The major source of excess lead absorption in children is lead-based paint, widely used in home interiors through the 1950s. In addition to the ingestion of macroscopic-size chips of paint, inner-city children are often exposed to house dust with a high lead content that results from finely crumbled paint particles, which gets on their hands and toys. Repetitive mouthing can lead to increased lead exposure even in the absence of observable pica. Although classically a disease of poor inner-city residents, the more recent phenomenon of young, middle socioeconomic level families moving into older sections of large cities and renovating town houses has led to an expanded population at risk. This is because the sanding, stripping, and burning of lead-based paint from woodwork in such houses has also been associated with lead intoxication in the occupants. Other unusual sources of lead exposure include the burning of battery casings for heat, soft well water carried by outdated lead pipes, improperly home-glazed ceramics, drinking glass-glazed decals, and dust or dirt alongside heavily traveled roads (resulting from auto emissions in communities still using leaded gasoline). Infants have also developed elevated lead levels when parents prepare formula with first-draw tap water or when they boil the water before mixing.

Pathophysiology

Absorption of lead occurs through GI and pulmonary routes, although the former is predominant in pediatric intoxications. Lead is then compartmentalized into three main areas: bone, soft tissues, and blood. Excretion occurs slowly through urine, feces, and sweat. Children are probably at double jeopardy as compared with adults in that there is experimental evidence that younger animals have increased absorption and also a heavier distribution into soft tissues (including the brain). Concomitant nutritional deficiency, especially low dietary iron and calcium, may enhance intestinal lead absorption. Unfortunately, the same children at greatest risk for lead poisoning by virtue of age and residence are also likely to be at risk for dietary deficiency, especially iron.

Lead exerts its toxic effect principally by two mechanisms: by interference with calcium function at the cellular level and by enzyme inhibition, particularly on enzymes rich in sulfhydryl groups. In humans, the most obvious effects are on neurologic function and on the heme synthesis pathway, which is interrupted at several points, resulting in abnormally high levels of porphyrins and their precursors.

Clinical Findings

Early signs and symptoms of plumbism are notably vague and nonspecific. Abdominal complaints, including colicky pain, constipation, anorexia, and intermittent vomiting, are common; of course, these same symptoms are often ascribed to relatively normal 2-year-old children by their parents. The child with early plumbism may also show listlessness and irritability. When encephalopathy begins, the child develops persistent vomiting and becomes drowsy, clumsy, or frankly ataxic. As encephalopathy worsens, the level of consciousness deteriorates further, and seizures commonly occur. Pathologic examination of brains of children who have died of lead encephalopathy shows severe cerebral edema with vascular damage; intracranial pressure is often, although not invariably, increased during the encephalopathy. When spinal fluid is examined, it often reveals a picture similar to that of aseptic meningitis with a mononuclear pleocytosis and elevated protein; however, lumbar puncture should be avoided if possible because of the risk of subsequent herniation. Peripheral neuropathy often occurs in adults with lead poisoning but is rare in children, although it is seen occasionally in those with an underlying hemoglobinopathy. Other organs may be damaged by lead. The kidneys may develop disturbances that range from slight aminoaciduria to a full Fanconi's syndrome with glycosuria and phosphaturia (in addition to aminoaciduria). High blood lead level (BLL) is also associated with a microcytic anemia that results from a defect in hemoglobin synthesis. However, much of the anemia seen in children with excess BLL may be caused by concurrent iron deficiency. A moderately sensitive laboratory measure of lead effect on heme synthesis is the evaluation of erythrocyte protoporphyrin (EP), a heme precursor. Moderately elevated EP levels are seen in iron deficiency, but levels above 250 to 300 μg per dL are almost always the result of chronic lead poisoning.

Management

The asymptomatic child discovered to have a BLL in the 20 to 44 μg per dL range, particularly if the EP level is higher than 250 μg per dL, deserves immediate referral to a pediatrician or

toxicologist. Such children warrant environmental investigation, clinical evaluation, and case management to reduce lead exposure as expeditiously as possible. Chelation therapy may be considered in some such children. All symptomatic children and those with BLL higher than 44 μg per dL need urgent treatment as outlined next, as well as pediatric consultation to ensure adequate postchelation follow-up.

The remainder of this discussion is addressed primarily to the early recognition and treatment of plumbism, including acute lead encephalopathy. This single aspect of chronic childhood lead poisoning is focused on because it represents a true medical emergency.

Recognition

As stated previously, to recognize mildly symptomatic patients with lead poisoning (or asymptomatic children with high lead levels, who are at great risk to soon become symptomatic) requires a high index of suspicion. All children between 1 and 5 years of age are suspect if they have (i) persistent vomiting, listlessness or irritability, clumsiness, or loss of recently acquired developmental skills; (ii) afebrile convulsions; (iii) a strong tendency to pica, including a history of acute exploratory ingestions or aural or nasal foreign body; (iv) a deteriorating pre-World War II house or a parent with industrial exposures; (v) a family history of lead poisoning; (vi) iron-deficiency anemia; or (vii) evidence of child abuse or neglect.

The child between ages of 1 to 5 years who comes to the ED with an acute encephalopathy and the above-cited risk factors presents the physician with a dilemma: lead intoxication requires urgent diagnosis, but confirmation with a BLL is usually not available on an immediate basis. A constellation of historical features of lead poisoning increases the likelihood of the diagnosis. These features include (i) a prodromal illness of several days' to weeks' duration (suggestive of mild symptomatic plumbism); (ii) a history of pica; and (iii) a source of exposure to lead. Several nonspecific laboratory findings make lead poisoning likely enough to warrant presumptive chelation therapy until confirmation by lead levels is available. These findings include (i) microcytic anemia; (ii) elevated EP level, especially if higher than 250 μg per dL (conversely, a normal or minimally elevated EP level, less than 50 μg per dL, would make lead encephalopathy caused by chronic lead paint exposure unlikely); (iii) basophilic stippling of peripheral erythrocytes or, if feasible, of red blood cell precursors on bone marrow examination; (iv) glycosuria; (v) aminoaciduria; (vi) radiopaque flecks on abdominal radiographs; and (vii) dense metaphyseal bands on radiographs of knees and wrists (lead lines—Fig. 102.10).

Abnormalities on examination of cerebrospinal fluid (CSF) are also indicative of lead encephalopathy, including a lymphocytic pleocytosis, elevated protein level, and increased pressure. However, a lumbar puncture should not be performed if lead encephalopathy is strongly suspected because the risk of herniation is considerable. If CSF must be examined to rule out bacterial meningitis, the minimal amount (less than 1 mL) necessary should be obtained. Alternatively, one might institute treatment for presumed meningitis, perform a determination of BLL, and consider a delayed lumbar puncture after several days if the BLL is normal.

Treatment

The treatment of lead poisoning involves relocation of the child to a lead-free environment, chelation therapy, and appropriate supportive care. Symptomatic patients are at risk of developing encephalopathy with subsequent death or neurologic sequelae. In addition, asymptomatic patients with high BLL (especially higher than 100 μg per dL) are also at significant risk for developing CNS involvement and might require urgent treatment.

FIGURE 102.10 Knee radiograph demonstrating increased calcium deposition at metaphysis—the so-called "lead lines." Reproduced with permission from Henretig FM. A toddler in status epilepticus. In: Osterhoudt KC, Perrone J, DeRoos F, et al., eds. *Toxicology pearls*. Philadelphia, PA: Hanley & Belfus, 2004:S2–S5.

The specific chelating drugs commonly used for symptomatic lead intoxication are edetate calcium disodium (CaEDTA) and 2,4-dimercaptopropanol [British Anti-Lewisite (BAL); Table 102.14]. Side effects of CaEDTA include local reactions at injection sites, fever, hypercalcemia, and renal dysfunction manifested by rising BUN and abnormal urine sediment with proteinuria, hematuria, and/or epithelial cells. The major side effects of BAL include nausea and vomiting, so for the first day or two of BAL therapy, it is prudent to maintain the patient on IV fluids and clear liquids or nothing by mouth. BAL is formulated in peanut oil, is given only by IM injection, and also induces hemolysis in patients with G6PD deficiency. Its use is hazardous if the patient has severe hepatic dysfunction, and it forms a toxic complex if given concurrently with iron. Succimer [dimercaptosuccinic acid (DMSA)] has been approved for pediatric use in cases in which BLL exceeds 45 μg per dL (Table 102.14). This water-soluble analog of BAL may be taken orally, and several studies have found such use to be as effective as CaEDTA given parenterally. Some centers use D-penicillamine as an enteral form of chelation for elevated BLLs.

TABLE 102.14

GUIDELINES FOR CHELATION THERAPY OF LEAD POISONING

Condition, BLL	Regimen[a]	Comment
Encephalopathy	BAL 450 mg/m^2/d +	75 mg/m^2 IM every 4 h for 5 days
	$CaNa_2EDTA$ 1,500 mg/m^2/d	Continuous infusion, or 2–4 divided IV doses, for 5 days (start 4 h after BAL)
Symptomatic, and/or BLL > 70	BAL 300–450 mg/m^2/d +	50–75 mg/m^2 every 4 h for 3–5 days (see text)
	$CaNa_2EDTA$ 1,000–1,500 mg/m^2/d	Continuous infusion, or 2–4 divided IV doses, for 5 days (start 4 h after BAL)
Asymptomatic, BLL 45–69	Succimer 700–1,050 mg/m^2/d	350 mg/m^2 TID for 5 days, then BID for 14 days
	or	
	$CaNa_2EDTA$, 1,000 mg/m^2/d	Continuous infusion, or 2–4 divided IV doses, for 5 days

BLL, blood lead level (μg/dL); BAL, British Anti-Lewisite; IM, intramuscular; IV, intravenous.
[a]Doses expressed in mg/kg: BAL 450 mg/m^2 (24 mg/kg), 300 mg/m^2 (18 mg/kg); $CaNa_2EDTA$ 1,000 mg/m^2 (25–50 mg/kg), 1,500 mg/m^2 (50–75 mg/kg); Succimer 350 mg/m^2 (10 mg/kg).
Adapted from American Academy of Pediatrics, Committee on Drugs. Treatment guidelines for lead exposure in children. *Pediatrics* 1995;1996: 155–160; and Henretig FM. Lead. In: Goldfrank LR, Flomenbaum NE, Lewin NA, et al., eds. *Goldfrank's toxicologic emergencies,* 9th ed. New York, NY: McGraw-Hill, 2009.

Asymptomatic children found to have BLL of 45 to 69 μg per dL should have urgent referral and treatment with oral DMSA (typically a 19-day course) or parenteral CaEDTA for 5 days (Table 102.14). If the BLL is higher than 69 μg per dL, combination therapy is initiated with both BAL and EDTA; the BAL may be discontinued in many cases after 2 to 3 days, but CaEDTA is continued for 5 days. Supportive care includes adequate hydration to promote good urine output. Symptomatic children without frank encephalopathy should receive chelation therapy with a combination of BAL for 3 to 5 days and CaEDTA for 5 days. Supportive care includes close monitoring for signs of encephalopathy and, again, maintenance of urine flow.

Patients with encephalopathy require combination chelation therapy with higher dose CaEDTA and BAL for 5 days, as well as intensive supportive care. Fluid therapy is critical and must be individualized. Adequate urine flow is needed to excrete the lead–chelate complexes; however, fluid overload must be avoided so that cerebral edema is not exacerbated. A reasonable goal is to supply basal water requirements, maintaining urine production at 0.35 to 0.5 mL per kcal per 24 hours. Basal water needs in children average 1 mL per kcal and may be calculated as 100 kcal per kg for 0 to 10 kg, plus 50 kcal per kg for 10 to 20 kg, plus 20 kcal per kg for each kilogram above 20 kg.

Seizures commonly occur in acute encephalopathy and should be controlled with anticonvulsant drugs (see Chapter 96). Hypothetical precautions have been made about the use of phenobarbital in lead encephalopathy (i.e., synergistic disturbances in porphyrin metabolism), but its clinical use has not been associated with any noticeable deleterious effect.

Recent advances in the management of cerebral edema and increased intracranial pressure (see Chapter 126 have not been evaluated in a controlled fashion in the context of lead encephalopathy. However, it seems reasonable that noninvasive measures such as prevention of hypoxia and hypercarbia with tracheal intubation and controlled ventilation, seizure treatment and prophylaxis, maintenance of adequate cerebral perfusion pressure, mild hyperventilation with PCO_2 of 30 to 35 mm Hg, and neutral head positioning with head of bed elevation to 30 degrees might have a beneficial effect. Mannitol administration may be helpful in deteriorating patients. Whether more aggressive measures, such as acute hyperventilation for impending herniation, intracranial pressure monitoring, ventricular CSF drainage, induced hypothermia, or barbiturate coma, would enhance survival or decrease morbidity further is unknown.

Oral Hypoglycemics

Although almost all juvenile diabetics require insulin therapy for control, the frequent prescription of oral hypoglycemic agents for patients with non–insulin-dependent, adult-onset diabetes has made the availability and, consequently, the ingestion of these medications commonplace among toddlers. The scenario typically involves visits to a grandparent's home (or conversely, a visit by the grandparent to the child's home). The sulfonylureas (chlorpropamide, glipizide, glyburide) are capable of inducing significant hypoglycemia in a toddler after the ingestion of a single tablet. In addition, the onset of hypoglycemia may be delayed up to 16 to 24 hours after ingestion. Thus, prudent management of such exposures generally implies prolonged close observation and a challenge period of fasting. Excretion of chlorpropamide may be enhanced by urinary alkalinization. The biguanides (e.g., metformin) are unlikely to create hypoglycemia but may promote metabolic acidosis.

Maintenance of euglycemia is usually accomplished in symptomatic patients with the infusion of hypertonic glucose (e.g., 10% to 20%) solutions, supplemented as necessary by bolus doses. Occasionally, patients may still exhibit hypoglycemia, requiring additional treatment. Octreotide, a somatostatin analog that antagonizes insulin release, has been used effectively in cases of refractory hypoglycemia at a suggested dose of 1 to 2 μg per kg per dose every 6 to 12 hours via either an IV or subcutaneous route. Occasionally, patients require glucose infusion for several days; as their condition improves, the glucose load may be tapered gradually with frequent monitoring. Historically, diazoxide has been a useful adjunct in correcting refractory drug-induced hypoglycemia, but its use has largely been replaced by octreotide.

Organophosphates

Background

Organophosphates are lipid-soluble insecticides that are commonly applied in sprayed dust or emulsion formulations. These compounds are found in agricultural and home use, and they form the basis of "nerve gases" in chemical warfare agents (see Chapter 7). Organophosphates are readily degraded in the environment and metabolized in mammals by hydrolic cleavage. Some of these chemicals are "systemic" insecticides, meaning that they are taken up by the roots of the plants and translocated into foliage, flowers, and/or fruits.

Pathophysiology

Compounds of this class can be absorbed by inhalation, ingestion, and skin penetration. They irreversibly phosphorylate the enzyme acetylcholinesterase in tissues, allowing acetylcholine accumulation at cholinergic junctions in autonomic effector sites (causing muscarinic effects), in skeletal muscle or autonomic ganglia (causing nicotinic effects), and in the CNS.

Clinical Findings

The symptoms of acute poisoning usually develop during the first 12 hours of contact. These include findings related to the CNS (dizziness, headache, ataxia, convulsions, and coma); nicotinic signs, including sweating, muscle twitching, tremors, weakness, and paralysis; and muscarinic signs characterized by the SLUDGE mnemonic (including *s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astrointestinal cramping, and *e*mesis). In addition there may be miosis, bradycardia, bronchorrhea, and wheezing; in severe cases, pulmonary edema develops. Severe intoxications may also cause a toxic psychosis that resembles alcoholism.

A history of exposure to organophosphates and the clinical manifestations already discussed are the best clues to an organophosphate poisoning. A depression of plasma or red blood cell cholinesterase activity provides the best laboratory marker of excessive absorption of organophosphates, although it is rarely available on a stat basis. A decrease in the cholinesterase activity of the red blood cells is more specific for organophosphate inhibition than is the plasma assay. Although plasma cholinesterase is depressed by liver injury from various causes and a small percentage of the population has a genetically determined deficiency of plasma cholinesterase activity, a depression of 25% or more is a strong evidence of excessive organophosphate absorption. However, it is important that treatment not be delayed until confirmation of plasma cholinesterase is obtained. Note that children may also encounter acetylcholinesterase inhibitors if they ingest an adult's medication for Alzheimer's or Parkinson's disease (i.e., rivastigmine, donepezil, tacrine, and galantamine).

Management

The management of a patient who has ingested organophosphates must always include safeguards against exposure for the persons who treat the patient because the organophosphates are readily absorbed through the skin and mucous membranes. Patients who have been poisoned by the topical application of organophosphates should receive a thorough scrubbing with a soap solution on admission to prevent further absorption of organophosphates. In addition, all contaminated clothing must be removed and stored in a plastic bag to protect the institutional personnel.

