* 5 to 10 mg per day in one to two divided doses.
Adverse Effects: Drowsiness, GI distress, paresthesias, cough, bronchospasm
Availability: Tablets: 5, 10 mg
Oral solution: 1 mg per mL

Drug: CHARCOAL, ACTIVATED (ACTA-CHAR®, ACTIDOSE®, LIQUI-CHAR®)

Route of Administration: PO

Dose: 1 g per kg (or approximately 5 to 10 times the amount of poison ingested), max 100 g per dose. Multiple doses should be considered for ingestions that are extended-release preparations, undergo enterohepatic recirculation, or form bezoars.

Precautions: Do not administer concurrently with syrup of ipecac or dairy products. Adequate airway protection is essential. Limited indications currently.

Adverse Effects: Use sorbitol-containing suspensions as initial dose with caution, generally not recommended in children. Sorbitol acts as a cathartic. Plain charcoal suspensions should be used for subsequent doses. Careful monitoring of fluid and electrolyte status is essential in patients receiving sorbitol. Vomiting, constipation, or diarrhea may occur. Stools will be black.

Availability: Loose powder for suspension, mix in 6 to 8 oz of water

Oral suspension in aqueous or sorbitol solution: many strengths such as 15 g in 75 mL or 120 mL, 30 g in 120 mL, or 50 g in 250 mL

Drug: CHLORAL HYDRATE (NOCTEC®)

Route of Administration: PO, PR

Dose: *Hypnosis:* 25 to 50 mg per kg per dose; may be repeated once at half the initial dose (max 1 g per dose). *Procedural sedation:* 50 to 100 mg per kg per dose; may be repeated once at 25 to 75 mg per kg per dose for inadequate sedation (total max 1g infants, 2 g children). Administer capsule with full glass of water or fruit juice. Dilute chloral hydrate syrup in water or fruit juice before administration.

Adverse Effects: CNS depression, vomiting (very common), abdominal pain, prolonged sedation, apnea

Availability: Capsule: 250, 500 mg

Oral syrup: 50, 100 mg per mL

Drug: CHLORAMPHENICOL (CHLOROMYCETIN®)

Route of Administration: IV

Dose: *Age younger than 7 days:* 20 mg per kg IV load, follow with maintenance dose 12 hours later of 25 mg per kg per day in two divided doses; *age 7 to 28 days:* 50 mg per kg per day in two divided doses; *age older than 1 month:* 50 to 100 mg per kg per day in four divided doses (max 6 g per day)

Precautions: Serum concentrations should be monitored.

Adverse Effects: Bone marrow depression, "gray baby syndrome" (failure to feed, abdominal distension, cyanosis, irregular respiration, cardiovascular collapse)

Availability: Injection: 1 g per vial

Drug: CHLOROQUINE

Route of Administration: IV, PO

Dose: *acute malaria*: Initial dose: 10 mg per kg of base (maximum 600 mg base per dose), followed by 5 mg base per kg at 6, 24, and 48 hours

Precautions: Adverse Effects: Cardiovascular collapse, GI distress, aplastic anemia, agranulocytosis, hepatic dysfunction

Availability: Injection: from CDC; Tablets: 500 mg (300 mg base)

Drug: CHLOROTHIAZIDE (DIURIL®)

Use caution, sound-alike drugs include: Hydrochlorothiazide (Hydrodiuril®)

Route of Administration: PO, IV

Dose: *PO:* 20 to 40 mg per kg per day in two divided doses (max dose: 2 g per day)

IV: 5 to 20 mg per kg per day in two divided doses

Precautions: Use with caution in patients with liver and severe renal disease.

Adverse Effects: Hypokalemia, metabolic alkalosis, hyperuricemia, hyperglycemia, rash

Availability: Tablets: 250, 500 mg

Oral suspension: 50 mg per mL (contains 9.5% alcohol)

Injection: 500-mg vial

Drug: CHLORPHENIRAMINE MALEATE (CHLOR-TRIMETON®)

Route of Administration: PO

Dose: *Age 2 to 5 years:* 1 mg every 4 to 6 hours (max 6 mg per day); *age 6 to 11 years:* 2 mg every 4 to 6 hours (max 12 mg per day); *age older than 12 years:* 4 mg every 4 to 6 hours (max 24 mg per day)

Precautions: May lower seizure threshold.

Adverse Effects: CNS stimulation or depression, anticholinergic effects

Availability: Syrup: 0.4 mg per mL (contains 7% alcohol)

Tablets: 2 mg (chewable), 4, 8, 12 mg

Sustained-released tablets and capsules: 8, 12 mg

Drug: CIMETIDINE (TAGAMET®)

Route of Administration: IV, PO

Dose: *Neonates:* 5 to 10 mg per kg per day every 8 to 12 hours; *older infants*: 10 to 20 mg per kg per day every 6 to 12 hours; *child*: 20 to 40 mg per kg per day in three to four divided doses (max 2,400 mg per day)

Precautions: Reduce dosage in patients with renal dysfunction. Extensive drug interactions because cimetidine inhibits the hepatic microsomal enzymes responsible for the metabolism of many drugs. Cimetidine may increase the plasma concentrations and pharmacologic activity of theophylline, phenytoin, propranolol, warfarin, lidocaine, and many more.

Availability: Tablets: 200, 300, 400, 800 mg

Oral solution: 60 mg per mL

Injection: 150 mg per mL

Drug: CIPROFLOXACIN (CIPRO®)
Route of Administration: PO, IV
Dose: 20 to 30 mg per kg per day in two divided doses (max 800 mg per day IV, 1,500 mg per day PO); *severe P. aeruginosa*: 30 mg IV per kg per day IV divided q12h (max 1,200 mg per day)
Precautions: Preliminary studies have shown cartilage damage in juvenile animals, currently not approved for use in children younger than 18 years of age EXCEPT for cases of suspected anthrax.
Adverse Effects: Headache, rash, photosensitivity, GI distress, interstitial nephritis, tendonitis
Availability: Oral suspension 50, 100 mg per mL
Tablets: 100, 250, 500, 750 mg
Injection: 200-, 400-mg premixed infusions per vials

Drug: CLARITHROMYCIN (BIAXIN®)
Route of Administration: PO
Dose: 15 mg per kg per day in two divided doses (max 1 g per day)
Precautions: Drug interactions with medications metabolized by the cytochrome P450 (hepatic) enzyme systems (see Erythromycin).
Adverse Effects: See Erythromycin. Incidence of side effects may be lower with clarithromycin.
Availability: Oral suspension 25, 50 mg per mL
Tablets: 250, 500 mg

Drug: CLINDAMYCIN (CLEOCIN®)
Route of Administration: IV, PO
Dose: *PO:* 10 to 30 mg per kg per day in three divided doses, max 1.8 g per day
IV: age younger than 1 month: 15 to 20 mg per kg per day in three divided doses; *age 1 month or older*: 25 to 40 mg per kg per day in three divided doses, max 4.8 g per day; *topical:* twice-daily application
Precautions: If diarrhea occurs during therapy, antibiotic-associated pseudomembranous colitis should be considered as a potential cause. IM use may result in formation of sterile abscesses, and this route of administration should not be used. The oral suspension has very poor palatability; compliance may be an issue.
Adverse Effects: GI disturbances (see Precautions), thrombophlebitis after IV administration, hypersensitivity reactions
Availability: Capsules: 75, 150, 300 mg
Granules for oral suspension: 15 mg per mL when reconstituted
Injection: 150 mg per mL
Topical solution: 1%

Drug: CLONAZEPAM (KLONOPIN®)
Use caution, sound-alike drugs include: Clonidine (Catapres®)
Route of Administration: PO
Dose: *Initial:* 0.01 to 0.03 mg per kg per day in two to three divided doses, increase slowly
Maintenance: 0.1 to 0.2 mg per kg per day in two to three divided doses
Adverse Effects: Sedation, hypotension, nausea, vomiting, anorexia
Availability: Tablets: 0.5, 1, 2 mg
Note: Several recipes for suspensions have been published.

Drug: CLONIDINE (CATAPRES®)
Use caution, sound-alike drugs include: Clonazepam (Klonopin®)
Route of Administration: PO, topical, epidural
Dose: *Hypertension: initial:* 0.005 to 0.01 mg per kg per day PO divided q8–12h; *maintenance:* 0.005 to 0.025 mg per kg per day PO divided q6h (max 0.9 mg per day); *ADHD*: *initial:* 0.05 mg per day, increase every 3 to 7 days to 0.003 to 0.008 mg per kg per day PO divided TID-QID (max 0.4 mg per day)
Transdermal patches may be used once a stable oral dose is achieved. Patches may be cut, if necessary. For hypertension, change patches once per week. For ADHD, it may be necessary to change the patch every 3 days.
Adverse Effects: Hypotension, sedation, rash, GI distress
Availability: Tablets: 0.1, 0.2 mg
Transdermal patches: 0.1, 0.2, 0.3 mg
Injection: 100 mcg per mL

Drug: CLOTRIMAZOLE (GYNE-LOTRIMIN®, MYCELEX-G®)
Route of Administration: Intravaginal
Dose: *Intravaginal tablet:* Two 100-mg vaginal tablets (total: 200 mg per dose) daily at bedtime for 3 consecutive days. Alternative treatment regimens include use of one 500-mg vaginal tablet for one dose or use of one 100-mg vaginal tablet daily for 7 days.
Intravaginal cream: Contents of one applicator at bedtime for 7 to 14 days, alternative 1- and 3-day preparations exist.
Adverse Effects: Rash, burning, or irritation at or near application site
Availability: Vaginal tablet: 100, 500 mg
Vaginal cream: 1%

Drug: COCAINE HYDROCHLORIDE
Route of Administration: Topical
Dose: Topical administration in each nostril for local anesthesia, refractory epistaxis (max single dose: 1 mg per kg)
Adverse Effects: CNS excitation or depression, euphoria, restlessness, hallucinations, increased BP, increase or decrease in heart rate, psychic dependence with repeated use
Availability: Topical solution: 4%

Drug: CODEINE
Route of Administration: PO
Dose: 0.5 to 1 mg per kg per dose PO q3–6h as needed (usual adult max 60 mg per dose)
Adverse Effects: Sedation, respiratory depression, GI distress, constipation
Availability: Tablet: 15, 30, 60 mg
Solution: 3 mg per mL

Drug: CROMOLYN SODIUM (INTAL®)
Route of Administration: Inhalation
Dose: *Asthma :* Usual dosage for adults and children 2 years of age and older is 20 mg QID via nebulizer or one to two puffs TID-QID via MDI; *allergic rhinitis:* 1 nasal spray in each nostril TID or QID
Precautions: Not for acute relief of bronchospasm. When used for exercise-induced bronchospasm, cromolyn should be administered 10 to 15 minutes before exercise (but no longer than 1 hour before exercise).
Adverse Effects: Oropharyngeal irritation, bronchospasm
Availability: MDI: 800 mcg per puff
Solution for nebulization: 10 mg per mL
Nasal solution: 40 mg per mL

Drug: CYCLOSPORINE (SANDIMMUNE®, NEORAL®, GENGRAF®)
Route of Administration: PO, IV
Dose: Dosage must be individualized based on blood or plasma concentration monitoring. For prevention of allograft rejection, the initial oral dose is 14 to 18 mg per kg preoperatively followed by 15 mg per kg per day divided in one to two doses for 1 to 2 weeks. Once patient is stabilized, the dosage is usually tapered over 6 to 8 weeks to a maintenance dosage of 5 to 9 mg per kg per day as a single daily dose. Oral preparations are not bioequivalent and are not interchangeable. The IV dose is *one-third* of the oral dose (initial 5 to 6 mg per kg IV preoperatively, then 2 to 10 mg per kg per day IV q8–24h).
Precautions: Blood or plasma concentrations should be monitored. Therapeutic plasma/blood concentration ranges differ according to assay method. Major adverse effects of cyclosporine include hypertension, hyperkalemia, renal dysfunction, hirsutism, gingival hyperplasia, tremor, seizures, hepatotoxicity, and abdominal discomfort. Anaphylaxis has occurred after IV administration and may be related to the polyoxyl castor oil component in the vehicle for the injectable product. The metabolism and toxicity of cyclosporine may be affected by many drugs, particularly those that are metabolized via cyp450 3A3/4 (antifungals, erythromycin, clarithromycin, calcium channel–blocking agents, corticosteroids, grapefruit juice, protease inhibitors, sirolimus, tacrolimus).
Note: Oral liquid doses may be mixed in a glass container with apple juice or orange juice to improve palatability. Do not mix the solution for emulsion (Neoral) in milk (may be unpalatable). Use mixture immediately to minimize adsorption to the secondary container. Rinse secondary container with diluting beverage to ensure complete administration of the dose. Solution for injection should be mixed in glass or hard plastic syringes only.
Availability: Oral solution (Sandimmune, Gengraf, Neoral): 100 mg per mL (may contain 12.5% alcohol)
Oral capsules: 25, 100 mg
Injection: 50 mg per mL

Drug: CYPROHEPTADINE (PERIACTIN®)
Route of Administration: PO
Dose: *Allergic conditions:* 0.25 to 0.5 mg per kg per day in three to four divided doses (max doses: age 2 to 6 years: 12 mg per day; age 7 to 14 years: 16 mg per day); *appetite stimulation*: *older than 13 years:* 2 mg PO QID, max 8 mg PO QID; *migraine headaches*: children 4 mg PO BID-TID, adolescents/adults 4 to 8 mg PO TID; *spasticity*: *older than 12 years:* 4 mg PO, max 36 mg per day
Adverse Effects: Anticholinergic effects, increased appetite
Availability: Tablets: 4 mg
Oral syrup: 0.4 mg per mL

Drug: DEFEROXAMINE (DESFERAL®)
Route of Administration: IM, IV, SC
Dose: *Chelation, iron acute:* 15 mg per kg per hour IV or 50 mg per kg IM q6h, max 360 mg per kg or 6 g per day, whichever is less
Adverse Effects: GI distress, hypotension, anaphylactoid reaction
Notes: Turns urine orange or pink when complex is excreted. Injection must be further diluted for IV infusion.
Availability: Injection 250 mg per mL

Drug: DESMOPRESSIN (DDAVP®)
Route of Administration: Intranasal, SC, IV
Dose: *Acute hemophilia, von Willebrands:* 0.3 mcg per kg IV over 30 minutes or HIGH-DOSE nasal spray. *Enuresis/diabetes insipidus:* LOW-DOSE nasal spray
Note: Do not use in patients younger than 2 years old.
Adverse Effects: Facial flushing, headache, hypertension, hypotension, water retention, hyponatremic seizures
Availability: Injection 4 mcg per mL; Intranasal 100 mcg per mL or 1.5 mg per mL; Tablet 0.1 mg, 0.2 mg; Tablet sublingual 60, 120, and 240 mcg

Drug: DEXAMETHASONE (DECADRON®, HEXADROL®)
Route of Administration: PO, IM, IV
Dose: *Dependent on disease:* usual range is 0.024 to 1 mg per kg per day. *Croup:* 0.6 mg per kg per dose (usual max 12 mg per dose); *inflammation:* 0.5 to 2 mg

per kg per day divided q6–8h; *bacterial meningitis:* 0.6 mg per kg per day IV in four divided doses beginning just previous to or with the first dose of antibiotics; *epidural abscess/cerebral edema:* 2 mg per kg IV load (max 100 mg) followed by 1 to 2 mg per kg per day in four divided doses for 24 hours.

Note: Equivalent dosing 5 mg methylprednisolone = 1 mg dexamethasone

Adverse Effects: Acute: sodium and water retention, hypokalemia, hyperglycemia, hypertension, leukocytosis, behavioral disturbances, peptic ulcer

Availability: Injection: 4, 8, 10, 16, 20, 24 mg per mL

Tablets: various strengths ranging from 0.25 to 6 mg per tablet

Oral liquid: 0.1 mg per mL, 1 mg per mL concentrate (oral liquid products contain 0% to 30% alcohol)

Drug: DEXTROAMPHETAMINE (DEXEDRINE®)

Route of Administration: PO

Dose: *3 to 5 years:* 2.5 to 5 mg daily, gradually increasing to a maximum of 40 mg per day

Precautions: Tolerance may develop and require adjustment of the dosage.

Adverse Effects: Insomnia, nervousness, loss of appetite, irritability, tachycardia

Availability: Tablets: 5, 10 mg

Sustained-release Spansules: 5, 10, 15 mg

Drug: DIAZEPAM (VALIUM®, DIASTAT®)

Route of Administration: PO, IV, PR

Dose: *Status epilepticus:* 0.05 to 0.3 mg per kg per dose IV over 3 to 5 minutes every 15 minutes to a cumulative maximum total dose of 0.75 mg per kg or 10 mg, whichever is less. Lower dose is used in neonates. *Epilepsy:* 0.1 to 0.8 mg per kg per day PO divided q6–8h; *sedation:* 1 to 2.5 mg per dose PO, TID-QID. Alternatively, initial dosages of 0.1 to 0.3 mg per kg per day PO in two to three divided doses may be used; *PR:* 0.5 mg per kg (max 20 mg per dose), then 0.25 mg per kg in 10 minutes if needed. Can also use injectable form of drug for PR administration.

Precautions: When given IV for status epilepticus, dose may be repeated at 15-minute intervals to a maximum total of 0.75 mg per kg or 10 mg, whichever is less. Lorazepam is usually the drug of choice in status epilepticus in children. Maintenance anticonvulsant therapy should also be initiated when status epilepticus has been controlled.

Adverse Effects: Sedation, cardiorespiratory depression, hypotension

Availability: Injection: 5 mg per mL

Tablets: 2, 5, 10 mg

Oral solution: 1, 5 mg per mL

Rectal gel: 2.5, 5, 10, 20 mg

Drug: DIAZOXIDE (HYPERSTAT®)

Route of Administration: IV, PO (for hypoglycemia only)

Dose: *For hypertensive crisis:* 1 to 3 mg per kg per dose (max: 150 mg) given by rapid IV injection: over 10 to 30 seconds. Dose may be repeated in 5 to 15 minutes, if necessary (max 10 to 15 mg per kg per day); *hyperinsulinemic hypoglycemia (PO): newborns/infants:* initial dosage of 10 mg per kg per day PO in two to three divided doses; *maintenance:* 8 to 15 mg per kg per day PO in two to three divided doses. *Children and adults:* initial dosage of 3 mg per kg per day PO in two to three divided doses; *maintenance*: 3 to 8 mg per kg per day PO in two to three divided doses

Precautions: Severe orthostatic hypotension may occur after IV administration. Hypersensitivity to thiazides or other sulfonamides.

Adverse Effects: Hyperglycemia, tachycardia, salt and water retention, nausea, vomiting, extrapyramidal reactions (after long-term oral use)

Availability: Injection: 15 mg per mL

Oral capsules: 50 mg

Oral suspension: 50 mg per mL

Drug: DICLOXACILLIN (DYNAPEN®, PATHOCIL®)

Route of Administration: PO

Dose: *Mild to moderate infections:* 25 to 100 mg per kg per day in four divided doses. *Osteomyelitis:* 50 to 100 mg per kg per day in four divided doses (max 2 g per day). Suspension unpalatable and is no longer made.

Precautions: See Oxacillin.

Adverse Effects: See Oxacillin.

Availability: Capsules: 125, 250, 500 mg

Drug: DIGOXIN (see Chapter 84)

Drug: DIGOXIN IMMUNE FAB (DigiFab®, Digibind®)

Route of Administration: IV

Dose: *Initial:* Determine the TBL (total body load) of digoxin:

$$\frac{\text{Serum level (ng/mL)} \times 5.6 \times \text{wt in kg}}{1{,}000} = \text{TBL}$$

Divide the TBL by 0.5 to get the initial number of vials to treat empirically. If the amount of digoxin ingested is known, multiply by 0.8 to determine TBL. Infuse over 5 minutes via a 1.2-micron filter.

Adverse Effects: Hives, anaphylaxis, hypotension, chills, wheezing, hypokalemia, ventricular dysfunction, atrial arrhythmias

Note: Fab fragments may persist in the body for days and interfere with subsequent digoxin assays. Infusion must be filtered.

Availability: Powder for injection: vial 38 mg

Drug: DIHYDROERGOTAMINE (DHE®)

Route of Administration: IV, IM, SC, intranasal

Dose: *Migraine headache:* 0.5 mg intranasal, may repeat in 15 minutes if necessary up to a total 4 mg. 1 mg if giving via IM/SC/IV injection, may repeat up to a total of 3 mg for IM/SC or 2 mg for IV. Maximum for all routes is 6 mg per week.
Adverse Effects: Nausea, vomiting, paresthesias, cramping, subarachnoid hemorrhage, ergot poisoning
Note: Prime nasal pump prior to using. Do not use in pregnancy, renal dysfunction, cardiac disease or if a triptan has been used in the past 24 hours. Many dangerous drug interactions, notably and inhibitors of cyp3A4.
Availability: Injection 1 mg per mL; nasal spray 4 mg per mL

Drug: DIMENHYDRINATE
Use caution, sound-alike drugs include: Diphenhydramine (Benadryl®)
Route of Administration: IV, IM, PO
Dose: *Antiemetic/antihistamine:* 2 to 5 years: 12.5 to 25 mg per dose every 6 to 8 hours (max 75 mg per day), 6 to 12 years: 25 to 50 mg per dose every 6 to 8 hours (max 150 mg per day), older than 12 years 50 to 100 mg per dose every 6 to 8 hours (max 400 mg per day)
Adverse Effects: Anticholinergic side effects: drowsiness, urinary retention, dry mouth, tachycardia
Availability: Tablet 50 mg

Drug: DIPHENHYDRAMINE (BENADRYL®)
Route of Administration: PO, IM, IV
Dose: 1 to 1.25 mg per kg per dose every 6 hours as needed (max 300 mg per day)
Adverse Effects: Anticholinergic effects, drowsiness, sedation, dry mouth, intramuscular injection can be very painful
Availability: Injection: 10, 50 mg per mL
Capsules/tablets: 25, 50 mg
Tablets, chewable: 12.5 mg
Elixir: 2.5 mg per mL (contains 14% alcohol)
Oral syrup: 1.25, 2.5 mg per mL (some products contain 5% alcohol)

Drug: DOBUTAMINE (see Resuscitation Drug List)

Drug: DOPAMINE (See Resuscitation Drug List)

Drug: DOXYCYCLINE (VIBRAMYCIN®)
Route of Administration: PO, IV
Dose: *For acute pelvic inflammatory disease/chlamydial infections:* 100 mg BID; *anthrax, other severe susceptible infections*: 2 to 5 mg per kg per day in two divided doses (max 200 mg per day).
Precautions: Due to teeth staining, limit use to patients older than 8 years of age and weighing more than 45 kg. Rocky Mountain spotted fever and anthrax should be treated with doxycycline, regardless of age.
Adverse Effects: See Tetracycline.
Availability: Capsules: 50, 100 mg
Tablets: 100 mg
Powder for oral suspension: 5 mg per mL when reconstituted
Syrup, suspension: 10 mg per mL
Injection: 100 mg per vial

Drug: EDROPHONIUM (TENSILON®)
Route of Administration: IV, IM, SC
Dose: *myasthenia gravis diagnostic test*: 0.04 mg per kg over 1 minute followed by 0.16 mg per kg within 45 seconds if no response (max dose 10 mg total); IM/SC: <34 kg 2 mg, >34 kg 5 mg; adults 10 mg; *reversal of neuromuscular blocking agents (NMBA)*: adult 10 mg over 30 to 45 seconds; may repeat every 5 to 10 minutes up to 40 mg.
Precautions: Atropine should be readily available during any use of edrophonium
Notes: IV route preferred for diagnostic testing. Always use atropine or glycopyrrolate in conjunction with edrophonium when reversing NMBAs to control secretions.
Adverse Effects: Hypotension, cardiac arrest, arrhythmias, seizures, GI distress, bronchoconstriction
Availability: Injection 10 mg per mL

Drug: ENOXAPARIN (LOVENOX®)
Route of Administration: SC
Dose: Adjust dose based on anti-Xa levels. Obese patients should receive adjusted body weight dosing. *Deep vein thrombosis (DVT) treatment: younger than 2 months*: 1.5 mg per kg per dose SC q12h; *older than 2 months*: 1 mg per kg per dose SC q12h
DVT prophylaxis: younger than 2 months: 0.75 mg per kg per dose SC q12h; *older than 2 months*: 0.5 mg per kg per dose SC q12h
Precautions: Do not use in patients with active hemorrhage or risk of GI bleeding.
Adverse Effects: Hemorrhage, edema, local irritation at injection site
Availability: Injection 100 mg per mL

Drug: EPINEPHRINE (see Resuscitation Drug List)

Drug: ERYTHROMYCIN (E-MYCIN®, E.E.S.®, PEDIAMYCIN®)
Route of Administration: PO, IV

Dose: *PO:* 30 to 50 mg per kg per day of erythromycin equivalent in three to four divided doses (max 4 g per day).
Note: Erythromycin base, erythromycin ethylsuccinate, and erythromycin estolate are available for oral use.
IV: 15 to 50 mg per kg per day of erythromycin equivalent in four divided doses (max 4 g per day).
Prokinetic: Initial 3 mg per kg IV over 60 minutes, then 20 mg per kg per day PO divided TID-QID before meals and at bedtime.
Precautions: Many significant drug interactions occur with erythromycin, particularly with medications metabolized via cyp3A3/4; use extreme caution when adding to a patient's existing drug regimen. Oral administration of the estolate salt has been associated with cholestatic jaundice. However, this reaction rarely occurs among children 12 years of age or younger. Erythromycin use in young infants is associated with pyloric stenosis. For IV use, the drug should be diluted to at least 5 mg per mL and infused over 30 to 60 minutes.
Adverse Effects: Rash, elevation of hepatic enzymes. IV administration of erythromycin may cause severe venous irritation and thrombophlebitis. PO administration may be associated with abdominal pain and cramping.
Availability: Injection: various concentrations
Estolate salt:
Capsules: 250 mg
Tablets: 500 mg
Oral suspension: 25, 50 mg per mL
Ethylsuccinate salt:
Chewable tablets: 200 mg
Tablets: 400 mg
Oral liquid: 40, 80 mg per mL
Lactobionate salt: 500-, 1,000-mg vials (for IV use)
Gluceptate salt: 250-, 500-, 1,000-mg vials (for IV use)

Drug: ERYTHROMYCIN ETHYLSUCCINATE AND SULFISOXAZOLE (PEDIAZOLE®)
Route of Administration: PO
Dose: Dose based on erythromycin component: 50 mg per kg per day in four divided doses (max 2 g per day erythromycin)
Adverse Effects: See Erythromycin and Sulfisoxazole.
Availability: Granules for oral suspension: erythromycin 40 mg per mL and sulfisoxazole 120 mg per mL when reconstituted.

Drug: ESMOLOL (BREVIBLOC®)
Route of Administration: IV
Dose: *Hypertensive crisis and supraventricular tachyarrhythmias:* Loading dose of 500 mcg per kg per minute over 1 minute, followed by 50 to 100 mcg per kg per minute for 4 minutes. If response is not adequate within 5 minutes, a second loading dose of 500 mcg per kg per minute for 1 minute, followed by an infusion of 100 mcg per kg per minute for 4 minutes, may be administered. Again, if response is not adequate, additional loading doses of 500 mcg per kg per minute over 1 minute may be administered every 5 minutes, followed by maintenance infusions for 4 minutes that have been increased by 50 mcg per kg per minute to a maximum infusion rate of 200 mcg per kg per minute. *Other cardiology experts have advocated much lower initial loading doses of 50 mcg per kg in pediatric SVT, using extreme caution in infants.*
Precautions: May worsen inadequate cardiac function. Avoid use in patients with overt CHF or bronchospastic disease. May mask signs and symptoms of hypoglycemia. Do not use in sympathomimetic overdose.
Adverse Effects: Hypotension, bronchospasm, worsening of CHF
Availability: Injection: 10 mg per mL
Concentrate, for preparation of IV infusions: 250 mg per mL

Drug: ESTROGENS, CONJUGATED (PREMARIN®)
Route of Administration: PO, IM, IV
Dose: *Abnormal uterine bleeding, stable hematocrit:* 1.25 mg PO BID, may increase to 2.5 mg PO QID if bleeding persists
Abnormal uterine bleeding, unstable hematocrit: 20 to 40 mg IV q4h for up to 24 hours
Urethral prolapse: Use vaginal cream applied to area BID-TID
Precautions: For uterine bleeding, the IV route of administration is preferred for a more rapid response. Administer IV injection slowly to avoid flushing reaction.
Adverse Effects: Flushing (with IV administration), hypertension, nausea, vomiting
Availability: Injection: 25 mg
Tablets: 0.3, 0.625, 0.9, 1.25, 2.5 mg
Vaginal cream: 0.625 mg per g

Drug: ETHACRYNIC ACID (EDECRIN®)
Route of Administration: PO, IV
Dose: *PO:* 1 mg per kg daily or BID (usual adult starting dose: 25 mg daily, max 3 mg per kg per day)
IV: 0.5 to 1 mg per kg per dose given once (max dose: 50 to 100 mg)
Adverse Effects: Ototoxicity, electrolyte imbalance (see Furosemide)
Availability: Injection: 50-mg vial (as sodium ethacrynate)
Tablets: 25, 50 mg

Drug: ETOMIDATE (see Resuscitation Drug List)

Drug: FabAV (Crofab®)
Route of Administration: IV

Dose: *Initial:* 4 to 6 vials, repeated as needed based on response. Each vial is reconstituted with 10 mL of sterile water and then the total dose is mixed in 250 mL of NS. The infusion should be started slowly, at a rate of 25 to 50 mL per hour for 10 minutes, while observing for allergic reaction. The rate should then be increased so the 250 mL is given over 1 hour.
Adverse Effects: Hives, anaphylaxis, hypotension, chills, wheezing
Note: Intravenous diphenhydramine is recommended to be given in conjunction with infusion. Slowing the rate of infusion is generally necessary if side effects develop.
Availability: Injection: vial 10-mL serum

Drug: FENOLDOPAM (CORLOPAM®)
Route of Administration: IV
Dose: 0.2 mcg per kg per minute, titrating up by 0.3 to 0.5 mcg per kg per minute every 20 to 30 minutes. Maximum rate 0.8 mcg per kg per minute.
Adverse Effects: Hypotension, tachycardia, increased intracranial pressure, increased intraocular pressure
Availability: Injection: 10 mg per mL

Drug: FERROUS SULFATE (FER-IN-SOL®, VARIOUS GENERICS)
Route of Administration: PO
Dose: *Maintenance/prophylaxis:* 1 to 2 mg per kg per day elemental iron, max 15 mg elemental iron per day
Treatment: 4 to 6 mg per kg per day elemental iron given in three divided doses, max 195 mg elemental iron per day
Adverse Effects: GI irritation, constipation, dark stools, solution may stain teeth
Note: Always prescribe dose based on elemental iron content. Elemental iron 65 mg = ferrous sulfate 325 mg.
Availability: Various liquid products: 15, 18, 25, 45 mg per mL (content expressed as mg per mL of elemental iron)
Tablets: 325 mg ferrous sulfate (65 mg elemental iron per 325 mg ferrous sulfate)

Drug: FLUMAZENIL (see Resuscitation Drug List)

Drug: FLUTICASONE (FLOVENT®, FLONASE®)
Route of Administration: Oral inhalation, nasal spray
Dose: Oral inhalation (MDI) depends on disease severity and previous steroid requirements. Consult manufacturer package insert for more information.
Nasal spray: 1 squirt to each nostril daily
Adverse Effects: Dry, itchy mouth and throat, hoarseness, epistaxis (nasal spray)
Note: Use spacer device. Instruct patient to use bronchodilator prior to fluticasone dose. Nasal spray should be held in hand opposite of nostril to avoid direct force and subsequent bleeding of the septum.
Availability: Oral inhalation: 44, 110, 220 mcg per actuation
Nasal spray: 50 mcg per spray

Drug: FOLIC ACID (FOLVITE®)
Route of Administration: PO, IM, IV
Dose: *Deficiency*: *infants*: 15 mcg per kg per dose daily, max 50 mcg per day; *children*: 1 mg per day initial, decrease to 0.1 to 0.4 mg per day; *adolescents and adults*: 0.25 to 1 mg per day
Adverse Effects: Do not use in patients with undiagnosed anemia. Use in patients with pernicious anemia may alleviate the hematologic manifestations but allow the neurologic disorder to progress.
Availability: Injection: 5, 10 mg per mL
Tablets: 0.4, 0.8, 1 mg

Drug: FOMEPIZOLE (ANTIZOL®, 4-MP)
Route of Administration: IV
Dose: 15 mg per kg IV load, then 10 mg per kg per dose IV q12h; at 48 hours, increase dose to 15 mg per kg per dose IV q12h. If patient receiving hemodialysis, increase interval to q6h.
Adverse Effects: Nephrotoxicity, headache, tachycardia, hypotension, allergic reactions
Availability: Injection: 1.5-g vial

Drug: FOSPHENYTOIN (CEREBYX®)
Route of Administration: IV, IM
Dose: Fosphenytoin is dosed in Phenytoin equivalents (PE) to avoid error. Loading dose is 10 to 20 mg PE per kg, maintenance 5 to 8 mg PE per kg per day divided q8–12h. For status epilepticus, infuse at 3 mg PE per kg per minute, max 150 mg PE per minute. Monitor trough phenytoin levels.
Adverse Effects: Fosphenytoin is a prodrug of phenytoin and has similar adverse effects, with the notable exception of tissue necrosis and arrhythmia secondary to rapid infusion. Fosphenytoin may be given IM. Hypotension may occur with rapid infusion; slow rate if this occurs. Fosphenytoin may cause severe perineum itching due to deposition of phosphate.
Availability: Injection: 50 mg PE per mL

Drug: FUROSEMIDE (LASIX®)
Route of Administration: IV
Dose: *IV: Initial:* 1 mg per kg over 1 to 2 minutes (max initial dose: 40 mg); *subsequent:* if no response in 20 to 30 minutes, a repeat dose of 1 to 2 mg per kg may be given. *Continuous infusion*: 0.05 to 0.1 mg per kg per hour, usual max 6 mg per kg per day; *oral*: 1 to 2 mg per kg per dose every 6 hours

Precautions: Hypokalemia in a patient on digoxin may result in the development of life-threatening arrhythmias.
Adverse Effects: Hypokalemia, hypocalcemia, metabolic alkalosis, hypotension
Availability: Injection: 10 mg per mL
Tablet: 20, 40, 80 mg
Oral solution: 8, 10 mg per mL

Drug: GABAPENTIN (NEURONTIN®)
Route of Administration: PO
Dose: *Initial:* 5 mg per kg per day, increase to 5 to 35 mg per kg per day divided TID. Max 90 mg per kg per day or 3,600 mg per day, whichever is less
Adverse Effects: Dizziness and somnolence (especially with rapid titration), mood alterations, nausea, vomiting, weight gain, tremor
Availability: Capsule: 100, 300, 400 mg
Oral solution: 50 mg per mL

Drug: GENTAMICIN (GARAMYCIN®)
Route of Administration: IV, IM
Dose: Many protocols exist. *Age: younger than 30 days, gestational age less than 35 weeks:* 3 mg per kg every 24 hours; *age: younger than 30 days, gestational age more than 35 weeks:* 4 mg per kg IV q24h. *Age: older than 30 days to 10 years:* 7.5 mg per kg per IV q24h or 2.5 mg per kg per dose IV q8h. *Age: older than 10 years:* 6 mg per kg IV q24h or 2 mg per kg per dose IV q8h
Precautions: Reduce dosage in patients with renal insufficiency; monitor serum gentamicin concentrations; use adjusted dosing weight when dosing obese patients.
Adverse Effects: Ototoxicity, nephrotoxicity
Availability: Injection: 10, 40 mg per mL

Drug: GRISEOFULVIN (GRIFULVIN®, FULVICIN U/F®)
Route of Administration: PO
Dose: *Microsized:* 10 to 20 mg per kg per day in one or two divided doses (max 1,000 mg per day); *ultramicrosized:* 5 to 10 mg per kg per day in one or two divided doses (max 750 mg per day)
Precautions: Several drug interactions exist, including warfarin and phenobarbital.
Adverse Effects: Agranulocytosis, hepatic dysfunction
Availability: Microsized suspension: 25 mg per mL
Capsules: 250 mg
Tablets: 250, 500 mg
Ultramicrosized tablet: 125, 165, 250, 330 mg

Drug: HALOPERIDOL (HALDOL®)
Route of Administration: PO, IM
Dose: Note: Pediatric dosages are not well established. IV use reported but not routinely recommended. Never use deconoate preparation IV. *Age older than 3 years: initial dose:* 0.01 to 0.03 mg per kg per day in two to three divided doses. *Acute agitation:* 0.025 to 0.075 mg per kg per dose q6h. *Usual maintenance*: 0.05 to 0.15 mg per kg per day in two to three divided doses (max 6 mg per day)
Note: Injectable lactate salt is used for acute management; a long-acting decanoate salt is available but is generally used at monthly intervals for maintenance therapy.
Adverse Effects: Dystonic reactions, tardive dyskinesia, hypotension, rash
Availability: Injection (lactate salt): 5 mg per mL
Tablets: 0.5, 1, 2, 5, 10, 20 mg
Oral solution: 2 mg per mL

Drug: HEPARIN
Route of Administration: IV
Dose: *Acute treatment*: 50 to 100 units per kg IV bolus over 10 minutes followed by 20 to 28 units per kg per hour by continuous IV infusion
Catheter flushing: 30 to 50 units every 8 hours as needed
Implanted port access: 300 to 500 units (use 100 units per mL concentration)
Precautions: Titrate dose to achieve desired activated PTT (usually one and one-half to two times control value). Heparin levels may be a more sensitive measure in some institutions.
Adverse Effects: Hemorrhage, heparin-induced thrombocytopenia
Availability: Injection: various concentrations are available; most commonly used are 1,000, 5,000, 10,000, 20,000 units per mL.