After decontamination, antidotal therapy begins with the administration of atropine sulfate given in a dose of 0.05 to 0.1 mg per kg to children and 2 to 5 mg for adolescents and adults. This dose should be repeated every 10 to 30 minutes or as needed to obtain and maintain full atropinization, as indicated by an end point of clearing bronchial secretions and pulmonary rales. Therapy is continued until all absorbed organophosphate has been metabolized and may require 2 mg to more than 2,000 mg of atropine over the course of a few hours to several days. After atropinization has been instituted, severe poisonings should be treated with the addition of pralidoxime. This drug is particularly useful in poisonings characterized by profound weakness and muscle twitching. A dose of 25 to 50 mg per kg should be administered in 100 mL of saline by infusion over approximately 30 minutes; adults may receive 1 to 2 g by IV. In life-threatening situations, 50% of the initial pralidoxime dose may be infused over 2 minutes, followed by the remainder of the dose over 30 minutes. After loading, a 1% concentration may be infused continuously at the rate of 500 mg per hour in adolescents and adults, or approximately 10 mg per kg per hour in children, and can be titrated to clinical effect. Occasionally, patients may require more than 48 hours of therapy; the end point should be persistent relief of neurologic and cholinergic signs.

Organophosphates are usually dissolved in hydrocarbon bases; thus, the clinician should be prepared to treat hydrocarbon pneumonitis if it develops. Also, bronchopneumonia that complicates the pulmonary edema has been observed in acute poisonings.

Because the organophosphates cause elevated levels of acetylcholine in the plasma, compounds that affect the uptake of acetylcholine and/or its release should be avoided in the management of these patients. Specifically, aminophylline and phenothiazines are contraindicated. In situations in which identification of the ingested insecticides is difficult, consultation may be obtained from the National Insecticide/Pesticide Hotline (800-858-7378). This hotline provides an around-the-clock consultation service for advice on pesticides.

Carbamate insecticides have a similar mechanism of action to organophosphate insecticides but the phosphorylation of acetylcholinesterase is reversible and temporary. Pralidoxime therapy is generally regarded as unnecessary after poisoning from carbamates.

Phenothiazines/Antipsychotics

Background and Pathophysiology

The phenothiazines are commonly prescribed major tranquilizers. Phenothiazines are also often used to treat nausea and vomiting in young children. The toxic effects of this drug class primarily involve the three components of the nervous system: central, autonomic, and extrapyramidal.

The three subgroups of phenothiazines—aliphatic, piperazine, and piperidine—vary in their effects on the different components of the CNS. In general, the aliphatic group (e.g., chlorpromazine) may cause sedation and hypotension in overdose. The piperazine group (e.g., prochlorperazine) is more likely to create extrapyramidal side effects. Several new classes of nonphenothiazine antipsychotic agents are now widely prescribed.

Clinical Findings

The manifestations of phenothiazine toxicity may be dose dependent or dose independent (idiosyncratic). These have significantly different features.

With dose-dependent effects, the manifestations of intoxication after acute ingestion vary from mild to severe. In mild intoxication, CNS signs such as sedation, ataxia, and slurred speech occur. The anticholinergic effects of these drugs may cause constipation, urinary retention, and blurred vision. Because phenothiazines have potent actions on the temperature-regulating center of the hypothalamus, temperature disturbances occur in up to 30% of patients and may consist of hypothermia or hyperthermia. Orthostatic hypotension, the probable result of peripheral vasodilation, may also be noted with mild intoxication.

In moderate intoxications, the patients may have significant depression in the level of consciousness. Extrapyramidal effects become notable at this level of intoxication with muscle stiffness or "cogwheel" rigidity seen on passive movement of the neck, biceps, or quadriceps. Anticholinergic manifestations are severe and include acute urinary retention and paralytic ileus; hypotension may be profound. Cardiac conduction disturbances may make their appearance and are often heralded by a prolonged Q-T interval.

In severe overdoses patients are unarousable. Deep tendon reflexes may be hyperactive. Dystonic reactions may occur, involving the head and neck and the cranial nerves (torticollis and opisthotonos). Arrhythmias and shock may result in death.

The dose-independent effect of the phenothiazines is the dystonic reaction. This striking clinical occurrence consists of episodic spasm of voluntary muscles, particularly those of the head and neck. Patients may develop torticollis, bruxism, tongue protrusion, or oculogyric crisis. Dystonic reactions are unrelated to the amount of ingested phenothiazine. They may or may not occur after the first dose. Their onset is 8 to 40 hours after ingestion of a single dose of phenothiazine. This marked delay between ingestion and clinical manifestations often interferes with obtaining an accurate history of ingestion. Fortunately, although painful and distressing, dystonic reactions are rarely life-threatening and usually resolve quickly after administration of anticholinergics.

The clinical chemistry of the newer antipsychotic agents is varied and complex. CNS depression, seizures, prolongation of the Q-T interval, and α-adrenergic blockade–mediated hypotension are common.

Management

Treatment of acute phenothiazine intoxication hinges on the severity of ingestion. The autonomic signs and symptoms are most often transient and require no treatment. In patients with moderate or severe overdoses, the potential for life-threatening manifestations requires prompt evaluation of vital signs, GI decontamination (if ingestion was within an hour of ED arrival), vascular access, and cardiac monitoring. Pressors such as norepinephrine (see Chapter 3) may be used to correct the hypotension. In those rare instances of hypertension, the use of nitroprusside (see Chapter 34) may be indicated. Severe arrhythmias should be treated aggressively, as detailed later under "Tricyclic Antidepressants" and in Chapter 84. Attention should be directed to the treatment of temperature instability and other autonomic disturbances.

Dystonic reactions are effectively controlled by the IM or IV administration of diphenhydramine in a dose of 1 to 2 mg per kg (max 50 mg per dose). This dose may be repeated within 15 to 20 minutes if no effect is noted. An alternative agent is benztropine mesylate (1 to 2 mg for an older child/adolescent). This agent reportedly causes less sedation than diphenhydramine. Another potential alternative, especially in younger children, is diazepam (0.1 to 0.2 mg per kg). After resolution of the dystonic reaction, oral treatment should be continued for an additional 24 to 72 hours to prevent recurrences.

Plants/Mushrooms

Plant Toxicity

Plants are among the more commonly reported exploratory ingestions in children. Most such ingestions involve common house and garden plants. Fortunately, of the many varieties of such plants, only a small fraction poses a serious toxic hazard (Tables 102.15 and 102.16).

TABLE 102.15

COMMON NONTOXIC PLANTS

Abelia	Eugenia
African daisy	Gardenia
African palm	Grape ivy
African violet	Hedge apples
Airplane plant	Hens and chicks
Aluminum plant	Honeysuckle
Aralia	Hoya
Asparagus fern (may cause dermatitis)	Impatiens
Aspidistra (cast iron plant)	Jade plant
Aster	Kalanchoe
Baby's tears	Lily (day, Easter, or tiger)
Bachelor buttons	Lipstick plant
Begonia	Magnolia
Bird's nest fern	Marigold
Blood leaf plant	Monkey plant
Boston ferns	Mother-in-law tongue
Bougainvillea	Norfolk Island pine
Cactus—certain varieties	Peperomia
California holly	Petunia
California poppy	Prayer plant
Camelia	Purple passion
Christmas cactus	Pyracantha
Coleus	Rose
Corn plant	Sansevieria
Crab apples	Schefflera
Creeping Charlie	Sensitive plant
Creeping Jennie, moneywort, lysima	Spider plant
Croton (house variety)	Swedish ivy
Dahlia	Umbrella
Daisies	Violets
Dandelion	Wandering jew
Dogwood	Weeping fig
Donkey tail	Weeping willow
Dracaena	Wild onion
Easter lily	Zebra plant
Echeveria	

TABLE 102.16

COMMON PLANT TOXIDROMES

Gastrointestinal Irritants
- Philodendron
- Diffenbachia
- Pokeweed
- Wisteria
- Spurge laurel
- Buttercup
- Daffodil
- Rosary pea
- Castor bean

Digitalis Effects
- Lily-of-the-valley
- Foxglove
- Oleander
- Yew

Nicotinic Effects
- Wild tobacco
- Golden chain tree
- Poison hemlock

Atropinic Effects
- Jimsonweed (thorn apple)
- Deadly nightshade

Epileptogenic Effects
- Water hemlock

Cyanogenic Effects
- Prunus species (chokecherry, wild black cherry, plum, peach, apricot, bitter almond)
- Pear (seeds)
- Apple (seeds)
- Crab apple (seeds)
- Hydrangea
- Elderberry

When a child visits the ED after plant ingestion, a general evaluation should be performed. Activated charcoal may be useful in adsorbing plant toxins. The child who remains asymptomatic after a period of observation may then be discharged and observed at home. Children who develop symptoms or for whom there is strong suspicion or confirmation that the ingested plant poses a potentially serious intoxication should be admitted for further observation and specific or supportive treatment.

Specific Categories of Plant Toxidromes

Plants with GI Irritation. Plants that cause GI irritation account for most plant poisonings in the United States. The range of symptoms extends from mild oral burning to a severe gastroenteritis syndrome. Representative species include *Philodendron* and *Dieffenbachia* species (leaves), which cause minor mouth and throat burning; pokeweed (roots, stem), Wisteria (seeds), spurge laurel (berries), buttercup (leaves), and daffodil (bulbs, accidentally substituted for onions), which cause severe vomiting, colicky abdominal pain, and diarrhea; and the toxalbumin-containing plants such as rosary pea and castor bean (seeds), which can cause a violent hemorrhagic gastroenteritis that leads to profound dehydration and circulatory collapse when the seeds are chewed up. The management of this group of ingestions consists essentially of fluid and electrolyte therapy.

FIGURE 102.11 The foxglove plant *(Digitalis purpurea)*.

Plants with Digitalis Effects. Several common garden or wildflowers contain digitalis, and they have been responsible for fatal ingestions. Instances of chewing on leaves or flowers or swallowing the berries of lily-of-the-valley, foxglove (Fig. 102.11), red squill, and oleander all have led to such poisonings. Intoxication has even occurred when water from a vase that contained these flowers was ingested. Early after ingestion, the child may complain of intestinal symptoms such as mouth irritation, vomiting, and diarrhea. As the digitalis is absorbed, typical digitalis effects may ensue, with conduction defects and, at times, serious arrhythmias. Treatment may include administration of digoxin-specific antibody fragments as was previously discussed.

Plants with Nicotinic Effects. Several species of plants contain nicotine or closely related alkaloids. Ingestion of wild tobacco (leaves), golden chain tree (seeds), and poison hemlock (leaves, seeds) usually leads to spontaneous vomiting within 1 hour. Salivation, headache, fever, mental confusion, and muscular weakness may follow, and the child may deteriorate to convulsions, coma, and death from respiratory failure. Charcoal may be useful in adsorbing these nicotinic alkaloids. Further treatment consists of intensive supportive care, with anticonvulsants and ventilatory assistance.

Plants with Atropinic Effects. The most common atropine-containing plant in the United States is jimsonweed, which is widely distributed. Cases most commonly occur in rural areas but have been seen even in inner-city children who managed to find this weed growing in their neighborhoods, where flora in general is scarce.

Symptoms and signs are those of atropinization (Table 102.7) and include visual blurring, dilated pupils, dryness of

the mouth, hot and dry skin, fever, delirium, and psychosis. Convulsions and coma may follow. Treatment consists of supportive care and, in severe cases, physiologic antagonism with physostigmine (Table 102.4).

Plants That Cause Convulsions. Convulsions represent the principal toxic effect of some plants. Water hemlock, with its potent cicutoxin, is the main species to cause convulsions in the United States. Within 1 hour after ingestion, nausea, vomiting, and profuse salivation occur. These initial symptoms are followed by tremors, muscle rigidity, and multiple major motor seizures. Treatment is with anticonvulsants, as for status epilepticus (see Chapters 69 and 96).

Plants That Contain Cyanogenic Glycosides. Many plants and particularly fruit seeds (pits) contain the cyanogenic glycoside amygdalin (Table 102.16). However, these glycosides are relatively protected within the seeds and would be unlikely to cause illness after an exploratory ingestion by a young child.

Symptoms and signs after ingestion are those of cyanide poisoning, with resultant cellular hypoxia. Initially, there is CNS stimulation and headache, with tachypnea, hypertension, and reflex bradycardia. Anxiety and excitation may progress to opisthotonus and seizures. Respiratory depression, with cyanosis, tachycardia, and hypotension, follows. An odor of bitter almonds may be detected. Treatment is initiated with 100% oxygen and cardiopulmonary resuscitation as necessary. Antidotal therapy for cyanide poisoning, with hydroxocobalamin, or with nitrates and sodium thiosulfate, is detailed in Table 102.9 and in Chapter 7.

Mushrooms

Mushrooms cause an estimated 50% of all deaths from plant and fungi poisoning in the United States. The difficulty in accurate identification of mushrooms makes reliance on such identification for appropriate management of ingestions extremely hazardous in the ED.

Two main groups of mushrooms can be characterized on the basis of the time interval between ingestion and symptom onset: those with the immediate onset of symptoms and those with delayed onset. Regardless of the mushroom, the initial management for all suspected poisonings includes consideration of activated charcoal and other GI decontamination strategies.

Onset of symptoms within 6 hours of ingestion usually confers a benign prognosis, although careful attention to fluid and electrolyte management is critical. Most mushrooms have GI effects. There are several general classes of mushrooms in this group, each possessing a unique toxicologic feature. Some "early-onset" mushrooms cause muscarinic effects, usually within 15 minutes, such as sweating, salivation, colic, and pulmonary edema. This syndrome responds to atropine therapy. Other early-onset mushrooms cause anticholinergic effects, including drowsiness, followed by mania and hallucinations. Another subgroup of early-onset mushrooms produces a severe gastroenteritis syndrome. Hallucinogenic mushrooms such as those containing psilocybin make up another class of mushrooms with early-onset symptoms. Finally, some mushrooms precipitate a disulfiram-like reaction if they are coingested with alcohol. Management for all these agents consists of supportive care and careful monitoring of fluid status.

The second, more important, category of mushrooms that are responsible for 90% of mushroom-related deaths are those associated with onset of symptoms that occur more than 6 hours after ingestion. The most important members of this group are those mushrooms that belong to the *Amanita phalloides* species. With these mushrooms, after a latent period of many hours, GI upset appears. Approximately 24 hours after ingestion, hepatic dysfunction appears, which may progress to fulminant hepatic failure. Without liver transplantation, such patients generally die.

Two compounds are known to produce the toxic effects of *A. phalloides*. Phallotoxin acts first, causing GI symptoms, including nausea, vomiting, abdominal pain, and diarrhea. Fever, tachycardia, and hyperglycemia may also occur during this stage. The other toxin, amatoxin, causes renal tubular and hepatic necrosis.

Treatment of the gastroenteric phase includes fluid and electrolyte replacement. If renal failure develops, dialysis may be necessary. Hepatic damage after *A. phalloides* ingestion may be attenuated by early use of repetitive activated charcoal, which appears to interrupt enterohepatic recirculation of amatoxin.

Additional therapies have shown mixed results in the treatment of *A. phalloides* poisoning. High-dose penicillin, cimetidine, *n*-acetylcysteine, thioctic acid, silibinin, prophylactic charcoal hemoperfusion, and other modalities await further investigation. A regional poison control center may offer guidance with experimental therapies, but multiple-dose activated charcoal and vigorous attention to supportive care remain the standard. For patients with poor prognosis, early referral for liver transplantation may be lifesaving.

In management of mushroom ingestions in which the specific mushroom cannot be identified, GI decontamination, including activated charcoal, should always be provided. Identification of the agent may be possible through consultation with a local mycologist, although mushroom cohabitation makes classification uncertain even if a fragment of mushroom is brought for direct inspection.

Tricyclic Antidepressants

Background

The ingestion of tricyclic antidepressant compounds is a significant problem in pediatric patients. The availability of these compounds in the household may be the result of therapy for depression for a parent or a grandparent or of treatment for enuresis in the patient or a sibling.

Clinical Findings

The ingestion of 10 to 20 mg per kg of most tricyclic antidepressants represents a moderate to serious exposure, with coma and cardiovascular symptoms expected. The ingestion of 35 to 50 mg per kg may result in death. Children have been reported to be more sensitive than adults to tricyclic antidepressants and often have symptoms at lower dosages.