Drug: HYDRALAZINE (APRESOLINE®)
Use caution, sound-alike drugs include: Hydroxyzine (Atarax®)
Route of Administration: PO, IM, IV
Dose: *PO:* 0.25 mg per kg per dose, up to four times a day (initial single dose should not exceed 25 mg), then increase gradually over 3 to 4 weeks as needed (max 7.5 mg per kg per day)
IV/IM: 0.1 to 0.2 mg per kg per dose every 4 to 6 hours as needed; initial dose should not exceed 20 mg IM/IV (max 1.5 to 3 mg per kg per day)
Precautions: When given IV, hydralazine should be infused over 15 to 20 minutes while BP is monitored.
Adverse Effects: Tachycardia, flushing, headache, vomiting, sodium and water retention
Availability: Injection: 20 mg per mL
Tablets: 10, 25, 50, 100 mg

Drug: HYDROCHLOROTHIAZIDE (ESIDRIX®, HYDRODIURIL®, ORETIC®)
Use caution, sound-alike drugs include: Chlorothiazide (Diuril®)

Route of Administration: PO
Dose: 2 to 3 mg per kg per day in two divided doses (max 200 mg per day)
Adverse Effects: See Chlorothiazide.
Availability: Tablets: 25, 50, 100 mg
Oral solution: 10 mg per mL

Drug: HYDROCORTISONE (SOLU-CORTEF®)
Route of Administration: PO, IM, IV
Dose: *Acute adrenal insufficiency:* 1 to 2 mg per kg IV initial dose, followed by 3 to 5 mg per kg per day in four divided doses
Status asthmaticus: 4 to 8 mg per kg IV initial dose followed by 2 to 4 mg per kg per day in four to six divided doses
Shock: 50 mg per kg IV initial dose followed by 50 to 75 mg per kg per day in four to six divided doses for 2 days (max 2 g per dose)
Adverse Effects: See Dexamethasone.
Availability: Injection: 100, 250, 500 mg, and 1 g per vial
Tablets: 20 mg (Cortef)
Oral suspension: 2 mg per mL (Cortef)

Drug: HYDROMORPHONE (DILAUDID®)
Route of Administration: PO, IV, SC
Dose: *Acute pain, moderate to severe: older than 6 months and weight less than 50 kg*: 0.015 mg per kg per dose IV/SC q3–6h (max 2 mg per dose) as needed OR 0.03 to 0.08 mg per kg per dose PO q3–4h as needed (max 4 mg per dose); *more than 50 kg*: 1 to 2 mg PO/IV/SC q3–4h as needed
Note: Patients with previous opiate exposure may require higher initial doses.
Adverse Effects: Respiratory depression, apnea, sedation, hypotension, allergic reaction
Availability: Injection: 1, 2, 3, 4, 10 mg per mL
Tablet: 2, 4, 8 mg

Drug: HYDROXOCOBALAMIN (CYANOKIT®)
Route of Administration: IV
Dose: C*yanide toxicity:* 70 mg per kg IV over 15 minutes (max 5 g per dose), may repeat dose
Precautions: Will interfere with colorimetric tests, such as bilirubin, Scr, and co-oximetry.
Adverse Effects: Headache, hypertension, discoloration of skin
Availability: Injection: 5-g kit

Drug: HYDROXYCHLOROQUINE (PLAQUENIL®)
Route of Administration: PO
Dose: *Malaria prophylaxis:* 5 mg per kg (base) once per week; *malaria treatment*: 10 mg per kg (base) load, then 5 mg per kg (base) daily—consult CDC for recommendations; *rheumatoid arthritis:* 3 to 6 mg per kg per day (sulfate) in a single daily dose (max 400 mg per day)
Precautions: This drug should be given with extreme caution to children and to any patients with potential G6PD deficiency; all patients should be followed with periodic complete blood cell counts and ophthalmologic examinations.
Adverse Effects: *Acute*: headache, drowsiness, visual disturbances, rash
Long-term: corneal deposits, retinopathy (may be irreversible), discoloration of skin and mucous membranes, alopecia, blood dyscrasias, behavioral changes
Availability: Tablets: 200-mg hydroxychloroquine sulfate (equivalent to 155 mg of hydroxychloroquine base)

Drug: HYDROXYZINE (ATARAX®, VISTARIL®)
Use caution, sound-alike drugs include: Hydralazine (Apresoline®)
Route of Administration: PO, IM, IV
Dose: *PO:* 2 mg per kg per day in three to four divided doses (max 100 mg per day); *IM/IV:* 0.5 to 1 mg per kg per dose given every 4 to 6 hours (max 100 mg)
Precautions: May potentiate effects of barbiturates or narcotics.
Adverse Effects: Drowsiness, dry mouth
Availability: Injection (HCl salt, Vistaril®): 25, 50 mg per mL
Tablets (HCl salt, Atarax®): 10, 25, 50, 100 mg
Capsules (pamoate salt, Vistaril®): 25, 50 mg
Oral syrup (Atarax®): 2 mg per mL
Oral suspension (Vistaril®): 5 mg per mL

Drug: IBUPROFEN (ADVIL®, MOTRIN®, NUPRIN®, PEDIAPROFEN®)
Route of Administration: PO
Dose: *Fever:* 10 mg per kg per dose every 6 to 8 hours (max 1,200 mg per day)
Inflammatory diseases: 30 to 50 mg per kg per day in three or four divided doses (max 3,200 mg per day)
Analgesia: 4 to 10 mg per kg per dose every 6 to 8 hours (max 1,200 mg per day)
Precautions: Avoid in patients with aspirin hypersensitivity, moderate to severe dehydration, bleeding disorders. Administer doses with food or milk.
Adverse Effects: GI upset, GI bleeding, headache, prolonged bleeding time, fluid retention, acute renal failure
Availability: Tablets: 200, 300, 400, 600 mg
Chewable tablets: 50, 100 mg
Oral suspension: 20 mg per mL
Oral drops: 40 mg per mL

Drug: IMIPENEM and CILASTATIN (PRIMAXIN®)
Route of Administration: IV
Dose: *Age: younger than 3 months*: 100 mg per kg per day divided q6h; *age: older than 3 months*: 60 to 100 mg per kg per day divided q6–8h (max 4 g per day)

Precautions: Administer drug diluted to 5 mg per mL over 20 to 60 minutes. Dosage must be adjusted in patients with renal dysfunction.
Adverse Effects: Hypotension, seizures, nausea, vomiting, neutropenia, transient elevation of liver enzymes
Availability: Injection: 500 mg, l g

Drug: INDOMETHACIN (INDOCIN®)
Route of Administration: PO, PR, IV
Dose: *Inflammatory diseases:* 1 to 4 mg per kg per day PO or PR in two to four divided doses (max 200 mg per day); *patent ductus arteriosus:* give the following doses IV at 12- to 24-hour intervals for three doses, interval determined by urine output:

	Dose (mg per kg)		
Age at first dose	1st	2nd	3rd
<48 h	0.2	0.1	0.1
2–7 day	0.2	0.2	0.2
>7 day	0.2	0.25	0.25

Precautions: Avoid in patients with a history of aspirin hypersensitivity. Indomethacin should be used with caution in patients with coagulation defects or impaired renal function. May inhibit naturetic effect of furosemide. May increase serum concentration of digoxin.
Adverse Effects: GI disturbances, GI bleeding, headache, visual changes, hypersensitivity reactions, renal dysfunction (reduced glomerular filtration rate, reduced urine output, fluid retention), inhibition of platelet aggregation
Availability: Capsules: 25, 50 mg
Oral suspension: 5 mg per mL
Rectal suppository: 50 mg
Injection: 1 mg per vial

Drug: INSULIN, HUMAN REGULAR (HUMULIN R®, NOVOLIN R®)
Route of Administration: IV, SC
Dose: *Acute management of DKA:* 0.1 units per kg SC/IV, followed by 0.1 units per kg per hour as a continuous infusion. *Emergent, symptomatic hyperkalemia:* 0.1 units per kg SC/IV × 1 dose along with 0.5 g per kg of dextrose. *Maintenance:* Highly variable; 0.5 to 1 units per kg per day divided two-thirds in the morning, one-third in the evening
Precautions: Tubing should be primed for 15 to 30 minutes prior to infusion, if possible, to ensure complete adsorption to binding sites. Do not consider all clear insulin preparations to be fast acting or appropriate for IV infusion. A diluent is provided by the manufacturer to dilute 100 units per mL to 10 units per mL for doses under 0.5 units.
Adverse Effects: Hypoglycemia, palpitations, tachycardia, confusion
Availability: Injection: 100 units per mL

Drug: IPRATROPIUM BROMIDE (ATROVENT®)
Route of Administration: Oral inhalation, nasal inhalation
Dose: *Nebulization: acute asthma: weight less than 10 kg:* 0.25 mg every 20 minutes for three doses, then q4–6h if needed; *weight more than 10 kg:* 0.5 mg every 20 minutes for three doses, then q4–6h if needed
MDI: 3 to 12 years: 1 to 2 puffs TID (max 6 puffs per 24 hours); *older than 12 years:* 2 puffs QID (max 12 puffs per 24 hours); *nasal spray:* 2 sprays each nostril two to four times per day.
Precautions: Do not use older MDI versions (non-HFA) in patients with peanut or soy allergy.
Adverse Effects: Exacerbation of respiratory symptoms, dyspnea, pharyngitis, blurred vision, nervousness, dizziness. Because of the drug's low lipid solubility, CNS side effects are uncommon.
Availability: Metered-dose aerosol: 18 mcg per spray
Solution for nebulization: 0.02% (0.5 mg per 2.5 mL)
Nasal spray: 0.03%, 0.06%

Drug: ISRADIPINE (DYNA-CIRC®)
Route of Administration: PO
Dose: *Severe hypertension and hypertensive emergencies:* 0.05 to 0.15 mg per kg per dose PO TID-QID, titrated up as needed, max 20 mg per day
Precautions: Use caution with concurrent use of CYP3A4 inhibitors as they can significantly increase the serum concentrations of isradipine. Should be used carefully in patients with CHF or hepatic dysfunction.
Adverse Effects: Nausea, excess hypotension, bradycardia, headache, dizziness
Availability: Tablets: 2.5, 5 mg
Tablets, controlled release: 5, 10 mg

Drug: KETAMINE (KETALAR®)
Use caution, sound-alike drugs include: Ketorolac (Toradol®)
Route of Administration: IV, IM, PO
Dose: *Procedural sedation:* 1 to 2 mg per kg per dose IV, may repeat 0.5 mg per kg per dose IV q2–5min as needed to maintain sedation (max 5 mg per kg or 500 mg, whichever is less) OR 4 to 5 mg per kg per dose IM, may repeat 2 mg per kg per dose IM × 1 if inadequate sedation in 10 minutes. Oral dose: 10 mg per kg × 1. *RSI*: see Resuscitation Drug List.
Precautions: Resources for managing laryngospasms must be immediately available. Do not use in emotionally labile children.

Adverse Effects: Emergence reactions, laryngospasm, possible increase in ICP
Availability: Injection: 10, 50, 100 mg per mL

Drug: KETOROLAC (TORADOL®)
Use caution, sound-alike drugs include: Ketamine (Ketalar®)
Route of Administration: IV, IM, PO
Dose: *IV, IM:* 0.5 mg per kg per dose every 6 hours to a maximum of 15 mg per dose for patients weighing less than 50 kg or a maximum of 30 mg per dose for patients weighing more than 50 kg.
PO: 16 years of age or older: 10 mg per dose every 6 hours. PO dosing recommendations are not available for children younger than 16 years of age.
Precautions: Treatment should be limited to a maximum of 5 days because of the increased risk of hemorrhage with long-term therapy.
Adverse Effects: GI bleed, edema, headache, dyspepsia, nausea, increased bleeding time, anaphylaxis, hypersensitivity reactions (contraindicated for use in patients with aspirin allergy)
Availability: Injection: 15, 30 mg per mL
Tablets: 10 mg

Drug: LABETALOL (NORMODYNE®, TRANDATE®)
Route of Administration: IV, PO
Dose: *Severe hypertension and hypertensive emergencies:* 0.25 to 1 mg per kg per dose IV q4–6h, max 20 mg per dose. Additional higher dosages may be administered at 10-minute intervals until control of supine BP or until a cumulative dose of 300 mg is achieved. Alternatively, continuous infusion rates of 0.25 to 1 mg per kg per hour have been used (max 3 mg per kg per hour). *Hypertension, oral*: Initial dose 3 mg per kg per day (max 100 mg PO BID); usual maintenance dosage is 5 to 20 mg per kg per day (max 1,200 mg per day).
Precautions: Due to extended half-life and duration of action, continuous infusions can be difficult to titrate. Additive hypotension occurs when administered with a diuretic. May worsen CHF; avoid use in patients with bronchial asthma, overt heart failure, or severe bradycardia. May mask signs and symptoms of hypoglycemia. Synergistic hypotension occurs with halothane anesthesia.
Adverse Effects: Nausea, excess hypotension, bradycardia, headache, bronchospasm
Availability: Tablets: 100, 200, 300 mg
Injection: 5 mg per mL

Drug: LACTULOSE (ENULOSE®)
Route of Administration: PO
Dose: *Portal systemic encephalopathy*: infants 2 to 10 mL per day, children 40 to 90 mL per day divided 3 to 4 times per day, titrate to 2 to 3 soft stools per day. *Constipation:* children 7.5 mL per day, adults 15 to 30 mL per day
Adverse Effects: Nausea, vomiting
Availability: Syrup 667 mg per mL

Drug: LAMOTRIGINE (LAMICTAL®)
Route of Administration: PO
Dose: Note: Consult manufacturer's package insert for initial dosing regimens, weeks 1 to 4.
Patients receiving enzyme-inducing anti-epileptic drugs (AEDs) without valproic acid: 0.6 mg per kg per day in two divided doses, increasing gradually to a maximum of 15 mg per kg per day (max 400 mg per day).
Patients receiving enzyme-inducing AEDs with valproic acid: 0.2 mg per kg per day in one to two divided doses, increasing gradually to a maximum of 5 mg per kg per day (max 250 mg per day)
Adverse Effects: Life-threatening rash (especially in children), angioedema, Stevens-Johnson syndrome, photosensitivity, nausea, vomiting, diplopia, amblyopia, nystagmus, dizziness, ataxia
Availability: Chewable tablets: 5, 25 mg
Tablets: 25, 100, 150, 200 mg

Drug: LEVONORGESTEROL (PLAN B®)
Route of Administration: PO
Dose: 0.75 mg PO × 1 dose, then repeat in 12 hours OR 1.5 mg PO × 1 dose
Adverse Effects: Nausea, vomiting, headache
Availability: Tablets: 0.75 mg, 2 tablets per package

Drug: LEVOTHYROXINE (LEVOXYL®, SYNTHROID®)
Route of Administration: PO, IM, IV
Dose: Oral:
0 to 6 months: 8 to 10 mcg per kg daily or 25 to 50 mcg per day
6 to 12 months: 6 to 8 mcg per kg daily or 50 to 75 mcg per day
1 to 5 years: 5 to 6 mcg per kg daily or 75 to 100 mcg per day
6 to 12 years: 4 to 5 mcg per kg daily or 100 to 150 mcg per day
Older than 12 years: 2 to 3 mcg per kg daily or more than or equal to 150 mcg per day
Growth and puberty complete: 1.6 mcg per kg daily
Note: IV and IM doses are 50% to 75% of oral dose.
Adverse Effects: Hypertension, palpitations, tachycardia, insomnia, diarrhea, weight loss
Availability: Injection: 0.2, 0.5 mg per vial
Tablets: 25, 50, 75, 88, 100, 112, 125, 150, 175, 200, 300 mcg
Note: Many recipes for compounding oral suspensions have been published.

Drug: LIDOCAINE (see Resuscitation Drug List for IV/ETT)

Drug: LIDOCAINE (Xylocaine®, LMX-4)
Route of Administration: Oral, topical

Dose: *Minor procedures, IV insertion:* 1 g per site, applied in a thick layer and covered with an occlusive dressing for at least 20 minutes. *Oral mouthwash:* use in a 1:1:1 mixture with diphenhydramine and Maalox; do not exceed 3 mg per kg per dose or give within 3 hours of previous dose.
Precautions: Allergic reaction, toxic absorption.
Adverse Effects: Possible absorption of the lidocaine
Availability: Cream: 4%, viscous: 2%

Drug: LIDOCAINE and PRILOCAINE (emla®)
Route of Administration: Topical
Dose: *Minor procedures:* 2.5 g per site, applied in a thick layer and covered with an occlusive dressing for at least 60 minutes. *Painful procedures:* 2 g per 10 cm^2 of skin, covered and left in place for at least 2 hours.
Maximum doses: Less than 10 kg: 100 cm^2
10 to 20 kg: 600 cm^2
More than 20 kg: 2,000 cm^2
Neonates: Use smaller amount of cream. Methemoglobinemia is of theoretical concern in these patients; the manufacturer does not recommend its use in patients younger than 1 month of age or in patients younger than 12 months of age who are receiving treatment with methemoglobin-inducing agents.
Precautions: Avoid use near eyes or mouth, especially in children.
Adverse Effects: Possible absorption of the lidocaine and prilocaine
Availability: Cream: Lidocaine 2.5% and prilocaine 2.5%

Drug: LITHIUM CARBONATE (ESKALITH® AND OTHERS)
Route of Administration: PO
Dose: 15 to 60 mg per kg per day divided in three to four doses (max initial: 300 mg per day, max maintenance: 2,400 mg per day). Sustained-release preparations are given in two divided doses. Lithium serum concentrations should be maintained at 0.6 to 1.4 mEq per L.
Precautions: Serum lithium concentrations must be monitored because toxicity is related to serum concentration. Increased sodium intake may result in decreased lithium serum concentrations. The following factors may increase lithium serum concentrations: reduced sodium intake, vomiting, and concomitant therapy with nonsteroidal antiinflammatory agents or diuretics.
Adverse Effects: Mild thirst at initiation of therapy, transient and mild nausea during first few days of therapy, nephrogenic diabetes insipidus, goiter. Lithium toxicity is characterized by CNS disturbances (tremor, confusion, somnolence) and GI disturbances (anorexia, nausea, vomiting).
Availability: Capsules (immediate release): 150 mg (4.06 mEq), 300 mg (8.12 mEq), 600 mg (16.24 mEq)
Tablets: 300 mg
Oral solution: Lithium citrate 1.6 mEq of lithium per mL (equivalent to 60 mg of lithium carbonate per mL)
Tablets (sustained release): 300, 450 mg

Drug: LOPERAMIDE (IMODIUM®)
Route of Administration: PO
Dose: *Acute diarrhea:* First day of therapy (initial 24 hours): 2 to 5 years (13 to 20 kg), 1 mg TID; 5 to 8 years (20 to 30 kg), 2 mg BID; 8 to 12 years (more than 30 kg), 2 mg TID. On second and subsequent days, dosages of 0.1 mg per kg per dose (not to exceed dosage appropriate for age recommended for first day) may be given after each unformed stool. *Chronic diarrhea*: 0.08 to 0.24 mg per kg per day divided in two to three doses, max 2 mg per dose. *Traveler's diarrhea (max 2 days of therapy)*: 6 to 8 years, 1 mg after each loose stool, max 4 mg per day; 9 to 11 years, 2 mg after first loose stool, followed by 1 mg after each loose stool, max 6 mg per day; older than 12 years, 4 mg after first loose stool, followed by 2 mg after each loose stool, max 8 mg per day.
Adverse Effects: Behavioral disturbances, sedation, abdominal cramping, constipation, dry mouth
Availability: Capsules, tablets: 2 mg
Oral solution: 0.2 mg per mL

Drug: LORACARBEF (LORABID®)
Route of Administration: PO
Dose: *Acute otitis media:* 30 mg per kg per day in two divided doses for 10 days using the suspension form of the drug because it yields higher plasma concentrations (max 800 mg per day). *Pharyngitis, tonsillitis:* 15 mg per kg per day in two divided doses (max 800 mg per day).
Adverse Effects: Possible cross-sensitivity with penicillin; diarrhea, nausea, vomiting, skin rashes
Availability: Capsules: 200 mg
Suspension: 100, 200 mg per 5 mL

Drug: LORAZEPAM (ATIVAN®)
Route of Administration: IV, PO
Dose: *Status epilepticus:* 0.1 mg per kg per dose IV every 5 to 15 minutes for two to three doses (max 4 mg per dose)
Anxiety: 0.05 to 0.1 mg per kg PO/IV q4–8h prn, max 4 mg per dose. Usual adult dose 2 mg
Antiemetic: 0.04 to 0.08 mg per kg per dose IV/PO (max 4 mg per dose)
Precautions: Avoid inadvertent intraarterial injection because it may induce arteriospasm leading to gangrene. Use caution with continuous infusions as propylene glycol may lead to toxicity and acute renal failure.
Adverse Effects: Excess sedation, respiratory depression, hypotension
Availability: Tablets: 0.5, 1, 2 mg

Injection: 2, 4 mg per mL
Oral solution: 2 mg per mL

Drug: MAGNESIUM SULFATE
Route of Administration: IV
Dose: *Acute asthma*: 40 mg per kg per dose IV over 20 minutes (max 2 g per dose)
Torsades de Pointes: 25 to 50 mg per kg per dose IV rapid infusion (max 2 g per dose)
Adverse Effects: Tachyarrhythmias, prolonged QRS, flushing, loss of deep tendon reflexes, change in mental status
Availability: Injection: 100, 125, 250, 500 mg per mL

Drug: MANNITOL (OSMITROL®)
Route of Administration: IV
Dose: Note: For patients with oliguria or suspected inadequate renal function, first establish adequate urine output with a test dose of 200 mg per kg (maximum 12.5 g) over 3 to 5 minutes (over 20 to 30 minutes for patients with cerebral edema/increased ICP) to produce at least 1 mL per kg per hour urine flow for 2 to 3 hours.
Initial dose: 0.5 to 1 g per kg, followed by 0.25 to 0.5 g per kg per dose every 4 to 6 hours as needed.
Precautions: Do not use in patients with hypotension, anuria, active intracranial bleeding, severe pulmonary edema or congestive heart disease. Mannitol must be filtered during administration. Never run as a continuous infusion.
Adverse Effects: Electrolyte imbalances, dehydration, CNS toxicity
Availability: Injection: 5%, 10%, 15%, 20%, 25%

Drug: MECLIZINE (ANTIVERT®)
Route of Administration: PO
Dose: *Motion sickness*: 12.5 to 25 mg 1 hour prior to travel, repeat every 12 to 14 hours. *Vertigo:* 25 to 100 mg per day in 2 to3 divided doses
Precautions: Do not use in patients younger than 12 years old.
Adverse Effects: Sedation, weight gain
Availability: Tablets; 12.5, 25, 50 mg

Drug: MEDROXYPROGESTERONE ACETATE (PROVERA®)
Route of Administration: PO
Dose: *Amenorrhea, uterine bleeding:* 5 to 10 mg per day for 5 to 10 days
Precautions: Avoid during pregnancy and in patients with a history of thromboembolic disease, breast malignancy, migraine, undiagnosed vaginal bleeding, or depression.
Adverse Effects: Breast tenderness, weight loss or gain, edema, thrombophlebitis, menstrual abnormalities, cholestatic jaundice, mental depression
Availability: Tablets: 2.5, 5, 10 mg

Drug: MEPERIDINE (DEMEROL®)
Route of Administration: PO, IM, IV
Dose: Adult: 1 to 2 mg per kg per dose IM or PO every 3 to 4 hours; 1 to 1.5 mg per kg per dose IV every 4 hours, if needed (max 100 mg per dose).
Precautions: Not recommended in children. Neurotoxic metabolite may accumulate in patients with renal failure or after prolonged use. May potentiate other CNS depressants. May induce dependence. Never use in patients taking monamine oxidase inhibitors; use extreme caution with SSRIs and TCAs.
Adverse Effects: CNS depression, respiratory depression, orthostatic hypotension, nausea, vomiting, urinary retention, decreased GI motility
Availability: Injection: 25, 50, 75, 100 mg per mL
Tablets: 50, 100 mg
Oral solution: 10 mg per mL

Drug: MEROPENEM (MERREM®)
Route of Administration: IV
Dose: 60 to 120 mg per kg per day divided every 8 hours, use higher dose in meningitis (max 6 g per day)
Adverse Effects: See Imipenem.
Availability: Injection: 500 mg, 1 g

Drug: METAPROTERENOL (ALUPENT®, METAPREL®)
Route of Administration: PO, inhalation
Dose: *PO: age 6 to 9 years and weight less than 30 kg:* 10 mg TID or QID; *adults and children older than 9 years of age and weight more than 30 kg:* 20 mg TID or QID
There is less experience in children younger than 6 years of age but PO dosages of 1.3 to 2.6 mg per kg per day in divided doses have been well tolerated though infrequently indicated.
Inhalation : 2 puffs every 4 hours from metered-dose aerosol (max dose: six doses per day). Via intermittent positive-pressure breathing (for patients 12 years of age or older): 0.2 to 0.3 mL of 5% solution diluted in 2.5 mL of 0.45% or 0.9% NaCl. Alternatively, 2.5 mL of commercially available 0.6% solution may be used. Do not repeat these doses more often than every 4 hours.
Precautions: Patients should be carefully instructed in the proper use of the inhaler.
Adverse Effects: Nausea, headache, tremor, tachycardia, dizziness, flushing
Availability: Tablets: 10, 20 mg
Oral solution: 2 mg per mL
Aerosol: 0.65 mg per inhalation
Solution for nebulization: 0.4%, 0.6%, 5%

Drug: METHOTREXATE
Route of Administration: IM
Dose: *Ectopic pregnancy:* 50 mg per m^2 as a single IM dose. A repeat dose may be needed on an outpatient basis.

Adverse Effects: Nausea, vomiting, bone marrow suppression, esophagitis
Availability: Injection 10 mg per mL, 25 mg per mL

Drug: METHYLENE BLUE
Route of Administration: IV
Dose: *Methemoglobinemia:* 1 to 2 mg per kg per dose (infuse over 5 minutes); may repeat after 1 hour, if needed.
Adverse Effects: Hypertension, discoloration of urine and feces, nausea, vomiting, abdominal pain, excessive formation of methemoglobin, cyanosis
Availability: Injection: 10 mg per mL

Drug: METHYLPHENIDATE (CONCERTA®, RITALIN®)
Route of Administration: PO
Dose: *Initial dose (age older than 6 years):* 0.3 mg per kg per dose (max 5 mg per dose) at breakfast and lunch. Gradually titrate dosage by 0.1 mg per kg per dose every week to effect (max 2 mg per kg per day or 60 mg per day, whichever is less). Some patients may require TID dosing.
Precautions: Tolerance may develop and require dosage adjustment.
Adverse Effects: Insomnia, nervousness, loss of appetite, irritability, growth suppression, increased or decreased BP, tachycardia
Availability: Tablets: 5, 10, 20 mg
Sustained-released tablets: 18, 20, 27, 36, 54 mg

Drug: METHYLPREDNISOLONE (see Resuscitation Drug List)

Drug: METOCLOPRAMIDE (REGLAN®)
Route of Administration: PO, IV
Dose: 0.1 to 0.2 mg per kg per dose PO/IV every 6 hours, max 10 mg per dose. Higher doses of 1 mg per kg per dose (max 50 mg per dose) may be used for acetaminophen overdose or chemotherapy-induced nausea and vomiting. Prophylactic diphenhydramine may be beneficial in decreasing extrapyramidal side effects seen with higher doses.
Adverse Effects: Dystonic reactions, hypertension, bradycardia, agitation, hallucinations, constipation, diarrhea
Availability: Injection: 5 mg per mL
Solution: 1, 10 mg per mL
Tablets: 5, 10 mg

Drug: METRONIDAZOLE (FLAGYL®)
Route of Administration: PO, IV
Dose: *Antibiotic-associated pseudomembranous colitis:* 20 to 35 mg per kg per day in four divided doses.
Amebiasis: 35 to 50 mg per kg per day PO in three divided doses for 5 to 10 days (max 750 mg TID).
Giardiasis: 15 mg per kg per day PO in three divided doses for 5 days (max 250 mg TID).
Helicobacter pylori infection: 15 to 20 mg per kg per day in two divided doses for 4 weeks (max 1 to 1.5 g per day). Many combination regimens exist.
Trichomonas vaginalis: 15 mg per kg per day PO in three divided doses for 7 days (max 1 g per day); usual adult dose: 500 mg PO BID for 7 days or a single dose of 2 g.
IV (for treatment of anaerobic infections): 30 mg per kg per day divided every 6 hours; IV doses should be administered over 1 hour (max 4 g per day).
Precautions: Disulfiram-like reaction may occur with ingestion of alcohol. Palatability is poor and compliance may be an issue.
Adverse Effects: Metallic taste, GI distress, peripheral neuropathy
Availability: Tablets: 250, 500 mg
Injection: 5 mg per mL
Note: Several recipes for suspensions have been published.

Drug: MICONAZOLE (MONISTAT®)
Route of Administration: Topical
Dose: *Cream or lotion:* Twice-daily application for 2 to 4 weeks
Vaginal cream: One applicatorful daily for 3 to 7 days
Vaginal suppository: One 100-mg suppository intravaginally at bedtime for 7 days or one 200-mg suppository intravaginally at bedtime for 3 days
Availability: Cream, lotion, vaginal cream: 2%
Vaginal suppositories: 100, 200 mg

Drug: MIDAZOLAM (VERSED®)
Route of Administration: IV, IM, PO, intranasal
Dose: *IM/IV sedation for procedures:* 0.05 to 0.1 mg per kg IM/IV just before procedure (max 2 mg per dose*), may repeat every 3 minutes with a dose of 0.05 mg per kg as needed to maintain sedation (total max 0.3 mg per kg or 10 mg, whichever is less); *PO sedation:* 0.25 to 1 mg per kg PO 30 to 45 minutes before procedure (max dose: 15 mg); *intranasal:* 0.2 mg per kg using the 5 mg per mL injection administered with a needleless syringe into the nares; *maintainence of sedation (i.e., postintubation):* 0.05 to 0.1 mg per kg per dose IV/IM every 1 to 2 hours as needed (max 10 mg per dose); *continuous infusion*: 0.05 to 0.1 mg per kg per hour.
Note: *Adolescents and adults require smaller doses of midazolam than children.
Adverse Effects: Hypotension, bradycardia, paradoxical excitement, local pain at the injection site, laryngospasm, bronchospasm
Availability: Injection: 1, 5 mg per mL
Oral syrup: 2 mg per mL

Drug: MIDODRINE (PROAMANTINE®)
Route of Administration: PO
Dose: *Postural hypotension:* 10 mg TID while patient is awake and upright (max 40 mg per day); *vasovagal syncope*: 5 mg while patient is awake and upright (max 15 mg per day)
Precautions: Do not use in patients younger than 12 years old.
Adverse Effects: Bardycardia, hypertension, leg cramps, nausea, weight gain
Availability: Tablets: 2.5, 5 mg

Drug: MINERAL OIL
Route of Administration: PO
Dose: *Constipation:* 5 to 11 yr: 5 to 20 mL per day; >12 yr: 15 to 45 mL per day in divided doses
Note: Do not use in children less than 3 years of age or any patient who is at risk for aspiration
Adverse Effects: Aspiration pneumonitis, loss of fat soluble vitamins, abdominal cramping, diarrhea
Availability: Liquid 100%: 30 mL, 480 mL

Drug: MORPHINE SULFATE (GENERIC)
Route of Administration: PO, IM, IV, SC
Dose: *Oral:* 0.1 to 0.5 mg per kg per dose PO q4–6h as needed
Initial (SC, IM, IV): younger than 6 months: 0.05 mg per kg per dose IV every 2 to 4 hours as needed; *older than 6 months:* 0.1 mg per kg every 2 to 6 hours as needed (usual max 10 mg per dose).
Initial IV infusion: 0.01 to 0.04 mg per kg per hour (postoperative pain) or 0.04 to 0.07 mg per kg per hour (sickle cell or cancer pain). For neonates, use an initial rate of 0.01 mg per kg per hour. Maximum initial dose: 2 mg per hour; accumulation may occur—titrate as necessary.
Precautions: IV morphine should be administered slowly (over 4 to 5 minutes) while monitoring respiratory rate, BP, and heart rate. May potentiate other CNS depressants.
Adverse Effects: Respiratory depression, apnea, hypotension, bradycardia, rash, allergic reaction
Availability: Oral solution: 2, 4, 20 mg per mL
Tablets: 15, 30 mg
Sustained release tablets: 15, 30, 60 mg
Injection: Multiple concentrations ranging from 2 to 15 mg per mL

Drug: MUPIROCIN (BACTROBAN®)
Route of Administration: Topical
Dose: Application of a small amount to affected area TID for 1 to 2 weeks
Availability: Ointment 2% in polyethylene glycol base

Drug: NAFCILLIN
Route of Administration: IM, IV
Dose: *Age 0 to 4 weeks, weight less than 1,200 g:* 50 mg per kg per day in two divided doses
Age 7 days or younger, weight 1,200 to 2,000 g: 50 mg per kg per day in two divided doses
Age 7 days or younger, weight more than 2,000 g: 75 mg per kg per day in three divided doses
Age older than 7 days, weight 1,200 to 2,000 g: 75 mg per kg per day in three divided doses
Age older than 7 days, weight more than 2,000 g: 100 mg per kg per day in four divided doses
Older infants and children: 50 to 200 mg per kg per day in four to six divided doses (max 2 g per dose)
Precautions: See Oxacillin; each gram of nafcillin contains approximately 3 mEq sodium. Dose must be adjusted in renal dysfunction.
Adverse Effects: See Oxacillin.
Availability: Injection: 500 mg; 1, 2 g

Drug: NALOXONE (see Resuscitation List)

Drug: NAPROXEN (NAPROSYN®, ANAPROX®)
Route of Administration: PO
Dose: *Dysmenorrhea:* 500 mg initial dose followed by 250 mg every 6 to 8 hours
Juvenile rheumatoid arthritis: 10 to 15 mg per kg per day in two divided doses (max dose: 1 g per day)
Precautions: Use with extreme caution in patients with history of aspirin hypersensitivity.
Adverse Effects: See Ibuprofen.
Availability: Oral suspension: 25 mg per mL
Tablets: 250, 375, 500 mg
Tablets, naproxen sodium: 275 mg (equivalent to 250 mg Naprosyn®), 550 mg (equivalent to 500 mg Naprosyn®)

Drug: NIFEDIPINE (ADALAT®, PROCARDIA®)
Route of Administration: PO
Dose: *Hypertension (adult):* 30 to 60 mg per day PO of extended-release tablet. Titrate dosage at 7- to 14-day intervals (max 120 mg per day). Usual initial dose of liquid-filled capsules is 10 mg TID (max 180 mg per day).
Hypertensive emergencies (child): Clinical experience is limited but doses in the range of 0.25 to 0.5 mg per kg per dose have been used (max 10 mg per dose).
Note: Rapid reduction of BP occurs when administered sublingually or intrabuccally by puncturing or chewing the liquid-filled capsule and expressing the liquid into the mouth. Many clinicians prefer that capsules be bitten, then swallowed to achieve higher peak serum concentrations and less variation in response.
Precautions: May increase serum concentrations and pharmacologic activity of digoxin and phenytoin. Additive or synergistic hypotension occurs with β-adrenergic-blocking agents, fentanyl, hydralazine, and other antihypertensives. Patients receiving extended-release

tablets should not be alarmed if a tablet-like substance appears in the stool because drug is released from a nonabsorbable shell during passage through the GI tract.
Adverse Effects: Excessive lowering of BP, worsening of heart failure, dizziness, flushing, peripheral edema
Availability: Capsules: 10, 20 mg
Extended-release tablets: 30, 60, 90 mg
Note: The liquid-filled capsules may be pierced on each end and the contents withdrawn for doses lower than 10 mg. The volume of each capsule may be obtained from the manufacturer.

Drug: NITROFURANTOIN (MACRODANTIN®, MACROBID®)
Route of Administration: PO
Dose: *Acute urinary tract infection:* 5 to 7 mg per kg per day in four divided doses (max 400 mg per day)
Prophylaxis or long-term therapy: 1 to 2 mg per kg per dose as a single evening dose (max 100 mg per day)
Precautions: Medication should be administered with food to minimize GI distress. Dosage should be reduced in patients with impaired renal function.
Adverse Effects: GI distress, interstitial pneumonitis, pulmonary fibrosis, peripheral neuropathy
Availability: Capsules 25, 100 mg
Extended release capsules: 100 mg
Oral suspension: 5 mg per mL

Drug: NITROPRUSSIDE (see Resuscitation Drug List)

Drug: NORETHINDRONE (NORLUTIN®, NORLUTATE®)
Route of Administration: PO
Dose: *Amenorrhea, uterine bleeding:* 2.5 to 10 mg per day norethindrone acetate, 5 to 20 mg per day of norethindrone
Precautions: Contraindicated in patients with history of thrombotic or thromboembolic disorders.
Adverse Effects: Breakthrough bleeding, edema, weight loss or gain, mental depression
Availability: Tablets: 5 mg norethindrone, 5 mg norethindrone acetate

---

Drug: NYSTATIN (MYCOSTATIN®, NILSTAT®)
Route of Administration: PO, topical
Dose: *PO: age younger than 28 days:* 400,000 units per day in four divided doses; *age older than 28 days:* 400,000 to 2,000,000 units per day in four divided doses. Rub in oral doses well to affected areas in the mouth.
Adverse Effects: GI disturbances
Availability: Topical cream, ointment, and powder
Oral tablets: 500,000 units
Oral suspension: 100,000 units per mL

Drug: OCTREOTIDE (SANDOSTATIN®)
Route of Administration: IV, SC
Dose: *Diarrhea:* 1 to 10 mcg per kg per dose every 12 hours; *GI hemorrhage*: *initial:* 1 to 2 mcg per kg, max 50 mcg per dose, followed by a continuous infusion 1 to 2 mcg per kg per hour, max 50 mcg per hour; *sulfonylurea overdose*: 1 to 2 mcg per kg, max 50 mcg per dose
Adverse Effects: Hyper/hypotension, palpitations, anxiety, headache, fever, rash, hyper/hypoglycemia
Note: Depot injection for monthly administration in stable patients only. Do not use for IV administration.
Availability: Injection: 0.05, 0.1, 0.2, 0.5, 1 mg per mL
Depot injection: 10, 20, 30 mg

Drug: OLANZAPINE (ZYPREXA®)
Route of Administration: PO, IM
Dose: *Oral maintenance*: 2.5 to 20 mg per day, titrated slowly. *Acute agitation:* 5 to 10 mg IM
Adverse Effects: Hypersensitivity reactions, cardiac arrhythmias, blood dyscrasias, suicidal ideation, hyperglycemia, hyperlipidemia, seizures
Note: Should only be prescribed for maintenance therapy in conjunction with psychiatry consult.
Availability: Injection: 10 mg; Tablets: 2.5, 5, 7.5, 10, 15, 20 mg

---

Drug: OMEPRAZOLE (PRILOSEC®)
Route of Administration: PO
Dose: 0.6 to 1 mg per kg per dose daily, may increase to 3.3 mg per kg per day divided BID; *usual adult:* 20 mg per dose
Precautions: Possible drug interactions with other medications metabolized via the CYP3A3/4 enzyme pathway. Do not use in patients receiving high-dose methotrexate.
Adverse Effects: GI distress, tachycardia, bradycardia, insomnia, anxiety, rash, myalgias, tinnitus
Availability: Capsules, delayed release: 10, 20, 40 mg
Note: Several recipes for suspensions have been published.

Drug: ONDANSETRON (ZOFRAN®)
Route of Administration: PO, IV, IM
Dose: *Nononcology nausea and vomiting:* 0.15 mg per kg per dose PO/IV/IM every 8 hours as needed. Lower doses have been shown to be effective and better tolerated. *Age-based dosing: 6 months to 1 year:* 2 mg; *1 to 12 years:* 4 mg; *>12 years:* 8 mg per dose, *Chemotherapy-associated nausea and vomiting:* 0.45 mg per kg per day IV/PO divided every 8 to 24 hours
Adverse Effects: Headache, dizziness, seizures, tachycardia, bradycardia, rash, fever
Availability: Injection: 2 mg per mL
Solution: 0.8 mg per mL
Tablet: 4, 8 mg
Tablet, orally dissolving: 4, 8 mg

Drug: OXACILLIN
Route of Administration: IM, IV
Dose: *Younger than 1 week of age and weight less than 2,000 g:* 50 mg per kg per day given in two divided doses
Younger than 1 week of age and weight more than 2,000 g: 100 mg per kg per day in four divided doses
Children: 100 to 200 mg per kg per day given in four to six divided doses (max 12 g per day)
Precautions: Each gram of oxacillin contains approximately 3 mEq of sodium. Dose must be adjusted in renal dysfunction.
Adverse Effects: Hepatic dysfunction, hypersensitivity reactions, blood dyscrasias
Availability: Injection: Various size vials containing 250 mg to 10 g per vial
Capsules: 250, 500 mg
Oral solution: 500 mg per mL when reconstituted

Drug: OXCARBAZEPINE (TRILEPTAL®)
Route of Administration: PO
Dose: *Initial*: 8 to 10 mg per kg per day divided BID, titrate up slowly over 2 weeks to an average dose of 5 to 60 mg per kg per day (total 2,400 mg per day)
Precautions: Do not discontinue abruptly, do not use in pregnancy unless benefit outweighs risk.
Adverse Effects: Psychomotor slowing, cognitive dysfunction, Stevens-Johnson syndrome, hyponatremia, suicidal ideation
Availability: Tablet: 150, 300 mg
Liquid: 60 mg per mL

Drug: PANTOPRAZOLE (PROTONIX®)
Route of Administration: IV, PO
Dose: 0.5 to 1 mg per kg per day given IV/PO q12–24h, 0.1 mg per kg per hour for continuous infusion
Precautions: Vessel irritant: dilute to 4 mg per mL for intermittent infusion, 0.8 mg per mL for continuous infusion. Note current controversy about using a protein pump inhibitors while receiving clopidrogel for antiplatelet effect.
Adverse Effects: Phlebitis, GI distress, diarrhea, myalgia, arthralgia
Availability: Injection: 40 mg per vial
Tablets: 20,40 mg
Oral suspension (compounded): 2 mg per mL

Drug: PANCURONIUM (PAVULON®)
Route of Administration: IV
Dose: *Intubation in patients younger than 1 month of age:* 0.06 to 0.1 mg per kg; *children:* 0.15 mg per kg
Maintenance of paralysis: 0.1 mg per kg per hour via continuous infusion or 0.1 to 0.15 mg per kg per dose IV q1h prn
Precautions: Pancuronium is not generally used for RSI due to long onset time. Neonates are particularly sensitive to the effects of neuromuscular-blocking agents and dosage must be individualized.
Adverse Effects: Tachycardia, respiratory depression, hypertension, excessive salivation
Availability: Injection: 1, 2 mg per mL

Drug: D-PENICILLAMINE (DEPEN®, CUPRIMINE®)
Route of Administration: PO
Dose: *Lead poisoning: initial:* 5 mg per kg per day in divided doses, titrate over several weeks to 20 to 30 mg per kg per day in three to four doses, max 1.5 g per day; *rheumatoid arthritis:* 3 to 10 mg per kg per day given as a single dose; start at a low dosage and titrate dosage upward over several months (max 1.5 g per day)
Precautions: Monitor CBC, urinalysis, renal and hepatic function. Give with food or flavored food substance to improve palatability.
Adverse Effects: Allergic reactions, rash, hematuria, proteinuria, anorexia, nausea, vomiting, diarrhea, bitter taste, stomatitis, blood dyscrasias, cross-sensitivity with penicillins, optic neuritis, obliterative bronchiolitis
Availability: Capsules: 125, 250 mg
Tablets: 250 mg

Drug: PENICILLIN G, BENZATHINE (BICILLIN®)
Route of Administration: IM only
Dose: *Staphylococcal and streptococcal infections: weight less than 27 kg:* single dose of 300,000 to 600,000 U; *weight more than 27 kg:* single dose of 900,000 U; *adult:* single dose of 1.2 million U; *syphilis:* single dose of 50,000 U per kg (max dose: 2.4 million U) only if neurosyphilis can be excluded; otherwise, penicillin G or penicillin G procaine are preferred
Precautions: Administer as deep IM injection; otherwise precautions are same as for penicillin G. Death has been reported after inadvertent IV administration.
Adverse Effects: See Penicillin G, Potassium.
Availability: Injection: 300,000, 600,000 U per mL

Drug: PENICILLIN G, POTASSIUM
Route of Administration: IM, IV
Dose: *Injection : age younger than 7 days:* 50,000 to 100,000 units per kg per day IV in two divided doses for most infections; *neonatal meningitis due to group B streptococcus:* 250,000 to 400,000 units per kg per day IV in four divided doses; *infants and children:* 100,000 to 400,000 units per kg per day IV in four to six divided doses (max 20,000,000 units per day)
Precautions: Each 1,000,000 units contains approximately 2 mEq of potassium.
Adverse Effects: Allergic reactions, interstitial nephritis, nausea, vomiting, diarrhea, seizures (with high doses)

Availability: Injection: many strengths ranging from 200,000 units per vial to 20,000,000 units per vial; sodium penicillin G is available in vials of 1,000,000 and 5,000,000 units.

Drug: PENICILLIN V, POTASSIUM (PEN VEE K®, V-CILLIN K®)
Route of Administration: PO
Dose: 25 to 50 mg per kg per day in three to four divided doses (max 2 g per day); *prophylaxis of pneumococcal infections or recurrent rheumatic fever*: *age younger than 5 years:* 125 mg BID; *age 5 years or older:* 250 mg BID
Precautions: Same as for penicillin G, potassium.
Adverse Effects: Same as for penicillin G, potassium
Availability: Tablets: 125, 250, 500 mg
Oral solution: 25, 50 mg per mL

Drug: PENTOBARBITAL (NEMBUTAL®)
Route of Administration: PO, IV
Dose: *Procedural sedation:* 1 to 2 mg per kg per dose IV every 5 minutes until adequately sedated, max 100 mg per dose; total max 300 mg or 6 mg per kg, whichever is less
Oral: 2 to 6 mg per kg PO × 1 dose
Adverse Effects: Prolonged sedation, respiratory depression, apnea, hypotension
Availability: Injection: 50 mg per mL
Capsule: 50, 100 mg
Oral solution: 3.64 mg per mL

Drug: PHENAZOPYRIDINE (PYRIDIUM®)
Route of Administration: PO
Dose: 12 mg per kg per day in three divided doses for 2 days (max 200 mg per dose)
Precautions: May mask signs of infection; therefore, do not use alone or for extended periods of time.
Adverse Effects: Headache, rash, discoloration of urine, methemoglobinemia
Availability: Tablets: 100, 200 mg

Drug: PHENOBARBITAL (LUMINAL®)
Route of Administration: PO, IM, IV
Dose: *Initial:* 10 to 20 mg per kg
Subsequent infants and children: 3 to 6 mg per kg per day in two divided doses
Adolescents: 1 to 2 mg per kg per day in one to two divided doses
Precautions: Administer by IV route at a rate no faster than 1 mg per kg per minute. Serum concentrations should be monitored. Be prepared to intubate if high doses are used in status epilepticus.
Adverse Effects: Sedation, ataxia, paradoxical excitation, hypotension, cardiorespiratory depression
Availability: Injection: 30, 60, 65, 130 mg per mL
Tablets: 8, 15, 30, 60, 100 mg
Oral elixir: 3, 4 mg per mL

Drug: PHENTOLAMINE (REGITINE®)
Route of Administration: IM, IV
Dose: *Hypertensive crisis:* 0.05 to 0.1 mg per kg per dose, do not exceed 5 mg per dose
Vasoconstrictor infiltration: Infants: 2.5 to 5 mg diluted in 10 mL of NS, administer as serial "pincushion" injections, do not exceed 0.1 mg per kg. Children and adolescents: 5 to 10 mg diluted in 10 mL of NS. Administer as above, do not exceed 5 mg.
Precautions: Must be on CV monitor for intravenous/intramuscular doses.
Adverse Effects: Hypotension, cardiac arrhythmias
Availability: Injection: 5 mg per mL

Drug: PHENYTOIN (DILANTIN®, VARIOUS GENERICS)
Route of Administration: PO, IV
Dose: *Initial loading dose:* 15 to 20 mg per kg (see Precautions)
Subsequent doses:

Age	Dosage
6 mo to 3 yr	8–10 mg per kg per day in two divided doses
4–6 yr	7.5–9 mg per kg per day in two divided doses
7–9 yr	7–8 mg per kg per day in two divided doses
10–16 yr	5–7 mg per kg per day in two divided doses

Precautions: IV phenytoin should be administered directly into a large vein or IV tubing at a rate no faster than 1 mg per kg per minute (25 to 50 mg per minute in an adult). Phenytoin should not be infused via small veins in the hand, foot, or scalp. Treat extravasations immediately. If dilution is necessary, NS should be used because other solutions cause precipitation of phenytoin. IM administration should be avoided because of erratic and incomplete absorption. Serum concentrations should be monitored.
Adverse Effects: Sedation, nystagmus, ataxia, gingival hyperplasia, rash, Stevens-Johnson syndrome. Drug interactions may occur when phenytoin is combined with phenobarbital, carbamazepine, chloramphenicol, isoniazid, salicylates, oral anticoagulants, and many others.
Availability: Injection: 50 mg per mL
Prompt-release oral capsules: 30, 100 mg
Extended-release oral capsules (Dilantin®): 30, 100 mg
Chewable tablets: 50 mg
Oral suspension: 6, 25 mg per mL

Drug: PHYTONADIONE (VITAMIN K, MEPHYTON®)

Route of Administration: Subcutaneous, IM, IV, PO

Dose: *Life-threatening bleeding:* Infants and children: 5 mg per dose IV, Adults: 2.5 to 10 mg per dose IV

Non-Life-threatening serious bleeding: Infants and children: 0.5 to 2.5 mg SC or IV

Precautions: Subcutaneous administration strongly preferred when possible due to serious infusion reactions occurring with IV administration. Dilute in 5 to 10 mL of NS for IV administration, give no faster than 1 mg per minute.

Adverse Effects: Anaphylactoid reactions, hypotension

Availability: Injection: 2, 10 mg per mL

Tablet: 5 mg

Drug: PIPERACILLIN/TAZOBACTAM (ZOSYN®)

Route of Administration: IV

Dose: Dose is based on piperacillin component. Usual 200 to 300 mg per kg per day divided every 6 hours. *Cystic fibrosis*: 300 to 500 mg per kg per day divided every 6 hours. Max 18 g per day as piperacillin

Adverse Effects: See Penicillin.

Availability: Injection: 2.25, 3.375, 4.5 g

Drug: POLYETHYLENE GLYCOL – PEG 3350 (MIRALAX®)

Route of Administration: PO

Dose: *Disimpaction:* 1 to 1.5 g per kg per day (max 100 g per day) PO daily × 3 days. *Constipation*: <10 kg: 4.25 g per day, 10 to 30 kg: 8.5 g per day, >30 kg: 17 g per day

Notes: 17 g = 1 tbsp = 1 capful or packet; mix every 17 g in 8 oz of fluid

Adverse Effects: Diarrhea, electrolyte imbalance with overdose

Availability: Powder for suspension

Drug: POLYETHYLENE GLYCOL with Electrolytes (GoLYTELY®)

Route of Administration: PO

Dose: *Disimpaction:*

Whole Bowel Irrigation (toxic exposure): Infants and young children: 500 mL per hour; Adolescents and adults: 2,000 mL per hour, max 4,000 mL

Adverse Effects: GI cramping, nausea, vomiting, electrolyte disturbances (rare with proper use)

Availability: Powder for solution

Drug: POLYSTYRENE SULFONATE, SODIUM (KAYEXALATE®)

Route of Administration: PO, PR

Dose: 1 g per kg per dose (max 60 g per dose); 1 g of resin binds approximately 1 mEq of potassium. Administer powder orally as a suspension in water. Dilute each 1 g of powder to at least 4 mL. If administering via NG tube, dilute suspension 1:1 with tap water to aid in delivery. If administered rectally, give as a retention enema. Dilute each 1 g of powder to at least 3 to 4 mL with 1% methylcellulose or 10% dextrose in water. PR administration is generally less effective than PO administration. Enema should be retained for at least 30 minutes.

Precautions: Monitor serum electrolytes. Each gram of resin contains approximately 4 mEq of sodium. Resin delivers 1 mEq of sodium for each 1 mEq of potassium removed. Resin may also bind other cations (e.g., calcium, magnesium).

Availability: Powder for suspension

Suspension: 0.25 g sodium polystyrene sulfonate per 1 mL (in approximately 30% sorbitol)

Drug: POTASSIUM CHLORIDE (MICROK, KLORCON®)

Route of Administration: PO, IV

Dose: *Oral, hypokalemia*: 1 to 2 mEq per kg per day; follow institutional guidelines for IV dosing and infusion restrictions – most use 0.5 mEq per kg per dose (max 40 mEq) infused over 2 hours at 0.1 mEq per mL for peripheral line, 0.2 mEq per mL for central line infusion

Precautions: Ensure adequate monitoring (laboratory, urine output, and cardiorespiratory), do not let patient break, chew, or crush extended release tablets or capsules. Use caution in patients with renal dysfunction.

Adverse Effects: Arrhythmias, GI erosion, rash

Availability: Capsules 8, 10 mEq

Liquid 20 mEq per 15 mL, 40 mEq per 15 mL

Capsules extended release 8, 10, 20 mEq

Powder for reconstitution 20, 25 mEq

Injection 2 mEq per mL concentrated; 10, 20, 30, and 40 mEq mixed in 100 mL NS

Drug: POTASSIUM IODIDE (IOST, THYROSHIELD, SSKI®)

Use caution, sound-alike drugs include: Potassium iodine (Lugol's solution®)

Route of Administration: PO

Dose: *Thyrotoxic crisis*: <1 year: 3 to 5 drops (150 to 250 mg) PO TID; >1 year: 6 to 10 drops (300 to 500 mg) PO TID; *Select radiation poisoning:* <1 month: 16.25 mg PO daily; 1 month to 3 year: 32.5 mg PO daily; 3 to 18 years: 65 mg PO daily; >68 kg: 130 mg PO daily until exposure is eliminated

Precautions: Dilute well prior to administration.

Adverse Effects: Gastritis, hypothyroidism, dermatitis, arrhythmias

Availability: Solution SSKI: 1 g per mL, ThyroShield 65 mg per mL

Tablets: 65, 130 mg

Drug: PREDNISOLONE (ORAPRED®, PRELONE®)
Route of Administration: PO
Dose: *Acute asthma*: 1-2 mg per kg × 1 dose, then 2 mg per kg per day in two divided doses; *antiinflammatory:* 0.5 to 2 mg per kg per day in divided doses. Max 80 mg per dose
Adverse Effects: See Methylprednisolone. Palatability may be an issue with compliance.
Availability: Oral solution: 3 mg per mL
Tablets: 5 mg
Oral disintegrating tablets: 15 mg, 30 mg

Drug: PREDNISONE (DELTASONE®)
Route of Administration: PO
Dose: *Physiologic replacement:* 0.1 to 0.15 mg per kg per day; *acute asthma:* 1-2 mg per kg × 1 dose then 1 to 2 mg per kg per day divided BID (max 80 mg per dose); *rheumatoid arthritis:* 1 to 2 mg per kg per day in one to four divided doses; *nephrotic syndrome:* 2 mg per kg per day
Precautions: Every-other-day therapy is advised once dosage is established to minimize adrenal suppression and growth retardation.
Adverse Effects: See Methylprednisolone.
Availability: Tablets: 1, 2.5, 5, 10, 20, 25, 50 mg
Oral solution: 1 mg per mL

Drug: PROCAINAMIDE (PRONESTYL®, PROCANBID®, PROCAN®)
Route of Administration: PO, IM, IV
Dose: *PO:* 15 to 50 mg per kg per day in four to eight divided doses (for prompt-release products); once stabilized, therapy can be changed to sustained-release product at same total daily dosage but administered in four divided doses (or two divided doses-Procanbid®).
IV: Initial loading dose of 3 to 7 mg per kg per dose (max 100 mg per dose) diluted and given slowly over 5 minutes, may be repeated after 10 to 30 minutes; *continuous IV infusion:* 20 to 80 mcg per kg per minute (0.02 to 0.08 mg per kg per minute); *maximum total daily dose:* 2 to 4 g PO or IM, or 1 to 2 g IV
Precautions: IV administration may cause hypotension if given too rapidly or in excessive doses. Dosage adjustment is recommended for patients with reduced renal function. Avoid using in patients with myasthenia gravis or second- or third-degree heart block.
Adverse Effects: Mental confusion, myocardial depression, cardiac arrhythmias (especially conduction block), lupus-like syndrome, nausea, vomiting
Availability: Injection: 100, 500 mg per mL
Capsules/tablets: 250, 375, 500 mg
Tablets, extended-release (Procan SR®): 250, 500, 750 mg; 1 g
Twice-daily extended-release (Procanbid®): 500 mg, 1 g

Drug: PROPRANOLOL (INDERAL®)
Route of Administration: PO, IV
Dose: *IV: acute antiarrhythmic*: 0.01 to 0.1 mg per kg per dose given slowly (max 1 mg per dose) every 6 to 8 hours as needed; *PO: hypertension:* usual starting dose 0.5 to 1 mg per kg per day in four divided doses; maintenance dose 1 to 5 mg per kg per day in two to four divided doses (max 240 mg per day); *migraine headache prophylaxis:* 0.6 to 1.5 mg per kg per day in three divided doses, max 4 mg per kg per day
Precautions: IV injection should be given slowly over 10 minutes. Use with extreme caution, if at all, in patients with asthma, diabetes, or CHF.
Adverse Effects: Myocardial depression, hypoglycemia, nausea, vomiting
Availability: Injection: 1 mg per mL
Tablets: 10, 20, 40, 60, 80 mg
Oral solution: 4, 8, 80 mg per mL

Drug: PSEUDOEPHEDRINE (SUDAFED®)
Route of Administration: PO
Dose: 4 mg per kg per day in four divided doses; or age 2 to 5 years: 15 mg every 4 to 6 hours (max 60 mg per day); age 6 to 11 years: 30 mg every 4 to 6 hours (max 120 mg per day); age 12 years or older: 60 mg every 4 to 6 hours (max 240 mg per day)
Precautions: Extended-release products containing 120 mg or greater should not be used in patients younger than 12 years of age.
Adverse Effects: CNS excitation or sedation, tachycardia, blurred vision, headache, hypertension
Availability: Tablets: 30, 60 mg
Capsules, timed-release: 120 mg
Liquid: 3, 6 mg per mL
Drops: 7.5 mg per 0.8 mL

Drug: PYRIDOSTIGMINE (MESTINON®)
Use caution, sound-alike drugs include: Physostigmine (Antilirium®)
Route of Administration: PO, IM, IV
Dose: *PO: myasthenia gravis:* usual starting dose 1 mg per kg per dose every four hours; IV/IM: 0.05 to 0.15 mg per kg per dose (max 10 mg per dose). *Reversal of NMBA*: 0.1 to 0.25 mg per kg per dose IV (max 20 mg per dose)
Precautions: Must use atropine or glycopyrrolate for secretion control when reversing NMBAs.
Adverse Effects: Nausea, vomiting, cramping, diarrhea, increased respiratory secretions
Availability: Tablets 60 mg
Injection: 5 mg per mL
Syrup: 12 mg per mL

Drug: QUINIDINE (VARIOUS)
Route of Administration: PO, IM, IV

Dose: *Test dose:* 2 mg per kg PO
Therapeutic: 15 to 60 mg per kg per day in four to six divided doses; *usual dose:* 30 mg per kg per day in five divided doses of quinidine sulfate PO or quinidine gluconate parenterally. Consult the CDC for dosing recommendations in the treatment of malaria.
Precautions: IV use of quinidine is recommended only when a cardiologist is in attendance. Absorption from IM injection sites is erratic and unreliable. Oral quinidine should be taken with food.
Adverse Effects: Adverse GI effects, hypotension, cardiac arrhythmias, blood dyscrasias, systemic lupus erythematosus-like syndrome. Cinchonism is a sign of quinidine toxicity, and is characterized by tinnitus, headache, vertigo, fever, nausea, and disturbed vision. Cinchonism may occur after single dose.
Availability: Sulfate injection: 200 mg per mL
Gluconate injection: 80 mg per mL
Quinidine sulfate tablets/capsules: 100, 200, 300 mg
Quinidine gluconate tablets (sustained release): 324 mg
Note: Sulfate salt contains 83% anhydrous quinidine; gluconate salt contains 62% anhydrous quinidine.

Drug: RABIES IMMUNE GLOBULIN (HYPERAB®)

Route of Administration: IM, infiltration around wound
Dose: 20 units per kg administered at the same time as rabies vaccine, but in a different site. Use one-half the dose to infiltrate the wound site unless the wound involves mucous membranes.
Adverse Effects: Local soreness, muscle stiffness at injection site, fever
Availability: Injection: 150 units per mL

Drug: RABIES VIRUS VACCINE (IMOVAX RABIES®, HDCV)

Route of Administration: IM
Dose: *Postexposure prophylaxis:* Five doses of 1 mL each administered on days 0, 3, 7, 14, and 28. Low risk patients do not require day 28 dose. The first dose should be administered at the same time as the immunoglobulin, but in a different muscle.
Adverse Effects: Local pain and erythema, fever, encephalomyelitis, peripheral neuropathy
Availability: Injection: 2.5 U per mL

Drug: RANITIDINE (ZANTAC®)

Route of Administration: IV, PO
Dose: *IV*: 1 mg per kg per dose IV every 8 hours (max 50 mg per dose); *continuous infusion*: 0.15 mg per kg per hour; *oral*: 2 mg per kg per dose PO every 12 hours (max 150 mg per dose). Higher dosages may be necessary in pathologic hypersecretory conditions.
Adverse Effects: Dizziness, headache, bradycardia, rash, thrombocytopenia
Availability: Injection: 25 mg per mL
Oral liquid: 15 mg per mL
Tablets: 75, 150, 300 mg

Drug: RASBURICASE (ELITEK®)

Route of Administration: IV
Dose: *IV*: 0.15 to 0.2 mg per kg per dose IV rounded to the nearest vial size
Note: All samples for uric acid levels must be sent on ice to avoid breakdown by the rasburicase in vitro. Do NOT use alkaline hydration prior to rasburicase (use hydration without sodium bicarbonate). Allopurinol should not be given simultaneously with rasburicase.
Adverse Effects: Dizziness, headache, nausea, severe hemolysis (G6PD)
Availability: Injection: 1.5, 7.5 mg

Drug: RIFAMPIN (RIFADIN®, RIMACTANE®)

Route of Administration: PO
Dose: *Prophylaxis against H. influenzae type b: age younger than 1 month:* 10 mg per kg per day as a single daily dose for 4 days; *age 1 month to 12 years:* 20 mg per kg per day as a single daily dose for 4 days (max 600 mg); *prophylaxis against Neisseria meningitidis: age younger than 1 month*: 10 mg per kg per day in two divided doses for 2 days; *age 1 month 12 years:* 20 mg per kg per day in two divided doses for 2 days (max 1,200 mg); *tuberculosis: age older than 1 week:* 10 to 20 mg per kg per day (maximum daily dose: 600 mg)
Precautions: When using rifampin in conjunction with isoniazid, limit rifampin dose to 15 mg per kg daily and isoniazid to 10 mg per kg daily to minimize risk of hepatotoxicity.
Adverse Effects: Hepatotoxicity, GI disturbances, flulike syndrome, red-orange discoloration of urine, feces, sweat, and tears. Discoloration of contact lenses may also occur.
Availability: Capsules: 150, 300 mg
Note: Several recipes for suspensions have been published usually reconstituted at 10 mg per mL.

Drug: RIMANTADINE (FLUMADINE®)

Route of Administration: PO
Dose: *Prophylaxis: children younger than 10 years of age:* 5 mg per kg daily (max 150 mg per day); *children older than 10 years of age:* 100 mg BID. Reduce dosage to 100 mg per day in patients with severe hepatic or renal dysfunction.
Precautions: Use with caution in patients with epilepsy.
Adverse Effects: Dizziness, headache, confusion, anxiety, restlessness, nausea, vomiting, urinary retention
Availability: Syrup: 10 mg per mL
Tablets: 100 mg

Drug: RISPERIDONE (CONSTA, RISPERDAL®)
Route of Administration: PO, IM
Dose: *Oral*: range is 0.5 mg per day titrated up to a max of 6 mg per day; IM 12.5 to 25 mg every two weeks
Adverse Effects: Prolonged QTc, arrhythmias, blood dyscrasias, neuroleptic malignant syndrome (NMS), dystonias, hyperglycemia, orthostatic hypotension, suicidal ideation
Note: IM is depot formulation, will not work acutely. Do NOT ever give intravenously. Orally-disintegrating tablets (ODTs) contain phenylalanine
Availability: Tablet: 0.25, 0.5, 1, 2, 3, 4 mg
Orally disintegrating tablet: 0.25, 0.5, 1, 2, 3, 4 mg
Oral solution: 1 mg per mL
Injection: 12.5, 25, 37.5, 50 mg with administration pack

Drug: ROCURONIUM (see Resuscitation Drug List)

Drug: SODIUM BICARBONATE (See Resuscitation Drug List)

Drug: SPIRONOLACTONE (ALDACTONE®)
Route of Administration: PO
Dose: 1 to 3.3 mg per kg per day in one or two divided doses (max 200 mg per day)
Adverse Effects: Hyperkalemia, hyponatremia, gynecomastia
Availability: Tablets: 25, 50, 100 mg
Note: Several recipes for suspensions have been published.

Drug: SUCCINYLCHOLINE (see Resuscitation Drug List)

Drug: SUCRALFATE (CARAFATE®)
Route of Administration: PO
Dose: 40 to 80 mg per kg per day divided q6h, max 1 g per dose
Precautions: Sucralfate binds many drugs, ensure adequate separation. Give on empty stomach. Aluminum toxicity may occur in patients with renal insufficiency.
Adverse Effects: Constipation, drug—drug interactions
Availability: Tablets: 1 g
Suspension: 100 mg per mL

Drug: SULFISOXAZOLE (GANTRISIN®)
Route of Administration: PO
Dose: *Initial:* 75 mg per kg as a single dose; *maintenance:* 120 to 150 mg per kg per day in four to six divided doses (max 4 to 8 g per day)
Precautions: Fluid intake should be encouraged to minimize risk of crystalluria.
Adverse Effects: GI distress, rash, fever, allergic reactions
Availability: Tablets: 500 mg
Pediatric solution/suspension: 100 mg per mL
Lipo-Gantrisin suspension (extended-release): 200 mg per mL

Drug: SUMATRIPTAN (IMITREX®)
Route of Administration: SC, PO, intranasal
Dose: Limited information suggests SC doses of 3 mg for children 6 years of age or older weighing 22 to 30 kg or 6 mg in children weighing more than 30 kg are safe and effective. Alternatively, a dose of 0.06 mg per kg SC has been used. Currently, only adult dosing is available for the oral and intranasal preparations.
Precautions: Use with caution in patients with preexisting coronary, hepatic, or renal disease or epilepsy.
Adverse Effects: Flushing, pain, and/ or edema at the injection site, chest tightness, and atypical nervous system effects such as tingling, numbness, feelings of warmth, heat, burning, cold or pressure, dizziness, or drowsiness
Availability: Injection: 12 mg per mL

Drug: TERBUTALINE (BRETHINE®, BRICANYL®)
Route of Administration: PO, IV, SC
Dose: *PO:* 0.05 mg per kg per dose three times per day, max 7.5 mg per day
SC: status asthmaticus load: 10 mcg per kg × 1 dose followed by continuous IV infusion (see below). Alternatively: 0.003 to 0.005 mg per kg per dose (3 to 5 mcg per kg per dose) to a maximum single dose of 0.25 mg; may repeat once after 15 to 20 minutes.
IV: status asthmaticus: load: 10 mcg per kg × 1 dose, followed by a continuous infusion of 0.4 mcg per kg per minute. Titrate as needed to maintain aeration and heart rate less than 200. Max dose 6 mcg per kg per minute. Suggested total β_2-agonist maximum: 20 mg per hour.
Precautions: Manufacturer does not recommend use in children younger than 12 years of age.
Adverse Effects: See Albuterol. Transient hypotension may occur at doses less than 2 mcg per kg per minute secondary to upregulation of the β_2-receptors in the vasculature.
Availability: Tablets: 2.5, 5 mg
Injection: 1 mg per mL

Drug: TETANUS IMMUNE GLOBULIN
Route of Administration: IM only (do NOT administer IV)
Dose: *Postexposure prophylaxis:* 250 units IM × 1 dose; *treatment:* therapeutic dose: 3,000 to 6,000 units IM × 1 dose.

Note: The need for TIG is dependent on previous immunization history. Consult the CDC website for further dosing recommendations.
Precautions: Allergic reactions are possible (epinephrine should be immediately available).
Adverse Effects: Pain at injection site, myalgias, fever, flulike symptoms, allergic reactions
Availability: Injection: 250 units per vial

Drug: TETANUS and DIPTHERIA TOXOID (Td, DT)
Route of Administration: IM
Dose: *Wound management*: *younger than 7 years:* 0.5 mL of the DT preparation IM × 1 dose; *older than 7 years:* 0.5 mL of the Td preparation IM × 1 dose.
Note: Number of postexposure doses and need for TIG is dependent on previous immunization history. Consult the CDC website for further dosing recommendations.
Adverse Effects: Fever, pain at injection site, allergic reaction
Availability: Injection: DT (pediatric), Td (adult)

Drug: TETANUS, reduced DIPTHERIA and PERTUSSIS (Tdap)
Route of Administration: IM
Dose: *Wound management*: 11 to 65 years: 0.5 mL IM × 1 dose
Note: At this time, only one booster of Tdap is recommended. Consult the CDC website for further dosing recommendations.
Adverse Effects: Fever, pain at injection site, allergic reaction
Availability: Injection

Drug: TETRACYCLINE (ACHROMYCIN®)
Route of Administration: PO
Dose: *PO: >8 years:* 25 to 50 mg per kg per day given in four divided doses (max 3 g per day)
Precautions: Avoid in children younger than 8 years of age because tetracycline may cause enamel hypoplasia and discoloration of permanent teeth. Tetracycline chelates divalent cations and should not be given with milk, iron, or antacids. Tetracycline should be given 1 hour before or 2 hours after meals or milk.
Adverse Effects: GI distress, photosensitivity, pseudotumor cerebri, and overgrowth of nonsusceptible organisms including fungi
Availability: Capsules: 100, 250, 500 mg
Oral suspension: 25 mg per mL

Drug: THEOPHYLLINE (SOMOPHYLLIN®, SLO-PHYLLIN®, THEOPHYL®, THEO-DUR®, MANY OTHERS)
Route of Administration: PO, IV form is aminophylline
Dose: *Acute asthma (age older than 1 year):* IV, initial dose of 6 mg per kg over 20 to 30 minutes followed by continuous infusion of 0.9 to 1.1 mg per kg per hour (adjust to maintain therapeutic serum concentration of 10 to 20 mg per L). Modify initial dose according to baseline serum concentration if patient is known to be on maintenance theophylline.
Chronic asthma: PO, 16 to 24 mg per kg per day in four divided doses. Sustained-release products may be given every 8 to 12 hours. Adjust dose to achieve serum concentration of 10 to 20 mg per L.
Apnea of prematurity: IV/PO: initial: 4 to 6 mg per kg (over 20 to 30 minutes if IV); *maintenance*: 3 to 5 mg per kg per day in two to three divided doses. Adjust to maintain therapeutic serum concentration (8 to 14 mg per L)
Adverse Effects: CNS irritability, tachycardia, nausea, vomiting, abdominal cramping, seizures (at toxic serum concentrations)
Availability: Many strengths and dosage forms (check local availability); most commonly used forms in children include oral liquid: 18 mg per mL; sustained-release capsules: 50, 60, 75, 100, 125, 200, 250, 300 mg
Injection as aminophylline: 25 mg per mL
Note: Aminophylline 0.8 mg = theophylline 1 mg. Alcohol- and dye-free liquid products are available.