Cyclic antidepressants have many pharmacologic effects. Anticholinergic activity causes altered sensorium and sinus tachycardia. α-Adrenergic blockade may lead to hypotension. However, the more severe cardiovascular effects are primarily caused by the membrane-depressant or "quinidine-like" effects

that depress myocardial conduction and may lead to multiple focal premature ventricular contractions and ventricular tachycardia. It has been shown that a QRS interval over 0.1 second is associated with a significant morbidity and mortality in these patients; this delay in conduction may progress to complete heart block and cardiac standstill and/or the previously mentioned ventricular arrhythmias. Another typical electrocardiographic finding suggestive of cyclic antidepressant poisoning is the finding of an R wave of greater than 3-mm amplitude in the QRS complex in lead aVR.

Neurologic findings include lethargy, disorientation, ataxia, hallucinations, and with severe overdoses, coma, and seizures. Fever is commonly present initially, but hypothermia may occur later. Additional anticholinergic symptomatology includes decreased GI motility, which delays gastric emptying time, and urinary retention. Muscle twitching has been observed and may be associated with increased deep tendon reflexes. Although the pupils may be dilated, they usually respond to light.

Management

Severe tricyclic antidepressant overdoses warrant gastric decontamination. Because tricyclic antidepressants decrease GI motility, unabsorbed drug may be left in the stomach for prolonged periods. Seizures should be treated aggressively with benzodiazepines and/or barbiturates, or even with neuromuscular paralysis if needed to prevent acidosis. Significant conduction delays or arrhythmias resulting from tricyclic antidepressants may benefit from alkalinization of the blood. A sodium bicarbonate bolus of 1 to 2 mEq per kg can be given during continuous EKG monitoring. Bicarbonate infusion can then be used to keep the serum pH at 7.45 to 7.55. These therapeutic maneuvers likely serve to decrease drug binding to the myocardium. Additional bolus doses of sodium bicarbonate may be required if the QRS interval is noted to widen. An additional benefit of the sodium cation may be to partially overcome the sodium channel blockade that is believed to represent the biomolecular substrate of the membrane depressant effect of these agents. If arrhythmias persist, appropriate antiarrhythmic therapy should be instituted, perhaps using lidocaine (see Chapters 1 and 84). Quinidine or procainamide should be avoided because each may increase heart block in this situation. Physostigmine, although previously recommended for its antidotal effects on the anticholinergic aspects of these poisonings, has the potential to worsen ventricular conduction defects and to lower the seizure threshold. Its use is considered to be contraindicated in cyclic antidepressant overdoses, particularly in the setting of an abnormal EKG. In the presence of hypotension, many clinicians have advocated the use of norepinephrine infusions (0.1 to 0.3 μg per kg per minute). This is based on the observation that the hypotension is the result of norepinephrine depletion secondary to the block of catecholamine uptake, caused by tricyclic antidepressants. Other clinicians have reported that dopamine is as effective; however, the occurrence of ventricular arrhythmias has been reported with dopamine. A novel potential therapy, the infusion of lipid emulsion, has shown promise in animal studies of cyclic antidepressant toxicity, as well as for calcium antagonists as noted previously. Several clinical cases of its efficacy in refractory local anesthetic cardiotoxicity and one in bupropion overdose are reported, although most experts would not recommend its use as yet, except as a last resort in patients facing refractory cardiotoxicity despite adequate efforts at cardiopulmonary resuscitation. During the recovery period, serum electrolyte levels should also be monitored because the infusion of bicarbonate may cause hypokalemia, which may aggravate tricyclic antidepressant-induced cardiac arrhythmias. It must be remembered in the treatment of such antidepressants that these compounds have long half-lives and slow elimination rates; therefore, the therapy for these ingestions is often protracted and intensive.

Other Antidepressants

Besides the tricyclic antidepressants, numerous agents designed to elevate mood are prescribed. The chemical structure of these agents and their profile of toxicity are diverse. Major groupings of nontricyclic antidepressants include (i) the selective serotonin reuptake inhibitors (SSRIs; e.g., fluoxetine, sertraline), (ii) the monoamine oxidase inhibitors (MAOIs; e.g., phenelzine, tranylcypromine), and (iii) other atypical antidepressants (e.g., amoxapine, venlafaxine, bupropion).

SSRIs most commonly produce CNS depression in overdose. Seizures may occur after large ingestions. Life-threatening events from acute overdose of these compounds rarely occur. The serotonin syndrome, manifested by the triad of autonomic instability, neuromuscular changes (myoclonus, rigidity especially in the lower extremities), and altered mental status, is potentially lethal. Amoxapine has anticholinergic activity but is best known for its convulsant properties and the tendency for patients to present with status epilepticus. Bupropion, prescribed perhaps most commonly in smoking-cessation programs, prevents reuptake of biogenic amines, is highly seizurogenic, and in large overdose, may cause QRS widening and life-threatening cardiotoxicity. The α-adrenergic antagonism of trazodone may lead to hypotension.

The MAOIs, although pharmacologically effective and therapeutically important, are some of the most toxic medications known. Acute single overdoses of as little as 6 mg per kg have been associated with a fatal outcome. In addition, because of their irreversible inhibition of the enzyme monoamine oxidase, which is responsible for the degradation of most biogenic amines, MAOIs possess several important interactions with foods and other medications that can lead to severe toxicity, even in the patient who takes them in appropriate doses. There are three important clinical pictures of MAOI toxicity. First, because GI tract activity of monoamine oxidase is also inhibited by these drugs, patients who take them appropriately and then ingest foods that contain biogenic amines (e.g., tyramine in wines, cheeses, or soy sauce) may develop severe hypertension with subsequent headache, seizures, or stroke. The second picture of MAOI toxicity appears when those who take the drug therapeutically are given certain sympathomimetic or serotonergic agents causing the serotonin syndrome. Important examples of such drugs include common agents in OTC cough and cold preparations such as dextromethorphan, analgesics such as meperidine, and psychotropic medications such as clomipramine and fluoxetine or other SSRIs. In these patients, this drug combination may quickly lead to hyperpyrexia, skeletal muscle rigidity, cardiac arrhythmias, and death. This is one of the few fatal drug interactions known. Finally, those with acute MAOI overdoses develop a clinical syndrome that includes blood pressure instability, hyperpyrexia, skeletal muscle rigidity, opsoclonus, seizures, and death.

Because of the toxicity of these agents and the frequent delay in their onset of activity (up to 24 hours), all patients

with a history of MAOI ingestion, regardless of symptoms, should be admitted to the hospital for 24 hours. Management of the patient with MAOI toxicity is largely dictated by the specific toxic manifestations. In those with hypertensive reactions, treatment consists of the immediate administration of an antihypertensive. The ideal agent may be nitroprusside because its brief duration of action permits titration of effect. In the treatment of hyperpyrexia, cooling measures are promptly instituted. Because hyperpyrexia is often accompanied by skeletal muscle rigidity and rhabdomyolysis, serum creatine kinase level should be measured and close attention should be paid to the urine for any signs of myoglobinuria. Benzodiazepines are often helpful in this situation and neuromuscular blockade may be beneficial in patients who have severe muscle rigidity with hyperthermia. In the patient with acute overdose, treatment is directed to hemodynamic stability. Because blood pressure changes occur quickly and consist of hypotension and hypertension, hypertension should be treated with short-acting agents (see Chapter 34) and hypotension with fluid and vasopressor support (see Chapter 3). Intensive care unit admission is mandatory for these patients because of their clinical instability.

Drugs Dangerous in Small Doses

Toddlers often are brought to EDs for evaluation after possibly having ingested one or two doses of a medication. This can be a particularly vexing problem. Most often these children will be fine with little treatment beyond reassurance. There are circumstances, however, when this situation can be life-threatening and proper intervention can be lifesaving. A large list of chemicals and poisons can be extremely toxic in small amounts; but, this is beyond the scope of this discussion. However, it is wise to be familiar with a modest list of pharmaceuticals that may cause dangerous toxicity to young children with just one or two doses (Table 102.17). Many of these agents have been discussed earlier in this chapter. The actual incidence of life-threatening

TABLE 102.17

MEDICATIONS DANGEROUS TO TODDLERS IN ONE TO TWO DOSES[a]

Agent	Minimal potential fatal dose[b]	Maximal dose size	Potential fatal dose	Major toxicity
Benzocaine	<20 mg/kg	10% gel 20% spray	~2 mL Baby Oragel	Methemoglobinemia, seizures
β-Blockers (propranolol)	Unclear	160 mg	1–2 tablets	Bradycardia, hypotension, seizures, hypoglycemia
Calcium antagonists (verapamil)	<40 mg/kg	240 mg	1–2 tablets	Bradycardia, hypotension
Camphor	<100 mg/kg	1 g/5 mL	1 tsp camphorated oil 2 tsp Campho-Phenique 5 tsp Vicks Vaporub	Seizures, CNS depression
Chloroquine	<30 mg/kg	500 mg	1 tablet	Seizures, arrhythmia
Clonidine	Unclear	0.3-mg tablet 7.5-mg patch	1 tablet 1 patch	Bradycardia, CNS depression
Diphenoxylate (Lomotil)	<1.2 mg/kg	2.5 mg/ tablet or tsp	2 tablets/tsp	CNS and respiratory depression
Hypoglycemics, oral (glyburide)	~1 mg/kg	5 mg	2 tablets	Hypoglycemia
Lindane	~6 mg/kg	1% lotion	2 tsp	Seizures, CNS depression
Methyl salicylate	~200 mg/kg	1.4 g/mL	½ tsp oil of wintergreen 2 tsp Icy Hot Balm	Seizures, cardiovascular collapse
Opioids	Variable by potency	Variable	1–2 tablets	CNS and respiratory depression
Phenothiazines (chlorpromazine)	~20 mg/kg	200 mg	1 tablet	Seizures, arrhythmia
Quinidine	~50 mg/kg	300 mg	2 tablets	Seizures, arrhythmia
Quinine	~80 mg/kg	650 mg	2 tablets	Seizures, arrhythmia
Theophylline	~50 mg/kg	500 mg	1 tablet	Seizures, arrhythmia
TCAs (imipramine)	~20 mg/kg	150 mg	1–2 tablets	Seizures, arrhythmia, hypotension

CNS, central nervous system; TCAs, tricyclic antidepressants.
[a]A long list of commonly-encountered, highly toxic, *non*pharmacologic agents can be severely poisonous in 1 to 2 doses. These are not included here.
[b]For the purposes of this table, a "dose" refers to a single pill or roughly a 5-cc swallow. Calculations are based on a previously healthy toddler of 10-kg body weight.

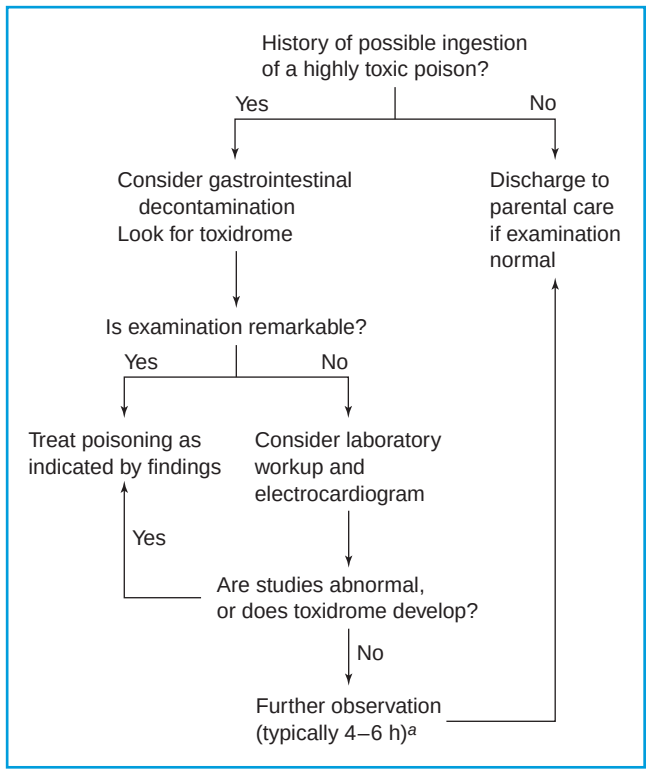

FIGURE 102.12 Algorithmic approach to a toddler having ingested one to two doses (1 to 2 pills or 5- to 10-cc swallow) of a drug. [a]Medications notorious for their ability to have delayed onset in toxicity, beyond 4 to 6 hours, include oral hypoglycemic agents, sustained-release preparations, monoamine oxidase inhibitors, drugs taken concomitantly with anticholinergic agents, and acetaminophen.

toxicity of each of these drugs, when just one or two doses have been ingested, is as yet undefined.

A systematic approach to these patients includes a careful history, an examination with attention to the presence of toxidromes (Table 102.5), and a guided laboratory assessment. This approach may allow narrowing of the differential diagnosis and may allow a determination of the possible severity of the ingestion. If the differential diagnosis includes any of the drugs listed in Table 102.17, it may be prudent to consider decontamination and prolonged observation. An algorithmic approach to this situation is provided in Fig. 102.12.

SUBSTANCE ABUSE

As a special category of pediatric toxicology, exposures to psychoactive drugs are outlined in this section. In a discussion of substance abuse, three distinct age populations in the pediatric group may be placed at risk from such exposures: (i) the adolescent or preadolescent who abuses drugs for their mind-altering effects (and, in the case of women, may do so when pregnant); (ii) the neonate who is exposed to substances of abuse during gestation and manifests signs of intoxication or abstinence after birth; and (iii) the infant or toddler who becomes exposed to drugs of abuse through either active administration by a caregiver (chemical child abuse), the ingestion of a drug left in an accessible place (e.g., the coffee table), or passive exposure created by being in an environment where drugs of abuse are used (e.g., marijuana, cocaine, phencyclidine (PCP), methamphetamine). In any of these circumstances, the exposure can be sufficient to produce severe intoxication. Thus, knowledge of the epidemiology and manifestations of substance abuse become important in the management of children of all ages.

Further discussion regarding the general phenomenon of chronic adolescent drug abuse and addiction, including alcoholism, is found in Chapter 130.

Clinical Manifestations

The drug-abusing child or adolescent may present to the ED after an unintentional overdose, a suicidal gesture, suicide attempt, sudden bizarre behavior, or multiple trauma (e.g., assault, motor vehicle collision). Often, the history of drug exposure is undeclared and may not be diagnosed unless there is a high index of suspicion and appropriate diagnostic tests are performed. In such cases, the patient's mental status can range from fully awake and responsive to comatose; physical examination can be without any signs of drug exposure or with overt signs of toxicity (e.g., seizures). Table 102.18 provides a summary of the common drugs of abuse, their typical routes of administration, associated symptoms, toxic levels, and duration of action.

Initial history from the patient, family, or friends must specify drugs taken and estimate quantities when an ingestion is suspected. In the absence of a history of exposure, it is important to inquire whether the patient has used any psychoactive drugs in the past. In many cases, the patient may admit to using a drug but may identify it by a street name. Although drug terminology tables are often available in pharmacology or toxicology texts as well as the Internet, temporal and regional changes in street drug terminology generally make such tables of limited value.

Management

Primary attention is paid toward assessment of vital signs and life support as needed to provide a patent, secure airway; to ensure adequate respiratory function; and to treat seizures, shock, or cardiorespiratory arrest. A key, but often overlooked, feature in the assessment of such patients is an accurate temperature because many drug intoxications are associated with hyperpyrexia. If there is any suspicion of hyperthermia, a rectal temperature must be obtained. In the agitated patient, physical and/or chemical restraint may be necessary to obtain vital signs. Chemical restraint should be used liberally to prevent patients from harming themselves or others. The preferred agents in such cases are diazepam (0.1 to 0.3 mg per kg IV) or midazolam (0.05 to 0.1 mg per kg IV). Haloperidol (0.05 mg per kg) given IM is also effective but reduces heat-dissipating capability and lowers the seizure threshold. Droperidol received an U.S. Food and Drug Administration (FDA) "black box" warning in 2001 due to concerns about QTc prolongation; subsequently, this medication is used less commonly in the agitated toxicology patient.