Drug: THIAMINE (VITAMIN B1)
Route of Administration: IV, PO
Dose: *Neonatal seizures*: 100 mg IV × 1 dose; *mitochondrial defects*: 100 to 200 mg PO daily.
Adverse Effects: Cardiovascular collapse with rapid infusion of large doses, GI distress, discoloration of urine, rash
Availability: Injection: 100, 200 mg per mL
Tablets: 25, 50, 100, 250, 500 mg

Drug: TICARCILLIN (TICAR®)
Route of Administration: IV, IM
Dose: *Neonates: younger than 7 days, weight less than 2,000 g:* 150 mg per kg per day in two divided doses; *younger than 7 days, weight more than 2,000 g:* 225 mg per kg per day in three divided doses; *older than 7 days, weight more than 2,000 g*: 300 mg per kg per day in three to four divided doses; *age older than 1 month:* 200 to 300 mg per kg per day in four divided doses (max 24 g per day)
Precautions: Ticarcillin contains 5.2 to 6.5 mEq of sodium per gram.
Adverse Effects: Hypernatremia, hypokalemia, metabolic alkalosis, seizures, reduced platelet function
Availability: Injection: 1, 3, 6 g

Drug: TOBRAMYCIN (NEBCIN®)
Route of Administration: IV, IM
Dose: See Gentamicin
Precautions: See Gentamicin.

Adverse Effe cts: See Gentamicin.
Availability: Injection: 10, 40 mg per mL, also available as preservative free

---

Drug: TOPIRAMATE (TOPAMAX®)
Route of Administration: PO
Dose: *Initial:* 0.5 to 1 mg per kg, increasing by 1 mg per kg per day weekly until 6 to 15 mg per kg per day is reached. Dose is usually divided BID.
Precautions: Sulfa allergy cross-reactivity
Adverse Effects: Drowsiness, ataxia, cognitive word finding difficulties, parasthesias, kidney stones, suicidal ideation
Availability: Tablet 25, 50, 100, 200 mg
Sprinkle capsules: 15, 25 mg

Drug: TRIMETHOPRIM -SULFAMETHOXAZOLE (BACTRIM®, SEPTRA®)
Route of Administration: PO, IV
Dose: Note: Dosage is expressed in terms of the trimethoprim component. Dosage forms contain a ratio of 5 mg of sulfamethoxazole (SMX) to 1 mg of trimethoprim (TMP).
Minor infections: 8 mg per kg per day TMP in two divided doses (max 320 mg per day TMP); *Pneumocystis carinii pneumonia (treatment dose):* 20 mg per kg per day TMP (PO) or 15 to 20 mg per kg per day TMP (IV) in four divided doses every 6 hours.
Precautions: Dilute IV doses and infuse over no less than 60 to 90 minutes. Dosage modification required in patients with renal impairment.
Adverse Effects: Most common are rashes and GI upset. Most serious are severe hypersensitivity reactions (e.g., Stevens-Johnson syndrome, erythema multiforme), blood dyscrasias, and hepatocellular necrosis.
Availability: Oral suspension: TMP 8 mg per mL and SMX 40 mg per mL
Tablets: TMP 80 mg and SMX 400 mg
Double-strength tablets: TMP 160 mg and SMX 800 mg
Injection: TMP 16 mg per mL and SMX 80 mg per mL

Drug: TROPICAMIDE (Mydracil®)
Route of Administration: Opthalamic
Dose: 1 to 2 drops within 30 minutes of eye exam
Precautions: Use with caution in young children.
Adverse Effects: Psychotic disturbances, blurred vision, increased intraocular pressure
Availability: Opthalamic solution 0.5, 1%

Drug: TYPHOID VACCINE (TYPHIM®)
Route of Administration: IM, PO
Dose: IM vaccination: 0.5 mL × 1 dose; Oral vaccine: 1 capsule PO every other day for 4 doses
Note: The injectable vaccine provides immunity for approximately 2 to 3 years. The live oral vaccine provides immunity for up to 5 years.
Precautions: ORAL typhoid vaccine can cause stomach upset, and is recommended to be taken in the evening prior to bedtime. Antibiotics should not be given concurrently with ORAL typhoid vaccine.
Adverse Effects: Nausea, vomiting
Availability: Capsules, Injection

Drug: VALPROIC ACID (DEPACON®, DEPAKENE®, DEPAKOTE®)
Route of Administration: IV, PO, PR
Dose: *Status epilepticus:* Load 20 mg per kg IV over 5 minutes; *epilepsy*: 15 to 60 mg per kg per day in two to three divided doses. If taking other enzyme-inducing AEDs, may require 100 mg per kg per day. Supplemental carnitine is recommended by some experts if using high doses.
Precautions: Valproic acid may interact with the following drugs: clonazepam, phenobarbital, phenytoin, salicylates, and warfarin. Serum drug concentrations should be carefully monitored in patients taking multiple drug products. Monitor liver function tests before and at frequent intervals during therapy (see Adverse Effects). IV doses may need to be divided q6h to maintain adequate levels. Infusion rate is 60 minutes, unless in status epilepticus.
Adverse Effects: Nausea, vomiting, sedation, hyperammonemia (with or without coma), thrombocytopenia, inhibition of platelet aggregation, pancreatitis, severe and potentially fatal hepatotoxicity
Availability: Capsules: 250 mg (valproic acid)
Capsules (containing coated particles or "sprinkles"): 125 mg
Delayed-release tablets: 125, 250, 500 mg (as divalproex sodium)
Injection: 100 mg per mL
Syrup: 50 mg per mL (sodium valproate)
Note: The syrup has been successfully administered by the PR route after dilution with water. Depakote ER has only been approved for migraine prophylaxis and should not be used for epilepsy at this time.

Drug: VANCOMYCIN (VANCOCIN®)
Route of Administration: IV, PO
Dose: *IV: age 1 to 2 months:* 10 mg per kg per dose every 12 hours; *age older than 2 months:* 40 to 60 mg per kg per day in three to four divided doses. Use higher doses for CNS infections.
PO, for treatment of antibiotic-associated pseudomembranous colitis only: 10 mg per kg per dose every 6 hours (max 2 g per day). Usual adult dose is 125 mg PO QID.
Precautions: Administer IV over 60 minutes to minimize risk of "red-man's syndrome" (hypotension and rash). PO route should not be used for treatment of systemic infections. Monitor trough levels. Poor palatability of oral solutions may influence compliance.

Adverse Effects: Ototoxicity and nephrotoxicity (especially when used in conjunction with other ototoxic and/or nephrotoxic drugs), thrombophlebitis, hypotension, rash
Availability: Capsules: 125, 250 mg
Injection: 500 mg, 1, 2 g per vial
Powder for oral solution: 1, 10 g

Drug: VARICELLA-ZOSTER IMMUNE GLOBULIN (VariZIG®)
Route of Administration: IM, IV
Dose: 125 units for every 10 kg of weight (min dose 125 units, max 625 units)
Notes: Give within 96 hours of exposure. May diminish efficacy of live vaccines, ensure administration of varicella vaccine if needed prior to or at the same time as the administration of VariZIG.
Precautions: Use only the supplied diluent. Watch for signs of varicella for 28 days post administration.
Adverse Effects: Site reaction, fever, anaphylaxis, pulmonary edema, renal dysfunction
Availability: Injection 125 units per vial

Drug: VECURONIUM (NORCURON®)
Route of Administration: IV
Dose: *Maintanence of paralysis postintubation*: 0.1 mg per kg per dose every 1 hour or more frequently as needed to maintain paralysis; *continuous infusion*: 0.05 to 0.07 mg per kg per hour. *RSI*: 0.3 mg per kg IV × 1 dose
Precautions: A higher dose is needed to obtain rapid onset needed for RSI; therefore, paralysis may persist for more than 2 hours postdose.
Adverse Effects: See Rocuronium.
Availability: Injection: 10-mg vial

Drug: VERAPAMIL (CALAN®, ISOPTIN®)
Route of Administration: IV
Dose: *Supraventricular tachycardia: age 1 to 16 years:* 0.1 to 0.3 mg per kg over 2 minutes (max dose: 5 mg). May repeat dose once after 30 minutes if adequate response is not achieved. Repeat dose in children 2 to 15 years of age should not exceed 10 mg.
Note: Although oral dosage forms are available, oral dosage requirements in children have not been established.
Precautions: Because of the risk of severe hypotensive responses, use with extreme caution, if at all, in neonates and children younger than 1 year of age. Use with continuous EKG monitoring in all children.
Adverse Effects: Hypotension, bradycardia, tachycardia, dizziness, headache, nausea. Hypotension or bradycardia caused by verapamil may be reversed by administration of calcium salts or β-adrenergic agents. IV fluids should also be used to treat hypotension. Atropine sulfate may counteract the bradycardia.
Availability: Injection: 2.5 mg per mL

Drug: WARFARIN (COUMADIN®)
Route of Administration: PO
Dose: *Load on day 1:* 0.2 mg per kg × 1 dose (max 10 mg per dose)
Maintenance: Dosing is based on INR. Usual maintenance is 0.1 mg per kg per day but is highly variable.
Precautions: Food and drug interactions should be thoroughly discussed with the patient. The potential for many serious drug interactions exist.
Adverse Effects: Hemorrhage, fever, skin lesions, anorexia
Availability: Tablet: 1, 2, 2.5, 4, 5, 7.5, 10 mg

Drug: ZINC SULFATE
Route of Administration: PO
Dose: 0.5 to 1 mg elemental zinc per kg per day in 1 to 3 divided doses, normal adult dose 25 to 50 mg elemental zinc (110 to 220 mg zinc sulfate) PO daily-TID
Precautions: Clinical response often takes several weeks, up to two months.
Adverse Effects: GI distress
Availability: Capsule 220 mg (50 mg elemental zinc); liquid can be compounded

---

Drug: ZIPRASIDONE (GEODON®)
Route of Administration: PO, IM
Dose: 20 to 100 mg per day depending on disease state and titration. *Acute agitation:* 10 mg IM every 2 hours or 20 mg every 4 hours, max 40 mg per day
Adverse Effects: Prolonged QTc, extrapyramidal side effects, nausea, chest pain, weight gain
Note: Change to oral therapy as soon as possible.
Availability: Injection: 20 mg
Capsule: 20, 40, 60, 80 mg

ABBREVIATIONS

AED, antiepileptic drug; BID, twice daily; BP, blood pressure; CBC, complete blood count; CDC, Centers for Disease Control and Prevention; CHF, congestive heart failure; CNS, central nervous system; CPK, creatine phosphokinase; D5W, dextrose 5% in water; EKG, electrocardiogram; ETT, endotracheal tube; G6PD, glucose-6-phosphate dehydrogenase deficiency; GI, gastrointestinal; ICP, intracranial pressure; IM, intramuscular(ly); INR, international normalized ratio; IO, intraosseous; IV, intravenous(ly); MAOi, Monoamine oxidase inhibitor; MDI, metered-dose inhaler; NMS, neuroleptic malignant syndrome; ODT, orally disintegrating tablets; PCA, patient-controlled analgesia; PE, phenytoin equivalents; PO, oral(ly); PPI, proton pump inhibitor; PR, rectal(ly); PRN, as needed; PTT, partial thromboplastin time; QHS (at bedtime); QID, four times daily; QTc, QT corrected; RSI, rapid sequence intubation; SC, subcutaneous(ly); TID, three times daily.

APPENDIX C ■ PRACTICAL INFORMATION

JOSHUA NAGLER, MD

VITAL SIGNS

Blood Pressure

Values:
Neonatal blood pressures vary significantly with age: systolic 40 to 80 mm Hg and diastolic 20 to 55 mm Hg.

	Percentile (systolic/diastolic)	
Age (yr)	50%	95%
2	96/60	108/66
6	106/68	112/72
9	112/72	116/76
12	118/76	122/82

Lower extremity pressures usually measure 10 to 40 mm Hg higher.

Complete blood pressure tables for children and adolescents are available from the National Heart Lung and Blood Institute at http://www.nhlbi.nih.gov/guidelines/hypertension/child_tbl.htm.

Pulsus Paradoxicus

Pulsus paradoxicus is defined as a drop in systolic blood pressure of greater than 10 mm Hg when first taken during inspiration and then taken during expiration.

Resting Respiratory Rate

Age	Breaths/min
Neonate	30–50
2–12 mo	30–40
12 mo—2 yr	22–30
2–12 yr	16–24
Adolescent	12–20

Resting Heart Rate

Age	Beats/min
Newborn	92–180
1 wk–1 mo	100–180
3 mo–2 yr	100–150
2–10 yr	65–120
10 yr–adult	55–110

Temperature

Conversion:
Fahrenheit versus centigrade

$$°C = (°F - 32) \times 5/9$$

Example: °C = (98.6 − 32) (or 66.6) × 5 (=333)/9 = 37
°F = (°C × 9/5) + 32
Example: °F = (39 × 9 = 351) (/5 = 70.2) + 32 = 102.2
Extrapolating points: 38°C = 100.4°F
39°C = 102.2°F
40°C = 104.0°F
41°C = 105.8°F

End-tidal Carbon Dioxide

End-tidal carbon dioxide level: normal 35 to 45 mm Hg. See Fig. C.1 for normal capnogram.

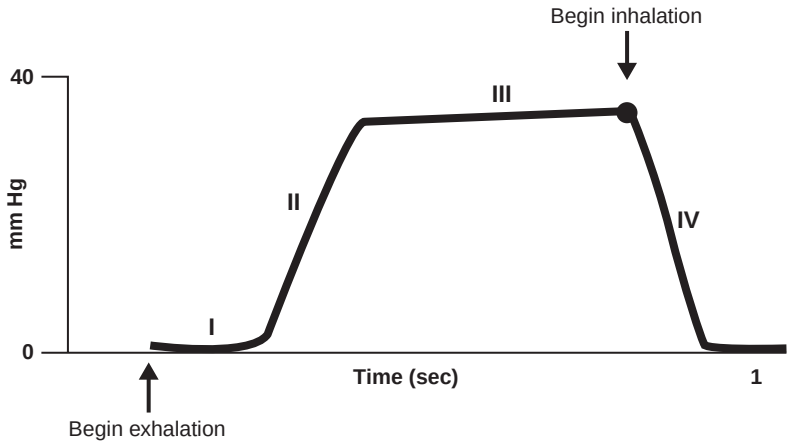
Weight

Conversion: Wt (lb)/2.2 = Wt (kg)

$$\text{Wt (kg)} \times 2.2 = \text{Wt (lb)}$$

Rapid weight estimation for children 10 years or younger:
Wt (kg) = [2 × age (yr)] + 8

	Percentile (using kg)		
Age	5%	50%	95%
Neonate, wk			
32	1.3	1.8	2.8
40	2.7	3.5	4.2
6 mo			
Female	5.9	7.2	8.6
Male	6.3	7.7	9.5
1 yr			
Female	7.8	9.5	11.4
Male	8.4	10.1	12.0
2 yr			
Female	9.8	11.8	14.0
Male	10.5	12.7	14.7
5 yr			
Female	14.1	17.9	22.2
Male	15.2	19.0	22.8
7 yr			
Female	15.5	19.5	29.0
Male	16.6	21.0	29.8
9 yr			
Female	21.7	28.0	40.6
Male	22.6	28.0	40.2



Phase I: Beginning of exhalation. Dead space is cleared from the upper airway.
Phase II: Rapid rise in CO_2 concentration as alveolar CO_2 reaches the upper airway.
Phase III: Plateau. Entire exhaled breath stream is alveolar gas. Maximum value for that tidal breath is the end-tidal CO_2.
Phase IV: Beginning of inhalation. Atmospheric air replaces alveolar CO_2.

FIGURE C.1 Normal capnogram.

Body Surface Area

Nomogram Method:
Body surface area (BSA) can be determined by connecting the height and weight numbers with a straight line. The point at which the line intersects the surface area abscissa is the reading for surface area in meters squared (Fig. C.2). To determine the approximate body surface area for normally proportioned children, use either the second line from the left in Fig. C.2 or the following formula:

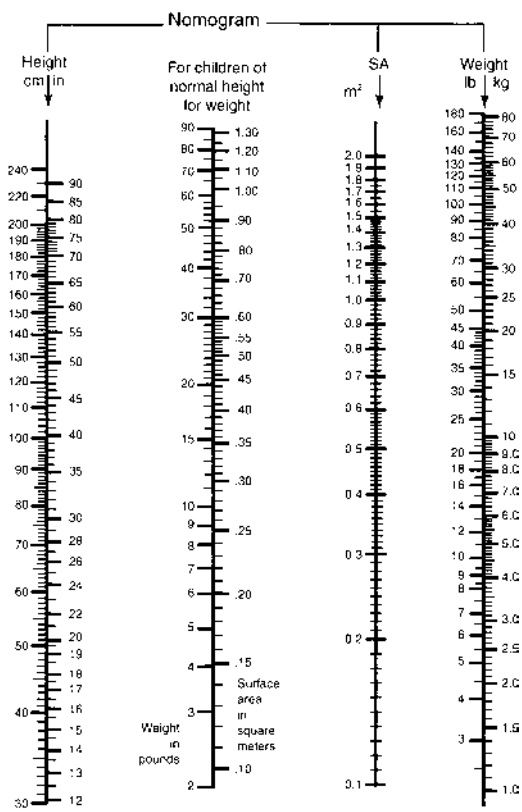


FIGURE C.2 Surface area. (Adapted from *Harriet Lane handbook*. 18th ed. St. Louis, MO: Mosby, 2008.)

Formulaic Method:

Mosteller's Formula: BSA (m^2) = Square root of: [Ht (cm) × Wt (kg)] ÷ 3600
Dubois Formula: BSA = ($W^{0.425} \times H^{0.725}$) × 0.007184

Body Mass Index

Body Mass Index (BMI) = weight (kg)/[height (m)]^2

Body Mass Index Calculator is available at the Centers for Disease Control and Prevention Web site at: http://apps.nccd.cdc.gov/dnpabmi/Calculator.aspx.

For children 2 years and older:

BMI < 5th percentile: Underweight
BMI > 85th percentile: Overweight
BMI > 95th percentile: Obese

IMMUNIZATIONS

HIV and other severely immunodeficient or immunosuppressed patients should be immunized in consultation with their primary caregivers and probably should not receive measles, mumps, or rubella (MMR) or varicella vaccine.

Recommendations for management upon exposure to tetanus; rabies; meningococcemia; *Haemophilus influenzae* type b; rubeola; rubella; hepatitis A, B, and C; pertussis; and varicella are defined in the "Prophylaxis After Exposure to Serious Disease" section, later in this appendix.

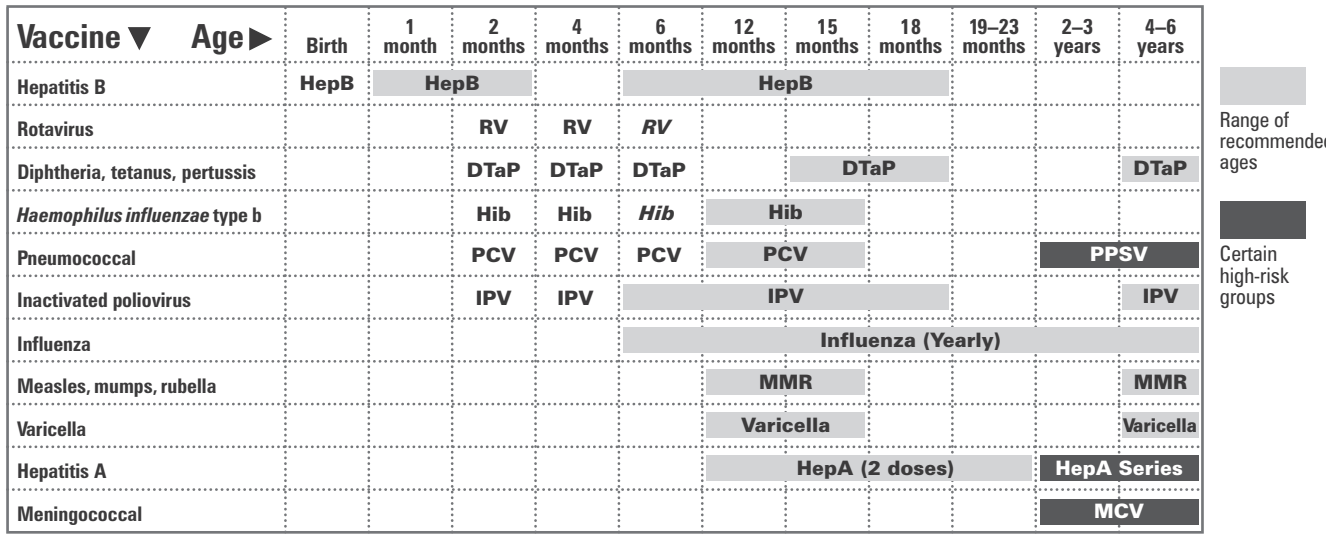
BEDSIDE LABORATORY TESTING

Rapid Screening Test for Cold Agglutinins

Collect a few drops of blood in a purple-top tube (small test tube with about 0.2 mL of 3.8 NaEDTA). Place in ice water bath for about 60 seconds. Tilt tube and look for flocculation

Recommended Immunization Schedule for Persons Aged 0 Through 6 Years—United States • 2009

For those who fall behind or start late, see the catch-up schedule

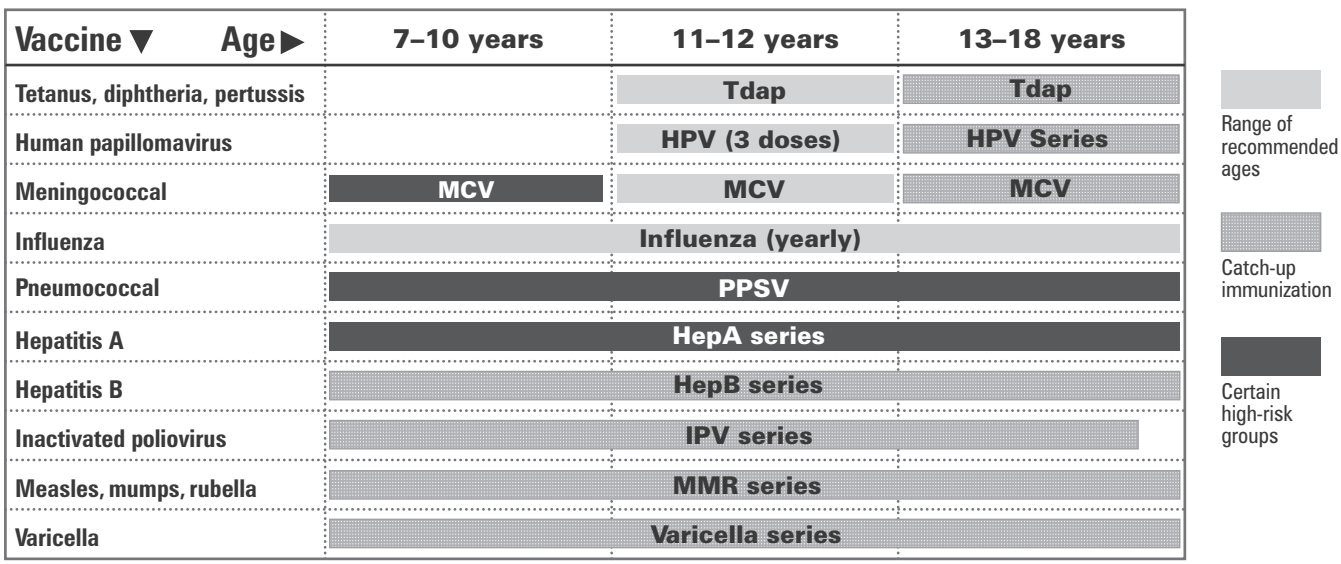


This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 0 through 6 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

FIGURE C.3 Immunization schedule for persons aged 0 through 6 years. (Adapted from Centers for Disease Control and Prevention. Recommended immunization schedules for persons aged 0 through 18 Years, United States, 2009. *MMWR 2008*; 57(51/52).) Also available at http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm.

Recommended Immunization Schedule for Persons Aged 7 Through 18 Years—United States • 2009

For those who fall behind or start late, see the schedule below and the catch-up schedule



This schedule indicates the recommended ages for routine administration of currently licensed vaccines, as of December 1, 2008, for children aged 7 through 18 years. Any dose not administered at the recommended age should be administered at a subsequent visit, when indicated and feasible. Licensed combination vaccines may be used whenever any component of the combination is indicated and other components are not contraindicated and if approved by the Food and Drug Administration for that dose of the series. Providers should consult the relevant Advisory Committee on Immunization Practices statement for detailed recommendations, including high-risk conditions: http://www.cdc.gov/vaccines/pubs/acip-list.htm. Clinically significant adverse events that follow immunization should be reported to the Vaccine Adverse Event Reporting System (VAERS). Guidance about how to obtain and complete a VAERS form is available at http://www.vaers.hhs.gov or by telephone, 800-822-7967.

FIGURE C.4 Immunization schedule for persons aged 7 through 18 years. (Adapted from Centers for Disease Control and Prevention. Recommended immunization schedules for persons aged 0 through 18 years, United States, 2009. *MMWR 2008*; 57(51/52).) Also available at http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm.

in the blood as it starts up the side of the tube. Warm the tube to room temperature and see if the flocculation disappears. Presence of flocculation when observed by the naked eye with subsequent disappearance on warming is a positive test for cold agglutinins and equates with about a 1:64 or greater cold agglutinin titer. There are widely varying reported sensitivities and specificities for positive cold agglutination tests for Mycoplasma or other diseases, and caution should be used in decision making based on this test alone.

Apt Test for Fetal Blood

If a stool specimen passed by a neonate is grossly bloody, mix a small sample of the specimen in a test tube with an equal quantity of tap water. Centrifuge briefly or filter out the solid material. The supernate should have a pink color due to the suspended blood. Add 1 part of 1.0% NaOH to 5 parts of the supernate. Wait for 2 minutes. A persistent pink color indicates presence of fetal hemoglobin because fetal hemoglobin is resistant to alkali denaturation; if the supernate turns yellow or brown, the hemoglobin is from an adult, suggesting swallowed maternal blood.

Stool Examination for Leukocytes

Smear a small specimen of stool on a glass slide. Mix with 1 to 2 drops of methylene blue stain. Cover with thin cover slip. Wait for 3 minutes before microscopic examination. Presence of more than 5 white blood cells per high-power field may increase the probability of a specific bacterial cause of diarrhea; however, widely varied sensitivities and specificities of this test have been reported.

Gram Stain

Make a thin smear of blood, spinal fluid, or vaginal or urethral secretion on a glass slide. Allow to air dry. Apply gentian violet; allow to sit for 1 minute; and then wash with water. Next, apply iodine solution for 1 minute and wash. Decolorize by applying acetone/alcohol for a few seconds and wash. Stain with safranin for 15 seconds and wash. Examine under high-power microscope.

Tzanck Preparation

Unroof a vesicular or bullous lesion, blot it, and scrape the base with the edge of a glass slide or scalpel. Spread the scraped material onto a glass slide and fix with methyl alcohol. Stain for 30 seconds with Wright stain and wash. Microscopic examination showing multinucleated giant cells is indicative of herpetic or zoster lesions.

Pinworm Evaluation

1. Place a piece of cellophane or tape over the end of a tongue depressor with sticky side out. Place over the perianal mucosa, applying moderate pressure for 1 minute. Spread the sticky side of the tape over a glass slide. Look through the microscope for ova.
   or
2. Instruct the parents to turn over the child who has been asleep for about an hour and look carefully at the perianal area. Live, threadlike worms, about 1 cm in length can be seen wiggling out of the anus to lay their ova.

Methemoglobin Screening Test

To evaluate for methemoglobinemia in the cyanotic patient who has no cardiac or respiratory impairment and does not respond to oxygen, place a drop of blood on white filter paper. Wave it in the air for 60 seconds. Dark red or violet blood without methemoglobin (i.e., deoxyhemoglobin) will brighten after exposure to atmospheric oxygen, whereas the dark (often chocolate brown) blood with methemoglobin will not change color. This differential response can be accelerated by gently blowing on the sample.

ELECTROCARDIOGRAPHIC CAVEATS

In young children, the right ventricle normally extends to the right of the sternum, as can be seen graphically on an anteroposterior chest radiograph. Because of this, an electrocardiogram in children younger than 5 years should include a chest lead taken on the right side of the chest, at a point analogous to the left-sided V4 lead (midclavicular line). This lead is called V4R. Rarely, if a heart is grossly enlarged and extends well to the right of the sternum, a V6R and even a V7R lead must be taken to complete a tracing that properly displays right ventricular potentials.

The right ventricle is normally the dominant ventricle in young children. Right axis is normal, and aVR usually has a dominant R wave in its QRS complex. The QRS progression across the chest leads usually goes from dominant R wave in V4R through the transitional zone to dominant R wave again in the left-sided chest leads. This may be true until as late as 4 years of age.

On the right-sided chest leads and in extremity lead III, T waves are normally inverted in infants and young children.

Determining whether a QT interval is prolonged is of particular importance in evaluating the patient with syncope and fainting. The following formula is used:

$$\text{Corrected QT (QTc)} = \text{Measured QT (in fractions of a second)} \div \sqrt{\text{R} - \text{R}}\ \text{interval in fractions of a second)}$$

QTc should not exceed: 0.45 in young infants
0.44 in older infants and children
0.43 in adolescents and adults

FLUID AND ELECTROLYTE AIDES

A *millimole* is the atomic weight expressed in milligrams.
Equivalents are the number of electric charges per liter or the atomic weight divided by valence.
A *milliequivalent* is the equivalent weight expressed in milligrams.

Serum osmolality is calculated with the formula:

$$\text{Calculated osm} = 2(\text{Na}) + \text{Glucose (mg/dL)} \div 18 + \text{BUN (mg/dL)} \div 2.8$$

Normal range is about 285 to 295 mOsm per L.

$$\text{Osmolar gap} = \text{Measured (osm)} - \text{calculated (osm)}.$$

A gap of more than 10 units is considered abnormal, most commonly seen with ingestion of various types of alcohol.

Anion gap is the difference between measured cations and measured anions in the serum. In practice, the formula most commonly used is:

$$\text{Anion gap} = (\text{Na}) - (\text{Cl} + \text{bicarb})$$

An anion gap of more than 15 mEq per L is considered elevated.

Maintenance fluid requirements for children:
For 24-hour calculations:

For the first 10 kg: 100 mL per kg
For the second 10 kg: additional 50 mL per kg
For each kg beyond 20 kg: additional 20 mL per kg

For per-hour calculations:

For the first 10 kg: 4 mL per kg
For the second 10 kg: additional 2 mL per kg
For each kg beyond 20 kg: additional 1 mL per kg

Maintenance electrolytes:

Sodium: 2–3 mEq per kg per day
Potassium: 1–2 mEq per kg per day
Chloride: 2 mEq per kg per day

Total body water (as percentage of body weight):

80% at birth
70% at 6 months
60% at 1 year
Two-thirds is intracellular fluid and one-third is extracellular.

Fluids Used for Enteral Rehydration and Maintenance

Ideally, oral fluids should have a carbohydrate concentration of 2% to 2.5%, sodium concentration of at least 70 mEq/L for rehydration and 40 to 45 mEq/L for maintenance, and potassium concentration of 20 to 25 mEq/L.

	CHO (g/dL)	Na^+ mEq/L	K^+ mEq/L	mOsm/kg H_2O Osmolarity
Pedialyte®	2.5	45	20	250
Naturalyte®	2.5	45	20	260
Rehydralyte®	2.5	75	20	310
WHO rehydration solution	2	90	20	310
Gatorade®[a]	5.9	21	2.5	377
Cow's milk[a]	4.9	22	36	260

[a]Not recommended as first-line therapies for rehydration; less effective for maintenance hydration.

PROPHYLAXIS AFTER EXPOSURE TO SERIOUS DISEASE

Tetanus Exposure

Exposure to *Clostridium tetani*, the causative organism for tetanus (lockjaw), occurs primarily through wounds incurred at a site contaminated by human or animal excreta. The first step in prevention involves thorough cleaning, irrigation, and possibly debridement of potentially contaminated wounds. A decision about the need for and extent of immunoprophylaxis should be based on the nature and severity of the wound and on the tetanus immunization status of the patient. The following table serves as a guide:

Prior tetanus toxoid immunization (doses)	Clean, minor wound	All other wounds
Infants <6 weeks old, no prior tetanus immunization	None	TIG only
Uncertain or did not complete primary series	DTaP (if <7 yr), Td (if 7–9 yr, or prior Tdap) Tdap (> 10 yr)	DTaP, Td, or Tdap *and* TIG
Primary series complete (most recent within past 5 yr)	None	None
Primary series complete (most recent between 5 and 10 yr ago)	None	Td (if 7–9 yr, or prior Tdap) or Tdap
Primary series complete (most recent more than 10 yr ago)	Td	Td (if prior Tdap) or Tdap

Primary series = minimum of 3 doses of tetanus and diphtheria containing vaccine (DTap, DTP, Tdap, DT, Td). DTaP; diphtheria, tetanus, acellular pertussis; Td, adult formulation of diphtheria, tetanus toxoid; TIG, tetanus immunoglobulin [dose: 250 U IM (intramuscularly) for all ages]. All immunocompromised patients with non clean, minor wounds should receive TIG.

Rabies Exposure

A bite or very close contact with the saliva of an animal carrying the rabies virus is considered a potential rabies exposure.

The most common animal reservoirs include bats, skunks, raccoons, foxes, and woodchucks. Dogs and cats that have been bitten by rabid animals will carry the virus in their saliva before becoming symptomatic and may transmit it to humans by bite or abrasion during this time. In the United States, the majority of rabies deaths have been associated with bat variants of the rabies virus, in most cases with no clear history of a bite. Worldwide, however, most cases result from dog bites.

The decision about when to institute prophylaxis after an exposure must be guided by the location and severity of the wound, the status of the offending animal if known, and knowledge of the local epidemiology. In the northeastern United States, for instance, rabies is prevalent in the raccoon population, with resultant fear of infection in the dog and cat population. Incarceration and observation of a biting animal for 10 days is advisable, if the offending animal is known. If a patient has closed-space exposure to bats in the home or workplace, whether or not there is history of a bite, prophylaxis with human diploid cell vaccine (HDCV) is recommended.

Active Immunization (Postexposure)

Prophylaxis should begin with thorough cleaning and irrigation of the wound.

Five doses of HDCV, 1 mL each, should be given in the deltoid muscle in adults, or in the anterior thigh in children, on days 0, 3, 7, 14, and 28* after exposure. Alternatively, purified chick embryo cell vaccine (PCECV) may be used on the same dosage schedule. Dosages are not decreased for children. Occasional allergic reactions have been reported with HDCV, particularly with booster doses.

Passive Immunization

In addition to HDCV, human rabies immunoglobulin (HRIG) should be given to patients who have had no prior immunization, in a dose of 20 IU per kg on day 0 of exposure. Most of the dose should be infiltrated around the wound and the remainder given IM, remote from the side of the HDCV administration.

Preexposure prophylaxis for those at high risk of exposure because of travel to or work in endemic areas consists of three injections of HDCV or PCECV, given IM on days 0, 7, and 21 or 28.

Meningococcal Infection Exposure

Any person who has had close contact with an index patient during the 14 days prior to onset of invasive disease should receive antibiotic prophylaxis. Chemoprophylaxis is most effective when given within 24 hours of exposure. Close contacts include household, day care center, and nursery school contacts, as well as medical personnel with exposure to oral secretions (i.e., anyone involved with intubation, suctioning, or mouth-to-mouth resuscitation).

Chemoprophylaxis

Rifampin—10 mg per kg per dose (maximum 600 mg/dose), twice a day for 2 days (infants younger than 1 month, 5 mg/kg/dose); not for pregnant women; urine and contact lenses may turn red. Consider alternative therapy in young women, using oral contraceptives.

Ceftriaxone—single IM dose of 125 mg for ages 15 years and younger and 250 mg for those older than 15 years.

Ciprofloxacin—single oral dose of 500 mg for nonpregnant contacts 18 years and older or for younger children if no acceptable alternative therapy is available.

Immunoprophylaxis

Meningococcal quadrivalent polysaccharide vaccine (groups A, C, Y, and W-135)—Current recommendations are for children 11 to 18 years of age to be vaccinated at routine 11 to 12 year health-care visits or at their earliest convenience. In addition, immunization should occur for those at increased risk of meningococcal disease including college students living in dormitories, military recruits, persons with complement deficiencies, and persons with anatomic or functional asplenia. Vaccination can be used as an adjunct to chemoprophylaxis following exposure, although serotype B is not included in current vaccines. Type-specific vaccine C is available for infants and children in Canada and Europe.

Varicella Exposure

Varicella-zoster virus (VZV) is highly contagious. Administration of the varicella vaccine is essentially free of risk, although effectiveness in preventing clinical illness if given within 3 days of exposure is not uniform.