Management must also include consideration of the need for GI decontamination. It is common with psychoactive drug use where several distinct routes of exposure are possible (e.g.,

TABLE 102.18

DRUG ABUSE: SUMMARY OF TOXICITY

Drug of abuse	Symptoms and signs of drug abuse	Diagnosis	Toxic dose	Toxic serum level	Half-life
Cannabis Group (marijuana; hashish; Δ9-THC; hash oil)	Pupils unchanged; conjunctiva injected; blood pressure (BP) decreased on standing; heart rate increased; increased appetite, euphoria, anxiety; sensorium often clear; dreamy; fantasy state; time–space distortions; hallucinations rare. Significant airway obstruction with heavy smoking, decreased forced expiratory volume, and decreased vital capacity. Major psychiatric toxic effects: Panic reaction most common Psychotic reactions (especially in patients with underlying psychopathology) Toxic delirium (disorientation, confusion, memory impairment) in heavy users	Blood, urine levels	20 mg Δ9-THC or 1 g cigarette of 2% Δ9-THC produces effects on mood, memory, motor coordination, cognitive ability sensorium, time sense		*1st phase,* minutes, distribution in lipid-rich tissues; *2nd phase,* 1½–2 days, until mobilized from lipid-rich tissue
Hallucinogens	Pupils dilated (normal or small with PCP); BP elevated, heart rate increased, hyperactive tendon reflexes, increased temperature, flushed face, euphoria, anxiety or panic, paranoid thought disorder, inappropriate affect, time and visual distortions, visual hallucinations, depersonalization.				
LSD	Psychosis with hyperalertness; changes in body image; sense of profound significance, delusions; hallucinations (also with amphetamines), visual perceptual distortions caused by peripheral effects of LSD on visual system.	Blood, urine levels	20–25 μg produce CNS effects; 0.5–2 μg/kg produce somatic symptoms; between 1 and 16 μg/kg intensity of pathophysiologic effects proportional to dose	Variable	3 h
PCP	Cyclic coma, extreme hyperactivity, violent outbursts, bizarre behavior, amnesia, analgesia, nystagmus, gait ataxia, muscle rigidity. Dystonic reactions, grand mal seizures, tardive dyskinesia, athetosis, bronchospasm, urinary retention, diaphoresis, hypoglycemia. Increased uric acid, increased creatine phosphokinase, increased creatinine, increased hepatic transaminases heralds onset of rhabdomyolysis (risk of renal failure).	Blood, gastric contents, urine (but level does not correlate with toxicity)	1 cigarette (PCP) = 1–100 mg. Psychosis may last several weeks after a dose. Fatal dose = 1 mg/kg; <5 mg = hyperactivity; 5–10 mg = stupor, coma; >10 mg = respiratory depression, convulsions	Individual variability (~0.1 μg/mL)	1–3 d

(continued)

TABLE 102.18

DRUG ABUSE: SUMMARY OF TOXICITY (CONTINUED)

Drug of abuse	Symptoms and signs of drug abuse	Diagnosis	Toxic dose	Toxic serum level	Half-life
CNS Stimulants					
Amphetamines	Pupils dilated and reactive. Increased BP, pulse, temperature, cardiac arrhythmias; dry mouth; sweating; tremors; sensorium hyperacute or confused; paranoid ideation; impulsivity; hyperactivity; stereotypy; convulsions; exhaustion.	Blood level, urine test	1. Variable 2. Rare under 15 mg 3. Severe reactions have occurred at 30 mg 4. 400–500 mg not uniformly fatal 5. Tolerance is striking; chronic user may take 1,700 mg/day without ill effects	Variable	3 h
Cocaine	1. Excitement, restlessness, euphoria, garrulousness. 2. Increased motor activity, physical endurance because of decreased sense of fatigue. 3. Increased tremors, convulsive movements. 4. Increased respiration, pulse, BP, temperature, chills.	Urine, serum	Fatal dose may be as low as 30 mg; ingested cocaine less toxic than by other routes		1 h (after PO or nasal route)
CNS Sedatives (barbiturates, chlordiazepoxide, diazepam, flurazepam, glutethimide, meprobamate, methaqualone)	Pupils normal or small (dilated with glutethimide); BP decreased, respirations depressed; drowsy, coma, lateral nystagmus, confusion, ataxia, slurred speech, delirium; convulsions or hyperirritability with methaqualone overdosage; serious poisoning rare with benzodiazepines alone.	Serum level			
Barbiturates (Secobarbital) (Seconal)	As above.	Serum level	100 mg per dose	30 μg/mL	19–34 h
Chlordiazepoxide (Librium)	As above.	Serum level	25 mg	8 μg/mL	8–25 h
Diazepam (Valium)	As above.	Serum, urine	15 mg or greater		20–90 h
Flurazepam (Dalmane)	As above.	Serum, urine		0.12 μg/mL (fatal)	47–100 h
Glutethimide (Doriden)	As above.	Serum level	>500 mg (acute intoxication, 3 g)	2 mg/100 mL (but even below, full ICU support may be required)	5–22 h
Meprobamate	As above.	Serum level	>800 mg	150 μg/mL	6–17 h

Methaqualone (Parest, Somnafae)	As above.	Serum level	200–400 mg	10 μg/mL	20–60 h
Narcotics	Pupils constricted (may be dilated with meperidine or extreme hypoxia); respiration depressed to absent with cyanosis; BP decreased, sometimes shock; temperature reduced; reflexes diminished to absent, stupor or coma; pulmonary edema; constipation; convulsions with propoxyphene or meperidine; arrhythmia with propoxyphene.	Serum, urine Serum, urine			
Heroin	As above.	Serum	—	—	1½ h[c]
Morphine	As above.	Serum	60 mg = toxic[b] 200 mg = fatal dose[b]	—	3 h[c]
Codeine	As above.	Serum	800 mg = fatal dose[b]	1.1 μg/mL	2 h[c]
Methadone	As above.	Serum	100 mg = fatal dose[b]	1.6 μg/mL (fatal)	18–97 h[c]
Propoxyphene	As above.	Serum	500 mg = fatal dose[b]	2 μg/mL (fatal)	3–12 h
Anticholinergics (atropine, belladonna, henbane, scopolamine, trihexphenidyl, tricyclic antidepressants, benzotropine mesylate)	Pupils dilated and fixed, heart rate increased, temperature increased, BP increased; drowsy, coma, flushed, dry skin and mucous membranes, erythematous skin, amnesia, disoriented, visual hallucinations, body image alterations.	Urine test			
Atropine	As above.		5 mg		24 h
Belladonna	As above.		5 mg		24 h
Scopolamine	As above.		5 mg		24 h
Imipramine (Tofranil)	As above.		500 mg		8–16 h
Amitriptyline (Elavil)	As above.		>500 mg	5 μg/mL	32–40 h
Desipramine	As above.		1 g	10 μg/mL	12–54 h

LSD, lysergamides; ICU, intensive care unit.
[a]Dose is amount given subcutaneously that produces same analgesic effect as morphine 10 mg subcutaneously.
[b]Higher doses given for addicts.
[c]Duration is for subcutaneous dose. Intravenous dose peak is more pronounced and overall effects have shorter duration.
Adapted from Dreisbach RH. *Handbook of poisoning.* Los Altos, CA: Lange Medical Publications, 1980.

ingestion, inhalation, injection, and/or nasal insufflation). Therefore, GI decontamination is not always necessary or appropriate.

However, because those who abuse drugs almost invariably use more than one drug, decontamination should be considered if there is any possibility of an ingestion, utilizing the same guiding principles regarding toxin and patient characteristics detailed earlier in this chapter. In the event that decontamination seems appropriate, assessment of the patient's mental status and gag reflex must be performed; in the presence of obtundation or a diminished gag reflex, airway protection by endotracheal intubation should be accomplished before decontamination measures.

Disposition

In the case of the adolescent who presents with intentional drug abuse, after initial assessment and medical stabilization, an evaluation must be made of the severity of the drug use problem. Although issues of patient confidentiality may require the physician to provide limited information to parents, obtaining a thorough psychosocial evaluation is necessary for complete management of the acute event. Such discussions may require or may be facilitated by an interview with a social services or psychiatry consultant. Once the severity of the drug problem has been established, referral to a treatment program should be discussed. Primary care physicians may be comfortable managing those patients who have no long-standing histories of drug abuse. Compulsive users or anyone who presents with a drug abstinence syndrome must be referred for intensive rehabilitation. Family therapy is often a vital component of this rehabilitation.

SPECIFIC DRUGS

The major categories of drugs of abuse that require the physician's familiarity with the whole spectrum of their physiologic effects are (i) hallucinogens [phencyclidine, ketamine, lysergic acid diethylamide, marijuana], (ii) stimulants (amphetamines, cocaine), (iii) central anticholinergics, (iv) sedatives (benzodiazepines, barbiturates), (v) opioids (morphine, codeine, heroin, methadone, buprenorphine, oxycodone, and hydrocodone), (vi) inhalants, and (vii) alcohol. (Acute alcohol overdose is discussed in the previous section; chronic alcoholism in teenagers is discussed in Chapter 130.)

Hallucinogens (Psychedelics)

No single characteristic distinguishes psychedelics from other classes of centrally active drugs such as anticholinergics, cocaine, and amphetamines. These drugs can produce a number of mental status changes, including illusions, hallucinations, delusions, and paranoid ideation. However, the psychedelic state is characteristically described as consisting of vivid and unusual visual experiences with diminished control over what is experienced. Images and sensations take on profound meaning, and the ability to differentiate oneself from the environment is decreased. Most drugs in this category are related to the indolealkylamines [psilocybin, dimethyltryptamine (DMT), diethyltryptamine], lysergamides (LSD), or phenylethylamines [mescaline, methylenedioxymethamphetamine (MDMA, Ecstasy)].

Phencyclidine, Ketamine, and Dextromethorphan

Identification. PCP was developed in the 1950s as a general anesthetic. It rapidly fell into disuse because of disturbing emergence syndromes that developed in postoperative patients. Sporadic abuse occurred in the 1960s, but its popularity peaked in the 1970s. The drug remains common in several metropolitan areas as does ketamine, a PCP analog with approximately one-tenth the potency and a shorter duration of action. Ketamine is discussed in detail in Chapter 4. Another drug with related structure, but milder effects, is dextromethorphan, which is popular with adolescents because of its ready availability as a legal, OTC cough suppressant. PCP is easily synthesized and is often sold on the streets misrepresented as LSD, mescaline, or marijuana. It is well absorbed across all mucous membranes and is most popularly used by inhalation (often mixed into cigarettes or marijuana "joints"), but it can be ingested, injected, or insufflated.

Chemically, PCP is an arylcyclohexylamine. This group of drugs has a range of CNS actions that range from hallucinations with smaller doses, to stimulation with moderate doses (occasionally associated with seizures), to profound CNS depression with respiratory arrest with large doses.

Pharmacodynamics. There is great variability in the metabolism of PCP. In general, 0.1 μg per mL is considered a toxic serum level. One cigarette may contain 1 to 100 mg. A dose of 5 to 10 mg may produce stupor and coma; with doses exceeding 10 mg, respiratory depression and convulsions occur. A fatal dose is in the range of 1 mg per kg. Because PCP has a long elimination half-life (18 hours), clinical symptoms may last for more than 12 hours; also, patients may have cyclic symptoms because the drug undergoes enterohepatic recirculation.

Pharmacologically, PCP acts as a dissociative anesthetic, meaning that it interferes potently with association pathways that link the cerebral cortex with deeper structures in the brain, thus diminishing the ability to integrate sensory input into meaningful behavior. Its anesthetic actions also lead to a marked diminution of pain sensation. In conjunction with bizarre behavior, this often leads patients to have feelings of invulnerability and to attempt life-threatening actions (e.g., stepping into automobile traffic).

Clinical Symptoms. Small doses of PCP produce signs and symptoms of inebriation with staggering gait, slurred speech, and nystagmus (vertical or rotatory). Users may also be diaphoretic and have catatonic muscular rigidity with a blank stare. Having sympathomimetic actions, it is often associated with hypertension and tachycardia. Dextromethorphan toxicity resembles the syndrome of low-dose PCP exposure; nystagmus and myoclonus may help distinguish this toxidrome from alcohol or sedative toxicity, and the urine drug screen may be falsely positive for PCP. Moderate doses of PCP cause other signs of intoxication, including hypersalivation, pyrexia, repetitive movements, and muscle rigidity. Larger doses can cause seizures, coma, or respiratory arrest. The typical "high" from a single dose lasts 4 to 6 hours and is followed by an extended "coming down"; PCP-induced psychotic states may be long lasting and may recur (flashbacks). Tolerance develops

to the behavioral and toxic effects of the drug. Chronic users report persistent difficulties with recent memory, speech, and thinking that last from 6 months to 1 year after the last dose; they also may be left with personality changes such as withdrawal, isolation, anxiety, nervousness, and depression.

Management. PCP is easily detected through a qualitative analysis of urine. Serum levels are rarely available and do not correlate with clinical manifestations. Therefore, management must often be based solely on a history of exposure or index of suspicion. Initial treatment is directed at stabilizing vital signs and treating life-threatening events such as seizures. If exposure is the result of ingestion, GI decontamination should be performed by administration of activated charcoal. A quiet room may be helpful, although the ability to monitor the patient cannot be compromised. Physical restraints should be avoided if possible because they may lead to significant rhabdomyolysis with resulting myoglobinuria and renal injury. For chemical restraint diazepam (0.1 to 0.3 mg per kg IV) or lorazepam (0.1 mg per kg IV) may be effective, although a major tranquilizer (e.g., haloperidol) is often necessary.

Although urine acidification (pH less than 5.0) enhances the urinary excretion of PCP, it should never be performed in these patients because it exacerbates metabolic acidosis and may promote deposition of myoglobin in renal tubules. In a review of 27 confirmed cases of PCP poisoning, 3 patients developed rhabdomyolysis and 2 progressed to acute renal failure. Both patients had received acidification measures before diagnosis. If tests for muscle enzymes and/or renal function are abnormal and the urine has a positive test for hemoglobin without red blood cells, the patient should be assumed to have rhabdomyolysis and should be treated accordingly (see Chapter 86).

LSD (Blotter, Acid)

Pathophysiology. LSD and related psychedelic drugs such as psilocybin, mescaline, and DMT have actions at multiple sites in the CNS (from the cortex to the spinal cord). In addition, dozens of congeners of these agents exist in mushrooms or have been synthesized, and they also cause signs and symptoms similar to those of LSD. The pharmacologic action that these drugs seem to have in common is as agonists of presynaptic serotonin-2 receptors (which modulate serotonin release into the synaptic cleft). Most of these agents have structural similarities to serotonin (5-hydroxytryptamine).

Pharmacodynamics. In humans, the somatic symptoms of dizziness, weakness, drowsiness, nausea, and paresthesias may be observed after one oral dose of 0.5 to 2 μg per kg. Between the dose range of 1 to 16 μg per kg, the intensity of LSD's psychoactive effects is proportional to the dose. A typical LSD "hit" is 200 to 400 μg. A high degree of tolerance to the behavioral effects develops after three to four daily doses, with sensitivity returning after a drug-free interval. Deaths directly attributable to LSD are virtually unknown, although fatal accidents and suicides have occurred during states of intoxication.

Clinical Symptoms. In general, the somatic effects of hallucinogens are sympathomimetic and include pupillary dilation, hypertension, tachycardia, hyperreflexia, and hyperpyrexia. Doses as low as 20 to 25 μg can produce CNS effects such as euphoria, visual perceptual distortions, alteration of subjective time so time passes slowly, lability of mood, or even an acute panic episode. Hallucinations and psychosis with hyperalertness are commonly seen. The clinical duration of action of LSD is somewhat dose dependent but averages 6 to 12 hours. The psychedelic state includes a heightened awareness of sensory input, often accompanied by an enhanced sense of clarity but a diminished control over what is experienced. There is often a feeling that one part of the self is a passive observer while another part receives vivid sensory input. The ability to separate one object from another or to separate self from the environment is diminished. There is an enhanced sense of oneness with humanity.

Management. LSD intoxication is rarely associated with life-threatening events. However, vital signs should be assessed to ensure that the patient is stable in the event there has been drug coingestion. Because LSD is ingested in minuscule doses and onset of symptoms occurs hours after ingestion, GI decontamination is unnecessary, unless coingestion is suspected.

Clinical management involves placing the patient in a quiet room. Someone who knows the patient may be able to quietly "talk down" and reassure the patient. The patient's loss of boundaries and fear of fragmentation or self-disintegration create a need for a structuring or a supportive environment. Both benzodiazepines (e.g., diazepam 0.1 to 0.3 mg per kg IV or midazolam 0.05 to 0.1 mg per kg IV) and haloperidol (0.05 mg per kg IM) are effective tranquilizers in the event that anxiety or agitation persists.

Marijuana (Pot, Reefer, Smoke, Grass, Hemp)

Pathophysiology. With the exception of ethanol, marijuana remains the most popular psychoactive drug of abuse. It is typically sold in "nickel" bags that produce two to three joints. Marijuana is occasionally laced with other psychoactive substances, including PCP and cocaine. Hashish is the concentrated resin of marijuana.

The flowering tops of the female marijuana plant contain the highest concentration of the active constituent, tetrahydrocannabinol (THC). In the 1970s, most marijuana contained approximately 1% to 2% THC by weight. More recently, cultivated seedless varieties of marijuana (sensimilla) have become popular, and they contain 5% to 8% THC by weight. Therefore, a joint is now likely to lead to a greater degree of altered mental status than previously.

Within minutes of smoking this material, perceptual, behavioral, and emotional states become altered for several hours. Patients often have the appearance of inebriation with dysarthria and ataxia. However, violence, hallucinations, and agitation are uncommon after marijuana use.

Pharmacodynamics. It is estimated that no more than 50% of the THC inhaled in a marijuana cigarette is actually absorbed. Pharmacologic effects begin immediately. In contrast, the onset of effects after oral ingestion occurs in 30 minutes to 1 hour, and peak effects may not occur until the second and third hours after ingestion; THC is three times more potent when smoked than when taken by mouth.

Clinical Symptoms. The most prominent effects in humans are on the CNS and cardiovascular system. In doses of up to 20 mg, THC produces effects on mood, memory, motor coordination, cognitive ability, sensorium, time sense, and self-perception.

There is an increased sense of well-being or euphoria accompanied by feelings of relaxation or sleepiness when subjects are alone. With greater intake of THC, short-term memory is impaired, and the capacity to carry out tasks that require multiple mental steps to reach a specific goal deteriorates. This effect on memory-dependent, goal-directed behavior has been called *temporal disintegration* and is correlated with a tendency to confuse past, present, and future. Depersonalization, a sense of strangeness, and unreality about one's self also occur. Marijuana smokers often report a voracious appetite (the munchies), dry mouth and throat, more vivid visual imagery, and a keener sense of hearing. Altered time perception is a consistent effect of cannabinoids, so minutes seem like hours. Larger doses of THC can produce frank hallucinations, delusions, and paranoid feelings. Thinking becomes confused and disorganized. Anxiety that reaches panic proportions may replace euphoria, often as a feeling that the drug-induced state will never end. Because of the rapid onset of effects when marijuana is smoked, most users can regulate their intake to avoid the excessive doses that produce these unpleasant effects. Marijuana may cause an acute exacerbation of symptoms in stabilized schizophrenics. Cardiovascular effects include tachycardia, hypertension, and marked conjunctival injection. Chronic smoking of marijuana and hashish is associated with bronchitis and asthma, even though THC is a mild bronchodilator.

Infants and toddlers passively exposed to marijuana may develop profound lethargy or coma, occasionally with tachycardia.

Management. In general, the only treatment required is discontinuation of the drug. In the adolescent patient with a psychotic reaction or acute toxic delirium, a sedative such as diazepam, 5 to 10 mg by mouth or 0.1 mg per kg IV, may be necessary. These acute symptoms should improve with drug abstinence over 4 to 6 hours.

Stimulants

Amphetamines (Crank, Speed)

Pathophysiology. Amphetamines have powerful CNS stimulant actions, in addition to peripheral adrenergic actions. Unlike epinephrine, amphetamines are effective after oral administration. However, they are often taken by injection and nasal insufflation. Amphetamines have been used medically to treat narcolepsy, obesity, fatigue, and nasal congestion. Several decongestant nasal inhalers continue to add amphetamine agents that may be extracted and ingested by drug-seeking adolescents. The pharmacologic effects of amphetamines include increased blood pressure, occasionally with a reflex slowing of heart rate, contraction of bladder sphincter, and dramatic CNS stimulation. Like other indirect sympathomimetics, amphetamines act by releasing endogenous biogenic amines from the presynaptic neurons.

Methamphetamine is the most commonly abused of these drugs, reportedly because its greater lipid solubility is associated with more potent CNS effects.

Abuse patterns of amphetamines have changed in more recent years because these drugs have begun to approach cocaine as widely abused stimulants. In fact, the National Institute on Drug Abuse reports a 58% increase in ED visits due to one type of amphetamine, Ecstasy, between 1999 and 2001. This increase has paralleled government interdiction efforts that have reduced the illegal entry of cocaine. Many drug users prefer amphetamines over cocaine because the clinical duration of action is considerably longer than that of cocaine. Also, the smokable form of methamphetamine (ice) is associated with more striking and prolonged alterations in CNS function. Children may be exposed to a myriad of dangerous chemicals when living with adults who operate clandestine meth laboratories. Finally, amphetamines have become a popular substance of abuse in pregnant women, leading to increases in neonatal intoxication or abstinence syndromes.

Pharmacodynamics. The therapeutic dose of dextroamphetamine in adolescents is typically 5 mg three times daily. The toxic dose is variable but is rarely less than 15 mg. Severe reactions have been reported at 30 mg, yet doses up to 400 to 500 mg may cause only mild symptoms. Tolerance is striking, with chronic users taking 10 to 15 g daily without ill effects. The elimination half-life of the amphetamines is about 3 hours, with much of the drug being excreted in the urine unchanged.

Clinical Symptoms. The psychic effect of amphetamines depends on the dose, mental state, and personality of the drug user. In general, 10 to 30 mg cause wakefulness, alertness, a decreased sense of fatigue, and an elevation of mood. Other behavioral changes may include increased initiative, self-confidence, ability to concentrate, elation, euphoria, and increased motor and speech activity. Physical performance in athletes may be improved. Prolonged use of large doses is followed by depression and fatigue. Amphetamines have an appetite-suppressant effect through an action on the lateral hypothalamic feeding center. However, tolerance to this effect also develops; thereafter, the effect is insufficient to reduce weight for a sustained period.

The acute toxic effects of amphetamine are usually extensions of its therapeutic actions. The central effects induce euphoria, restlessness, dizziness, tremor, hyperactive reflexes, talkativeness, irritability, weakness, insomnia, and fever. In addition, confusion, assaultiveness, anxiety, delirium, paranoid hallucinations, panic states, and suicidal or homicidal tendencies can occur, especially in patients who have underlying mental illnesses. However, these psychotic effects may occur in anyone who chronically abuses amphetamines. Cardiotoxic effects include palpitations, anginal pain, and rarely, hypertensive crisis or circulatory collapse. GI effects include anorexia, nausea, vomiting, diarrhea, and abdominal cramps. Severe overdoses may cause convulsions, coma, and cerebrovascular accidents. Both psychological and physical dependence occurs with chronic use. Chronic amphetamine abuse causes symptoms similar to many of those seen after acute overdose. The most common serious effect is a psychotic reaction with vivid hallucinations and paranoid delusions, often mistaken for schizophrenia. Recovery may or may not occur after withdrawal of the drug. In patients with persistent psychotic symptoms, it has been theorized that the amphetamine has hastened the onset of incipient schizophrenia. Chronic amphetamine abuse is also associated with the development of cerebral vasculitis.

An amphetamine derivative, MDMA, or Ecstasy, is popular among drug-abusing college students and may find its way into the high school scene. It is a drug with mildly hallucinogenic

effects. In larger doses, it causes perceptual distortions, hallucinations, and agitation.

Management. Treatment of intoxication after ingestion of these agents should include GI decontamination. For severe agitation, specific treatment consists of administration of a benzodiazepine (e.g., diazepam 0.1 to 0.2 mg per kg IV) or haloperidol (0.01 to 0.05 mg per kg IM). Severe hypertension unresponsive to benzodiazepines may be treated with such agents as phentolamine, hydralazine, or IV sodium nitroprusside. Because up to 45% of amphetamines are excreted in the urine unchanged, ample fluids are beneficial.

Cocaine

Pathophysiology. Cocaine occurs in the leaves of *Erythroxylon coca* and other species of *Erythroxylon* trees indigenous to Peru and Bolivia, where the leaves have been used for centuries by the natives to increase endurance and to promote a sense of well-being. Chemically, cocaine is benzoylmethylecgonine. Ecgonine is an amino alcohol base closely related to tropine, the amino alcohol in atropine. Cocaine may be used by injection, inhalation (in the form of cocaine alkaloid or "crack"), nasal insufflation, and rarely, ingestion. Although oral ingestion is uncommon, there are two circumstances under which cocaine may be ingested in toxic quantities: the "body packer" and the "body stuffer." In the body packer, large quantities of cocaine are enclosed in plastic and ingested in an attempt to smuggle the drug, usually across international boundaries. In the case of the body stuffer, the person in fear of being found with the substance suddenly ingests cocaine. Body stuffers are typically at greater risk of cocaine intoxication because they do not take sufficient care to guarantee that the cocaine does not leach from the bag.

Cocaine is reportedly used in up to 15% of women during pregnancy. This gestational use has led to epidemic increases in the number of "cocaine babies" who are often preterm, small for age, irritable, and show neurodevelopmental delay. Beyond the postnatal age, passive cocaine exposure in infants and toddlers has been associated with severe intoxication, including the development of convulsions.

Pharmacodynamics. The relief from fatigue that occurs with cocaine use results from central stimulation that masks the sensation of fatigue. Cocaine potentiates the excitatory and inhibitory responses of sympathetically innervated organs to norepinephrine and epinephrine by blocking the reuptake of catecholamines at adrenergic nerve endings. This explains why cocaine, unlike other local anesthetics, produces vasoconstriction and mydriasis. The most important pharmacologic action is its ability to block the initiation or conduction of the nerve impulse after local application. Cocaine is still occasionally used as a local anesthetic for ophthalmologic or otorhinolaryngologic procedures. It also can be used as a topical anesthetic for laceration repair in the form of TAC (tetracaine, adrenaline, cocaine), although this formulation has largely been replaced by the less toxic combination of lidocaine, epinephrine, and tetracaine.

Although fatalities have been associated with cocaine doses as low as 30 mg, 1 to 2 g is generally the lethal dose in adults. Ingested cocaine is less toxic than that taken by other routes because of its prolonged absorption by this route. The elimination half-life of cocaine is approximately 1 hour. Cocaine metabolism is complex and consists of nonenzymatic degradation to form benzoylecgonine and metabolism by plasma cholinesterases to form ecgonine methyl ester. A small fraction of cocaine is also metabolized through the cytochrome P-450 enzymes to form norcocaine. Individuals with congenital deficiencies in plasma cholinesterase are believed to have exaggerated responses to cocaine; cocaine abusers have been known to ingest inhibitors of cholinesterases or P-450 3A4 enzymes (e.g., organophosphate insecticides, cimetidine) to enhance the effect of the cocaine. Cocaine metabolites are readily detected in urine for approximately 3 days after exposure.

Cocaine is absorbed from all sites of application, including GI mucosa. Body packing may lead to severe toxicity (seizures and cardiorespiratory collapse) if the container ruptures. If smuggling is suspected, a flat plate may show opaque densities within the bowel highlighted by a gas halo.

In addition to nasal application, cocaine can be used by injection or inhalation. The latter is called *freebase* (crack) and is a dangerous practice. In making crack, street cocaine (which is in the form of cocaine hydrochloride) is converted to cocaine alkaloid by removal of the salt moiety. This reaction is accomplished by mixing the cocaine with water and sodium bicarbonate. The crack is then separated from the water by filtration and drying. The paste hardens and is cut into chips that resemble soap. It is then smoked in a pipe or sprinkled onto a cigarette or joint. A small piece, called a *quarter rock*, produces a 20- to 30-minute high when smoked in a water pipe. Probably because of its enhanced lipid solubility, crack crosses the blood–brain barrier rapidly, causing an intense rush of pleasure. This habit is highly addictive. Presently, crack is primarily used by older teenagers and persons in their early 20s, in part because it is relatively inexpensive (approximately $5 to $10 per rock).

Clinical Symptoms. Cocaine's most dramatic clinical effect is CNS stimulation. In humans, this manifests in a feeling of well-being and euphoria, often accompanied by gregariousness, restlessness, excitement, and a sense of clarity. However, as the dose is increased, tremors, forced speech, agitation, and even tonic-clonic convulsions may result from excessive stimulation.

Initially, small doses (1 to 1.5 mg per kg) may slow the heart rate through central vagal stimulation. After moderate doses, pulse increases, the result of both central and peripheral adrenergic effects. Hypertension may appear abruptly and lead to cerebrovascular accidents. Fortunately, hypertension is generally short lived. Larger doses of cocaine may cause hypertension that may be followed quickly by cardiovascular collapse, often the result of myocardial ischemia and infarction. Myocardial injury that ranges from angina pectoris to massive infarction can be seen in young adults after acute cocaine exposure. With chronic cocaine use, a cardiomyopathy may develop that results in depressed cardiac function and death.

Rhythm disturbances are also characteristic of acute cocaine intoxication. These may consist of ventricular or supraventricular tachyarrhythmias and may be intractable. Arrhythmias are the most common cause of death after severe cocaine exposure.

Use of crack has been associated with a number of pulmonary disturbances, including bronchospasm, hemoptysis, pneumothorax, and pneumomediastinum. These lesions are

believed to result from the barotrauma associated with inhalation of hot, particulate matter, followed by a Valsalva maneuver.

Cocaine has been associated with other syndromes of organ dysfunction, including hyperpyrexia and renal failure. *Coke fever* (or *pyrexia*) is a common occurrence after acute cocaine use. It is often associated with muscle rigidity (resembling neuroleptic malignant syndrome) or rhabdomyolysis (the result of agitation and/or physical restraint). Rhabdomyolysis may result in subsequent myoglobinuric renal failure if not promptly recognized and treated. Recent reports of cocaine adulterated with levamisole, a veterinary antihelminth that potentiates cocaine's euphoric effects, describe patients presenting with fever and reversible agranulocytosis.

Infants exposed to cocaine may also exhibit CNS excitation that includes hyperactivity, dystonic posturing, altered mental status, or frank seizures.

Management. Among substances of abuse, cocaine is the most likely to create the unstable patient with life-threatening manifestations. Therefore, this intoxication requires rapid, thorough assessment and management. Immediate attention should be paid to the vital signs, including temperature (which should be obtained rectally). The patient who develops seizures requires immediate airway control as well as anticonvulsant therapy. Benzodiazepines (e.g., diazepam 0.1 to 0.3 mg per kg) are considered the anticonvulsants of choice because of their rapid onset of action and because animal data have associated their use with decreased mortality from cocaine intoxication. Benzodiazepines should also be administered liberally to the patient with mild to moderate toxicity (agitation, hypertension, tachycardia) because of their efficacy in reversing many of these clinical manifestations.

Because circulatory function can range from hypertensive crisis to cardiovascular collapse, early vascular access is important. Blood pressure instability should be anticipated and treated accordingly. For treatment of hypertensive crises, liberal benzodiazepine use may be combined with a short-acting antihypertensive (e.g., nitroprusside). Immediate treatment of hypertension is recommended because it may lead to cerebrovascular or myocardial injury, although the use of IV β-blockers alone is contraindicated. Cardiac arrhythmias are treated according to advanced cardiac life support protocols (see Chapters 1 and 82).

Hyperthermia must be recognized and treated promptly to prevent its complications. Management is discussed in Chapter 89. IV fluids should be used aggressively if urinalysis is suggestive of myoglobinuria.

Patients with CNS depression or a lateralizing neurologic examination should receive cranial tomography to rule out an intracranial vascular event.

Because cocaine is rarely ingested, the need for GI decontamination is confined to body packers/stuffers or when drug coingestion is suspected. With body stuffers, because bag leakage can lead to abrupt onset of severe intoxication and possibly death, activated charcoal should be administered immediately. Gastric emptying maneuvers and endoscopic removal of cocaine bags are relatively contraindicated because of the risk of bag rupture. Instead, decontamination is confined to administration of activated charcoal and WBI. Multiple-dose activated charcoal may be recommended to maximize the opportunity for cocaine to be adsorbed by the charcoal. Because cocaine bags and crack vials are radiopaque in up to 50% of cases, an abdominal radiograph is recommended to determine the location and extent of retained packets after decontamination has been initiated. A contrast study or computed tomography scan may be considered to improve detection.

In the event of severe intoxication or ingestion of more than 1 to 2 g of cocaine, transfer to the intensive care unit is essential for appropriate monitoring.

Central Anticholinergics

Pathophysiology

Increasingly, drugs, plants, and mushrooms with anticholinergic properties are ingested for their psychoactive effects. Because antidepressants, antihistamines, antispasmodics, and belladonna alkaloids are in widespread use, these compounds are more readily available than illicit psychoactive substances. Also, many OTC drugs having anticholinergic activity are available without prescription and are ingested to get "high." These agents are competitive antagonists with acetylcholine at the neuroreceptor site (Table 102.19). The major effects of these drugs are on the myocardium, CNS, smooth muscle, and exocrine glands. These effects include tachycardia, mydriasis, facial flushing, hyperpyrexia, cardiac arrhythmias, urinary retention, dry mucous membranes, decreased sweating, and decreased or absent bowel sounds. CNS effects include delirium, anxiety, hyperactivity, visual hallucinations, illusions, and disorientation. These signs and symptoms lead to the common mnemonic, "Mad as a hatter, red as a beet, dry as a bone, blind as a bat, and hot as a hare." In excess, anticholinergics may lead to severe toxicity that includes cardiac arrhythmias, seizures, and death.