The only assured protection for the contact is provided by varicella-zoster immunoglobulin (VZIG). Its use should be confined to those who have been exposed and who are at high risk of developing complications of varicella. In emergency medicine, this will be largely limited to those who are immunosuppressed or immunodeficient (including HIV patients). Other patients who may require treatment with VZIG include varicella exposures in the following groups: premature infants weighing less than 1,000 g and neonates born to mothers who develop the disease within 5 days before or 2 days after delivery.

The dosage of VZIG is 125 U [1.25 mL (1 vial) IM] per each 10 kg or less, up to a maximum of 625 U [6.25 mL (5 vials)].

With the advent of acyclovir as an effective modifier for varicella, it is not necessary to give VZIG to the healthy susceptible adolescents or adult patients who are exposed to the disease. Treatment of varicella and zoster infection is discussed in Chapter 92.

Pertussis Exposure

Older siblings, adolescents, and adults, often with only mild and atypical disease, can be a significant source of exposure of pertussis for infants and young children.

Maintaining high vaccination rates is the most effective means of prevention. Current immunization schedules include acellular pertussis vaccinations at 2, 4, 6, and 15 to 18 months and 4 to 6 years. Tdap booster at 11 to 18 years has recently been added. Exposed children younger than 7 years who are

*The 28-day dose is not necessary in healthy nonimmunocompromised patients except in high-risk areas.

not immunized or who are partially immunized should have immunization initiated or brought to completion.

Chemoprophylaxis for close contacts for asymptomatic household contacts within 21 days of onset of cough in the index patient can prevent symptomatic infection. Potential regimens include the following:

- Azithromycin:
  - First line in most children given equivalent efficacy, better tolerated, and no effect on liver metabolism.
  - Infants younger than 6 months: 10 mg per kg per day for 5 days.
  - Infants and children 6 months or older: 10 mg per kg (max 500 mg) on day 1, followed by 5 mg per kg per day (max 250 mg) on days 2 to 5.
  - Adults: 500 mg on day 1, followed by 250 mg per day on days 2 to 5.
- Erythromycin:
  - Cheaper, generics available
  - Infants younger than 1 month: increased risk for pyloric stenosis.
  - Dose: 40 to 50 mg per kg per day in four divided doses (max 2 g/day) for 14 days.
- Clarithromycin:
  - Infants younger than 1 month: not recommended.
  - Infants and children 1 month or older: 15 mg per kg per day (max 1 g/day) in two divided doses for 7 days.
  - Adults: 1 g per day in two divided doses for 7 days.
- Trimethoprim-sulfamethoxazole:
  - Infants younger than 2 months: not recommended.
  - Infants 2 months or older and children: trimethoprim 8 mg per kg per day, sulfamethoxazole 40 mg per kg per day in two divided doses for 14 days.
  - Adults: trimethoprim 320 mg per day, sulfamethoxazole 1,600 mg per day in two divided doses for 14 days.

Hepatitis A Exposure

Hepatitis A virus is food- and waterborne. It is also transmitted by close person-to-person contact with infected individuals, who may or may not be symptomatic, and less commonly by needle sharing and sexual contact. The hygienic measure of careful handwashing for all medical, day care center, and restaurant personnel should be followed at all times. Potentially contaminated food and water should be avoided.

Immunoprophylaxis

Routine Hepatitis A vaccination is now recommended for all children at 1 year of age, and any child 2 to 18 years of age who lives in a community with a high incidence of disease. Therefore, the number of patients requiring postexposure prophylaxis is likely to decrease in coming years.

Unimmunized household and close personal contacts and children and staff at day care centers (particularly those with diapered children) who are exposed to an index case should receive immunoprophylaxis. Household contacts of children exposed at day care center should also be treated. Exposure in schools, offices, and hospital settings do not require prophylaxis unless there has been a spread within the institution.

Prophylaxis for children older than 1 year is single-antigen hepatitis A vaccine. For children younger than 12 months or those with immunocompromised or chronic liver disease, low-dose immunoglobulin (IG) (0.02 mL/kg IM) should be given. Prophylaxis should be initiated as soon as possible, up to 14 days of exposure.

Hepatitis B Exposure

Hepatitis B virus (HBV) is transmitted by exposure to contaminated blood, semen, cervical secretions, or saliva through open wounds, needle exposure, medical management, improperly prepared transfusion, sexual activity, and maternal–child transmission.

Universal administration of HBV vaccine is begun in infancy. Medical and institutional personnel and others at high risk of exposure should also be vaccinated with HBV vaccine. There are two approved vaccines, both without thimerosal, and doses will vary for each. Higher doses should be considered for immunodeficient patients.

Postexposure prophylaxis guidelines depend on whether the source is known to be hepatitis B positive, on the immunization status of the exposed, and on whether the exposure is occupational or not. For nonoccupational exposure, anyone who is unimmunized or partially immunized and is exposed to a known hepatitis B-positive source should receive vaccination as well as Hepatitis B immunoglobulin (HBIG) at 0.06 mL per kg (minimum dose: 0.5 mL). Anyone who has completed the hepatitis B series but has not had a documented postvaccination response should receive a hepatitis B vaccine booster. For exposure to a source with an unknown hepatitis B status, immunizations series should be initiated/completed but HBIG is not required. In the occupational setting, providers are more likely to know (or can rapidly determine) their postvaccination status, and guidelines for vaccination and HBIG can be made accordingly. See *MMWR Recomm Rep* 2001;50(RR-11) and *MMWR Recomm Rep* 2008;57(RR08), the latter also available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5708a1.htm, for details on prophylaxis following occupational exposure. Where warranted, prophylaxis should be given as soon as possible, preferably within 24 hours.

Neonates born to hepatitis B surface antigen–positive mothers should receive HBV vaccine within 12 hours of birth. HBIG (0.5 mL) should be given simultaneously but at a different site.

Hepatitis C Exposure

Hepatitis C is parenterally transmitted through contaminated blood or blood products and through maternal–infant transmission. Transmission through breast-feeding has not been reported. IG prophylaxis is not recommended. No vaccine is available.

For additional information, refer to Pickering LK, ed. *Red book: 2006 report of the Committee on Infectious Diseases*, 27th ed. Elk Grove Village, IL: American Academy of Pediatrics, 2006.

HIV Health-care Occupational Exposure

Medical and dental personnel (MDP), particularly those working in emergency departments and in the various surgical and laboratory areas, are susceptible to inadvertent exposure to

HIV. This may occur (i) percutaneously (needle stick or scalpel wound); (ii) by contact of MDP skin or mucous membranes with potentially contaminated body fluid such as blood, semen, or vaginal secretions; or (iii) by direct MDP skin or mucous membrane contact with laboratory specimens. If MDP skin is previously irritated or abraded, the risks under (ii) and (iii) are increased. Actual incidents of infection under such circumstances is minimal (less than 0.3% to 0.1%).

The first step in prophylaxis is always, when possible, prevention of exposure. This is best accomplished by MDP carefully following the guidelines of appropriate handwashing, use of gloves, proper cleaning and draping for any procedure that may involve exposure, careful disposal of all needles and other disposable instruments and syringes, and effective sterilization of all reusable equipment and devices.

When exposure does occur to MDP, careful cleaning of the wound area is essential. Relevant details of the exposure should be documented in a confidential record, including date and time, job duty being performed, full details of the circumstances and nature of the exposure, and description of the source of the exposure material. An ongoing record should include details of counseling, postexposure management, and follow-up of the MDP and the individual who was the source of the exposure material.

With permission, HIV testing should be performed on the source individual and, if found negative, testing should be repeated periodically for 6 months. The exposed MDP should undergo baseline HIV testing at the time of exposure. If the source individual for the exposure material is HIV positive, becomes HIV positive, or refuses to be tested, the MDP should be retested at 4- to 6-week intervals for up to 6 months. Seroconversion usually occurs within 3 months of exposure.

Consideration should be given to early initiation of postexposure prophylaxis for the MDP when the source individual is known to be, or is at high risk for being, HIV positive. A 4-week course of two drugs should be prescribed (zidovudine plus lamivudine, stavudine plus lamivudine, or stavudine plus didanosine). A third antiretroviral drug should also be added for highest-risk exposures. The potential toxicity of the drug regimens should be balanced against the degree of risk imposed by the exposure to the MDP. A decision must be made by the MDP and personal physician after adequate and appropriate counseling and after consideration of all factors involved in weighing benefit versus risk and toxicity. Hepatitis B prophylaxis should be considered as described previously.

Further details are available at: Centers for Disease Control and Prevention. Updated guidelines for management of occupational exposures to HBV, HCV, and HIV. *MMWR Recomm Rep* 2001;50(RR-11):1–42. Also see *MMWR Recomm Rep* 2006;55(RR-16), available at http://www.cdc.gov/mmwr/preview/mmwrhtml/rr5516a2.htm..

Postexposure prophylaxis for nonoccupational exposures is discussed in Chapter 93, with additional information available at CDC: Centers for Disease Control and Prevention. Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States: recommendations from the U.S. Department of Health and Human Services. *MMWR* 2005;54 (No. RR-2).

SCORES

Glasgow Coma Scale

Older children	Infants	Points
Eye Opening		
Spontaneous	Spontaneous	4
To verbal command	To verbal stimuli	3
To pain	To pain	2
None	None	1
Best Motor Response		
To verbal command		
Obeys	Moves spontaneously and purposefully	6
To painful stimulus		
Localizes	Withdraws to touch	5
Flexion withdrawal	Withdraws to pain	4
Flexion decorticate	Flexion decorticate	3
Extension decerebrate	Extension decerebrate	2
No response	No response	1
Best Verbal Response		
Oriented and interactive	Smiles, babbles, or coos	5
Disoriented	Cries but consolable	4
Inappropriate words	Persistent inappropriate crying or screaming	3
Incomprehensible	Moans or grunts	2
No response	No response	1

AVPU

A—alert
V—responds to vocal stimuli
P—responds to painful stimuli
U—unresponsive

Note: The following two trauma scores have some limited value in determining whether to triage a pediatric trauma patient to a level I trauma center. Higher scores are generally associated with more favorable outcomes. Refer to Furnival RA, Schunk JE. ABCs of scoring systems for pediatric trauma. *Pediatr Emerg Care* 1999;15:215–223; and Narci A, Solak O, Turhan-Haktanir N, et al. The prognostic importance of trauma scoring systems in pediatric patients. *Pediatr Surg Int* 2009;25:25–30.

Revised Trauma Score

Attribute	Coded value
Respiratory Rate	
10–29	4
>29	3
6–9	2
1–5	1
0	0
Systolic Blood Pressure	
>89	4
76–89	3
50–75	2
1–49	1
0	0

Glasgow Coma Scale	
13–15	4
9–12	3
6–8	2
4–5	1
3	0

Unweighted Revised Trauma Score

Pediatric Trauma Score

Component	+2	+1	−1
Size	>20 kg (40#)	10–20 kg	>10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic blood pressure	>90 mm Hg	50–90 mm Hg	<50 mm Hg
Central nervous system	Awake	Obtunded/ loss of consciousness	Coma/ decerebrate
Skeletal	None	Closed fracture	Open/multiple fractures
Cutaneous	None	Minor	Major/ penetrating

Assign a value to each component. A score of 8 or less may suggest that care should be provided in a pediatric trauma center.

APGAR Score

Sign	0	1	2
Heart rate	Absent	<100 beats/min	>100 beats/min
Respiratory effort	Absent	Slow, irregular	Good, crying
Muscle tone	Limp	Some flexion of extremities	Active motion
Response to catheter in nostril (tested after oropharynx is clear)	No response	Grimace	Cough or sneeze
Color	Blue, pale	Body pink, extremities blue	Completely pink

To be checked on each newborn at 1 minute and again at 5 minutes after completion of birth.

Trauma Protocol

To be done simultaneously under direction of a team leader and including a recorder if sufficient personnel are available in unstable patients or those with significant risk of morbidity/mortality.

Primary Survey and Resuscitation

"A" AIRWAY—Evaluate for: adequacy of air movement, positioning, foreign material (blood or emesis), speech, midline trachea, subcutaneous air

Interventions: oral or nasopharyngeal airway, bag-mask ventilation, or intubation as needed; maintain C-spine immobilization

"B" BREATHING—Evaluate for: breath sounds, open pneumothorax, tension pneumothorax, hemothorax, flail chest, gastric distension, hypoxia

Interventions: supplemental oxygen; positive pressure ventilation as indicated

"C" CIRCULATION—Evaluate for: hemorrhage, peripheral pulses, heart sounds, capillary refill, jugular vein distension

Interventions: vascular access (venous, intraosseous), bloods for laboratory tests, including type and cross-match

"D" DISABILITY—Evaluate for: pupils, level of consciousness, AVPU, Glasgow Coma Scale and/or Revised Trauma Score, other cranial nerves, if possible

"E" EXPOSURE—Evaluate for: open wounds, penetrating trauma, front and back

Interventions: Avoid prolonged exposure, hypothermia

"F" FOLLOW—monitors, rhythm strip, catheter, nasogastric tube

"G"—blood gases if indicated

"H" HISTORY—preliminary

Secondary Survey

- Complete physical examination, ventral and dorsal, including cranial nerve check, fundoscopic examination, careful neurologic screening, abdominal examination, check for blood from penis, rectal examination, and evaluation of all open wounds
- Complete history of the current episode and medical history, if possible
- C-spine film, chest radiograph, abdominal and pelvic films; consideration of emergency ultrasound and/or computed tomography scan
- Careful splinting and wound dressing as indicated
- Continuous reevaluation and ongoing monitoring.

APPENDIX D ■ PARENTAL INSTRUCTION SHEETS

NANETTE C. DUDLEY, MD

ABSCESS/MRSA

Your child has an abscess. An abscess is a skin infection that has a collection of pus. Larger abscesses are drained and the pus removed. Most abscesses are treated with antibiotics. The *Staphylococcus aureus* causes most abscesses and the term MRSA (methicillin-resistant *S. aureus*) is used if the bacteria is resistant to many antibiotics. This bacteria can spread to family members and close contacts. Your child will need close follow-up until he/she is better.

Your antibiotic is _____
Your follow-up is _____

Home Treatment

1. Keep any draining wound covered with a clean, dry bandage. If a drain was placed, do not remove it and follow-up with your child's doctor as recommended to remove it or have the abscess checked.
2. Wash your hands and your child's hands with soap and water or hand sanitizer after touching the infected area or any item with drainage from the wound.
3. Wash and dry thoroughly any towels, clothes, bedding that touches the skin, and do not share bar soap or razors.
4. Do not allow your child to play sports, return to day care, or be part of any activity with skin-to-skin contact until the wound is healed.

Call your Doctor or Return to the Emergency Department If:

1. Your child has fever, looks sick or is extremely irritable or lethargic.
2. The wound seems more painful, has spreading redness, looks more swollen.
3. You think your child is not improving or is getting worse after 2 to 3 days of antibiotics.

To Prevent Spreading the Bacteria to Others in Your Family

1. Do not share anything that comes in contact with the infected skin (bath products, athletic equipment, sheets/towels, etc.).
2. Clean surfaces and equipment (doorknobs, light switches, counters) touched by bare skin with a disinfectant (Lysol® or Pine-Sol® or similar product) that says it works for *S. aureus* on the label.
3. Discard all old razors and toothbrushes.
4. Your doctor may want to try using medicine or a cleansing routine to get rid of the staphylococci in your household. These treatments do not always work, but to have the best result **all household** members need to be treated at the same time. Your doctor recommends:

_____
_____

ANIMAL BITES

Your child was bitten by an animal. This can be frightening to some children, and your child may need some extra comfort to feel better. Your doctor suggests the following if needed for comfort.

The examining doctor cleaned the bite wound. The doctor may have given you instructions to clean the wound at home. They are:

_____
_____

[ ] Your child was given a **tetanus** shot in the emergency department (ED). Show this to your child's doctor to update his/her records.

_____

[ ] Your doctor has decided that **antirabies** treatment is needed. Your child was given the first injection (shot) today. He/she will need to return to the ED for the rest of the shots. The 28th day injection is only necessary under certain circumstances.

3rd day_____ 7th day_____ 14th day_____
28th day*_____

If your child gets a fever or the needle site is red or swollen, call your doctor. All the shots must be given to protect your child.

[ ] Your doctor has given your child a prescription for **antibiotics.** Not all bites need antibiotic treatment. Your child must take all the medicine as directed. Your dose is:

_____

Signs of Infection

Call your doctor or return to the ED if any of these signs develop after your visit:

1. Increased redness around the bite
2. Pain
3. Discharge or pus from the bite
4. Increased swelling
5. Bad smell
6. Fever

ASTHMA

Children with asthma have a reactive airway. The tubes that carry air to the lungs and the small passages in the lungs are sensitive to many things. When triggered, the airways react by getting smaller, swelling, and forming mucous plugs. This reaction can occur with colds and viruses; with exposure to pets, dust, odors, or allergens; or with exercise and emotional stress. The treatment your child received in the ED helps open the airways and reduce the swelling.

Asthma is a condition that can affect your child for many years. Identifying something that triggers wheezing in your child may help avoid future episodes. **No smoking** should be allowed in the house because smoke irritates the airways of all children with asthma or respiratory illness. Your child can return to school if he/she is feeling better. If medicine needs to be taken at school, talk with your doctor and the school nurse. If an older child uses an inhaler, get permission for him/her to carry it. Your child can participate in gym class but may need to be excused during a cold if coughing or mild wheezing is present. If your child has multiple episodes of asthma, he/she should wear a medical alert bracelet.

Home Treatment

1. If your child starts wheezing, keep him/her calm or playing quietly. Excitement and physical activity can make the wheezing worse.
2. Give the medicine as prescribed. Talk with your doctor about an **asthma action plan** giving you instructions on how to manage your child's asthma to prevent future episodes.
3. Home treatment can be a combination of both quick relief medicine and medicine for long-term control of asthma.
4. Do not run out of the medicine. Make sure you always have refills.
5. Over-the-counter medicines often do not work in asthma. Call your doctor before giving your child a nonprescription medicine.

Your doctor has prescribed the medicine below:

Quick Relief Medicine _____ *(works fast)*

Inhaler

[ ] Use _____ puffs_____ inhaler _____.

[ ] Use a spacer with the inhaler to help your child get all the medicine.

Nebulized Medicine (Aerosol)

[ ] Give _____ by aerosol _____.

Steroids (used to decrease airway swelling)

[ ] _____

Long-term Control Medicine (used regularly, helps keep asthma "under control")

[ ] _____

_____

Call Your Doctor or Return to the Emergency Department If:

1. Your child has increasing shortness of breath or trouble breathing.
2. Your child is breathing hard or fast.
3. Your child looks blue or passes out (**call an ambulance immediately, do not drive yourself**).
4. Your child looks sick or anxious.
5. You have any questions or concerns.

BRONCHIOLITIS

Children with bronchiolitis have an infection with a virus that produces wheezing and trouble breathing. The tubes that carry air to the lungs and the small passages in the lungs themselves are infected by the virus. The symptoms can last a few weeks. This condition causes the most problems in young babies (younger than 3 months), children with heart or lung problems, and babies who were premature or have other medical problems. Breathing cigarette smoke can make your baby worse. The most common virus causing bronchiolitis is the respiratory syncytial virus (RSV) but other viruses lead to similar illness. Because it is a virus, antibiotics do not help. We do try to make children more comfortable and help them breathe easier. Your doctor has decided that your child can be treated at home, but we know that this infection can sometimes worsen. If you think your child is getting worse, you need to return to the ED.

Home Treatment

1. If your child starts wheezing, keep him/her calm or playing quietly. Excitement and physical activity can make the wheezing worse.
2. Run a vaporizer in your child's room. (We prefer a cool mist vaporizer to avoid the risk of burns.)
3. If your child's nose is stuffy you may use a bulb syringe and salt water drops to suction the mucus.
4. Encourage fluids.
5. Over-the-counter medicines often do not work in bronchiolitis. Check with your doctor before giving your child a nonprescription medicine.

Sometimes breathing treatments with asthma medications that open the airways help children breathe easier. Sometimes these treatments do not help. If your doctor prescribes breathing treatments, he/she believes these will help. Use them as instructed. However, if you do not think the treatments are helping and your child has trouble breathing, please return to the ED.

Your doctor has prescribed the medicine below:

Inhaler

[ ] Use _____ puffs _____ inhaler _____.

Use a spacer with the inhaler to help your child get all the medicine.

Nebulized Medicine (Aerosol)

[ ] Give _____ by aerosol _____.

Other Medicines

[ ]_____

_____

_____

Call Your Doctor or Return to the Emergency Department If:

1. Your child has increasing shortness of breath or trouble breathing.

2. Your child is breathing fast (faster than 60 times per minute).
3. Your child stops breathing (even without turning blue) or seems tired or lethargic.
4. Your child is unable to drink (often a sign of trouble breathing).
5. Your child looks blue or passes out (**call an ambulance immediately, do not drive yourself**).
6. Your child looks sick or anxious.
7. You have any questions or concerns.

BURNS

Your child was treated for a burn. Burns occur when the skin is injured by contact with heat, fire, chemicals, or electricity. Your child has a clean dressing on the burn to protect it and prevent infection. For some burns, it is important to schedule a recheck in 24 to 48 hours to reassess the depth of the burn injury. Other burns can be cared for at home. Your doctor's instructions are:

_____

Your child may have received a tetanus booster in the ED. If so, notify your child's doctor to update his/her records.

How to Change the Dressing at Home

1. Wash your hands thoroughly with soap and water.
2. Remove the old bandage. If it sticks, you can soak it for a few minutes in warm (not hot) water.
3. Wash the burn with warm, soapy water.
4. Rinse and pat dry with a clean towel.
5. With a sterile tongue depressor, apply the antibiotic _____ to the burned area in a thin layer. Do not reuse a dirty tongue depressor.
6. Carefully rewrap the burn with a sterile bandage as directed by your doctor.

Signs of Infection

1. Increasing redness or red streaks around the burn
2. Swelling
3. Pain
4. Yellow pus or discharge
5. Fever

If you notice any signs of infection, call your doctor immediately or return to the ED.

Pain

Acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Advil®, Motrin®) can be used for pain. Table D.1, Table D.2. If your child was given a prescription for a different pain medication, you should use that medication as prescribed. Speak with your doctor about timing the dose with the dressing changes to relieve pain. Your medication is: _____

Exercise/Physical Therapy

Your doctor may have directed your child to perform certain exercises or physical therapy to help maintain or regain use of the burned area. Please ask your doctor if you have questions about the exercises or if you think your child is becoming stiff or tight around a burned area.

Long-term Care

Once the skin has healed, apply a lubricating cream or lotion to the burned area. This treatment will keep it soft and decrease itching. Avoid extremes of heat or cold for 1 year after the burn. Avoid direct sunlight for 1 year after the burn and apply a sunscreen to any burned areas to protect the new skin.

CAST OR SPLINT CARE

Your child has a serious injury or fracture that the doctors want to keep quiet and immobile in a cast or splint. A cast completely covers the injured body part with solid fiberglass or plaster. A splint has a hard frame, but some areas are not covered by a hard surface and are wrapped with padding or an ace wrap only. A splint is often put on right after an injury to allow for swelling and rechecking the injury site.

What to Do in the First 48 Hours

1. Keep the injured area with the cast elevated as much as possible to prevent swelling.
2. If your child has a splint and there is a lot of pain or the fingers or toes are cold and pale, unwrap the bandage wrap to relieve the pressure from swelling. If this helps, rewrap it a little looser. If this does not help, rewrap the splint, call your child's doctor or return to the ED.
3. Give ibuprofen (e.g., Motrin®, Advil®) every 6 hours as needed for pain. Your child's dose is:

_____

[ ] Your child may need additional pain medicine. Your doctor has written a prescription for:

_____

General Cast or Splint Care

1. Do not allow your child to walk or put weight on the cast unless your doctor specifically tells you to do this.
2. Keep long arm casts in a sling at all times, except when sleeping.
3. Do not get the cast wet unless you are told this is okay.
4. Do not allow your child to place objects inside the cast.
5. Do not use devices such as knitting needles, coat hangers, and so forth to scratch underneath the cast.
6. Your child can take a bath if the cast is covered with a plastic bag and kept above the water.
7. Keep the skin around the cast edges clean and dry. You can put rubbing alcohol on the skin near the cast edge to prevent irritation.

8. If the cast edge feels rough, you can put adhesive tape around it or "petal" around the edge with moleskin. Ask your doctor or nurse how to do this.
9. If your child is unable to go to school, have his/her teacher provide homework assignments and ask for a tutor, if necessary.

Return to the Emergency Department or See Your Orthopedic Doctor If:

1. Your child's fingers or toes feel numb or cold, look blue or pale, and unwrapping the splint does not help.
2. Your child complains of tingling, tightness, or worsening pain in the injured arm or leg.
3. There is pain under the cast in one spot, or pain anywhere for no apparent reason.
4. It hurts your child to move the fingers or toes.
5. Your child has a fever.
6. You smell a bad odor coming from the cast.
7. The skin around the cast edge is red or irritated.
8. The cast gets soft or cracked.
9. The pain medication does not make your child feel better.

[ ] *Use of Crutches*

1. Help your child walk with crutches as demonstrated. Do not allow him/her to put weight on the cast unless told to do so.
2. Help your child go up and down stairs until you are comfortable he/she can do it well.
3. Do not have your child rest his/her underarms on the crutches. Putting weight on the underarms can cause nerve damage.
4. Always use crutches with rubber tips, and wipe the tips dry if they get wet so they are not slippery.

COMMON COLD (UPPER RESPIRATORY INFECTION)

The common cold is an infection of the nose and throat that is usually caused by a virus. It can make your child have sneezing, coughing, fever, and not feel well. Cold symptoms can last as long as 7 to 10 days. Colds spread from person to person by coughing or direct breathing and when people do not wash their hands well after blowing their nose or sneezing. Over-the-counter cold medicines do not "cure" a cold and do not help cold symptoms for children. They can have dangerous side effects and are not recommended at all for children younger than 2 years. Your child can return to school or day care when he/she feels well and does not have a fever. During cold season, send your child to school with a pack of tissues and hand sanitizer to help prevent spreading infection.

Home Treatment

1. Home treatment is aimed at keeping your child comfortable. If your child is uncomfortable or looks sick, he/she may need to see a doctor for a reexamination.
2. Encourage your child to drink plenty of fluids such as juice, soda, or Kool-Aid®. Do not force him/her to eat because it may cause vomiting. Your child may not feel like eating, but it is important that he/she drinks to prevent dehydration. If your child is interested in his/her regular diet, that should be encouraged.
3. Warm liquids sometimes ease a sore throat and help open a clogged nose. Grandmother's chicken soup may be the perfect meal for a child with a cold!
4. For nasal congestion (runny nose), you can use salt water drops to loosen the mucus. These drops should be used before feeding your child and at bedtime, but they can also be used in between if you think your child's nose is clogged and he/she has trouble breathing. You can buy saline (salt water) drops at the grocery or drug store or make your own.

   To make salt water drops:
   Mix ¼ tsp salt with ½ cup warm water. If you have a clean medicine bottle, you can store this solution for 24 hours (label it salt water). If you do not have a clean bottle, throw away the salt water after each use.

   Using a medicine dropper, put two drops of the salt water in one nostril. Have your child lying flat when you do this. You may want to support his/her neck or shoulders with a rolled-up towel. Wait 30 to 60 seconds before suctioning the mucus with a rubber bulb syringe. Squeeze the air out of the bulb, put the tip of the bulb into the nostril. Let the air come back into the bulb, and the suction will pull the mucus out of the nose. Squeeze the mucus out of the bulb onto a tissue.

   Repeat this process with the other nostril. Do not do this more often than six times per day. In young infants, the best time to do this is often before meals or a bottle. Wash the bulb syringe in warm soapy water after each use. Squeeze it in the water to clean the inside.
5. Do not use over-the-counter cold medicines without discussing this with your doctor first. **Do not use an adult cold medicine for a child!**
6. Use a cool mist vaporizer in your child's room. This will moisten the air and help loosen your child's nasal secretions. We prefer a cool mist vaporizer to avoid the risk of burns. Do not add medicine to the vaporizer; use plain water. Wash the vaporizer as instructed after each use.
7. Give acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Advil®, Motrin®) if your child has a fever. Your dose is: _____

Call Your Doctor or Return to the Emergency Department If:

1. Your child has trouble breathing or starts wheezing.
2. Your child gets a new fever higher than 102° F (38.5° C) [or higher than 100.5° F (38.0° C) if your baby is younger than 6 months].
3. Your child has trouble swallowing.
4. Your child is not drinking well or you think he/she is dehydrated (dry).
5. Your child complains of ear pain or you have concern of an ear infection.
6. Your child is sleepy or lethargic.
7. Your child looks sick.
8. You have any questions or concerns.

CONCUSSION

Your child was diagnosed with a concussion. A concussion is a head injury that causes symptoms of neurologic (brain)

dysfunction. Usually with a concussion, images of the brain (CT or MRI) are normal and often not necessary. Your child's symptoms may include confusion, headache, amnesia, dizziness, unsteadiness or incoordination, nausea and vomiting, problems concentrating or focusing, problems sleeping, mood or behavior changes, and problems with speech. Rest is an important part of treatment. Children who are reinjured in the week or so after a concussion can occasionally have more serious problems if the return to full activity after the first injury was premature. Having more than one concussion may put your child at risk for life-long problems, so it is important to wear helmets and other athletic equipment to prevent future head injuries.

Home Treatment

1. Quiet activities and rest from both physical and mental exertion (including videogames or school) is recommended after a concussion.
2. Acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Motrin®, Advil®) may be given for headache.
3. Clear liquids should be given if your child is nauseous or vomiting.
4. Ice can be applied to any areas of swelling or bruising on the scalp.

Return to Play

When your child returns to sports, physical activity, or school, depends on his/her symptoms and whether this is a first concussion or if your child has had other concussions. A doctor should examine your child before allowing him/her to participate in contact or competitive sports. At minimum, your child should be completely symptom free (both at rest and when active) for at least 1 week before being allowed to participate in competitive sports. A slow return to full activity is recommended before returning to a specific sport. Your doctor has written specific instructions for your child's concussion and return to play:

_____

Call Your Doctor or Return to the Emergency Department If:

1. You are unable to awaken your child or he/she seems more sleepy or confused.
2. Your child has severe or worsening headache.
3. Your child has a seizure.
4. Your child has continued or worsening vomiting, fever, or neck stiffness.
5. Your child loses control of urine or stool.
6. Your child has weakness or numbness of the face or an arm or leg.
7. Your child has trouble walking, seems more unsteady.

CONJUNCTIVITIS (PINK EYE)

Conjunctivitis is an infection or irritation of the outer part of the eye. It makes the "white" of the eye appear pink or red and is commonly called pink eye. It can be caused by allergies or infections from viruses (most common) or bacteria. Most pink eye is contagious. All members of your household should wash their hands carefully, and other children should not touch your child's eye. Your child should have his/her own washcloth and towel. Whenever you touch his/her eye, you must wash your hands.

Treatment

1. Clean any pus or drainage with a warm, wet washcloth or cotton ball.
2. Your doctor may have prescribed antibiotic drops or ointment. Place this medicine in your child's eyes as directed by the doctor. Do not use the same medicine for other people in the house. Have them examined by a doctor and given their own medicine. Your medicine is:

   _____
3. Try not to get the medicine in the other eye if it is not affected.
4. Do not use the medicine longer than directed. If the infection persists, see your doctor.

Call Your Doctor If:

1. The eyelids get red or swollen.
2. Your child has trouble seeing or blurry vision.
3. Your child gets a fever or looks sick.
4. The infection is not better in 2 to 3 days.
5. You have any other questions or concerns.

CONSTIPATION

Constipation is the delayed or difficult passage of hard, dry stools. They usually hurt or cause pain when they are passed. There are no rules about the number of stools a child needs to have in a day or week. As long as your child has soft stools, he/she probably is not constipated. It can be normal for babies or small children to grunt, strain, and even cry while they are having a bowel movement. It can also be normal for a baby to go a few days without a bowel movement. Each child develops a pattern of his/her own.

The doctor who examined your child decided that he/she is constipated. Most constipation can be treated by some **dietary changes.**

1. If your baby is younger than 4 months, add 1 to 2 oz of apple, prune, or pear juice to your baby's diet each day until stools are soft and regular. Constipation is very rare in breast-fed babies; talk with your doctor if you breast-feed. Do not continue the juice for more than 1 week without checking with your doctor. You can also move your baby's legs in gentle bicycle motions if you think he/she is having trouble passing a hard stool.
2. If your baby is older than 4 months, give him/her one 4-oz bottle of apple, prune, or pear juice per day, and encourage fruits and vegetables if he/she has begun taking baby food.
3. If your child is eating table food:
   a. Increase the amount of fruits and vegetables he/she eats. Adding raw ones provides increased "roughage."
   b. Increase the bran content of his/her foods. Feed your child bran cereal, bran muffins, oatmeal, and whole wheat bread if possible.

c. Make sure your child drinks enough fluids, encourage 4 to 6 oz apple, prune, or pear juice each day.

4. Some children have severe constipation or a long-term problem that needs additional help with medication. Your doctor has written any additional instructions below.

_____

_____

Additional Tips

If your child complains of pain with a bowel movement, he/she may have a small tear or fissure in the rectal area. You can put Vaseline® or a protective diaper cream in this area to allow it to heal.

Give older constipated children protected time at least twice each day for toilet sitting. Your child should be able to sit on the toilet for about 15 uninterrupted minutes two times per day. After meals is the best time for your child to sit on the toilet.

Exercise also helps improve constipation, and you and your child may want to participate in activities together.

Call Your Doctor If:

1. The constipation does not improve in 2 weeks.
2. Your child has severe abdominal pain or vomiting.
3. You see more than a few drops of blood in the stool.
4. Your child begins losing control of bowel movements or soiling his/her underwear.

Final Note: Although you may reward your child for a successful bowel movement, never punish your child for not having a bowel movement or for soiling his/her underwear.

CORNEAL ABRASION

Your child has a scratch on the cornea, which is the outer surface of the eye. The doctor who examined your child put some drops in the eye. These drops ease the pain and prevent the scratch from getting infected. Some doctors will place a patch over your child's eye. This helps protect the eye from further injury and allows it to rest while it heals. We understand that some children try to remove the patch. If this occurs, the scratch should still heal without a problem. Pain medication (Tylenol®, Motrin®, or Advil®) may help your child. Most corneal abrasions will heal overnight.

It is **very important** to be checked within a day or two to see if the scratch is healed. An infected scratch or one that does not heal well can cause a permanent scar on the surface of the eye. Your doctor has arranged the following follow-up: _____

Call us if you have any questions or concerns.

CROUP

Croup is a swelling of the upper airway in the area commonly called the windpipe and voice box, or more technically, the trachea and larynx. Most children with croup have a virus, and some children are likely to get croup more than once. Croup is worse at night and during sleep in infants and better during the day. It usually lasts about 5 days.

Children with croup may have a fever and cold symptoms. The cough is harsh like a barking dog or seal. The noisy breathing is called stridor and is caused by the narrowing of the airway from the swelling.

Treatment

[ ] A steroid medicine dexamethasone (Decadron®) can help with the airway swelling in croup. Your doctor has decided to use this medicine for your child. Your dose is: _____

Home Treatment

1. Stay calm and keep your child calm. It can be frightening when your child has trouble breathing, but if he/she is anxious or crying, it will make things worse.
2. Use a cool mist vaporizer in your child's room to humidify the air. Do not use a hot steam vaporizer because it could burn your child if he/she gets too close.
3. Prop your child's head up with a few pillows, or sit up with him/her. Your child may find his/her own position that makes breathing easier, but sitting up often helps.
4. Give acetaminophen (e.g., Tylenol®) for fever. Use a suppository if your child has trouble breathing or is throwing up.
5. Encourage your child to drink clear liquids. Do not force your child to eat if he/she does not want to eat or has difficulty in breathing.
6. If your child's breathing sounds worse or the noisy stridor is louder, turn on the hot water in the bathroom shower or sink. Close the door and let the room steam up. Take your child in the bathroom with you and sit down for about 15 minutes. Keep your child occupied by reading to him/her or playing with toys. **Stay calm!**
7. Sometimes cool air will also help your child. If the steamy bathroom does not help, you can dress your child for the outdoors and then take him/her outside for 10 minutes.

Return to the Emergency Department Immediately If:

1. Your child has trouble breathing, is using his neck or abdominal muscles to breathe, is pulling in his chest to breathe.
2. Your child looks pale or has blue areas around the mouth/lips, fingernails, or toenails.
3. Your child passes out.
4. Coughing is continuous, or there is no improvement after mist or cool air is tried.
5. Your child is uncomfortable or unable to sleep.
6. Your child is drooling or has trouble swallowing.
7. Your child has a high fever [greater than 102° F (38.5° C)].
8. Your child seems to be getting tired of breathing.
9. You have any concerns or the child is rapidly getting worse.