Pharmacodynamics

The effects of anticholinergics vary according to the specific drug ingested, particularly because the many classes of drugs

TABLE 102.19

DRUGS AND CHEMICALS THAT MAY PRODUCE THE CENTRAL ANTICHOLINERGIC SYNDROME

Antidepressants: amitriptyline (Elavil), imipramine (Tofranil), doxepin (Sinequan, Adopin)
Antihistamines: chlorpheniramine (Ornade, Teldrin), diphenhydramine (Benadryl), orphenadrine (Norflex)
Ophthalmologic Preparations: cyclopentolate (Cyclogel), tropicamide (Mydriacyl)
Antispasmodic Agents: propantheline (Probanthine), clidinium bromide (Librax)
Antiparkinson Agents: trihexyphenidyl (Artane), benztropine (Cogentin), procyclidine (Kemadrin)
Proprietary Drugs: Sleep-Eze (scopolamine, methapyrilene), Sominex (scopolamine, methapyrilene), Asthma-Dor (belladonna alkaloids), Excedrin-PM (methapyrilene)
Belladonna Alkaloids: atropine, homatropine, hyoscine, hyoscyamus, scopolamine
Toxic Plants: mushroom (*Amanita muscaria*), bitter-sweet (*Solanum dulcamara*), Jimsonweed (*Datura stramonium*), potato leaves and sprouts (*Solanum tuberosum*), deadly nightshade (*Atropa belladonna*)

lead to secondary actions that are independent of anticholinergic actions. An important universal anticholinergic effect, however, is decreased GI motility. This is associated with delayed absorption of drug and, if GI decontamination is not performed, the appearance of severe toxicity may be delayed 12 to 24 hours after ingestion.

Management

The management of a patient with a known central anticholinergic syndrome is a challenge, particularly because one must also be prepared for the other distinct toxicities of the ingested drug or plant. Also, most plants and many drugs are not detected on toxicology screens, so the diagnosis must rely on history and clinical suspicion. Along similar lines, serum drug levels do not predict the degree of anticholinergic symptoms.

GI decontamination may be valuable beyond an hour after anticholinergic poison ingestion because of the likelihood of drug persistence in the gut lumen for an extended time. Once again, activated charcoal remains the drug of choice.

On the basis of presenting signs and symptoms, the patient may require sedation and monitoring in an intensive care unit setting to provide ventilatory support for coma, anticonvulsants for seizures, and antiarrhythmic drugs for cardiac arrhythmias. Adequate sedation may be achieved with titrated doses of benzodiazepines. Physostigmine, a potent anticholinesterase, is a recognized antidote for anticholinergic-induced mental status alterations; however, its use is controversial. Physostigmine can produce bronchospasm, bradycardia, hypotension, and seizures. It is therefore reserved for those who have normal EKGs and mental status dysfunction confined to hallucinations or severe agitation. The adult dose is 1 to 2 mg via slow IV infusion over 5 minutes. The trial dose can be repeated in 10 to 15 minutes up to a maximum of 4 mg. The pediatric dose is 0.5 mg IV administered slowly, with repeat every 10 minutes up to a maximum of 2 mg. The smallest effective dose may be repeated every 30 to 60 minutes if symptoms recur over 6 to 8 hours. The muscarinic toxicity of physostigmine may be treated with IV atropine at one-half the physostigmine dose given; physostigmine-related seizures may be treated with benzodiazepines.

Central Nervous System Sedative-Hypnotics

Pathophysiology

The sedative-hypnotics reversibly depress the activity of all excitable tissues. For most of these agents, CNS effects occur with little action on skeletal, cardiac, or smooth muscle. Uncommonly, serious depression in cardiovascular and other functions may occur. The prevalence of abuse of these agents was formerly exceeded by opioid abuse. However, with the increasing popularity of cocaine, these agents have become the preferred choice in treating cocaine-induced tension and anxiety. Many of these agents, including glutethimide, meprobamate, methaqualone, and barbiturates, are uncommonly available and have been replaced by the benzodiazepines. Because they have retained some popularity and still make periodic appearances on the streets, however, they should be included in discussions of such drugs.

Pharmacodynamics

The sedative-hypnotics have tranquilizing, euphoriant effects that may be similar to morphine. With all these agents—prescribed for this tranquilizing action—it is difficult to draw the line between appropriate use, abuse, habituation, and addiction. However, for all, tolerance is common and physical dependence quickly develops. Therefore, their abuse potential is considered high.

The pharmacologic characteristics of each drug are largely determined by their specific chemical nature. For example, all barbiturates are bound by plasma proteins. These characteristics have important implications in affecting their renal elimination and the effectiveness of extracorporeal drug removal techniques (hemodialysis, hemoperfusion).

For all sedative-hypnotics, patterns of abuse vary, ranging from infrequent sprees of intoxication to compulsive daily use. Introduction to these drugs may be through street use or drug trade (which is most common in adolescents), but, commonly, exposure is initiated through a physician's prescription to a parent for insomnia or anxiety. Because tolerance develops to most of the actions of these drugs, no signs of chronic use may be apparent.

Clinical Symptoms

After sedative-hypnotic use, the adolescent may exhibit sluggishness, difficulty in thinking, dysarthria, poor memory, faulty judgment, emotional lability, and short attention span. Irritability and lability are common. With chronic use, these drugs also lead to dependence, so a picture of abstinence may appear after their disuse, with clinical manifestations of apathy, weakness, tremulousness, agitation, or frank convulsions. In its mildest form, the abstinence syndrome may consist only of rebound increases of rapid eye movement sleep, insomnia, or anxiety.

Management

With patients of acute sedative-hypnotic ingestion, attention should be directed to ensuring a patent airway and an intact gag reflex. Cardiovascular disturbances are rare after sedative use, but because of the possibility of drug coingestion, thorough hemodynamic assessment is necessary. Most sedative-hypnotics are detectable on comprehensive toxin screens, so specimens of serum and urine may be sent for analysis; however, these "send out" screens rarely come back in real time, thus minimizing their importance at the bedside. GI decontamination should be considered and can typically be confined to administration of activated charcoal. Repeated doses of charcoal have been shown to enhance clearance of certain barbiturates and benzodiazepines. Urinary alkalinization aids in the excretion of phenobarbital. In extreme cases, charcoal hemoperfusion should be considered.

Optional treatment of sedative overdose includes continuous monitoring in an intensive care unit with intubation and ventilator support as indicated. Flumazenil, a benzodiazepine antagonist, can be administered in cases of suspected benzodiazepine ingestion. Its pediatric dose is 0.01 to 0.02 mg per kg IV (max 0.2 mg per dose) and may be repeated to a max of 0.05 mg per kg or 1 mg, whichever is less. Indications for flumazenil administration may be (i) to reverse a witnessed, unintentional benzodiazepine overdose in a young child or (ii)

to prevent airway intubation after an iatrogenic overdose. Flumazenil must not be given empirically in unknown or intentional overdoses for which induction of seizures may be life-threatening.

Opioids (Morphine, Codeine, Heroin, Methadone, Propoxyphene, Oxycodone, and Hydrocodone)

Epidemiology. In the United States, three distinct groups who abuse opioids have been described: (i) those who are prescribed an opioid as medical treatment and then go on to become dependent and develop drug-seeking behaviors (this group constitutes a minority of opioid abusers), (ii) those who begin with recreational drug use and quickly progress to regular use, and (iii) women who abuse opioids when pregnant. Such women and their offspring are at risk for a number of adverse pregnancy outcomes. For the patient who abuses opiates through injection, other consequences include the risk of hepatitis, endocarditis, acquired immunodeficiency syndrome (AIDS), and vasculitis.

In the past decade, recreational abuse of insufflated heroin and ingested prescription opioid analgesics (particularly oxycodone and hydrocodone) has risen to epidemic proportions in the United States and may be partly responsible for the first increase in overall drug-related mortality in a generation. In addition, some opioid-related deaths are likely inadvertent and represent inappropriate misuse of combinations of alcohol, sedative-hypnotic agents, and prescription analgesics. The significant rate of opioid abuse has also given rise to the common treatment of opioid addiction by the outpatient prescription of opioid antagonists such as buprenorphine, which has resulted in the relatively common occurrence of an opioid syndrome in toddlers due to exploratory ingestion of this agent.

Toxicology. The opioids produce their major effects by combining with receptors in the brain and other tissues. Effects include analgesia, drowsiness, change in mood, respiratory depression, decreased GI motility, nausea, and vomiting. The opiate receptors appear to be the normal sites of action of several endogenous opioid-like substances (e.g., the endorphins).

Generally, the toxic opioid dose for a person who is not addicted depends on the particular drug. For example, with morphine, clinical toxicity (excessive sedation) may appear with doses that exceed 5 mg in the adolescent. Tolerance rapidly develops to many CNS effects. However, death may occur as a result of marked respiratory depression and consequent anoxia. In particular, those individuals who are ultrarapid metabolizers of codeine through CYP2D6 may have increased morbidity and mortality. Other toxicities of opiates include (neurogenic) pulmonary edema, mast cell degranulation (which leads to histamine release and an "anaphylactoid" reaction), cardiac disturbances (with propoxyphene intoxication), and neurotoxicity with seizures (with meperidine intoxication).

Clinical Symptoms. Opioids invariably cause miosis, even after development of tolerance. Respiration may be depressed because of decreased responsiveness of brain stem respiratory centers to increases in carbon dioxide tension. Therapeutic doses of morphine have no effect on blood pressure or cardiac rate or rhythm. When blood pressure changes occur, they result from histamine release. Because histamine dilates capacitance blood vessels and decreases the ability of the cardiovascular system to respond to gravitational shifts, sitting or standing may produce orthostatic hypotension.

Many opioids have extensive effects on the GI tract. They decrease the secretion of hydrochloric acid, GI motility, and pancreatic secretions while increasing colonic tone to the point of spasm. In addition, the tone of the anal sphincter is augmented. Therapeutic doses of morphine and codeine can also increase biliary tract pressure, producing epigastric distress and biliary colic.

Management. The presence of coma, pinpoint pupils, and depressed respiration should suggest opioid poisoning in the absence of history. The finding of needle marks on the body further suggests this diagnosis. To confirm the diagnosis, toxicologic analysis of urine and/or serum should be conducted (of note, however, several important synthetic or semisynthetic opioids such as methadone, fentanyl, and oxycodone may not be detected on routine urine drug screens).

The first management step with opioid intoxication is to ensure adequate ventilation of the patient. Endotracheal intubation may be necessary if there is severe respiratory depression or pulmonary edema. If appropriate, GI decontamination should be performed. The narcotic antagonist naloxone (1 to 2 mg) should be given by IV. If there is no response despite the suspicion of opiate intoxication, the naloxone dose should be repeated (up to 8 to 10 mg), depending on effect and level of suspicion. Naloxone can precipitate an abstinence syndrome in those who have developed physical dependence; in such patients, smaller initial doses of 0.2 to 0.4 mg, with upward titration as needed, are preferable.

When patients who are addicted to opiates are hospitalized, small doses of an opiate may be necessary to prevent severe withdrawal. Methadone substitution is the preferred agent, because in small doses, it is less euphorigenic and its long elimination half-life permits once- or twice-daily dosing. With the patient under observation, 10 to 20 mg of methadone are given, ideally before the appearance of withdrawal symptoms (insomnia, irritability, agitation, piloerection). Other agents, such as buprenorphine and clonidine, are also being explored.

γ-Hydroxybutyrate, γ-Hydroxybutyrolactone, and 1,4-Butanediol

The related agents, γ-hydroxybutyrate (GHB), γ-hydroxybutyrolactone (GBL), and 1,4-butanediol (1,4 BD), have become popular substances of abuse among teenagers and young adults. GHB is an endogenous compound with neurotransmitter and/or neuromodulator function and interacts with dopamine, serotonin, GABA, and endogenous opioid-based neural systems. GHB and its congeners, when used for human consumption, can be considered a schedule I drug by the FDA. In the 1990s, it had been widely available through the purchase of kits (e.g., by mail order, via the Internet) that allow its home synthesis; access to these may be more limited currently. GBL is actually a precursor to GHB and is the primary ingredient of such kits and has also been sold in health food stores. However, GBL is rapidly metabolized in vivo to GHB, and the clinical effects of ingesting either agent are nearly indistinguishable. 1,4 BD is also metabolized to GHB via alcohol

dehydrogenase. These agents are used for a variety of reasons, but primarily as euphoriants and aphrodisiacs at parties or all-night dance clubs (raves). GHB has gained a particular notoriety as a date-rape agent. This class also has a reputation in the body-builder community as growth hormone stimulants and thus enhancers of muscle development and fat loss.

GHB, GBL, and 1,4 BD are CNS depressants that cause rapid onset of deep sleep that can progress to coma and respiratory depression. Patients who have overdosed may have transient seizure activity and are often hypothermic and bradycardic. The coma is usually relatively short in duration, on the order of 1 to 2 hours. During emergence, transient delirium and vomiting are often observed. Depressed respiratory effort and airway-protective reflexes are common in the more severe cases, although aspiration pneumonia as a complication has been rare. Many patients are surprisingly responsive to stimulus, and attempts at laryngoscopy to effect endotracheal intubation in a seemingly deeply comatose patient may result in an angry, combative patient who sits up and swears at the endoscopist.

Most patients with acute overdose can be managed with the provision of ambient oxygen, suctioning, and attention to the airway. A nasal trumpet is helpful in some cases, and endotracheal intubation may be required occasionally, although it may necessitate rapid sequence induction for the reasons previously noted. Atropine has been used for severe bradycardia with success. Blood pressure support is rarely necessary.

Inhalants

The High School Senior Survey, conducted by the National Institute on Drug Abuse, has suggested that the abuse of inhalants is relatively common in adolescents, with a lifetime prevalence rate of up to 20%. Additional data suggest that these psychoactive agents are even more common in school-aged children and preadolescents. The prevalence of inhalant abuse among young children has been related to the ready availability of these products. Patterns of abuse are also strikingly region-specific, with the highest rates of abuse in the southwestern and southeastern United States.

The psychoactive inhalants can be placed into three broad categories: (i) hydrocarbons, (ii) nitrous oxide, and (iii) nitrites. The hydrocarbons can be subdivided further into the aliphatic hydrocarbons, the halogenated hydrocarbons, and solvents. Regardless of the class, all inhalants possess the pharmacologic property of narcosis, leading to euphoria and lightheadedness after inhalation. Typically, the agents are abused by "huffing" or "bagging." In huffing, the agent is placed into a rag or handkerchief, held under the nose, and then deeply inhaled. With bagging, a common method of abuse at parties, the compound is placed into a large bag (e.g., garbage bag) with the drug user placing his or her head into the bag.

Several distinct profiles of toxicity have been described after inhalant abuse. The inebriation that these agents produce may be associated with mental status changes that include coma with respiratory arrest or aspiration. The halogenated hydrocarbons all possess potent cardiotoxicity, leading to myocardial irritability and cardiac arrhythmias. This action has been associated with many reports of spontaneous ventricular fibrillation in adolescents during a binge. Finally, the act of bagging is associated with the risk of simple asphyxia. A syndrome known as *sudden sniffing death* has been described in adolescents who abuse inhalants. This syndrome may be the result of any of these previously described toxicities. Finally, acute exposure to those inhalants that contain nitrites may lead to methemoglobinemia, often severe.

Other toxicities are associated with chronic inhalant abuse. The solvents, particularly toluene, may lead to a syndrome that includes abdominal pain, muscle wasting, electrolyte disturbances (hypokalemia), and renal tubular acidosis. Patients of chronic solvent abuse may also develop a leukoencephalomalacia with cerebral atrophy.

Management

Because inhalant abuse may lead to the development of life-threatening symptoms, close attention should be directed to the vital signs and their stability. Patients with depressed levels of consciousness may require airway support and ventilation. Because of the risk of cardiac arrhythmias when halogenated hydrocarbons are abused, vascular access should be established early. Arrhythmias should be treated according to the standard protocol (see Chapters 1 and 82); however, the use of epinephrine is relatively contraindicated because it has been associated with worsening of rhythm disturbances. As a part of the evaluation, a complete metabolic panel that includes electrolyte levels, with calcium, phosphate, and magnesium; amylase level; liver function tests; creatine phosphokinase level; and urinalysis should be obtained.

Treatment of methemoglobinemia is discussed in Chapter 91.

CHAPTER 103 ■ EVALUATION OF THE ILL RETURNING TRAVELER

MARK L. WALTZMAN, MD, AND RICHARD MALLEY, MD

The world is a book, and those who do not travel read only one page.

Augustine of Hippo (354–430)

Trips do not end when you return home—usually this is the time when in a sense they really begin.

Agnes E. Benedict and Adele Franklin (*The Happy Home*)

In the United States, outbound travel by residents has increased from less than 52 million people in 1995 to more than 63.5 million in 2005. Approximately 20% to 70% report some illness associated with their travel. While most illnesses are mild, between 1% and 5% of travelers seek medical attention either during or immediately after travel and 1 in 100,000 travelers die secondary to travel-related illness. An estimated 1.9 million children from the United States travel internationally each year. While some travel health concerns are similar for children and adults, international pediatric travelers may experience unique problems related to their developing immune systems and different age-based behaviors. As with non–travel-related illness and injury, a newly ambulating toddler will have different health risks than a "high-risk" taking adolescent. Although data about the incidence of pediatric illnesses associated with international travel are limited, there are studies that report serious morbidity and mortality in pediatric travels. The most common reported health problems are diarrheal illnesses, malaria, motor vehicle accidents, and water-related injuries. There are differences in preventative medicine options for children, as several travel-related vaccinations and medications indicated for adults are not licensed or recommended for pediatric use.

Pediatric travelers may be classified into at least two groups: tourists and travelers visiting friends and relatives (VFR). In general, VFR travelers are predominantly immigrants and their children returning to their home countries for vacations, to maintain family ties, or to visit sick relatives. This latter group of travelers may have an increased risk of illness, as family and relatives who are living in developing countries may be more likely to have endemic infectious diseases that are contagious, such as intestinal parasites and tuberculosis. In addition, travelers visiting friends and relatives are less likely to seek pretravel preventive care.

There are several schemata that have been proposed for the evaluation of the returning traveler who is ill. A systematic approach beginning with the chief complaint allows for a rational and stepwise method of developing a differential diagnosis. Ill patients returning from international travel tend to have complaints that fall into one of three categories:

1. Fever
2. Diarrheal/ gastrointestinal complaints
3. Dermatologic issues

FEVER

Fever in the returning traveler is not uncommon. Nearly 3% of travelers returning even from brief international trips (less than 1 month) report fever. The initial assessment should include a detailed history of travel itinerary (including visits to all rural areas, irrespective of the length of time spent in those regions). This will allow for the determination of the likely incubation period as well as possible exposures to infectious agents. It will also allow for the determination of the length (duration) and characteristics of the fever [fever profile including height of the fever, characteristics of the fever (i.e., waxing and waning)], immunization status, and whether appropriate antimalarial prophylaxis was utilized and, if so, whether the medication was taken at appropriate dose, intervals, and proper length of time after leaving the endemic area. The degree of illness, exposure history, time course of illness, and associated signs and symptoms all contribute to the degree of intensity of the evaluation. Some causes of fever in the returning travel are benign, while others are potentially fatal, and still others may pose a public health concern.

The timing of onset of symptoms will vary by causative agents. Knowledge of the incubation period of the infectious causes of fever will allow the clinician to perform a more focused evaluation (Table 103.1). For example, if a fever begins less than 2 weeks after a traveler's return from a short international trip, then tuberculosis, leishmaniasis, and schistosomiasis are unlikely almost regardless of the exposure history.

Although there will be some overlap, further classification of the type of fever may help focus the differential diagnosis. A categorization of fever into the following groups can be useful: undifferentiated (isolated) fever, fever associated with hemorrhage, respiratory complaints, eosinophilia, or central nervous system (CNS) involvement.

Undifferentiated Fever

Malaria

Worldwide there are more than 2.5 million deaths per year caused by malaria, with approximately 1 million deaths in children younger than 5 years. Official estimates of mortality

TABLE 103.1

INFECTIOUS CAUSES OF UNDIFFERENTIATED FEVER IN THE RETURNING TRAVELER

Disease	Distribution	Incubation period
Incubation < 14 days		
Malaria	Most tropical and subtropical areas; some temperate areas	6 days to years
Dengue	Tropics and subtropics, including urban areas	4–8 days (3–14 days)
Spotted fever (rickettsiae)	Worldwide	Few days to 2–3 wk
Scrub typhus (*Orientia tsutsugamushi*)	Widespread in Asia; also in Australia	10 days (6–21 days)
Leptospirosis (*Leptospira interrogans*)	Widespread; most common in tropics	7–12 days (2–26 days)
Campylobacteriosis, salmonellosis, shigellosis	Widespread, most common in developing countries	2–6 days (1–20 days)
Typhoid fever (*Salmonella enterica* serotype *typhi*)	Developing countries, especially Indian subcontinent	7–18 days (3–60 days)
Acute HIV infection	Worldwide	Acute illness, 10–28 days (10 days–6 wk) (may also lead to asymptomatic infection)
East African trypanosomiasis (*Trypanosoma brucei rhodesiense*)	Sub-Saharan East Africa, with focal distribution	Acute illness, 5–16 days (3–21 days); chronic illness, months to years
Incubation 14 days to 6 wk		
Malaria	See malaria above	
Typhoid fever	See typhoid fever above	
Hepatitis A	Widespread	28–30 days (15–50 days)
Hepatitis E	Widespread; outbreaks in Asia, Africa, and Latin America	26–42 days (2–9 wk)
Acute schistosomiasis (Katayama fever)	Parts of Africa, Asia, and Latin America	Katayama fever, 4–8 wk
Amebic liver abscess (*Entamoeba histolytica*)	Widespread; most common in developing countries	Weeks to months
Leptospirosis	See leptospirosis above	
Acute HIV infection	See HIV infection above	
East African trypanosomiasis	See East African trypanosomiasis above	
Incubation > 6 wk		
Malaria	See Malaria above	
Tuberculosis	Worldwide; common in parts of Africa, Asia, Latin America, Eastern Europe, and Russia	Primary, weeks; reactivation, years
Hepatitis B	Worldwide; chronic infection common in parts of Asia, Africa, and Latin America	60–90 days (45–180 days; rarely 9 mo)
Visceral leishmaniasis (*Leishmania donovani*, *L. chagasi*, others)	Many parts of Africa, Asia, South America, and the Mediterranean basin, especially rural	2–6 mo (10 days to years)
Lymphatic filariasis (*Wuchereria bancrofti* and other filariae)	Widespread in tropical areas	3–6 mo or longer
Schistosomiasis	See acute schistosomiasis above	
Amebic liver abscess	See amebic liver abscess above	
Chronic mycosis	Worldwide	1 wk to years
African trypanosomiasis (*T. brucei rhodesiense*, *T. brucei gambiense*)	Sub-Saharan Africa, with focal distribution	Chronic illness, months to years

among children younger than 5 years in sub-Saharan Africa in 2002 show that 22% of all deaths were related to malaria, 16% to acute respiratory infections, 14% to diarrheal illness, 13% to "neonatal deaths," 8% to measles and HIV infection, and 19% to "all other causes." Malaria has varied presentations and outcomes that are largely based on the infecting plasmodium species. VFR travelers are at particular risk since many fail to take the necessary precautions either to avoid insect exposure or to take prophylaxis. Approximately 40% of the reported cases of malaria in the United States are from

VFR travelers. Infections with *Plasmodium falciparum* can progress rapidly, some fatally, and must be considered in the differential diagnosis in all febrile children who have recently visited an endemic region. Approximately 90% of *P. falciparum* infections are acquired in sub-Saharan Africa, and up to 90% of travelers who are infected begin to have symptoms within 1 month after their return. In contrast to *P. falciparum* infections, travelers infected with *Plasmodium vivax* and *P. ovale* may show symptoms several months to years after exposure. Seventy percent of *P. vivax* infections are acquired in Asia or Latin America.

Chloroquine-sensitive malaria exists in Central America as well as the Caribbean and limited parts of South America. There are regions that have developed chloroquine and mefloquine resistance (specifically in Southeast Asia). It is vital for the clinician to ask about not only malaria prophylaxis but also the type and how it has been taken. Both chloroquine and mefloquine kill the parasite only in the hematogonous phase; it is thus vital to take these medications for 4 weeks upon leaving the endemic region. Early termination of these medications could result in malaria even in someone who was "taking prophylaxis."

Malaria infections in children typically present with fever; however, 10% to 40% may be afebrile at the time of the initial evaluation. The fever pattern of malaria, when present, is usually continuously elevated in *P. falciparum* infection.

The life cycle of the malarial parasites begin when the *sporozoites* are inoculated into humans by the bite of an *Anopheles* mosquito and invade hepatic parenchymal cells. The parasites undergo asexual multiplication or *schizogony* (where the parasites are known as *trophozoites*); in this tissue phase, it is also referred to as the exoerythrocytic schizogony. After a period of development (7 to 10 days for *P. falciparum*, *P. ovale*, and *P. vivax* and 10 to 14 days for *P. malariae*), *merozoites* emerge to invade the erythrocytes and begin the symptomatic phase of illness. The last few hours of the erythrocytic stage of the parasite's life cycle, where the parasite is called a *schizont*, comprise the actual replicative phase in which the parasite undergoes mitosis, subdivides, and differentiates into merozoites. It is the subsequent rupture and release of merozoites that lead to fever and other malarial symptoms. If infections are synchronized, there periodicity of symptoms is 48 hours in *P. ovale* and *P. vivax* malarial infection, whereas it is 72 hours in *P. malariae* infections. While periodicity may be every 48 hours in *P. falciparum* infections, it often is irregular. Parasite populations do not become synchronized until at least the second week of clinical illness in the benign malarias, so that it is unusual to see the classical 48- or 72-hour cyclic pattern of fever produced by simultaneous lysis of erythrocytes and release of merozoites. The parasite's reproductive cycles often are not synchronized with any of the species and the absence of periodicity does not rule against malaria being the cause of fevers. Other symptoms at presentation include sweats, rigors, nausea, vomiting, abdominal pain, headache, and malaise. The malaria species and degree of parasitemia will affect the types and degree of symptoms that are displayed. Given the constellation of symptoms, malaria should be considered in all febrile travelers almost regardless of their clinical presentation.

The blood smear is considered the "gold standard" in the diagnosis of malaria. Both thick and thin smears should be obtained. Thick smears allow for a much larger volume of blood to be examined and thus for the detection of smaller numbers of parasites (leading to increased sensitivity), while the thin smear will allow for the identification of the species and the percentage of affected red blood cells. If the initial blood films are negative for malaria and the disease is still clinically suspected, examination of the thick and thin smears should be repeated at least once within 12 to 24 hours after the initial evaluation. Thrombocytopenia without leukocytosis is a characteristic feature of malaria as is splenomegaly.

In 2007, the U.S. Food and Drug Administration approved a rapid test for the detection of malaria. The Binax NOW® is an immunochromatographic test that detects *P. falciparum*–specific HRP2 antigen to a panmalaria aldolase common to all malaria species. The assay has 94% sensitivity for the detection of *P. falciparum* (up to 96% for pure *P. falciparum* infection) and 87% sensitivity for pure *P. vivax* infection.

Malaria is a reportable disease to the U.S. Center for Disease Control and Prevention (CDC). Empiric treatment should be decided upon in consultation with an infectious disease specialist and the CDC. Drugs of choice usually include quinidine or chloroquine (dependent upon the resistance patterns in the visited areas and the use of prophylactic medications) with the addition of primaquine for *P. vivax* or *P. ovale* infections. Both chloroquine and quinidine are available in intravenous preparations from the CDC.

Dengue Fever

Dengue is caused by one of four strains of the mosquito-borne flavovirus. It has become one of the major infectious disease threats in the tropical and subtropical areas of the world, accounting for approximately 50 million cases and at least 12,000 deaths annually. Seasonal epidemics of dengue occur frequently in many tropical and subtropical regions, with recent outbreaks in Rio de Janeiro, Singapore, Puerto Rico, Haiti, and the Dominican Republic. It has become a common cause of fever in recently returned travelers and, in contrast to malaria, is often acquired during urban travel. Dengue is most often transmitted during daylight hours because of the feeding preferences of its vector, the *Aedes aegypti* mosquito.

The incubation period of dengue is typically 4 to 7 days, with symptoms manifesting most often as a mild influenza-like illness with fever, headache, and myalgia, but sometimes as high fever, severe retroorbital headache, and severe muscle pain (breakbone fever). The fever usually lasts 5 to 7 days. A rash, typically macular or maculopapular and often confluent with the sparing of small islands of normal skin, has been reported in approximately 50% of patients. This rash typically appears near the time of defervescence, often lasts for 2 to 4 days, and may be accompanied by scaling and pruritus. Other signs and symptoms may include flushed facies (typically in the first 24 to 48 hours), lymphadenopathy, injected conjunctivae, inflamed pharynx, and mild respiratory and gastrointestinal symptoms.

Dengue shock syndrome and dengue hemorrhagic fever are uncommon in travelers, as is death from dengue; however, two deaths were reported in a series of more than 200 cases of dengue imported to the United States between 1993 and 2000. The risk of dengue hemorrhagic fever is more than 4 times higher in immigrants and in VFR travelers to areas where the disease is endemic than in general travelers to the same area.

This is likely because dengue shock syndrome and dengue hemorrhagic fever develop as a result of antibody-dependent enhancement (overstimulation of the immune response to an infection with a prior serotype) in individuals who have had pervious infections. Thus, in contrast to malaria, dengue infection may result in more severe disease in previously exposed individuals.

Dengue fever is typically diagnosed on the basis of clinical suspicion and confirmed by comparing serum antibody titers during acute and convalescent phases. The most commonly used test is the IgM capture ELISA; however, this test is often gives negative results early in the course of the disease and therefore should optimally be performed at least 4 to 5 days after the onset of symptoms. Primary infections are characterized by an increase in the dengue-specific IgM antibodies 4 to 5 days after the onset of fever and increase in the IgG antibodies only after 7 to 10 days. A test for capillary fragility, the tourniquet test, gives positive results if 20 or more petechiae appear in a 1-in^2 (6.25-cm^2) patch on the forearm after inflation and deflation of a blood pressure cuff. This test has been incorporated in the WHO clinical case definition of dengue hemorrhagic fever, but the definition differentiates poorly between dengue and dengue hemorrhagic fever and is not very specific.

Treatment of dengue is symptomatic. Appropriate administration of intravenous fluids is associated with marked reductions in the rates of death due to dengue shock and dengue hemorrhagic fever Avoidance of nonsteroidal antiinflammatory medications and aspirin is recommended because of the thrombocytopenia and increased risk of bleeding.

Typhoid Fever

Typhoid fever is not an uncommon cause of fever in children or adults returning from travel. It is caused by fecal-oral transmission of *Salmonella typhi* or *S. paratyphi*, which are gram-negative bacteria. More than 70% of cases of typhoid fever in the United States are associated with international travel, with most occurring in travelers who have visited family or friends on the Indian subcontinent, in the Philippines, or in Latin America. Common manifestations include fever, headache, abdominal pain, and initial diarrhea followed by constipation. Frequently patients will manifest a "relative bradycardia" (a heart rate that is not as high as one would expect with the height of the fever), although this finding is not specific for typhoid fever and can be associated with other infections by other intracellular organisms such as *Plasmodium*, *Legionella*, and *Babesia*. Other physical examination findings of typhoid fever include a toxic appearance, hepatosplenomegaly, "rose spot" rash, as well as CNS manifestations such as altered mental status and syndrome of inappropriate release of antidiuretic hormone. Bowel perforation can occur in the second week of illness, accompanied by leukocytosis.

The diagnosis of typhoid fever relies on a combination of physical examination findings and serological and microbiological tests. The "Widal" test evaluates the presence of somatic (O) and flagellar (H) agglutinins to *S. typhi* in the patient's serum using suspensions of O and H antigens. The historical recommended method of performing the Widal test is the tube agglutination technique, in which serial twofold dilutions of the subject's serum from 1:20 to 1:1,280 are tested. Subsequent improvements of the test resulted in a rapid slide test. Although this test is widely used in developing countries, it is not commonly used in the United States, as it has been found to be neither sensitive nor specific. Isolation of *Salmonella* from blood or stool is the current standard in the developed world. Initial blood cultures are up to 70% sensitive, whereas the stool culture is rarely positive during the first week of illness. As the disease advances, the stool culture becomes increasingly sensitive, whereas the blood culture loses sensitivity, dropping to less than 30% sensitivity during the second week of illness. The most sensitive test to confirm typhoid is the bone marrow aspirate, with a sensitivity of up to 93%. If typhoid fever is suspected, empiric therapy with a fluoroquinolone or a third-generation cephalosporin antibiotic for 10 to 14 days may be considered. Shorter courses of third-generation cephalosporins have resulted in relapse. Because of the difficulty in diagnosing typhoid fever and its potential seriousness, prevention of the disease is critical. Prophylactic measures, including carefully observing food and water precautions, consuming only commercially bottled or boiled water, and eating only cooked foods or raw foods that can be pealed, aid in prevention. Furthermore, vaccination is indicated for at-risk travelers. The current options for vaccines include the injectable Vi-polysaccharide vaccine (with reported rates of efficacy up to 70%). However, because it is a pure polysaccharide vaccine, it is only indicated in patients older than 2 years. This vaccine has an estimated duration of protection of 2 to 3 years. The live oral Ty21a vaccine is licensed for patients older than 6 years. This oral vaccine has efficacy rates that are similar to that of the Vi polysaccharide but has a duration of protection estimated around 3 to 5 years. Protein–Vi conjugate vaccines have been developed, shown to be effective in the prevention of typhoid fever in children and would theoretically induce long-lasting immunity even if given in infancy but are not commercially available at this time.