Transport your child yourself if you have your own car, the drive is less than 15 minutes, and your child seems comfortable and stable. When driving with a sick child, have two people in the car, one in the back with the child and one in front driving. Keep the child in his/her car seat. Open the windows and allow some cool air inside. **Call an ambulance if your child has trouble breathing, is passed out, looks blue, or is getting worse.**

DIAPER RASH

A diaper rash is usually caused by irritation of the baby's skin from contact with urine or bowel movements. Sometimes the skin can also be infected with yeast or bacteria, and your doctor will let you know if your baby has an infection.

Treatment of Diaper Rash

1. Keep the baby's bottom as clean and dry as possible. Change the diapers often. Wash the diaper area gently with soap and water at each change and pat dry. Avoid premoistened wipes while the rash is present because they may irritate and sting.
2. Leave the diaper off, if you can, to allow the air to dry and heal the rash. This can best be done at naptime with your baby lying on his/her back on an open diaper.
3. If your doctor ordered a protective ointment, you should apply this with each diaper change. Medicated ointments or creams should be used as prescribed.

   _____
4. Do not use talcum powder or baby powder because it can injure your baby's lungs if inhaled.
5. Avoid plastic pants if possible. They trap in moisture and make the rash worse. If you use cloth diapers, consider changing to disposable while your child has a rash.

Call Your Doctor or Return to the Emergency Department If:

1. Your baby develops a fever.
2. The rash does not appear to be improving after 5 to 7 days.
3. The rash is getting worse or pimples or blisters develop in the diaper area.
4. You are concerned about your baby.

EAR INFECTIONS

Your child has an ear infection, which is an infection of the middle ear, the space behind the eardrum. Ear infections can be caused by viruses or bacteria and are more common in the winter months. An ear infection is not contagious, but it can start as a cold. The germs in the throat or nose migrate into the middle ear. Fluid also can build up in the middle ear and swelling from a cold prevents it from draining into the throat. The combination of germs and fluid becomes an infection and pus is produced, putting pressure on the eardrum and causing pain. If your child has drainage from the ear, this may mean the eardrum has torn. The small tear in the eardrum will heal itself if the infection is treated. However, if fluid stays behind the eardrum for long periods, your child may have hearing problems. Any child with hearing problems or problems with speech/language should follow up with his/her doctor to make sure the fluid is gone. Your child can return to school or day care as soon as he/she is feeling better.

Treatment

1. **Pain and Fever:** Your child may have a fever or some ear pain. Acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Motrin®, Advil®) will treat this pain. Your child's dose is:

   _____.

   Your doctor may also give you drops to numb the eardrum and help the pain. These drops should not be used if there is fluid draining out of the ear. Your instructions are:

   _____.
2. **Observation:** Ear infections caused by viruses may get better without antibiotics. If you and your doctor decided to watch your child without antibiotics, then you can still use medicine for pain and fever to help your child. Your child should get better in 2 to 3 days, and if not getting better you need to follow up with your doctor.
3. **Antibiotics:** Ear infections are often treated with antibiotics. The fever and pain may continue for 2 to 3 days after starting the antibiotic. Some antibiotics cause diarrhea. If the diarrhea is severe or you think your child is getting dehydrated (not urinating well, not drinking well, no tears when crying), see your doctor. If your child gets a rash, he/she may be allergic to the antibiotic. See your doctor. Your dose of medicine is:

   _____.

   Give your child the antibiotic prescribed, even if your child feels better. The full course is needed to kill the infection. Keep all medicines out of reach of small children.
4. **Ear Drops:** Your doctor may give you ear drops to treat an infection in the ear canal or external ear. Have your child lie on your lap with the infected ear up. Put drops in the ear canal and massage in front of the ear to help the drops fall into the canal. Do not put anything else in the ear canal. Ear drops: _____. Use the drops _____ times per day for _____ days.
5. **Follow-up:** Follow-up with your regular doctor in 2 to 3 days if your child is not feeling better (still has pain, fever, or ear drainage).

Call Your Doctor or Return to the Emergency Department If:

1. Your child looks sick or fever continues for more than 2 days after starting antibiotics.
2. Your child has a new drainage from the ear.
3. Your child gets a rash.
4. Diarrhea becomes severe or you think your child is dehydrated (dry).
5. Your child is sleepy or lethargic, or if you have any questions or concerns.

ECZEMA (ATOPIC DERMATITIS)

Eczema is common. Children with eczema may have a family history of allergies, hay fever, or asthma. All children with eczema have dry skin. Keeping your child's skin moist, and avoiding skin irritants will help control the eczema. Eczema usually improves as your child gets older.

Avoiding Skin Irritation

1. Avoid wool or synthetic clothing because it can be irritating. Dress your child in cotton when possible, and try to keep his/her arms and legs covered (tights or long pants, long-sleeve shirts).
2. Keep your child's room free of dust, and keep the air moist with a cool mist vaporizer or humidifier.
3. Wash your child's clothes in a mild detergent and avoid fabric softeners that can be irritating.

Skin Care

1. Do not overdo bathing. A **short** daily bath is fine, but your doctor may recommend changing to every other day baths.

Use a mild soap with moisturizer. Avoid deodorant soaps or those with scents. Avoid vigorous scrubbing, and bathe in warm, not hot, water. Do not use bubble baths. After bathing, pat dry and apply any medicated creams or moisturizing creams immediately (within 3 minutes) to seal in the moisture.

2. Your doctor may have prescribed a cream for specific areas. Apply this medicated cream as directed to those areas.
   Apply _____
3. After applying the medicated cream, apply a general moisturizing cream or ointment to your child's entire body. Apply this moisturizer two times per day, *everyday*.

   _____
4. If itching is a problem, your doctor may prescribe a medicine to be used for a short period.

   _____

These medicines can make your child sleepy and teenagers should not drive a car while taking this medicine. Keep your child's fingernails cut short if scratching is a problem. Some children need to wear socks on their hands when they go to sleep to keep them from scratching.

Call Your Doctor If:

1. The eczema is red or irritated looking, your child develops sores or scabs or painful lumps, or your child gets a fever.
2. You think the eczema is not under good control.
3. You have any questions or concerns.

FEBRILE SEIZURE

A febrile seizure is a "fit" or "convulsion" that occurs with a fever. Most children who have febrile seizures outgrow them by 4 to 5 years of age. Having a febrile seizure does not mean that your child has brain damage or will be delayed. They are fairly common, often happening in the first day of a fever and are not related to development of a seizure disorder or epilepsy. There is a chance, however, that your child may have another seizure when he/she has a fever.

When your child becomes sick, the suggestions below will help you control the fever and prevent a seizure:

1. Give acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Advil®, Motrin®) in the correct dose for your child's age. Table D.1, Table D.2 Acetaminophen can be given every 4 hours, ibuprofen every 6 hours while your child's temperature is 101° F (38.0° C) or higher.
2. Do not bundle or overdress your child. The body loses heat through the skin, and if you bundle him/her, the excess heat cannot escape.
3. Sponge your child with lukewarm water or put him/her in a shallow tub containing 2 to 3 in of water and drip water over his/her body. **Do not** use alcohol or cold water to bring your child's fever down. If your child begins shivering or shaking, stop sponging and remove him/her from the bath water.
4. While your child has a fever, give plenty of fluids to prevent dehydration.
5. Give any medications prescribed by your doctor.
   Your child may have another febrile seizure because they can occur before you realize your child is ill.

If Your Child Has Another Seizure:

1. Stay calm.
2. Do not put anything in your child's mouth.
3. Place your child on his/her side to help drain secretions.
4. Loosen clothing.
5. Do not try to hold your child still. Move objects away from your child so he/she does not get hurt.
6. Support your child's head with a pillow or soft object.

Call an ambulance if the seizure is lasting longer than 5 minutes or if your child has difficulty breathing or looks blue. Otherwise, once the seizure stops, call your doctor for further instructions or bring your child to the office or ED for a physical examination. Your child may be sleepy after the seizure and need to be checked by a doctor for the cause of the fever.

FEVER

Your child has a fever. This means the body temperature is above normal. In the mouth, normal temperature is 98.6° F (37° C); under the arm, normal is 98° F (36.6° C); and by rectum, normal is 100° F (37.7° C). A fever is the body's way of fighting an infection and is not always a bad thing. You only need to treat the fever if it is high [greater than 102° F (38.5° C)] or if your child is uncomfortable. The height of the temperature does not indicate how severe the illness is that causes the fever. Your child should see a doctor if you have any concerns.

What to Do to Keep Your Child Comfortable

1. Dress your child lightly to be comfortable in your home's temperature. Do not overbundle or use heavy blankets because this will raise your child's temperature further. A T-shirt and underwear or diaper with a light sheet or blanket is fine for sleeping.
2. Encourage plenty of liquids. Your child may not be hungry but it is important that he/she continues to drink and does not get dehydrated.
3. Keep the room around 70° F if possible. In the winter, do not overheat, and in the summer, use a fan or air conditioner if available.
4. Acetaminophen (e.g., Tylenol®) lowers fever. Your pharmacy may sell acetaminophen as a generic fever product. This is just as effective and may cost less. Check your child's temperature before giving the medicine. The dose can be repeated every 4 hours. Table D.1

   If your child is vomiting or does not like to take medicine, you can buy acetaminophen suppositories at your pharmacy without a prescription. Ask your doctor or nurse about how to use a suppository.
5. Ibuprofen (e.g., Advil®, Motrin®) may also be used for fever control in children 6 months and older. The dose can be repeated every 6 hours. Table D.2
6. Do not use aspirin for fever control in children.
7. Sponging your child with lukewarm water will also lower his/her temperature but is not as helpful as fever medicine. Do not use alcohol or add alcohol to a bath. Never leave your child alone in a bath. If your child starts shivering,

TABLE D.1

ACETAMINOPHEN DOSAGE BY AGE AND WEIGHT

Age	Weight (lb)	Drops[a] (80 mg/0.8 mL)	Liquid (160 mg/5 mL)	Chewable (80 mg)	Junior Caplet, Junior Chew (160 mg)
0–2 mo	Consult your doctor right away				
2–3 mo	6–11	½ dropper			
4–11 mo	12–17	1 dropper	½ tsp		
12–23 mo	18–23	1½ droppers	¾ tsp		
2–3 yr	24–35	2 droppers	1 tsp	2 tablets	1 tablet
4–5 yr	36–47	3 droppers	1½ tsp	3 tablets	1½ tablets
5–8 yr	48–59	4 droppers	2 tsp	4 tablets	2 tablets
9–10 yr	60–71		2½ tsp	5 tablets	2½ tablets
11–12 yr	72–95		3 tsp	6 tablets	3 tablets

[a]Use the dropper that comes with the acetaminophen bottle. Other droppers may be of a different size.

take him/her out of the bath and dry off. Shivering can raise the body temperature.

Call Your Doctor or Return to the Emergency Department If:

1. Your child is younger than 6 months and has a fever greater than 101° F (38.2° C).
2. The fever continues for more than 2 additional days without other symptoms.
3. Your child has the fever with other symptoms—rash, trouble breathing, ear pain, headache, stiff neck, vomiting, diarrhea, joint swelling, or pain.
4. Your child acts sick, is irritable, sleeps a lot, stops playing, or does not eat or drink.
5. You have any questions or concerns.

FEVER LESS THAN 2 MONTHS

Your baby has a fever. This means the body temperature is above normal. We worry about young babies with fever because they can have more trouble fighting a serious infection, and it is harder for parents and doctors to tell when they are getting sick. Your baby was evaluated in the ED and the doctor decided he/she could be cared for at home. You should follow-up as instructed.

What to Do to Keep Your Baby Comfortable

1. Dress your child lightly to be comfortable in your home's temperature. Do not overbundle or use heavy blankets because this will raise your child's temperature further. A T-shirt and diaper with a light sheet or blanket is fine for sleeping.
2. Encourage plenty of liquids. It is important that he/she continues to drink and does not get dehydrated.
3. Keep the room around 70°F if possible. In the winter, do not overheat, and in the summer, use a fan or air conditioner if available.
4. Acetaminophen (e.g., Tylenol®) lowers fever. Your pharmacy may sell a generic fever product with acetaminophen. These are just as effective and may cost less. Check your baby's temperature before giving the medicine. The dose can be repeated every 4 hours.

   Your baby's dose is: _____

   Use the dropper that comes with the acetaminophen bottle. Other droppers may be of a different size.

TABLE D.2

IBUPROFEN DOSAGE BY AGE AND WEIGHT

Age	Weight (lb)	Drops[a] (50 mg/1.25 mL)	Liquid (100 mg/5 mL)	Chewable (50 mg)	Junior Caplet (100 mg)
0–6 mo	Consult your doctor before using				
7–11 mo	15–17	1½ droppers	¾ tsp		
12–23 mo	18–23	2 droppers	1 tsp		
2–3 yr	24–35	3 droppers	1½ tsp	3 tablets	
4–5 yr	36–47	4 droppers	2 tsp	4 tablets	
6–8 yr	48–59		2½ tsp	5 tablets	2½ tablets
9–10 yr	60–71		3 tsp	6 tablets	3 tablets
11–12 yr	72–95		4 tsp	8 tablets	4 tablets

[a]Use the dropper that comes with the Ibuprofen (Advil®, Motrin®) bottle. Other droppers may be of a different size.

5. Follow-up is usually arranged with your physician or the ED within 24 hours of this visit. **Your follow-up is:** _____

Return to the Emergency Department If:

1. The fever continues for more than 2 additional days without other symptoms.
2. Your baby has other symptoms—rash, grunting or trouble breathing, stiff neck, vomiting, diarrhea, or pain.
3. Your child acts sick, is irritable, sleeps a lot, or does not drink.
4. You have any questions or concerns.

HEAD INJURY

The doctor who examined your child determined that he/she can safely be observed at home. You will need to watch your child for the next 24 to 72 hours and bring him/her back to the ED, if necessary. Please tell your nurse or doctor before leaving the ED if you do not think you can do this. If you were told your child has a concussion, he/she should not play sports until symptom free at least 1 week and cleared by a doctor.

Normal Behaviors in the First 8 Hours After a Head Injury

1. Your child may be **sleepy.** It is okay to let him/her sleep. Your child should be able to wake up and behave normally, recognize people and things, and speak clearly.
2. **Vomiting,** or throwing up, is also normal in the first few hours following a head injury.
3. Your child may complain of a **headache.** You can give acetaminophen (e.g., Tylenol®).

What to Do

1. Have your child rest or play quietly for the first 24 to 72 hours.
2. Feed your child a lighter than normal diet.
3. Give acetaminophen for a headache.

Return to the Emergency Department Immediately If:

1. **Vomiting** continues after the first 8 hours or begins later than the first few hours after the injury.
2. Your child is **difficult to wake up** or is **not acting normally** when awakened.
3. Your child's **headache worsens,** changes your child's behavior, or is not relieved by acetaminophen.
4. Your child has **trouble seeing** or **walking** or **acts clumsy** or uncoordinated.
5. Your child has **bleeding** or **clear drainage** from his/her **nose** or **ears.**
6. Your child has a **convulsion** or **seizure.**
7. Your child is unusually **sleepy** or has any **unusual behavior** or **change in behavior.**

HIVES

Urticaria, or hives, are red blotches on the skin due to a substance called histamine. They can be of many different sizes and are very itchy. Most hives are an allergic reaction to something your child touched, ate, or put on his/her skin. Hives can also be a reaction to cold, heat, emotional stress, or a viral infection. Some common substances that cause hives are milk, eggs, peanuts, strawberries, shellfish, plants, perfumes, medicines, pets, insect bites, soaps, and detergents. Hives can last only a few hours or several weeks. Often, the cause is unknown, but if you think you know what caused the hives, you should try to avoid reexposing your child to this substance.

Treatment

1. Sometimes no treatment is necessary, and the hives go away on their own.
2. Warmth makes the itching worse, so use a cool washcloth or cool bath to make your child more comfortable.
3. Your doctor may prescribe a medicine (usually an antihistamine) for itching. These medicines can make your child sleepy. Teenagers should not drive while using this medicine. Your medicine is _____
   _____
4. The best treatment is to avoid whatever caused the hives, so try to determine what caused them.

Call the Doctor If:

1. Your child has **trouble breathing** or feels a **tightness in his/her throat or chest or has lip or tongue swelling. Call an ambulance immediately and get to the nearest ED.**
2. The itching is not relieved by the medicine prescribed.
3. The hives do not go away after a few weeks.

IMPETIGO

Impetigo is a skin infection caused by bacteria. You can get impetigo by scratching and infecting insect bites or dry skin or by touching sores on other people. It is easily spread to other parts of the body and to other people, so your child should not return to day care or school until the crusts are gone.

Things to Do If Your Child Has Impetigo

1. Wash your hands before and after caring for your child or use a hand sanitizer to kill bacteria.
2. Gently wash the crusty areas three times each day with soap and water. You may need to soak the area in warm water to remove all the crusts.
3. Blot the areas dry.
4. If your doctor prescribed an ointment, apply this to the sore and the area around it. Rub it in well. _____
5. If your doctor prescribed a medication by mouth, give it to your child as directed until it is all gone. Your dose is: _____
6. Carefully wash the bathtub or bathroom sink your child used with soap and water. Do not use the kitchen sink if possible. Wash your child's towel, washcloth, and bed linens separately. Do not allow your child to share these.
7. Keep your child's fingernails cut short and try to keep him/her from scratching.

Call Your Doctor or Return to the Emergency Department If:

1. Your child gets a fever.
2. The infection is not improving in 3 to 4 days.
3. The sores appear to be spreading, the skin is red, painful, swollen, or draining pus.
4. The sores are not cleared up after 10 days.

LICE

Head lice are small, gray insects that live on humans. They can be spread by direct contact and by shared combs, hats, and clothes. They live in the hair and lay tiny white eggs called nits that stick to each hair shaft. Lice can cause itching.

Treatment

Your child was given a prescription for either cream rinse or shampoo (permethrin or pyrethrin) to treat the lice. **To use the shampoo:**

1. Apply to dry hair until thoroughly coated. (Wear rubber gloves when applying the shampoo.)
2. Leave the shampoo on the hair for 10 minutes and not longer.
3. Add a small amount of water to get lather and shampoo the hair.
4. Do not get shampoo in the eyes or mouth. If you do, rinse immediately with water.
5. Rinse the hair with water and towel dry. Use a fine-tooth comb to remove all nits. They may stick to the hair shaft and be difficult to remove. If so, rinse hair with a dilute vinegar and water solution (dilute vinegar with an equal amount water). This will make nits easier to remove.

To Use the Cream Rinse

1. Wash the hair with your regular shampoo and towel dry.
2. Apply the cream rinse to coat the hair thoroughly.
3. Leave the cream rinse on the hair for 10 minutes.
4. Rinse the hair with water and towel dry. Remove nits as previously described.

Re-treat with the shampoo or cream rinse in 7 days. Two treatments are recommended to kill all lice. Itching may continue for a few weeks even though the lice are gone.

To Eliminate Lice From Your Home

1. Vacuum all surfaces thoroughly.
2. Clean combs and brushes in hot water with some antilice shampoo or cream rinse.
3. Wash all pieces of clothing worn in the last 2 days and any sheets, blankets, and pillow cases your child used in hot water (more than 130° F) and dry in a hot dryer for at least 20 minutes.
4. Any items not washable—stuffed toys, coats, hats—must be set aside in airtight plastic bags for 2 weeks.

NOSEBLEEDS

Nosebleeds are common in children. They are usually caused by dryness inside the nose plus some irritation from rubbing, picking, or cold symptoms. They can begin suddenly and sometimes occur during sleep.

How to Stop a Nosebleed

1. Have your child sit up and lean forward. You may need a container so that your child can spit out any blood that has drained into his/her throat.
2. Firmly pinch the soft part of the nostrils (not the tip or the bone) together for a **full** 5 minutes. Use a clock to time this, and do not let go sooner. Tell your child to breathe through his/her mouth.
3. When you release the pressure, if the bleeding begins again, repeat step 2 one time.
4. If the bleeding continues, call your doctor or take your child to the ED. If possible, have someone hold pressure on the nose while traveling to the ED.
5. Do not place anything inside the nose while it is bleeding (e.g., gauze, tissue).
6. Cold washcloths or ice to the face will not help stop the bleeding.
7. Swallowed blood can irritate the stomach, causing your child to vomit up bloody material.

How to Prevent Nosebleeds

1. Using your finger, gently place a small amount of Vaseline® on the inside of the nose. This will help ease the dryness and irritation.
2. Use a cool mist vaporizer or humidifier in your child's room.
3. Discourage your child from picking his/her nose, and keep fingernails cut short.
4. If your child has a stuffy nose, you can use saline nose drops to make the mucus easier to clear. Avoid vigorous nose blowing.
5. Do not give your child aspirin unless directed by your doctor. If your child has many nosebleeds and is on aspirin, tell your doctor.

Call Your Doctor If:

1. You cannot stop the bleeding or your child has many nosebleeds in one day.
2. You think a lot of blood was lost, or your child faints, or looks dizzy or pale.
3. You see blood elsewhere—in urine, stool—or your child has bruises or a rash.
4. Your child looks sick.

RINGWORM

Ringworm is a fungal infection that can cause a skin rash or infect the scalp and cause hair loss, scaling or pimples, and pus. Your doctor can usually diagnose this condition by looking at it. Sometimes he/she will scrape the rash and take a

culture. Ringworm is spread from person to person; from animals; or from shared combs, towels, or hats.

Treatment

Skin Infection: Your doctor prescribed a cream. Put this cream on the rash as directed. The rash should improve in 7 to 10 days, but you should continue the cream for a full 2-week course. If it is not gone after 2 weeks, call your doctor.

Scalp Infection: Your doctor prescribed a medicine (griseofulvin) to be taken orally. Your child's dose is _____. This medicine should be taken for the full course and is best taken with milk or a fatty meal. If your child begins vomiting or experiences diarrhea, abdominal pain, or a rash, or if he/she looks ill while taking this medicine, call your doctor. Your doctor also prescribed a special shampoo (selenium sulfide 2.5%) to decrease the time that your child is contagious. This shampoo can be used twice a week or as directed by your doctor. If your child wears braids or ponytails, they should be undone so the shampoo can penetrate to the scalp. Your child's combs, brushes, and clothing should be cleaned with ordinary soap and water. Ask your doctor or school nurse about when your child can return to school.

Call Your Doctor If:

1. The rash is not gone after a full course of the medicine.
2. Your child gets ill while taking griseofulvin.
3. You have any questions or concerns.

SCABIES

Scabies are little bugs that burrow in the skin and cause severe itching and a rash. These bugs are best seen with a microscope. They can spread easily from person to person by direct contact or by wearing clothes that have the scabies bug living in them. The itching and rash may last for 2 to 4 weeks after treatment. Your doctor may be able to give your child some medicine that helps the itching. If it continues longer than this, return to your doctor. Everyone in your household should be treated at the same time because scabies spread easily from person to person. Even people without symptoms should be treated; ask your doctor about this.

Treatment

[ ] Your doctor has prescribed a special cream containing 5% permethrin (Elimite®). Massage the cream into the skin from the head to the soles of the feet, including the scalp for an infant. Try to avoid the eyes because the cream can irritate them. If any of the cream gets in the eyes, wash them with cool water. Scabies like to live between the fingers and toes, under arms, and around the waist and genitals. Make sure to include all these areas. Leave the cream on for at least 8 hours, and then give your child a bath to wash off the cream.

[ ] Older children (more than 33 lb) can also be treated with a medicine (ivermectin), one dose now and one in 2 weeks. Your dose is: _____

The itching and rash may last for 2 to 4 weeks after treatment. Your doctor may be able to give your child some medicine that helps the itching. If it continues longer than this, return to your doctor. Everyone in your household should be treated at the same time because scabies spread easily from person to person. Even people without symptoms should be treated; ask your doctor about this.

Medication for itching: _____

Cleaning Your House

1. Scabies can live on clothing or bed linens for up to 1 week.
2. Using hot water (more than 120°F), wash all clothing, bed linens, towels, and washcloths used in the past week, and dry them with high heat for 20 minutes to kill the scabies.
3. Items that cannot be washed (e.g., toys, blankets) should be placed in a plastic bag and stored for 1 week.
4. Clean clothes and clean sheets should be used after applying the cream.

   Your child can return to school after treatment with the cream. Remember to keep the cream stored out of reach of your child because it can be poisonous if swallowed.

Call Your Doctor If:

1. The itching persists longer than 4 weeks after using the cream.
2. You think the skin has become infected or looks red with blistering or crusting.

SEDATION

Your child was given sedation in the ED. The sedation medicine was _____.

After sedation, your child may still be sleepy and may be unsteady when walking. Keep your child safe and avoid climbing, riding a bike, operating motorized equipment, or other activities where your child could get hurt for at least 6 hours after sedation. Vomiting may also occur. If your child vomits, allow him/her to rest and offer small sips of clear liquids.

What to Do

1. It is okay to let your child sleep, but he/she should be able to wake up and behave normally, recognize people and things, and speak clearly.
2. Plan quiet activities for the rest of the day.
3. Feed your child a lighter than normal diet. Some sedation medicines lead to nausea or some vomiting.
4. If your child has pain, offer pain medications as instructed.

Call or Return to the Emergency Department If:

1. Your child is not acting normally 6 hours after sedation.
2. Your child is difficult to arouse or unable to recognize you.
3. Your child is vomiting frequently and unable to keep down small sips of fluids.
4. Your child has trouble breathing, coughing, or fast breathing.
5. Your child has fever greater than 101°F (38.5° C).
6. Your child's pain is not eased by the pain medication.
7. You have any questions or concerns.

SEIZURE

Your child has had a seizure. A seizure occurs when the brain cells send electrical discharges that cause the arms and legs to jerk or twitch and the eyes to stare or blink. Usually, a child is sleepy or confused after having a seizure.

What to Do If Your Child Has a Seizure

1. Stay calm.
2. Do not put anything in your child's mouth.
3. Place your child on his/her side to help drain secretions.
4. Loosen clothing.
5. Do not try to hold your child still. Move objects away from your child so that he/she does not get hurt.
6. Support your child's head with a pillow or soft object.
7. Do not try to give your child any medicine by mouth during a seizure. It may cause him/her to choke.
8. Try to observe what your child looks like during the seizure and how long the seizure lasts. This information may help your doctor decide how to treat the seizure.

[ ] Rescue Medicine

Your doctor wants your child to use a "rescue" medicine if the seizure lasts more than 5 minutes. This medicine is _____. Your instructions are: _____

_____

Keep this medicine out of reach of children.

Call for Help If:

1. Your child has trouble breathing or looks blue.
2. The seizure is lasting longer than 5 minutes (even if you used a rescue medicine).
3. You cannot wake your child 30 minutes after the seizure.

After the Seizure

Your child may be sleepy and should be allowed to rest. Continue to give any medications prescribed for the seizure disorder. Do not give extra medicine or change the dosage without calling your doctor. Make sure you do not run out of the medication. Give all medicine as scheduled.

Follow-up with your regular doctor when a seizure occurs. This can be a good time to review your child's medical care and make changes if necessary. Your child may want to participate in sports or activities such as bicycle riding, swimming, or driving a car or motorcycle. Discuss this with your doctor before you allow your child to participate.

SORE THROAT

A sore throat occurs when the tonsils or back of the mouth become infected by a virus or bacteria. The infection usually spreads from person to person by coughing or sneezing but can also spread by sharing drinking cups or eating utensils.

Your doctor may have sent a swab of your child's throat for a culture. The culture will diagnose a strep throat caused by the streptococci. The culture may take up to 2 days for a result, and so a quicker test called rapid strep is used. The quick test misses some of the streptococci that may show on the culture.

[ ] **The rapid strep test was negative or not available at this time.** If the rapid test was negative, this does not absolutely mean your child does not have strep throat. Call _____ for the culture results on _____ from _____. Have your pharmacy phone number ready in case the doctor needs to phone in a prescription for your child.

[ ] **The rapid strep test was positive.** Your child has strep throat and needs antibiotic treatment. Your doctor may give you a prescription for an antibiotic, or your child can get a shot of long-acting penicillin in the ED. Both medicines will treat the infection. If you choose the antibiotic at home, you need to give your child all the medicine.

Your dose is:_____

Home Treatment

1. The antibiotic will not make your child feel better right away. It may take 2 to 3 days to see improvement. Watch for a rash; trouble breathing; or swelling of the face, hands, or feet as signs of an allergic reaction to the antibiotic.
2. Encourage your child to drink plenty of fluids such as juice, soda, and fruit drinks. Soft foods such as applesauce, pudding, and mashed potatoes may be less irritating to the throat.
3. Give acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Motrin®, Advil®) for fever. Your child's dose is: _____

   _____
4. Salt water gargles (½ tsp salt in 1 cup warm water) may make an older child's sore throat feel better. Do not let your child swallow the salt water. Have him/her spit it out. Use over-the-counter medicine that soothes the throat in school-age children as recommended.
5. Your child may go back to school 24 hours after starting the antibiotic as long as he/she feels well and does not have a fever.

Call Your Doctor or Return to the Emergency Department If:

1. Your child has drooling or difficulty in swallowing.
2. Your child has a stiff neck.
3. Your child has trouble breathing.
4. Your child has a rash or swelling of the hands or feet.
5. Your child still has a fever 2 to 3 days after starting antibiotics.
6. You are unable to give your child the antibiotic.
7. Your child looks sick or you have any questions or concerns.

SPRAINS AND STRAINS

A *sprain* is an injury to the ligaments that hold your bones together. A *strain* is an injury to the muscle or muscle tendon from stretching or pulling.

Treatment

1. Keep the injured area quiet. If your doctor gave you a splint or crutches, have your child use these as instructed. If you

were given an elastic bandage, keep it on as much as possible to help with swelling.
2. Keep the injured area elevated as much as possible. Prop up an arm or leg with pillows.
3. Use an ice pack for the first 48 hours. Do not put the ice directly against the skin; wrap it in a towel first. Keep the ice on the area for 15 minutes every 3 hours while awake.
4. You may give your child ibuprofen (e.g., Motrin®, Advil®) for pain. Your dose is: _____
_____
5. Follow-up with your doctor or with an orthopedic surgeon in _____ days.

Exercise

Follow your doctor's instructions for exercise. Sprains often improve faster when exercises are begun early. Moving the injured area in all directions without putting weight or stress on the area is a good start. (For an ankle sprain, your child can write the alphabet with his/her foot.) Do not advance your activity if you are having a lot of pain. Do not stop using crutches until you can walk normally without pain. Your instructions are: _____
_____

Call Your Doctor or Return to the Emergency Department If:

1. Your child has increased redness or swelling at the injury site or worsening pain.
2. Your child gets a fever.
3. Your child has no feeling in the injured arm or leg or it feels cold.
4. Your child is not feeling better in 3 to 5 days or is not making steady progress in 3 to 5 days.
5. You have any questions or concerns.

STOMATITIS

Stomatitis is a viral infection that can cause sores or blisters on the gums, tongue, and other areas inside the mouth. Your child may have a fever, and the ulcers are painful. He/she may not want to eat or drink. Because this is a viral infection, it will usually clear up by itself within 5 days. However, some children may have sores in the mouth for 1 to 2 weeks.

To Keep Your Child Comfortable and Prevent Dehydration

1. Give acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Advil®, Motrin®) at the correct dosage for your child's age. This medicine will help with the pain and fever. Acetaminophen suppositories are available at your pharmacy without a prescription. Your dose is: _____.
_____
2. Encourage cold or cool liquids. These may be soothing to the mouth and help numb the pain. Avoid citrus and carbonated drinks (e.g., orange and grapefruit juices, lemonade, soda). Soft foods such as applesauce, yogurt, or pudding may be less irritating to the mouth.
3. Avoid salty or spicy foods.
4. If your doctor has given you a mouthwash or other medication, use as directed.
_____

To Prevent Spread of This Infection

1. Wash your hands and your child's hands frequently and before eating.
2. Do not share your child's eating utensils or drinking cups while sick; wash after each use.
3. Wash any toys your child places in his/her mouth before and after your child plays with them.

Call Your Doctor or Return to the Emergency Department If:

1. Your child is repeatedly refusing to drink or cannot swallow.
2. Your child appears dehydrated (no urine output in the last 8 hours, no tears when crying, lips are dry or cracked).
3. You think your child looks worse than when you were initially seen in the ED.
4. Your child is not getting better after 1 week.

URINARY TRACT INFECTION

Your child has been diagnosed with a urinary tract infection. This is an infection of the bladder or kidneys. It can cause symptoms of fever, abdominal or back pain, vomiting, or burning with urination, or it may have no symptoms in small babies. The diagnosis is made by looking at a clean sample of urine under a microscope and then growing bacteria with a urine culture.

Treatment

1. Antibiotics are used to treat the infection. Your child's medicine is _____.
Make sure to give all doses for the full course to completely get rid of the infection. Diarrhea can be a side effect of antibiotics, so do not stop them if this occurs. If your child does get a rash or severe diarrhea, call your doctor.
2. Encourage extra fluids by mouth to help clear the infection.
3. Allow your child to urinate as often as he/she desires, and encourage him/her not to "hold" the urine.
4. Follow-up is important to ensure the infection is cured.

Long-term Follow-up

Urinary tract infections can sometimes come back. Your doctor may want to follow your child more frequently and look at urine samples. Most children with a first time infection need to have their kidneys and bladder evaluated to ensure there is not a problem that led to the infection. Your doctor may schedule tests to look for this.

Tips for Prevention

1. Teach your child to wipe from front to back and then throw away the toilet paper.

2. Have girls wear cotton underwear. Synthetics can irritate the genital area and lead to infection.
3. Bubble baths, creams, or powders in the genital area may be irritating and lead to holding urine, causing an infection.
4. Encourage your child to drink plenty of fluids each day.
5. Encourage him/her to empty the bladder completely every 3 to 4 hours during the day and to urinate before bedtime.

Call Your Doctor or Return to the Emergency Department If:

1. Fever lasts longer than 2 days with antibiotic treatment or your child develops a fever while taking the antibiotic.
2. Your child stops urinating or the urine becomes bloody.
3. Your child gets worse.
4. Your child refuses to take the antibiotic.
5. Your child gets a rash or has severe diarrhea while taking the antibiotic.

VIRAL INFECTION

Your child is sick with a viral infection. This does not mean that there is nothing wrong with your child. Viruses are microbes that survive on living cells and cause many types of illnesses. There are many viruses, and we do not always know which one is causing your child's illness. We do know that antibiotics do not help treat viral infections and that overuse of antibiotics can make some harmful bacteria more difficult to treat. We do not give children with viral infections antibiotics because they will usually get better without them, and we want to keep levels of resistant bacteria low. Children with viral infections often have fever and body aches. You can help your child feel better by treating his/her symptoms. **Ask your doctor or nurse for fever instructions to take home.**

Treatment

Pain and Fever: Use acetaminophen (e.g., Tylenol®) or ibuprofen (e.g., Motrin®, Advil®) to ease body aches and treat fever. Your child's dose is:_____.

Fluids: Offer your child liquids to drink to keep him/her from getting dehydrated (dry). Children should urinate at least two to three times per day.

Other Instructions: _____

_____

_____

Follow-up: A typical viral infection may last 5 to 7 days. If your child is getting worse or not improving, particularly if vomiting persistently, you need to see a doctor.

Call Your Doctor or Return to the Emergency Department If:

1. Your child is irritable, and it is difficult to calm him/her down.
2. Your child is unable to take fluids or is weak, sleepy, or lethargic.
3. You think your child looks dry (eyes look sunken, soft spot is depressed, no tears when crying, mouth looks dry).
4. Your child has other symptoms—rash, trouble breathing, ear pain, headache, stiff neck, vomiting, diarrhea, joint swelling, or pain.
5. You think your child looks sick or is getting worse.
6. You have any questions or concerns.

VOMITING AND/OR DIARRHEA

Vomiting or diarrhea occurs when the lining of the stomach or intestines is irritated by an infection. Usually, the infection is a virus and needs to run its course, which may vary from 1 day to 1 week. The doctor who examined your child decided that you could treat this illness at home. To make your child feel better, he/she needs to rest the stomach and intestines and help prevent more vomiting and diarrhea. This can be done by giving your child clear liquids and foods that are easily digested and by avoiding spicy or greasy foods that can further irritate the gastrointestinal tract. The goal is to keep your child from becoming dehydrated (dry). Your child can return to school or day care when the diarrhea or vomiting have resolved and he/she is feeling better.

Follow the Instructions Below

For Babies 2 Months to 1 Year

1. Feed your baby an oral electrolyte solution (e.g., Pedialyte®, Infalyte®) until he/she has not vomited for 2 hours. If your baby vomits the electrolyte solution, then give small amounts at frequent intervals (e.g., ½ to 1 oz every 15 minutes for babies 5 to 10 kg or 11 to 22 lb).
2. **Do not give plain water.**
3. If your child is not vomiting, continue his/her regular diet. You may give extra oral electrolyte solution (e.g., Pedialyte®, Infalyte®) to keep your child from getting dehydrated. You can give your child food even if he/she has diarrhea.
4. If you are breast-feeding, continue breast-feeding on demand.
5. If you are formula feeding, restart formula when your child has not vomited for 2 hours. Continue formula even if your child has diarrhea. If the diarrhea is worse with formula, your baby may have trouble absorbing the formula. Call or see your child's doctor.
6. See your doctor or return to the ED if the vomiting and diarrhea continue. **Do not give your baby only Pedialyte® or Infalyte® for more than 24 hours.**

For Children Older Than 1 Year

1. Give your child clear liquids (ones you can see through) until the vomiting improves and allow the stomach to rest. Oral electrolyte solutions (e.g., Pedialyte®, Infalyte®) are best for your child with the right amount of sugar and salt. Use of these alone for more than 24 hours is NOT RECOMMENDED. Other clear liquids may have high amounts of sugar and can worsen diarrhea. Some children do not like the taste of the electrolyte solution. If your child will not drink the oral electrolyte solutions, other clear liquids may keep him/her from getting dry. Examples are flat soda (shake out the fizz), Kool-Aid®, Gatorade® diluted with an equal amount of water, Hawaiian Punch®, juices (not apple, orange, grapefruit), tea with sugar, Jell-O®, popsicles, water ice, sherbet, clear soups, or broth. DO NOT GIVE MILK. If your child vomits the clear liquids, try giving only small sips. Giving your child a straw may keep him/her from drinking large amounts.

2. If the vomiting improves, you may continue your child's regular diet. Soft, bland foods such as oatmeal, rice cereal, bananas, applesauce, dry toast, crackers, vanilla wafers, dry mashed potatoes, noodles, lean meats, vegetables, and fruits may be better. STAY AWAY FROM FRIED OR SPICY FOODS. You can give your child food even if he/she has diarrhea.
3. Resume milk if your child's stomach feels better and if vomiting and diarrhea are improving.
4. See your doctor if the vomiting and diarrhea continue. Do not give your child only clear liquids for more than 48 hours without calling your doctor.

Call Your Doctor or Return to the Emergency Department If:

1. The vomiting and diarrhea do not improve.
2. Your child is unable to take fluids or is weak, sleepy, or lethargic.
3. You think your child looks dry (eyes look sunken, soft spot is depressed, no tears when crying, mouth looks dry).
4. Your child has not urinated in 8 hours.
5. There is blood in the vomit or stool, brown flecks like coffee grounds in the vomit, or green vomiting.
6. Your child has abdominal pain.
7. Your child has a fever higher than 102°F (39°C).
8. You think your child looks sick or is getting worse.
9. You have any questions or concerns.

WOUND CARE

Your child has an injury in which the skin was broken. These injuries can be fixed in different ways, depending on the age of your child and the size and location of the injury. However, all such wounds heal with a scar. This scar will remodel itself within 12 months.

Stitches (Sutures) or Staples

[ ] Your child had _____ stitches or staples placed for an injury to his/her _____. These must be removed in _____ days. Call your doctor for an appointment to remove the stitches or return to the ED for removal.

[ ] The stitches do not need to be removed. They will come out by themselves. Follow-up with your regular doctor in _____ days.

[ ] Your child's wound should be rechecked in _____ days. Call your doctor for an appointment or return to the ED.

Washing with a washcloth or a quick shower is okay. Do not take a bath, soak the stitches/staples, or allow your child to swim with them. If the stitches should loosen or if the wound pops open, bring your child back to the ED. If the wound starts bleeding, apply direct pressure for 15 minutes. If it continues to bleed, call your doctor or return to the ED.

Apply an antibiotic ointment to the stitches _____ times per day.

Keep the area covered with a clean bandage.

No cover is necessary after the first 48 hours.

Apply sunscreen to wound area when outdoors to protect new skin.

[ ] *Wound Adhesive*

Your child had a special glue (Dermabond®) used to fix your child's wound. Keep clean and dry. Do not soak in water or allow your child to swim for the next 7 days. Allow the glue to peel off by itself (usually in 7 days).

[ ] Your child received a tetanus shot in the ED. Show this to your child's doctor to update their records.

[ ] Your doctor has given your child a prescription for antibiotics. Not all wounds need antibiotic treatment. Your child must take all the medicine as directed. Your dose is:

Signs of Infection

Call your doctor or return to the ED if any of these signs develop:

1. Increased redness around the wound
2. Pain
3. Discharge or pus from the wound
4. Increased swelling
5. Bad smell
6. Fever

APPENDIX E ■ CLINICAL PATHWAYS IN EMERGENCY MEDICINE

JANE M. LAVELLE, MD, AND CYNTHIA R. JACOBSTEIN, MD, MSE

The ability to provide effective, safe, and reliable bedside care for a wide range of presenting complaints in the emergency department (ED) is of the utmost importance. This task has become increasingly complex and challenging with the explosion of knowledge and technology. Incorporating education to physicians in training in a setting that demands efficient (reduction of unnecessary testing) and timely practice is an additional challenge. The ED clinical pathways were created to meet these competing goals. The availability of the intranet browser, the electronic medical record, and physician order entry were the catalysts needed to make the clinical pathways and order sets that are immediately available to bedside clinicians a reality. We believe that use of these pathways reduces variability of bedside care, error, unnecessary testing and treatment, as well as reducing length of stay and cost. We and others believe that use of these pathways/guidelines helps us standardize the care for the large majority of patients with common and important conditions and leaves the ED team more effective time to provide medical decision making for complex and higher risk patients. To date, the Children's Hospital of Philadelphia Emergency Department has developed 22 clinical pathways for a variety of common and uncommon chief complaints. We have provided five of these in this chapter: asthma, bronchiolitis, dehydration, diabetic ketoacidosis, and suspected appendicitis.

The clinical decision-making algorithms are based on current evidence in the medical literature as well as expert consensus from providers within our institution. Multidisciplinary teams work together to review literature and create the algorithm for critical clinical decision making as well as for the necessary processes to execute the care. For example, the appendicitis pathway was created by physicians and nurses from radiology, general surgery, and the emergency department. Each pathway contains certain standard elements. These include triage parameters, a clinical decision-making algorithm, key components of physician and nursing assessment, nursing bedside procedure, educational PowerPoint presentations for nurses and physicians, and links to key articles and useful websites. Each pathway is also accompanied by computerized order sets specific to each complaint, which can assist in decision support to follow the pathway/guideline. When a patient presents with a complaint for which a pathway exists, a brief discussion between the bedside nurse and physician allows care, including IV placement, lab draws, and other initial care to begin as early in the ED visit as possible.

We have made these pathways available on our intranet site, so they are readily accessible to all bedside providers. We have reproduced the clinical algorithm here. The underlined text represents a hyperlink on our internet website, which is represented in table form here.

We intend to link each pathway to a quality metrics allowing the bedside team of providers to receive feedback to improve clinical decision making as well as to identify system issues that need to be addressed. These pathways are currently being used for nursing and physician education. We eventually hope to include these as part of the resident curriculum during their ED rotations.

ED Guidelines for Evaluation/Treatment of Children with Asthma

JOSEPH ZORC, M.D., JANE LAVELLE, M.D.

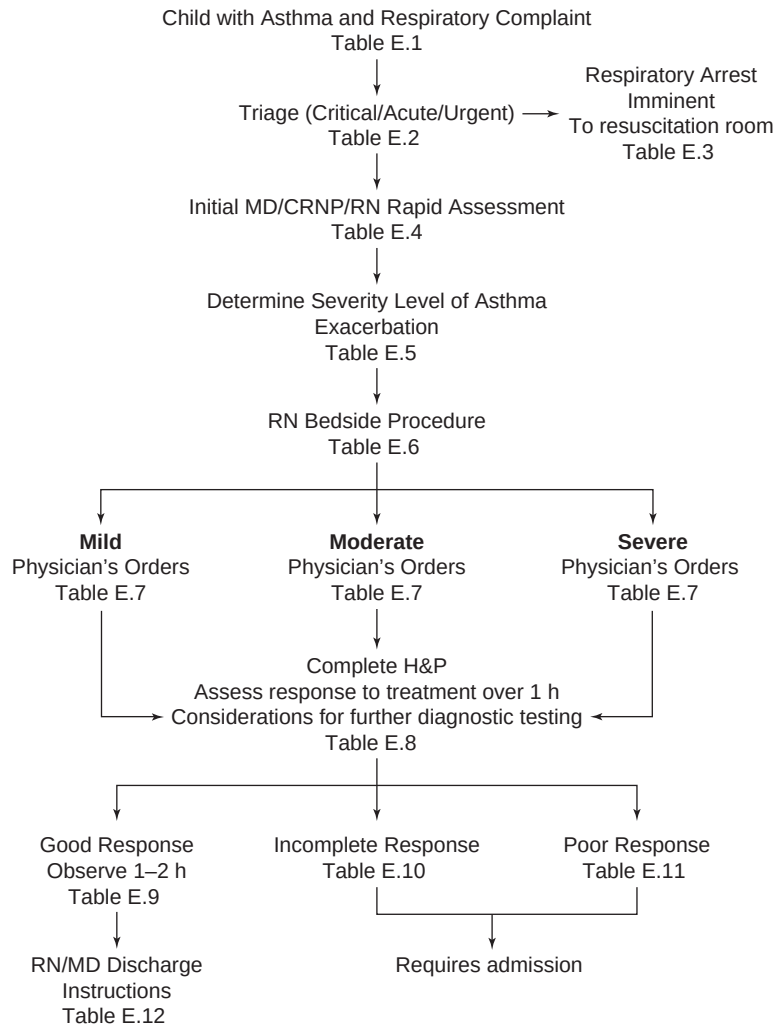

TABLE E.1

CHILD WITH ASTHMA AND RESPIRATORY COMPLAINT

Asthma definition for pathway:
- Acute trouble breathing/wheezing
- Age >12 mo, and
- Prior diagnosis of asthma or history of two significant wheezing episodes

TABLE E.2

TRIAGE (CRITICAL/ACUTE/URGENT)

Respiratory distress

Critical	Acute	Urgent
■ Severe wheezing with: Severe tachypnea Bradypnea/apnea Severe retractions Nasal flaring Grunting respirations Decreased muscle tone Lethargy ■ Absent breath sounds ■ Agonal respirations ■ Pulse oximetry <92%	■ Wheezing with moderate: Increased work of breathing (WOB) Tachypnea Retractions Intermittent grunt ■ Decreased aeration with moderate tachypnea and WOB ■ Pulse oximetry <95%	■ Wheezing with mild: Increased WOB Tachypnea Mild retractions ■ Pulse oximetry ≥95%

Guide to rates of breathing in awake children

Age	Normal rate (in min)
<2 mo	<60
2–12 mo	<50
1–5 yr	<40
6–8 yr	<30

TABLE E.3

RESPIRATORY ARREST IMMINENT

■ Drowsy, confused
■ Paradoxical breathing, absence of wheeze
■ Bradycardia

Impending Respiratory Failure
■ ABCs
■ Consider IM epinephrine (1:1,000) 0.01 mL/kg (maximum 0.5 mL)
■ Methylprednisolone (Solumedrol®) 2 mg/kg IV (maximum 60 mg)
■ Albuterol nebs × 3 plus Ipratropium

Albuterol weight-based dosing

Weight (kg)	Unit dose (0.5%)	Continuous
<5	1.25 mg (0.25 mL)	5 mg/h (1 mL/h)
5–10	2.5 mg (0.5 mL)	10 mg/h (2 mL/h)
10–20	3.75 mg (0.75 mL)	15 mg/h (3 mL/h)
>20	5 mg (1.0 mL)	20 mg/h (4 mL/h)

Ipratroprium weight-based dosing

5–10	250 μg q20min × 3
>10	500 μg q20min × 3

■ IV magnesium sulfate 50 mg/kg, maximum 2 g
■ IV terbutaline
Bolus: 2–10 μg/kg
Infusion: 0.08–0.4 μg/kg/min (maximum 6 μg/kg/min)
■ Heliox (consult critical care medicine)
■ Rapid sequence intubation
Atropine 0.01 mg/kg IV, maximum 1 mg
Midazolam 0.05 mg/kg IV, maximum 2 mg
Ketamine 1–3 mg/kg IV
Vecuronium 0.2 mg/kg IV

TABLE E.4

INITIAL MD/CRNP/RN RAPID ASSESSMENT

General
- Reassess VS, pulse and perfusion
- General appearance
- Respiratory status—rate, work of breathing (WOB), and air entry

Brief History
- Onset of symptoms
- Use of bronchodilators
- Chronic asthma medications
- Symptoms of infectious disease

TABLE E.6

RN BEDSIDE PROCEDURE

- Obtain and administer PO prednisone/prednisolone as soon as ordered
- Identify if:
  Family has an asthma care plan for flares
  Child uses a controller medication
  Child has a source for follow-up care

TABLE E.5

DETERMINE SEVERITY LEVEL OF ASTHMA EXACERBATION

Mild	Moderate	Severe
Pulse oximetry >95%	Pulse oximetry 90–95%	Pulse oximetry <90%
Mild tachypnea	Moderate tachypnea	Severe tachypnea
Normal mental status	Mildly anxious	Anxious
Minimal ↑ WOB	Moderate ↑ WOB	Severe ↑ WOB
Good aeration	Fair–good aeration	Poor aeration
End expiratory wheeze	Loud expiratory wheeze	Inspiratory, expiratory wheezing, or no wheezing
PEF ≥70%	PEF 40–69%	PEF <40%

Guide to rates of breathing in awake children

Age	Normal rate (min)
<2 mo	<60
2–12 mo	<50
1–5 yr	<40
6–8 yr	<30

TABLE E.7

PHYSICIAN'S ORDERS FOR MILD/MODERATE/SEVERE ASTHMA

Options:
- Albuterol puffs × 3 with MDI spacer are the preferred treatment for patients with mild wheezing
- Albuterol nebs × 3 (plus Ipratropium)
  Consider IM epinephrine (1:1000) 0.01 mL/kg (maximum 0.5 mL)
  See Table E.3 for further therapy for severe asthma

Albuterol weight-based dosing

Weight (kg)	Unit dose (0.5%)	MDI puffs	Continuous
<5	1.25 mg (0.25 mL)	2	5 mg/h (1 mL/h)
5–10	2.5 mg (0.5 mL)	4	10 mg/h (2 mL/h)
10–20	3.75 mg (0.75 mL)	6	15 mg/h (3 mL/h)
>20	5 mg (1.0 mL)	8	20 mg/h (4 mL/h)

Ipratroprium weight-based dosing

5–10	250 μg q20min × 3
>10	500 μg q20min × 3

Prednisone/Prednisolone—Administer 2 mg/kg PO (maximum of 60 mg) for moderate/severe or mild with incomplete response

TABLE E.8

COMPLETE HISTORY AND PHYSICAL

History
- Duration of symptoms
- Presence of infectious disease or allergic symptoms
- Home therapy
- Most recent oral steroid use
- Prior ED visits/hospitalizations, particularly in the last year
- Prior ICU admissions, intubations
- Chronic lung or heart disease, immunodeficiency
- Asthma management doctor

Physical Exam
- Vital signs, mental status, pulse oximetry
- Consider peak expiratory flow (PEF) in children ≥6 yr following initial β-agonist therapy
- WOB, wheezing, aeration

Further Diagnostic Testing

Consider chest x-ray:
- Persistent asymmetry
- Persistent pulse oximetry <90%
- Prolonged fever
- ICU admission

TABLE E.9

GOOD RESPONSE

Patient has **mild** symptoms:
Pulse oximetry >95%
Mild tachypnea
Normal mental status
Minimal ↑ WOB
Good aeration
End expiratory wheeze
PEF >80%

- Observe minimum of 30 min if only single nebulization given
- Observe 1–2 h following albuterol nebulization ×3

TABLE E.10

INCOMPLETE RESPONSE

Patient continues with **moderate** symptoms:
Pulse oximetry 90–94%
Moderate tachypnea
Mildly anxious
Moderate ↑ WOB
Fair–good aeration
Loud expiratory wheeze
PEF 40–70%

- Continue q2h albuterol nebulizations (weight-based)
- Consider continuous albuterol nebulization
- Assess need for additional therapies (see poor response)

TABLE E.11

POOR RESPONSE

Patient continues with severe symptoms:
Pulse oximetry <90%
Severe tachypnea
Anxious
Severe ↑ WOB
Poor aeration
Inspiratory, expiratory wheezing

- Place IV, send basic metabolic panel
- Continuous albuterol nebulization
- IV magnesium sulfate 50 mg/kg, maximum of 2 g
- IV terbutaline
  Bolus infusion 2–10 μg/kg
  Infusion 0.08–0.4 μg/kg/min (maximum 6 μg/kg/min)

TABLE E.12

RN/MD DISCHARGE INSTRUCTIONS

At Discharge from ED
1. ED discharge instructions, review asthma recovery plan
2. Prescribe oral steroids for 4 days if indicated
3. Review dosing of medications at discharge
4. Review home medications
5. Review need for follow-up with a primary care provider within 3–5 days
6. Review signs that would require a return to the ED

ED Guidelines for Evaluation/Treatment of Children with Bronchiolitis

KATHY SHAW, M.D., M.S.C.E., JOSEPH ZORC, M.D., JANE LAVELLE, M.D.

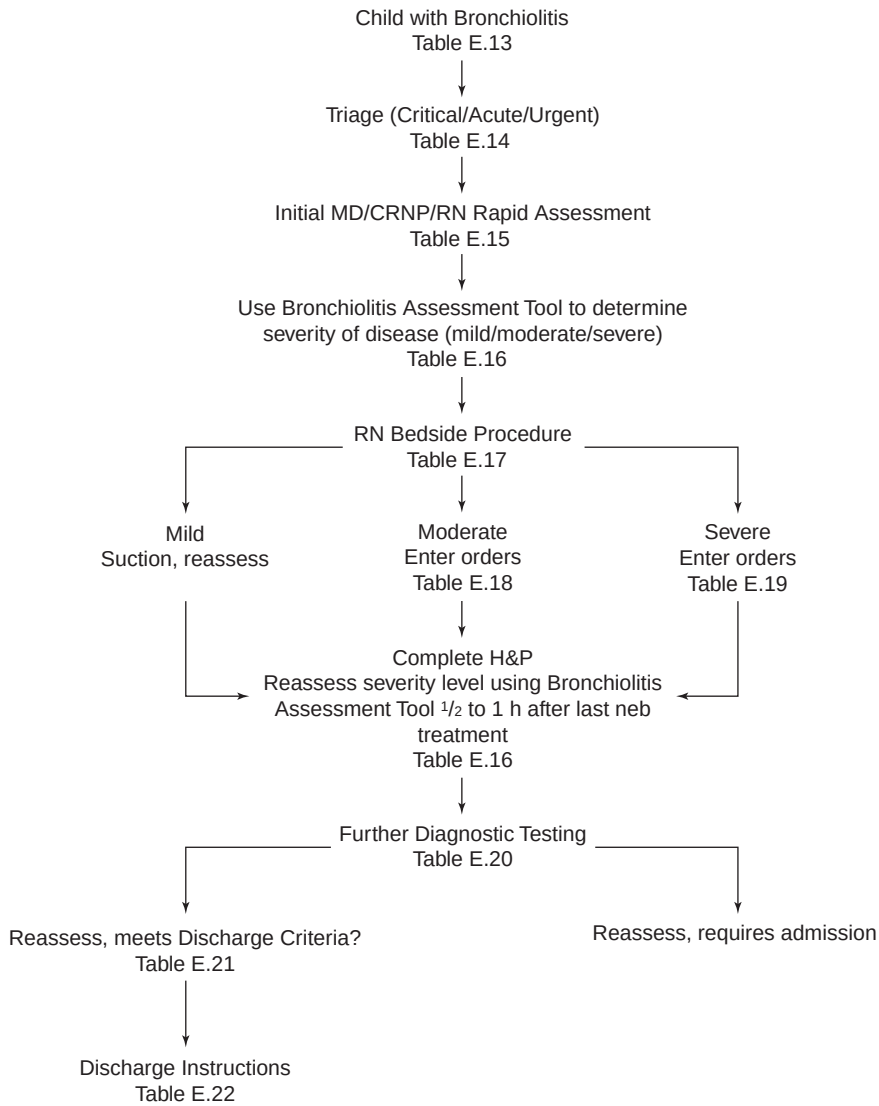

TABLE E.13

CHILD WITH BRONCHIOLITIS

Bronchiolitis definition for pathway
- Previous healthy infant
- <12 mo of age with URI symptoms and wheezing

TABLE E.14

TRIAGE (CRITICAL/ACUTE/URGENT)

Respiratory distress

Critical	Acute	Urgent
■ Agonal respirations Severe wheezing with: Severe tachypnea (RR ≥80) Bradypnea/apnea Severe retractions Nasal flaring Grunting respirations Absent breath sounds ■ Decreased muscle tone or Lethargy ■ Pulse oximetry <90%	■ Wheezing with moderate: Increased work of breathing (WOB) Tachypnea (RR ≥70) Retractions Intermittent grunting ■ Decreased aeration with moderate tachypnea and WOB ■ Pulse oximetry <95%	■ Wheezing with mild: Increased WOB Tachypnea Mild retractions ■ Pulse oximetry >95%

Guide to rates of breathing in awake children

Age	Normal rate (per min)
Newborn	<65
<2 mo	<60
2–6 mo	<55
7–12 mo	<50

TABLE E.15

MD/CRNP/RN RAPID ASSESSMENT

History of Illness

- Preceding upper respiratory illness and/or rhinorrhea
- Symptoms, when they began, presence of fever
- History of apnea?
- Ability to maintain hydration
- Infectious exposures
- Medications received
- Identify high risk factors:
  History of prematurity, gestational age <34 wk
  Receiving Synagis™ treatments
  Heart disease
  Lung disease
  Immunodeficiency
- Allergies

Physical Exam

- Overall appearance
- Vital signs, pulse oximetry reading
- Mental status
- Respiratory status
  Work of breathing
  Flaring
  Grunting
  Breath sounds
  Wheezing
  Crackles

TABLE E.16

BRONCHIOLITIS ASSESSMENT TOOL

Respiratory assessment	Mild	Moderate	Severe
Pulse ox in room air	≥95%	91–94%	≤90%
Respiratory rate	<60	60–70	>70
Mental status	Normal	Irritable but active	Lethargic
Feeding	Normal	Less but adequate	Poor
Increased WOB			
Retractions	Minimal/None	Intercostal	Substernal
Accessory muscles			Neck or abdominal muscles
Wheeze	Minimal/none	Moderate expiratory	Severe inspiratory/expiratory
Air exchange	Good, equal BS	Localized decreased BS	Multiple areas decreased
Classification of severity by using assessment tool			
Single Severity			
Mild		≥5 factors in the mild category	
Moderate		≥5 factors in the moderate category	
Severe		≥5 factors in the severe category	
Mixed Severity			
Mild/moderate		Majority of factors are in mild and moderate categories	
Moderate/severe		Majority of factors are in moderate and severe categories	
Measuring response to albuterol/racemic epi using the assessment tool			
Improvement noted in at least 3 of 7 categories			

TABLE E.17

RN BEDSIDE PROCEDURE

1. Suction nasopharynx/oropharynx
2. Obtain pulse oximetry reading
3. Administer oxygen for SaO_2 < 90% and consider for consistently 91–94%
4. Babies in the severe category should have continuous pulse oximetry and CR monitoring
5. Obtain physician's respiratory orders for treatment, as needed
6. Assess hydration:
   a. Infants with mild/moderate distress, offer Pedialyte™
   b. Infants with severe distress, assess need for IV fluids, maintain NPO status
7. Obtain order for IV, laboratory studies for infants <2 mo with a temperature >38.2°C
8. Document vital signs, pulse oximetry every hour in moderate and severe categories

TABLE E.18

IMMEDIATE PHYSICIAN'S ORDERS FOR MODERATE BRONCHIOLITIS

Albuterol trial × 1 treatment, MDI with spacer is the preferred method of delivery
Pulse oximetry prior to each nebulization treatment
Administer steroids if 2 prior episodes of wheezing
Consider racemic epinephrine treatment for moderate/severe patients

Albuterol weight-based dosing

Weight (kg)	Unit dose (0.5%)[a]	MDI puffs (90 μg)	Continuous
<5	1.25 mg (0.25 mL)	2	5 mg/h
5–10	2.5 mg (0.5 mL)	2	10 mg/h

Single dose: 0.083%—1.5 mL <5 kg, 3 mL >5 kg
Racemic Epi (1% solution) with NS to volume of 2.5 mL
<5 kg 0.25 mL
5–10 kg 0.5 mL

OR

L-epinephrine (1:1,000)
<5 kg 1.25 mL
5–10 kg 2.5 mL

[a]Dilute with 2 mL NS.

TABLE E.19

IMMEDIATE PHYSICIAN'S ORDERS FOR SEVERE BRONCHIOLITIS

Continuous pulse oximetry and CR monitor
Albuterol trial × 2
Consider racemic epinephrine treatment
Administer steroids if any prior episode of wheezing

Albuterol weight-based dosing

Weight (kg)	Unit dose (0.5%)[a]	MDI puffs (90 μg)	Continuous
<5	1.25 mg (0.25 mL)	2	5 mg/h
5–10	2.5 mg (0.5 mL)	2	10 mg/h

Single dose: 0.083%–1.5 mL <5 kg, 3 mL >5 kg
Racemic Epi (1% solution) in 2 mL NS
<5 kg 0.25 mL
5–10 kg 0.5 mL

OR

L-epinephrine (1:1,000)
<5 kg 1.25 mL
5–10 kg 2.5 mL

[a]Dilute with 2 mL NS

TABLE E.20

FURTHER DIAGNOSTIC TESTING

Chest x-ray

Obtain chest x-ray on infants with:

- Age <2–3 mo
- Persistent fever beyond third day of illness
- Severe disease
- Signs, symptoms concerning for another diagnosis
- High risk factors
  - – Heart disease
  - – Lung disease
  - – Immunodeficiency

Routine radiographs are not indicated in babies with mild/moderate disease

Viral Antigen Testing

RSV or other viral antigen testing **ONLY** for patients requiring admission for cohorting for infection control.

Other Laboratory Studies

Consider work up for serious bacterial illness in infants <2 mo presenting with fever >38.2°C or who appear ill out of proportion to bronchiolitis.

Electrolytes, bedside glucose testing in patients with significant dehydration

TABLE E.21

DISCHARGE CRITERIA (MUST MEET ALL CRITERIA)

1. Patient severity score
   - ■ Mild severity score
   - ■ Mild to moderate severity score
     - i. Not in first 1–2 days of illness
     - ii. Absence of high-risk factors
       - – History of prematurity, gestational age <34 wk
       - – Receiving Synagis™ treatments
       - – History of apnea
       - – Heart disease
       - – Lung disease
       - – Immunodeficiency
2. Patient is able to maintain hydration at home
3. Caregivers able to assess infant and understand care and follow-up instructions
4. MD follow-up is recommended within 24 h for:
   - ■ All infants presenting in the first 2 days of illness
   - ■ All infants with moderate severity of illness

TABLE E.22

RN/MD DISCHARGE INSTRUCTIONS

1. If patient had a good response to β-agonists, discharge home with:
   - ■ MDI and spacer: requires practice with patient, family in ED.
   - ■ Respiratory therapist should review use of the above with the family
2. Use bronchiolitis discharge instructions
3. Focus instructions on:
   - ■ Use of saline nose drops, humidifier
   - ■ Tylenol for analgesia and fever
   - ■ Signs of inadequate hydration
   - ■ Signs of respiratory distress
   - ■ When to return to the ED
   - ■ When follow-up is required

ED Guidelines for Evaluation/Treatment of Children with Gastroenteritis and Dehydration

MERCEDES BLACKSTONE, M.D., PHILIP SPANDORFER, M.D., JANE LAVELLE, M.D.

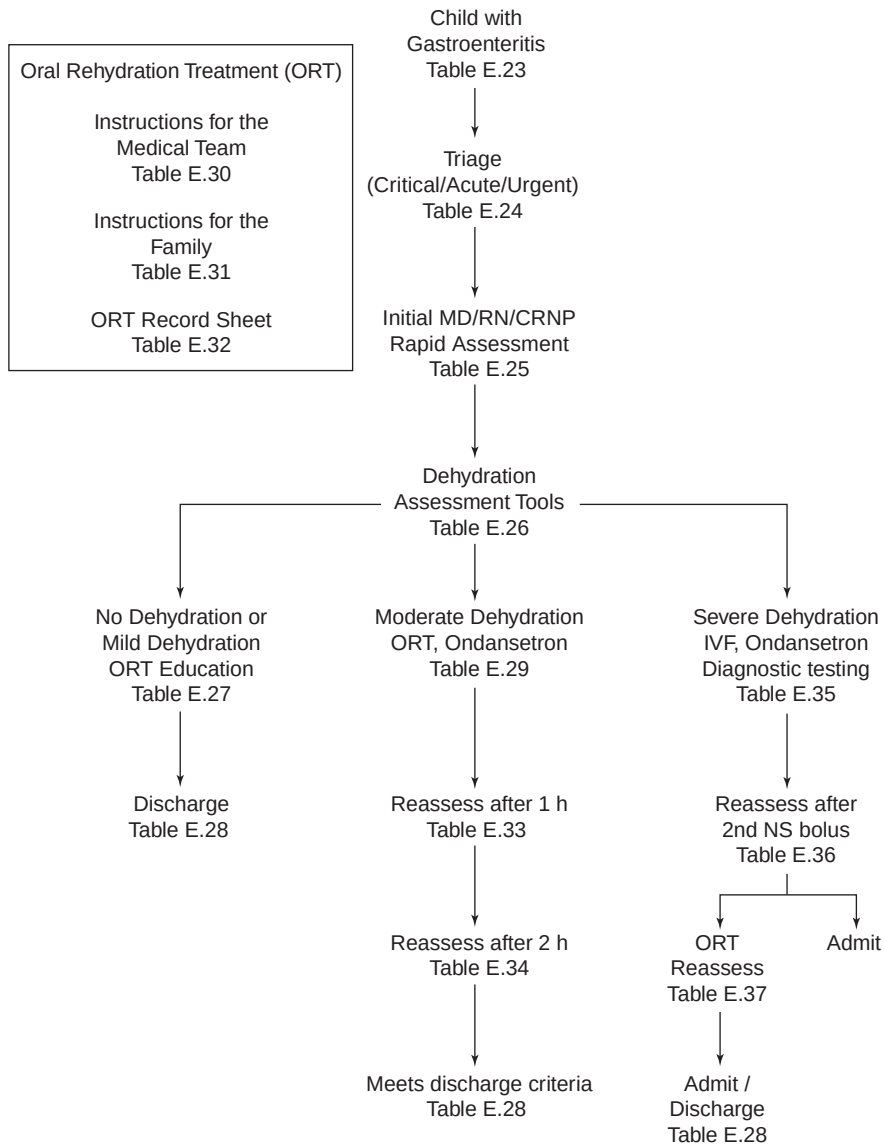

TABLE E.23

CHILD WITH GASTROENTERITIS

This pathway is to be used for the treatment of children with gastroenteritis and associated dehydration. It is important to assess the child for surgical, neurologic, and metabolic conditions before using this treatment pathway. Oral rehydration therapy (ORT) may also be used for other causes of dehydration, e.g., fever, pharyngitis, stomatitis.

Children who have vomiting or diarrhea but who are not dehydrated or have only mild dehydration, do not need to be rehydrated in the ED. These patients and families will benefit from education about use of ORT at home.

TABLE E.24

TRIAGE CRITERIA

Critical
- Cardiopulmonary failure
- Extreme tachycardia, poor capillary refill and/or hypotension
- Hyperpnea (Kussmaul respirations) associated with severe metabolic acidosis
- Unresponsive
- Inborn errors of metabolism with physiology of **Acute**

Acute
- Ill-appearing
- Lethargic (awaken with significant or noxious stimulation)
- Irritable or inconsolable
- Significant tachycardia
- Unable to keep any fluids down due to active vomiting/diarrhea
- 10–15% weight loss
- Abdominal pain
- Pre-existing metabolic disease including insulin-dependent diabetes mellitus (IDDM)

Urgent
- Listless
- 5–10% weight loss
- Any two:
  Oliguria
  Tacky mucous membranes
  Absent tears`
  Mild tachycardia
  Sunken fontanelle
  Sunken eyes
  Prolonged capillary refill, >2 second

Pediatric vital sign normal ranges

Age group	Respiratory rate (per min)	Heart rate (per min)	Systolic blood pressure (mm Hg)
Newborn	30–50	120–160	50–70
Infant (1–12 mo)	20–30	80–140	70–100
Toddler (1–3 yr)	20–30	80–130	80–110
Preschooler (3–5 yr)	20–30	80–120	80–110
School Age (6–12 yr)	20–30	70–110	80–120
Adolescent (13+ yr)	12–20	55–105	110–120

Guide to rates of breathing in awake children

Age	Normal rate (per min)
<2 mo	<60
2–12 mo	<50
1–5 yr	<40
6–8 yr	<30

TABLE E.25

INITIAL MD/RN/CRNP RAPID ASSESSMENT

Goal

- Rapidly assess degree of dehydration
- Identify patients who have other underlying cause for their symptoms (surgical, metabolic or CNS Disease)

History

Onset of symptoms, presence of fever	
Emesis	How many, last time, bilious/bloody, worse in the AM
Diarrhea	How many, last time, blood/mucous
Intake	Type and amount of fluid given
Urination	How many times, last time, color/odor
Exposure	Ill-contacts, new foods, farm animals, foreign travel
Pain	Location, quality, radiation, duration
Preillness weight	Compare current weight with recent previous weight, weight loss is a sensitive indicator of dehydration
Identify high-risk factors:	Underlying medical problem, such as cardiac, GI, renal, metabolic, endocrine (diabetes), immunodeficiency, history of abdominal surgery

Physical Exam

- General appearance, VS, Weight
- Mental status (lethargic, listless, decreased activity)
- Respiratory status: tachypnea, hyperpnea (Kussmaul respirations)
- Abdominal tenderness, rebound, or guarding; sunken or distended?
- Concerns for increased ICP (focal neurologic exam, papilledema)

Signs of Dehydration

- Tachycardia, tachypnea, capillary refill >2 seconds
- Absence of tears
- Sunken fontanelle, sunken eyes, tenting, sunken abdomen
- Dry mucous membranes
- Poor skin turgor

Gorelick MH, Shaw KN, Murphy KO. Validity and reliability of clinical signs in the diagnosis of dehydration in children. *Pediatrics* 1997;99(5):e6.

TABLE E.26

DEHYDRATION ASSESSMENT TOOLS

10 Point Dehydration Assessment Tool

Ill-appearance
Tachycardia (HR >150/min)
Abnormal respirations
Sunken eyes
Absent tears
Dry mucous membranes
Abnormal radial pulse
Capillary refill >2 seconds
Decreased skin elasticity
Decreased urine output

4 Point Dehydration Assessment Tool

Ill-appearance
Dry mucous membranes
Absent tears
Capillary refill >2 seconds

10 Point score			4 Point score		
# Features present	**Degree of dehydration**	**% Fluid deficit**	**# Features present**	**Degree of dehydration**	**% Fluid deficit**
<3	Mild	<5	1	Mild	<5
≥3 and <7	Moderate	5–10	2	Moderate	5–10
≥7	Severe	>10	3–4	Severe	>10

Gorelick MH, Shaw KN, Murphy KO. Validity and reliability of clinical signs in the diagnosis of dehydration in children. *Pediatrics* 1997;99(5):e6.

TABLE E.27

NO DEHYDRATION OR MILD DEHYDRATION

RN Bedside Care

- Initial weight, VS
- Antipyretics as appropriate
- Education:
  a. Give specific written and verbal instructions on use of ORT
  b. Provide oral syringes and/or medicine cup for home use
  c. Give clear instructions for follow-up should condition change

TABLE E.28

DISCHARGE

Discharge Criteria

- Clinical signs of dehydration are absent, mild or have resolved
- Caregivers understand how to give ORT and can continue to do so at home
- Caregivers understand discharge instructions and know what to look for

Discharge Instructions

Print out gastroenteritis/dehydration instructions with emphasis on the facts that:

- Oral rehydration solution alone replaces fluid but won't stop the diarrhea
- Breastfeeding should be continued through the illness
- Start appropriate diet once the patient is rehydrated (and preferably early)
  - Complex carbohydrates, fresh fruits, vegetables, lean meats, yogurt
  - Full-strength formula
- Avoid antidiarrheal medications
- Antipyretics as usual

TABLE E.29

MODERATE DEHYDRATION (5–10% DEHYDRATION)

RN Bedside Care

- Initial weight, VS
- Antipyretics as appropriate
- Monitor and document I/O's, urine-specific gravity, and dip with first void
- Initiate ORT, refer to:
  - Instructions for the Medical Team
  - Instructions for the Family
  - ORT Record Sheet—to print instructions, open link, then right click and select print
  - Teach the family to document on the I/O Worksheet
  - Enter I/O in EHR

Ondansetron (Oral)

Consider using for patients with:

- Persistent emesis
- Severe nausea

Patient weight (kg)	Oral dose of ondansetron (mg)
8–15	2
>15–30	4
>30	8
Less than 6 mo or 8 kg, off label use, review with pharmacy/attending staff	

TABLE E.30

ORT INSTRUCTIONS FOR THE MEDICAL TEAM

ORT works via the sodium glucose cotransport mechanism, which optimizes intestinal absorption of water. Utilizing the correct electrolyte solution is critical for its success. Adding juice to the solutions alters the sodium to glucose concentration and diminishes the efficacy of ORT.

Appropriate Solutions

- Pedialyte
- Gatorade ½ strength with saltine crackers in older patients

Total Volume to be Given over 3–4 h

Mild/moderate dehydration	5–10% dehydration	50 mL/kg
Moderate/severe dehydration	>10% dehydration	100 mL/kg

Ongoing Losses

- 5–10 mL/kg for each diarrheal stool
- 2 mL/kg for each emesis

Aliquot Volume to be given every 5 min

Mild/moderate dehydration	1 mL/kg
Moderate/severe dehydration	2 mL/kg

Double the aliquot volume as tolerated after the first 30 min
Maximum aliquot volume is 30 mL

TABLE E.31

ORAL REHYDRATION THERAPY INSTRUCTIONS FOR FAMILIES

- ORT is a treatment we use for dehydrated patients.
- A small amount of liquid (1–2 mL/kg of the child's body weight is administered every 5 min with a syringe or small cup over 3–4 h. To treat your child today, we will start with _____mL every 5 min.
- Pedialyte is the best fluid choice for young children. Older children may refuse this, so ½ strength Gatorade with saltine crackers is substituted. These fluids have the most favorable ratio of glucose and sodium, which helps the intestines to reabsorb water.
- Although your child may want more, it is important to give the fluid slowly. This allows the stomach to absorb the liquid and helps prevent vomiting. Please watch the clock and give only the recommended amount every 5 min.
- Your child may refuse the fluid initially, but with a few feeds it often gets much easier and the child begins to take the fluids.
- If your child vomits, let your nurse know. If it is only a small amount, we will continue ORT. If it is a large amount, we may need to stop and place an IV.
- If your child repeatedly refuses the feeds or is passing frequent, large-volume stools, we may need to place an IV.

TABLE E.32

HOME ORAL REHYDRATION THERAPY RECORD SHEET

Pre-weight:_____

Post-weight:_____

Time	Amount of fluid taken (mL)	Emesis (# times)	Diarrhea (# times)

TABLE E.33

REASSESS AFTER 1 HOUR

RN Bedside Care
- Repeat VS
- Antipyretics as appropriate
- Assess I/O's and Urine Specific Gravity (USG)
- Repeat Dehydration Assessment Tools

ORT Success
- After 30–60 min, double aliquot volume if patient is doing well

ORT Failure
- Patient has received less than half of hourly requirement
- Patient repeatedly refusing ORT
- Persistent emesis, significant ongoing losses from diarrhea (see "Severe Dehydration" for IVF recommendations)

TABLE E.34

REASSESS AFTER 2 HOURS

RN Bedside Care
- Repeat VS
- Antipyretics as appropriate
- Assess I/O's and USG
- Repeat Dehydration Assessment Tools

ORT Success
- Prepare patient and family for discharge

ORT Failure
- Patient has received less than half of hourly requirement
- Patient repeatedly refusing ORT
- Persistent emesis, significant ongoing losses from diarrhea (see "Severe Dehydration" for IVF recommendations)

TABLE E.35

SEVERE DEHYDRATION

MD/RN Bedside Care
General
Initial weight, VS
Antipyretics as appropriate
Monitor and document I/O's, urine-specific gravity, and dip with first void

Place IV
Bedside glucose, alert MD immediately if result <70 mg/dL
D_{10} bolus when indicated, repeat glucose in 30 min
Dextrose 10%—0.25–0.5 g/kg OR 2.5–5 mL/kg
Serum electrolytes for all patients
Consider other labs as indicated for individual patients

IVF
NS 20 mL/kg over 15–30 min
Reassess with Dehydration Assessment Tool
Repeat NS 20 mL/kg as needed

Ondansetron (Oral or IV)
Consider using for patients with:
Persistent emesis
Severe nausea

Patient weight (kg)	Oral dose of ondansetron (mg)
8-15	2
>15–30	4
>30	8
(Less than 6 mo or 8 kg consultation regarding usage)	

Recommended IV dose for Ondansetron is 0.15 mg/kg, maximum dose 8 mg
Further Diagnostic Testing
- Consider need for urinalysis, urine culture
- Stool for bacterial culture and *Clostridium difficile*

Bloody, mucous stools
Diarrhea >7–10 days

ORT
- Initiate when patient is able
  Refer to ORT Box
  To print instructions, open link, then right click and select print
  Teach the family to document on the I/O Worksheet
  Enter I/O in EHR

TABLE E.36

REASSESS AFTER 2ND NS BOLUS

RN Bedside Care
- Repeat VS
- Antipyretics as appropriate
- Assess I/O's, and USG
- Repeat Dehydration Assessment Tools

Criteria for ORT
- Significant improvement in Dehydration Assessment Score
- Emesis resolving
- Diarrheal output not excessive
- Laboratory studies not concerning
- Initiate ORT
  - Refer to ORT box
  - To print instructions, open link, then right click and select print
  - Teach the family to document on the I/O Worksheet
  - Enter I/O in EHR

Criteria for Continued IV Therapy/Admission
- Little to no improvement in Dehydration Assessment Score
- Persistent significant losses
- Hypoglycemia, significant electrolyte abnormalities

IVF

Consider need for third NS bolus

Moderate dehydration	1.5 × maintenance
Severe dehydration	2 × maintenance

To calculate maintenance mL/h, use patient's weight in kg:
4 mL/kg for the first **10** kg
+ **2** mL/kg for the next **10** kg
+ **1** mL/kg for each kg over **20** kg

Example: 25 kg
4 × 10 = 40
+ **2** × 10 = 20
+ **1** × 5 = 5

Maintenance rate is 65 mL/h
1½ Maintenance is 98 mL/h

TABLE E.37

ORT/REASSESS

RN Bedside Care
- Repeat VS
- Antipyretics as appropriate
- Assess I/O's and USG
- Repeat Dehydration Assessment Tools

ORT Success
- Prepare patients and family for discharge

ORT Failure/Admission
- Patient has received less than half of hourly requirement
- Patient repeatedly refusing ORT
- Persistent emesis, significant ongoing losses from diarrhea
- Reinstitute IVF, admit

ED Guidelines for Evaluation/Treatment of Children with Known/Suspected Type I Insulin-Dependent Diabetes Mellitus (IDDM) with DKA

CYNTHIA JACOBSTEIN, M.D., JANE LAVELLE, M.D., STEVEN WILLI, M.D.

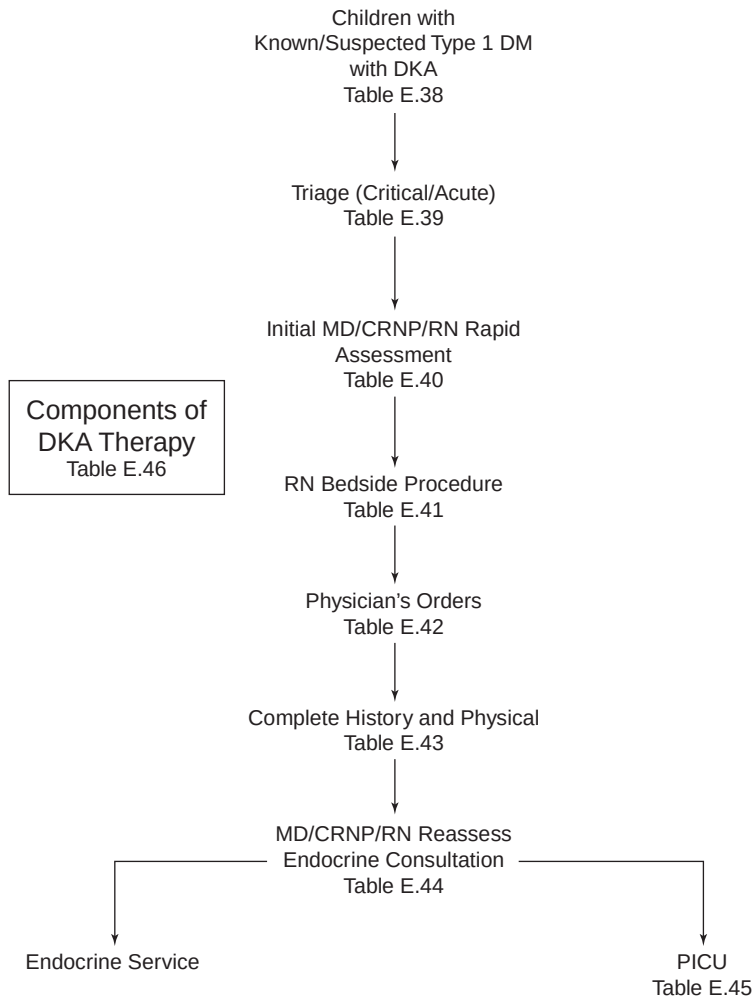

TABLE E.38

CHILDREN WITH KNOWN/SUSPECTED TYPE 1 DM WITH DKA

Definition:	
■ Hyperglycemia	Blood sugar >200 mg/dL
■ Acidosis	pH <7.3
■ Ketonuria/Ketonemia	HCO_3 <15 mEq/L

TABLE E.39

TRIAGE (CRITICAL/ACUTE)

Critical	Acute
Hypotension	IDDM with illness:
Abnormal Mental Status	Vomiting
Severe tachycardia, hyperpnea (Kussmaul respirations)	Fever
	H/O hyperglycemia
	H/O ketonuria

TABLE E.40

INITIAL MD/CRNP/RN RAPID ASSESSMENT

History
- Serum glucose levels (home, office, EMS provider)
- Home urine ketones
- Insulin use, most recent dose?
- Insulin pump?
- Other symptoms—fever, vomiting, other

Physical Exam
- Vital signs
- Brief neurologic assessment
  Level of alertness/AVPU/GCS
  Pupils—size and responsiveness
- Respiratory status—distress, hyperpnea, other?
- Perfusion
  Capillary refill
  Pulses

TABLE E.41

RN BEDSIDE PROCEDURE

General
- Place patient on CR monitor
- Begin documentation on DKA flowsheet
- Document vital signs every 15 min

IV Placement
- Discuss the need for IV placement with patient/family, obtain the following specimens:
  Bedside glucose
  Venous blood gas (VBG) or bedside I-stat/other
  Serum electrolytes, glucose, Mg, PO_4
  CBC with differential

Urine Specimens
- Obtain urine for ketones, glucose
- Pregnancy tests in postpubertal girls

IVF Fluids
- Begin normal saline (NS) bolus 10 mL/kg over 30 min

TABLE E.42

PHYSICIAN'S ORDERS

Use the DKA Order Set that includes the following:

Laboratory
Venous blood gas
Serum electrolytes with glucose, Mg, PO_4
CBC with differential
UA dip
Bedside glucose
Urine for HCG (as needed)

IV Fluids
NS bolus (complete 20 mL/kg bolus)
Confer with ED physician/provider for subsequent boluses
Two bag IVF system:
D_0 NS with 20 mEq KCl/L and 13.6 mmoles KPO_4/L[a]
D_{10} NS with 20 mEq KCl/L and 13.6 mmoles KPO_4/L

Insulin Infusion
Administer 0.1 units/kg/h of regular insulin (based on standard concentrations of continuous infusion at your institution)
Discontinue the patient's personal insulin pump when the insulin infusion is ready

[a]13.6 mmoles KPO_4 provides 20 mEq of potassium.

TABLE E.43

COMPLETE HISTORY AND PHYSICAL—IDENTIFY POSSIBLE CAUSES FOR DKA

History
- Onset of symptoms
  - If first onset, obtain history of polyuria, polydipsia, amount of weight loss, etc.
- Other systemic symptoms:
  Fever
  Respiratory
  GI/GU
- Recent blood glucose levels, urine ketones, insulin use
- Age at diagnosis of IDDM
- Past history of DKA
- Other PMH
- Medications, allergies

Physical Examination
- Review vital signs
- Complete exam with focus on:
  Airway
  Breathing
  Circulation (perfusion, capillary refill)
  Neurologic system
  Other systems related to complaints

TABLE E.44

MD/CRNP/RN REASSESS

MD/CRNP Reassess
- Mental status, vital signs, I/O
- Review venous blood gas or I-stat, glucose, urine ketones
- Consider 12 lead ECG for patients who have K > 6

Characteristics of High-Risk Patients

Age <5 yr, especially <2 yr
Obtunded or decline in mental status in the ED
pH <7.1
Glucose >1,000 mg/dL
Na (measured) >155 mEq/L or falling calculated Na
K <3.5 mEq/L

- Endocrine consultation
- Evaluate the need for CNS imaging if mental status not good, improving in first few hours of RX.

RN Reassess/Documentation on DKA Flowsheet
- Frequent vital signs (q15min)
- Mental status check (q30min)
- Hourly (time from start of IV)

Blood glucose
I/O

- One hour after insulin infusion begins:

Repeat VBG (or bedside I-stat), serum electrolytes with Mg, PO_4
Repeat these every 2 h as needed, discuss with the MD

TABLE E.45

CRITERIA FOR PICU ADMISSION

- Obtundation, coma, or decline in mental status during therapy
- Uncompensated shock; labile compensated shock
- Respiratory—failure of ability to compensate for metabolic acidosis
- Significant metabolic acidosis

Consider also:
- Age <2 yr
- Glucose >1,000 mg/dL
- Falling corrected serum Na[a] see Table E.46
- Significant hypokalemia (K persistently <3.5 mEq/L)

TABLE E.46

THREE KEY COMPONENTS OF DKA THERAPY

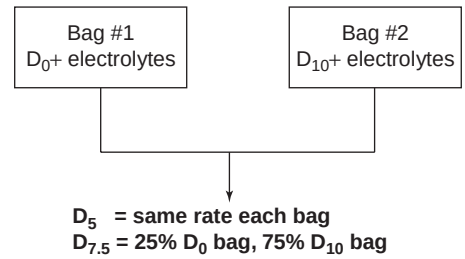
1. **Fluid Therapy**

NS Resuscitation

NS bolus 20 mL/kg
Repeat NS boluses only with EM staff review

Two Bag System (IVF following the initial saline bolus)

Bag #1: NS, KCl, KPO_4
Bag #2: Same as bag#1 plus D_{10}



Electrolytes

Patient's K mEq/L	mEq KCL/L	mEq KPO_4/L	mmol KPO_4/L[a]
<3.5	30	30	20.4
3.5–5	20	20	13.6
5–6	10	10	6.8
>6	0	0	0

Dextrose

Start dextrose when the patient's glucose is <300 mg/dL
Change dextrose delivered by changing flow rates of the two bags

Rate

Run IVF at 1½ maintenance rate based on patient weight
To calculate maintenance cc/h, use patient's weight in kg:
4 mL/kg for the first 10 kg
+ **2** mL/kg for the next 10 kg
+ **1** mL/kg for each kg over 20 kg

Example: 25 kg

4 × 10 = 40
+ 2 × 10 = 20
+ 1 × 5 = 5
Maintenance rate is 65 mL/h
1½ Maintenance is 98 mL/h

2. **Insulin Infusion**

Regular insulin at rate of 0.1 unit/kg/h
No insulin boluses
Goal—Drop glucose by 50–100 mg/dL every hour

3. **Reassessment**

Frequent vital signs (q15min)
Mental status check (q30min)

Hourly:

Blood glucose
I/O

One hour after insulin infusion begins:

Repeat VBG or I-stat as needed, serum electrolytes with Mg, PO_4

http://www.guidelines.gov/summary/summary.aspx?doc_id=6826&nbr=004193&string=dka

[a]Formula for correction of serum Na: $Na_{corrected} = Na_{measured} + 1.6 \times [\text{Serum glucose} - 100]/100$

ED Evaluation of Children with Suspected Appendicitis without Known GI Disease

JANE LAVELLE, M.D., MICHAEL NANCE, M.D., KASSA DARGE, M.D., MARK JOFFE, M.D.

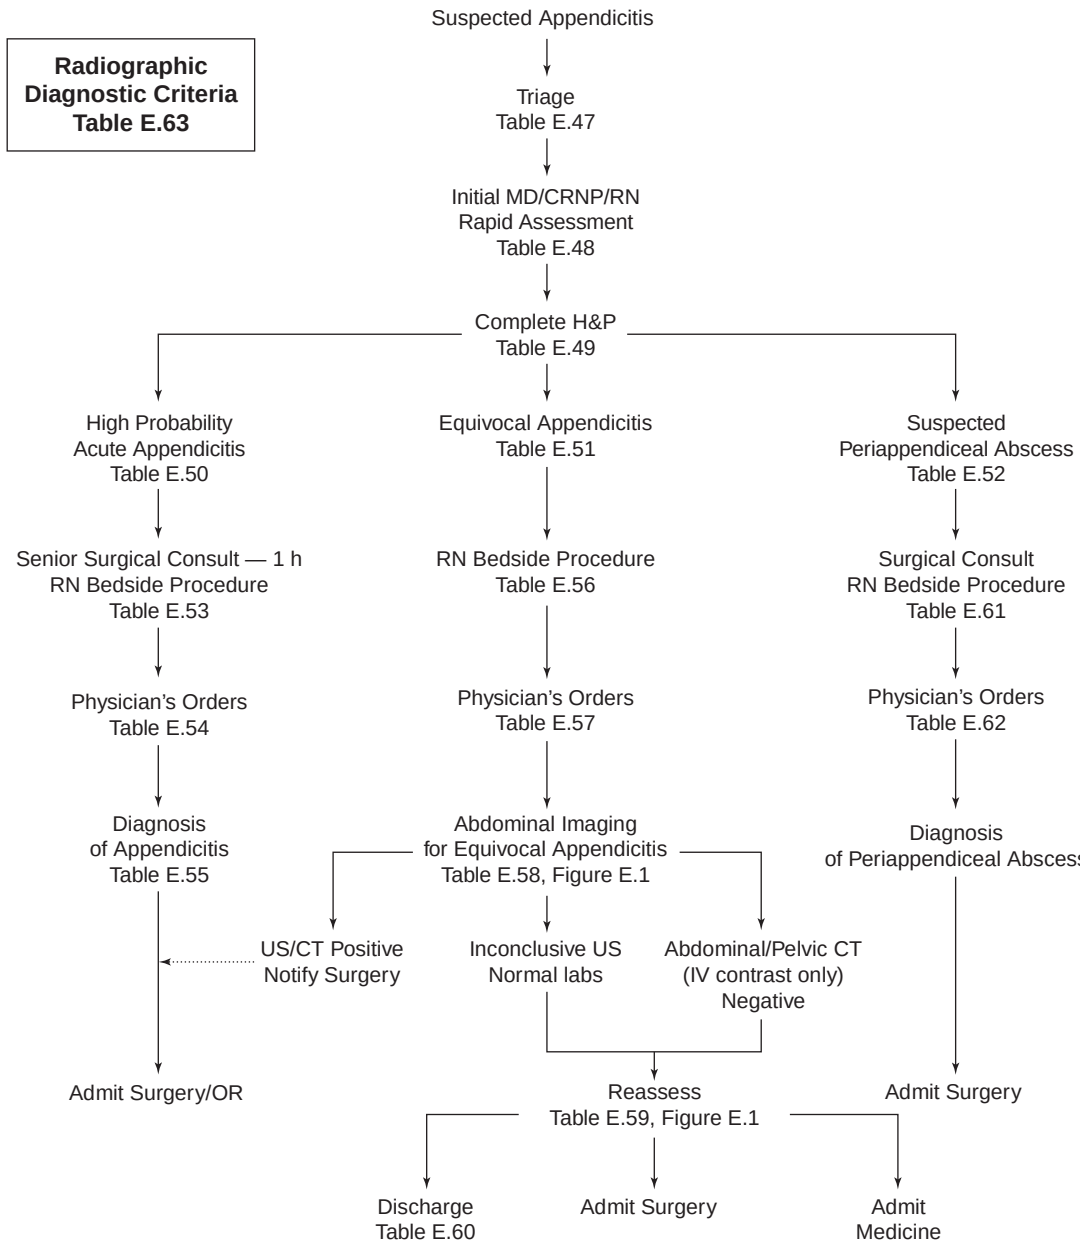


TABLE E.47

TRIAGE

Critical	Acute	Urgent
Abnormal mental status	Peritoneal irritation Pain with ambulation Inability to stand erect Pain with cough Pain with bumps during car ride	Periumbilical pain with anorexia
Abnormal VS	Focal right-sided abdominal pain or tenderness Bilious emesis Significant abdominal distension	Nausea and vomiting

Maintain NPO status—Inform patient and family of NPO status and apply as needed

Pediatric Vital Sign Normal Ranges

Age group	Respiratory rate (per min)	Heart rate (per min)	Systolic blood pressure (mm Hg)
Newborn	30–50	120–160	50–70
Infant (1–12 mo)	20–30	80–140	70–100
Toddler (1–3 yr)	20–30	80–130	80–110
Preschooler (3–5 yr)	20–30	80–120	80–110
School Age (6–12 yr)	20–30	70–110	80–120
Adolescent (13+ yr)	12–20	55–105	110–120

TABLE E.48

INITIAL RN/CRNP/MD RAPID ASSESSMENT

Review triage information, vital signs
Place all critical/acute patients on CR monitor
Reinforce NPO status
Assess hydration status, need for IV placement
Assess need for pain control
Apply Lidocaine 4% (LMX-4) prior to IV *immediately* as per protocol

TABLE E.49

COMPLETE H&P

History	
Onset of Symptoms	
Pain	Onset, description, duration, location, migration Severity (use pain scale score) Evidence of peritoneal irritation
Anorexia/nausea	Lack of appetite Last good meal Oral intake since symptom onset Fluid intake, urine output
Vomiting	Time of onset, last episode Number of episodes Bilious/bloody
Stool	Time of last stool Diarrhea, blood/mucous
Fever	Duration, height Medications given
Other associated symptoms	Cough, URI, GU, etc.
Past medical history	Prior abdominal pain episodes
Physical Examination	
General Appearance, Vital Signs	
Abdomen	Focal tenderness, guarding/rebound, distension Psoas, obturator, Rovsing's signs CVA tenderness
Genital	Tanner stage Inguinal canal abnormality Scrotum/testicles abnormalities Bimanual exam, as indicated Rectal exam, as indicated

TABLE E.50

HIGH-PROBABILITY ACUTE APPENDICITIS

RLQ tenderness with or without rebound
Pain with movement (cough, car ride, jumping on right foot)
Symptoms less than 24–48 h
Anorexia, followed by vomiting
Pain **preceding** vomiting
Migration of pain from periumbilical region to RLQ

TABLE E.51

EQUIVOCAL ACUTE APPENDICITIS

Presenting with focal abdominal tenderness (usually right-sided) with variable number of the features of high-probability acute appendicitis

TABLE E.52

SUSPECTED PERIAPPENDICEAL ABSCESS

Systemic toxicity
Fever
Symptoms >48–72 h
Diffuse abdominal tenderness and guarding
Urinary and/or rectal urgency
Palpable RLQ mass
WBC, ANC, CRP consistent with marked inflammation

TABLE E.53

SENIOR SURGICAL CONSULT/RN BEDSIDE PROCEDURE

Senior Surgical Consultation
- Goal—Surgery fellow/attending to evaluate patient **within 30–60 min**

RN Bedside Procedure
General
- Place critical/acute patients on CR monitor
- Document VS q1h
- Document IVF, voids, urine concentration specific gravity

IV Placement
Discuss the need for IV placement with patient/family, obtain the following specimens:
- CBC, C-reactive protein, serum electrolytes and glucose, other as indicated.
- Consider need for bedside glucose testing
- Blood culture for toxic patients

Urine Specimens
- Urinalysis (i.e., urine dip or laboratory)
- Urine HCG (for girls ≥12 yr of age).

IVF Fluids
Begin NS bolus 20 mL/kg over 60 min

TABLE E.54

USE PHYSICIAN'S ORDERS FOR SUSPECTED APPENDICITIS

Laboratory
CBC with differential, C-reactive protein, electrolytes and glucose
Urinalysis or UA dip, Urine HCG

IV Fluids
NS bolus 20 mL/kg; repeat as needed
Continued fluids:
Use D_5 ½ NS with 20mEq KCl/L (add KCl after patient urinates)
Rate 1½ maintenance

To calculate maintenance mL/h, use patient's weight in kg:
4 mL/kg for the first 10 kg
+ **2** mL/kg for the next 10 kg
+ **1** mL/kg for each kg over 20 kg

Example: 25 kg
4 × 10 = 40
+ **2** × 10 = 20
+ **1** × 5 = 5
Maintenance rate is 65 mL/h
1½ Maintenance is 98 mL/h

Analgesia
Assess pain and treat with parenteral medication

Antibiotics with high-risk appendicitis preoperatively or with abscess to be admitted.

Administer:
Unasyn® (ampicillin/sulbactam) Dose—50 mg/kg ampicillin component up to 2 g IV
Clindamycin (in PCN allergic patients)—10–15 mg/kg (maximum 600 mg) IV

TABLE E.55

DIAGNOSIS OF APPENDICITIS

Other Criteria Supporting High Probability
- ANC > 6,750
- CRP > 2
- WBC > normal for age
- Negative UA
- Fecalith

Further Radiographic Testing
The need for further imaging should be discussed between responsible ED staff and surgical consult. Ultrasound is the study of choice for nonobese patients. Its advantages include lack of patient exposure to ionizing radiation, as well as evaluation of ovarian anatomy and flow.

Optimal study in nonobese patients	Ultrasound
Alternative choice	Abdominal/pelvic CT with IV contrast only **Use pediatric CT settings to minimize radiation exposure**

TABLE E.56

RN BEDSIDE PROCEDURE

General
Place critical/acute patients on CR monitor
Document vital signs as per protocol
Document IVF, urine output and urinalysis with specific gravity

IV Placement
Discuss the need for IV placement with patient/family, obtain the following specimens:
CBC, C-reactive protein, electrolytes, and glucose
Consider need for bedside glucose
Blood culture for toxic patients

Urine Specimens
Urine dip
If urine dip is positive, send for formal lab UA
Send urine culture if formal lab UA suggests UTI

For postpubertal girls add:
Urine pregnancy test
Consider urine screen for GC/Chlamydia

IVF Fluids
Begin NS bolus 20 mL/kg
Prepare for bladder catheterization as per US-Foley protocol

TABLE E.57

PHYSICIAN'S ORDERS

Use ED Physician's Orders for Suspected Appendicitis

Laboratory
CBC, C-reactive protein, electrolytes and glucose.
UA dip
Urine for HCG, culture and screen for GC/Chlamydia as needed

Radiology
Consider obstruction series
See Abdominal Imaging for radiographic study indicated (Figure E.1)

IV Fluids
NS bolus 20 mL/kg; repeat as needed
Continued fluids:
Use D_5 ½ NS with 20mEq KCl/L (add KCl after patient urinates)
Rate 1½ maintenance

To calculate maintenance mL/h, use patient's weight in kg:
4 mL/kg for the first **10** kg
+ **2** mL/kg for the next **10** kg
+ **1** mL/kg for each kg over **20** kg

Example: 25 kg
4 × 10 = 40
+ 2 × 10 = 20
+ 1 × 5 = 5
Maintenance rate is 65 mL/h
1½ Maintenance is 98 mL/h

Analgesia
Assess pain and treat

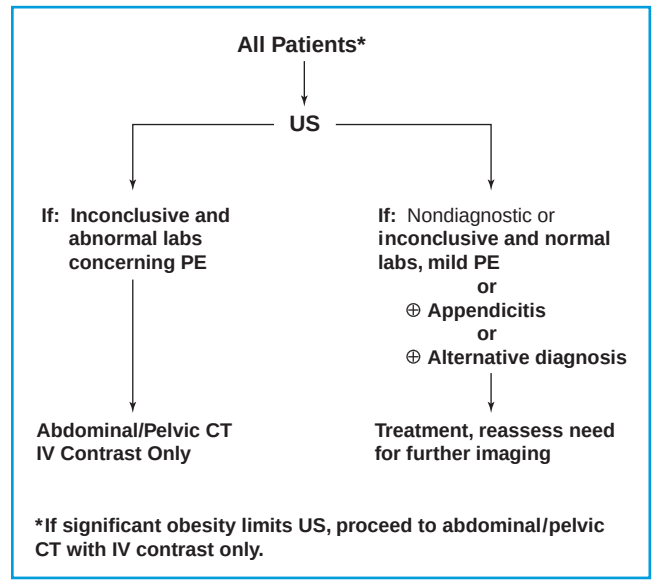

FIGURE E.1 Abdominal Imaging for Equivocal Appendicitis.

TABLE E.58

ORDERS FOR ABDOMINAL IMAGING

US	Male	Limited abdomen, focus on RLQ
	Female	Limited abdomen, focus on RLQ Pelvic with Doppler study

Abdominal/pelvic CT IV Contrast Only

TABLE E.59

REASSESS

- VS, pain, abdominal exam
- Review all laboratory and radiology studies
- Reassess need for further imaging with abdominal/pelvic CT with IV contrast only
- Consider other diagnoses vs. very early appendicitis
- Complete surgical consultation, as needed
- Consider po challenge as clinically indicated

Negative Predictors for Appendicitis
- WBC <10,000/μL
- ANC <6,750/μL
- No percussion tenderness on physical examination
- No guarding on physical examination
- No nausea, emesis

Patients with symptoms >24 h, CRP <2, and ANC < 6,750 are highly unlikely to have acute appendicitis

TABLE E.60

DISCHARGE

Anticipatory Guidance
Return to MD for persistent/worsening symptoms
Monitor hydration
Analgesia instructions
Treatment for disease identified
Use discharge instructions for abdominal pain

TABLE E.61

SURGICAL CONSULT/RN BEDSIDE PROCEDURE

Surgical Consult
Consult surgery resident/fellow/attending for suspected acute abdomen, especially with potential periappendiceal abscess

RN Bedside Procedure
General
Place critical/acute patients on CR monitor
Document vital signs as per protocol
Document IVF, urine output, urine specific gravity

IV Placement
Discuss the need for IV placement with patient/family, obtain the following specimens:
CBC, C-reactive protein, serum electrolytes, with glucose
Consider need for bedside glucose
Blood culture for toxic patients

Urine Specimens
Urine dip
Urine HCG

IVF Fluids
Begin NS bolus 20 mL/kg over 30–60 min

TABLE E.62

PHYSICIAN'S ORDERS WITH SUSPECTED ABSCESS

Use Physician's Orders for Suspected Periappendiceal Abscess
Laboratory
CBC, CRP, electrolytes and glucose
UA dip, Urine HCG

Radiology
Order abdominal/pelvic CT with oral and PO contrast at 0 h and 2 h, and IV contrast

IV Fluids
NS bolus 20 mL/kg; repeat as needed
Continued fluids:
Use D_5 ½ NS with 20 mEq KCl/L (add KCl after patient urinates)
Rate 1½ maintenance

To calculate maintenance mL/h, use patient's weight in kg:
4 mL/kg for the first **10** kg
+ **2** mL/kg for the next **10** kg
+ **1** mL/kg for each kg over **20** kg

Example: 25 kg
$4 \times 10 = 40$
$+ 2 \times 10 = 20$
$+ 1 \times 5 = 5$
Maintenance rate is 65 mL/h
1½ Maintenance is 98 mL/h

Analgesia
Assess pain and treat

Antibiotics
Administer:
Unasyn (dosing noted) + Gentamycin (2–2.5 mg/kg, max 120 mg)
Clindamycin + Gentamycin (PCN allergic patients)

TABLE E.63

RADIOGRAPHIC DIAGNOSTIC CRITERIA

Ultrasound
Positive for Appendicitis
Noncompressible fluid-filled distended tubular structure with diameter ≥6 mm
With or without an appendicolith
No peristaltic activity
Constant shape and position
Anterior to the psoas muscle or in the retrocecal position
Suggestive for Appendicitis
Pericecal inflammatory changes in the absence of visualizing an abnormal appendix

CT
Positive for Appendicitis
Enlarged appendix >6 mm
Nonopacified appendiceal lumen
Significant wall enhancement with IV contrast material
Periappendiceal fat stranding
Appendicolith
Free fluid or abscess in RLQ/pelvis
Focal cecal wall thickening

FIGURE 101.13 Periungual desquamation during the convalescent phase of Kawasaki disease.

FIGURE 111.6 Photographs of a 3-year-old boy after an attack by a dog. The **top** photograph shows the child before sharp debridement, facial nerve exploration, and layered closure of his complex wound. The **middle** panel is a photograph of the child 1 week after his repair and demonstrates the precise reapproximation of the facial soft tissues. The **bottom** photograph was taken 8 months after the attack and demonstrates a nicely healed facial scar that will continue to fade and soften. (Courtesy of David W. Low, MD.)

FIGURE 117.2 Normal right retina as viewed by indirect ophthalmoscope. Central dark area *(thick arrow)* represents fovea. Note that the apex of the branch point of the blood vessels *(thin arrows)* always points back toward the direction of the optic nerve head.

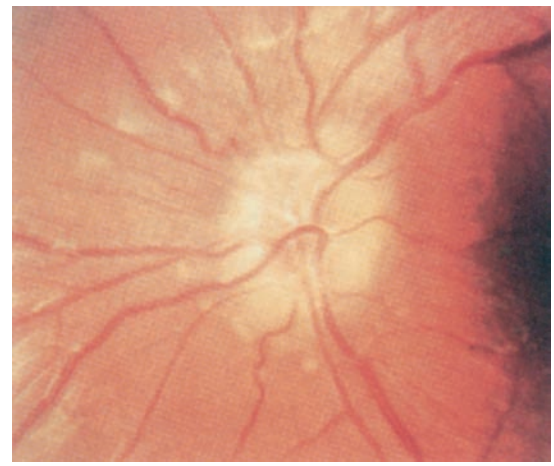

FIGURE 117.3 Papilledema. Note blurred disc margins and loss of view of blood vessels on disc.

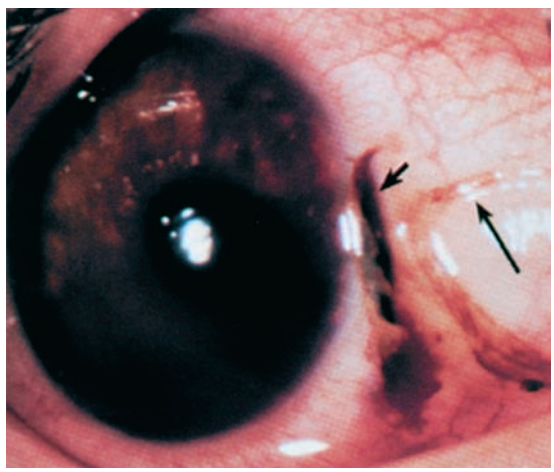

FIGURE 117.7 Ruptured globe. The scleral laceration *(short arrow)* appears as a linear brown line on the white of the eye. The pupil has a teardrop shape, the apex of which points in the direction of the rupture. The *long arrow* points to the upper border of a large conjunctival laceration. Note that the underlying sclera is intact under the conjunctival laceration. There is a diffuse hyphema in the anterior chamber, which partially obscures the pupil.

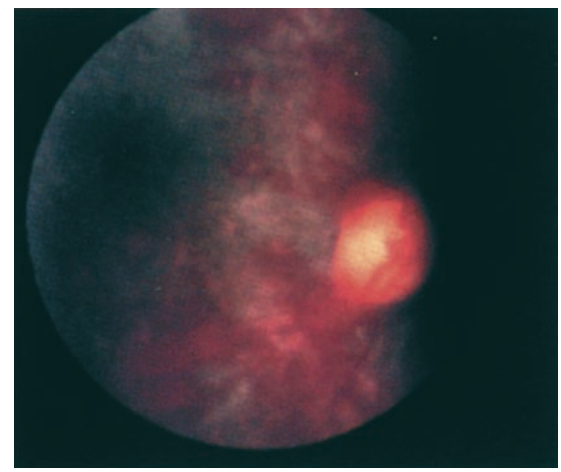

FIGURE 117.14 Retinal hemorrhages in abusive head injury.

FIGURE 119.5 Dermoid cyst abscess. (From Fleisher GR, Ludwig W, Baskin MN, eds. *Atlas of pediatric emergency medicine*. Philadelphia, PA: Lippincott Williams & Wilkins, 2004. Reprinted with permission.)