Rickettsial Diseases

Fever, headache, and myalgia in persons who have recently traveled should prompt the consideration of rickettsial infections. These infections include African tick typhus (*Rickettsia africae*), Mediterranean tick typhus (*R. conorii*), and scrub typhus (*Orientia tsutsugamushi*). Rickettsiae are transmitted by arthropods, and the detection of a painless eschar at the inoculation site ("site of the bite of the mite") can be an important diagnostic clue. High-risk travelers include those that have been hiking, camping, or traveling on safari in grassy or scrubby regions. Regional lymphadenopathy, rash, leukopenia, and thrombocytopenia are often present, although rash is frequently absent in African tick typhus. The diagnosis of rickettsial infection is generally made on the basis of clinical suspicion, which should prompt treatment (generally with tetracycline antibiotics) pending serologic confirmation.

Leptospirosis

Leptospira interrogans are motile, finely coiled, catalase-producing spirochetes that infect humans through intact mucous membranes or disrupted skin, invade the bloodstream, and can disseminate rapidly to multiple organs. The usual incubation period is approximately 10 days (range = 7 to 14 days), although symptoms can be seen in as short as 2 days and as long as 25 days. The clinical manifestations are divided into the initial "septicemic" phase and the subsequent "immune" phase.

Anicteric leptospirosis may begin abruptly with a viral-like illness marked by fever, myalgia, and headache. Abdominal pain, vomiting, diarrhea, anorexia, and conjunctival suffusion may be present. Symptoms usually last 4 to 7 days and resolve spontaneously. Some patients experience a second, immune phase of the illness that begins 1 to 3 days later that may or may not be accompanied by a low-grade fever. During this phase, patients usually have headache, myalgia, rash, and conjunctival suffusion, as well as hepatomegaly. Typically, the headache is severe and may be associated with nuchal rigidity. Interstitial nephritis is common; renal involvement can range from incidental pyuria, hematuria, and proteinuria to renal failure. The rash of leptospirosis is immune-mediated and nonspecific. It can be macular, maculopapular, urticarial, petechial, or purpuric. The more severe, icteric form of leptospirosis, also called Weil syndrome, is indistinguishable in the early phase from the benign, anicteric form. The hallmarks of Weil syndrome are jaundice, azotemia, and hemorrhage, becoming evident 4 to 6 days after the onset of symptoms and may progress through the second week of illness. Weil syndrome has a mortality of 5% to 10%.

A history of exposure to fresh water (rafting or kayaking or wading through flooded streets) in a person with relevant symptoms should suggest the diagnosis of leptospirosis. Antibiotics such as penicillin and tetracycline are effective, and the diagnosis is usually confirmed serologically by a fourfold or greater increase in antibody titers between serum samples obtained during the acute and convalescent phases.

Fever Associated with Hemorrhage

There are several treatable infections that may affect travelers that manifest as fever with hemorrhage. These include meningococcemia, malaria, leptospirosis, and rickettsial infections. There are a handful of viral infections (in addition to dengue and yellow fever) that are also associated with fever and hemorrhage; these, however, are rarely acquired by travelers. Viral hemorrhagic fevers (such as Lassa fever and Ebola fever) need to be considered in travelers who present with fever and hemorrhage; these diseases also have important infection control and public health concerns. Epidemiologic clues include history of visits to rural areas or recent contact with ill persons in areas where the viral hemorrhagic fevers are endemic. Most patients with viral hemorrhagic fevers note the onset of fever within 3 weeks after exposure to infected persons, contaminated water, or infected insects/vectors.

There is currently no specific treatment available for the viral hemorrhagic fevers. Supportive care with special attention to careful fluid and electrolyte management is indicated. Endothelial dysfunction makes hydration challenging; pulmonary edema occurs rapidly with intravenous hydration. To prevent agitation, analgesia and sedation may be useful.

Of special consideration is the yellow fever virus. This flavivirus is transmitted to humans primarily by infected *Aedes* and *Haemogogus* mosquitoes in tropical areas of Africa and South America. There have been sporadic human infections occurring following exposure to the enzootic mosquito vectors (*Haemogogus* species in South America and *Aedes africanus*, *A. furcifer*, *A. vittatus*, *A. luteocephalus*, and *A. simpsoni* in Africa). These mosquitoes acquire the yellow fever virus from infected monkeys and transmit the virus to humans.

There is a 3- to 6-day incubation period, followed by the development of symptoms, including headache, fever, chills, and myalgia, often accompanied by photophobia, back pain, anorexia, vomiting, and restlessness. During this phase, patients are viremic. Viremia usually clears about 4 days following the onset, as fever and other symptoms subside ("period of remission"). Although patients may remain anicteric and then fully recover, approximately 15% to 20% of patients enter a "period of intoxication," characterized by return or persistence of fever, development of jaundice, nausea, vomiting, epigastric tenderness, oliguria, and hemorrhage. Viral invasion of the CNS is rare, but neurologic manifestations can include delirium, convulsions, and coma. The case fatality rate of severe disease ranges from 20% to 50%. Laboratory abnormalities include elevated aspartate and alanine aminotransferases, proteinuria, thrombocytopenia, leucopenia, and abnormal blood coagulation studies.

Patients with confirmed or suspected yellow fever require intensive supportive care with careful attention to optimizing fluid and metabolic balance. Secondary bacterial infections should be treated with appropriate antibiotics.

The live-attenuated yellow fever vaccine has been available since 1937 and is recommended for persons who travel to yellow fever endemic areas. It is currently contraindicated in persons younger than 6 to 9 months, those with allergy to egg or egg products, patients who are pregnant, or those who have underlying immunocompromised disease. The effective duration is approximately 10 years.

Fever Associated with Respiratory Findings

Respiratory symptoms in a febrile returning traveler should suggest the presence of common agents such as influenza and other respiratory viruses, *Mycoplasma*, *Streptococcus pneumoniae*, and *Legionella pneumophila*, the etiologic agent of legionnaires disease. *L. pneumophila* has been documented as a source of infection by travelers on cruise ships or those spending times in spas or hotels. Another important consideration is tuberculosis, an infection that is becoming more prevalent in travelers, although its presentation can occur months or years later. In travelers to regions of Mexico, consideration should be given as well to histoplasmosis and coccidioidomycosis.

The constellation of fever, pneumonia, and hepatitis should prompt consideration of *Coxiella burnetti* (Q fever), particularly if there has been exposure to farm animals. Cough, nonspecific pulmonary infiltrates, and peripheral eosinophilia should lead one to the consideration of Löffler's syndrome, which results from a transient migration of larval helminths (ascaris, hookworm, or *Strongyloides*) through the alveolar spaces.

Fever with Associated Eosinophilia

Elevated eosinophil counts are associated with a myriad of illnesses, including allergic reactions, drug reactions, and hematologic and neoplastic conditions. Infections with HTLV-1 and HIV, as well as *Bartonella*, *Mycobacterium tuberculosis* or *M. leprae*, streptococci (during recovery), and diseases such as syphilis, coccidiomycosis, and acute bronchopulmonary

aspergillosis can all induce eosinophilia. A useful mnemonic for diseases associated with eosinophilia is "worms, wheezes, and weird diseases." It is important to note that, in consideration of eosinophilia, the absolute eosinophil count is probably more important than the percentage of eosinophils present. A total peripheral white blood cell count of 5,000 with 5% eosinophils is quite different than a patient with a total peripheral white blood cell count of 25,000 with 5% eosinophils. Although these cutoffs are somewhat arbitrary, it is useful to consider an absolute eosinophil count of less than 400 as normal, 400 to 1,000 as moderate, and greater than 1,000 as more consistent with parasitic infections. Although fever in association with peripheral eosinophilia of greater than 400 may be due to hematologic conditions or acute allergic reactions, the presence of both fever and eosinophilia in a pediatric traveler should prompt consideration of an infectious cause. Peripheral eosinophilia is characteristically associated with helminthic infections in which the worms dwell in or migrate through tissues. In the febrile traveler with eosinophilia, diagnoses to be considered include acute hookworm, ascaris, or *Strongyloides* infections; acute schistosomiasis (Katayama fever); visceral larva migrans (toxocariasis); lymphatic filariasis; and acute trichinosis. The initial evaluation of travelers with eosinophilia should include examination of several stool specimens for ova and parasites, serologic tests for strongyloidiasis, schistosomiasis, or other helminthic infections, and examination of blood smears or skin biopsy to detect microfilariae, all dictated by the geographic regions traveled and the clinical findings.

Fever Associated with Central Nervous System Involvement

There are numerous processes that may cause fever associated with neurologic changes; however, special consideration should be given to specific etiologies in the returning traveler. Malaria, tuberculosis, typhoid fever, rickettsial infections, leptospirosis, poliomyelitis, rabies, and the viral encephalitides (including Japanese encephalitis, West Nile encephalitis, and tick-borne encephalitis) are possible infections that affect the CNS. Travelers to the "meningitis belt" regions in Africa (during the months of December to June) and those who travel to the Arab world around the time of the annual pilgrimage to Mecca for the *Hajj* are at increased risk for developing meningococcal meningitis. CNS involvement with eosinophilia should also raise the possibility of coccidioidomycosis and angiostrongyliasis (the latter caused by invasion of the meningeal space by the rat lungworm *Angiostrongylus cantanensis*). Rare causes of CNS involvement in travelers also deserve mention. East African trypanosomiasis (the so-called "African sleeping sickness") is transmitted through the bite of the tsetse fly. It manifests as an erythematous swelling or chancre at the site of the fly bite, intermittent high fevers, headache, myalgia, and myocarditis, which can be fatal. These symptoms precede the meningoencephalitis. During the acute phase, trypanosomes are often detectable on smears of peripheral blood. Early treatment is essential because the prognosis is poor once CNS involvement has occurred. In the absence of CNS disease, suramin and eflornithine are the drugs of choice. Suramin sodium is useful only in the treatment of early *Trypanosoma brucei gambiense* and *T. brucei rhodesiense* infections because it does not cross the blood–brain barrier. Melarsoprol (a combination of melarsen oxide and dimercaprol) and eflornithine are the most effective compounds for the treatment of the second stage of the disease since they can cross the blood–brain barrier. Neither agents are commercially available in the United States, and treatment would need to be coordinated with the CDC.

DIARRHEAL AND GASTROINTESTINAL COMPLAINTS

Many children who travel to developing countries develop diarrhea. Most episodes of traveler's diarrhea resolve during or shortly after the travel. Five to 10% of travelers report diarrhea that lasts for 2 weeks or longer and 1% to 3% have diarrhea that lasts 4 weeks or longer. In the majority of cases, the etiologic agent of traveler's diarrhea cannot be isolated. However, among cases in which a pathogen is isolated, 50% to 75% are identified within 2 weeks of developing symptoms. As the duration of the diarrhea increases (typically greater than 2 weeks), the likelihood of identifying a specific bacterial cause decreases; in contrast, the likelihood of identification of a parasitic cause increases. The most commonly identified parasitic infections include *Giardia lamblia*, *Cryptosporidium parvum*, *Entamoeba histolytica*, and *Cyclospora cayetanesis*, although even these are detected in less than one-third of travelers with chronic diarrhea and in only 1% to 5% of travelers with acute diarrhea. Infected children are predominantly asymptomatic, but bloody or nonbloody diarrhea, hepatobiliary symptoms, and failure to thrive may occur.

Viral hepatitis should be considered when evaluating a child with nonspecific gastrointestinal symptoms, particularly when jaundice is present. Hepatitis A is prevalent in both developed and developing nations and is acquired through contaminated food and water. Hepatitis A is usually asymptomatic or manifests as mild symptoms in young children. Hepatitis E must be considered because it is a common etiology of acute hepatitis in developing countries. Although rarely presenting acutely, hepatitis B and C are common in the developing world and should be considered in any adolescent or young adult who is sexually active or has had a tattoo or body piercing while traveling.

Invasive or inflammatory enteropathy (e.g., dysentery) should be suspected in persons with bloody diarrhea, fever, or leukocytes detected in the mucous portion of the stool. Invasive enteropathy has a fairly abrupt onset (over a period of hours generally) and may be complicated by metastatic infections, reactive arthropathy, or, in the case of infection with *Campylobacter jejuni*, the Guillain-Barré syndrome. Amoebic dysentery, caused by *E. histolytica* among other amoebae, often presents slowly over the course of days and may be complicated by hepatic abscess formation.

Prolonged diarrhea with malabsorption should prompt consideration of a protozoal infection of the small bowel (such as *G. lamblia*) as well as tropical sprue. Tropical sprue is a syndrome characterized by acute or chronic diarrhea, weight loss, and malabsorption of nutrients. It occurs in residents of or visitors to the tropics and subtropics. The exact causative factor is unknown, but an intestinal microbial infection is believed to be the initiating insult. The infection results in enterocyte injury,

intestinal stasis, and possible bacteria overgrowth. Villous destruction and demonstrable nutrient malabsorption occur in varying degrees. Folate, vitamin B_{12}, and iron are the most common nutrient deficiencies. Tropical sprue is pathologically indistinguishable from nontropical sprue (i.e., gluten-sensitive enteropathy or celiac disease), but it is not associated with antigliadin and antiendomysial antibodies and does not respond to removal of gluten from the diet. Useful therapeutic interventions involve treatment with antibiotics and replacement of nutrients (e.g., folic acid, vitamin B_{12}, iron), deficient fluid, and sometimes blood. The use of antibiotics to treat tropical sprue is controversial. Despite success in some regions, studies in southern India have not suggested any benefit on outcomes. The general recommendation is to consider a combination of antibiotics (tetracycline is recommended for children older than 8 years) and folic acid for patients for 3 to 6 months.

There are several common noninfectious causes of chronic diarrhea in travelers including postinfectious disaccharidase deficiency and irritable bowel syndrome. Importantly, a diarrheal illness that develops more than 1 month after travel is not likely due to travel exposure.

Returning travelers with diarrhea should have stool samples cultured for enteric pathogens and examined microscopically for ova and parasites if there is evidence of an invasive enteropathy, if the diarrhea is persistent, if the diarrhea is unresponsive to empirical therapy, or if the infected person is immunocompromised. Assays for the detection of *Clostridium difficile* toxins may also be indicated. The routine microbiologic techniques often times cannot detect many of the bacteria associated with persistent diarrhea. The sensitivity of a single stool specimen for the detection of ova and parasites varies, depending on the parasite, but it rarely exceeds 80%. The likelihood of identifying a parasite may be increased by examining additional stool samples (three samples obtained on separate occasions increase the sensitivity to more than 90%).

In many cases of persistent diarrhea, no causative agent can be identified. In these cases, some experts recommend empiric antimicrobial therapy such as a fluoroquinolone or a macrolide for suspected bacterial diarrhea. Metronidazole (or a related agent) is recommended for presumed giardiasis, since *G. lamblia* is the most commonly identified intestinal parasite in travelers. Multiple courses of antimicrobial agents should be avoided. For travelers whose diarrhea persists, endoscopic examination and biopsy should be considered to exclude entities such as tropical sprue and inflammatory bowel disease.

DERMATOLOGIC CONDITIONS

Dermatologic conditions are common among persons who have recently traveled. The location of the lesions, the lesion type (macular, papular, urticarial, etc.), and the presence or absence of associated symptoms (i.e., pain, pruritus, fever) are helpful in establishing the diagnosis. The skin can be affected through a primary process or secondary to a systemic disease.

Papular Lesions and Urticaria

There are numerous causes of urticaria, including allergic, viral, bacterial, medication-induced, or parasitic exposure. The parasites commonly associated with urticaria include *Strongyloides stercoralis* and *Schistosoma* species. Bites from insects (such as bedbugs and fleas) are the most common cutaneous finding in the returning traveler. These lesions cause pruritic, papular lesions that generally occur in clusters or in a linear distribution. *Sarcoptes scabiei* is the parasite that causes scabies and is common in the developing world. Seabather's eruption is a pruritic, papular rash that is generally confined to the skin covered by a bathing suit or wet suit. It is caused by larval forms of sea anemones such as *Edwardsiella lineate* as well as jellyfish such as *Linuche unguiculata* that become trapped under the fabric after exposure to salt water. Fresh water exposure–related causes of rashes include cercarial dermatitis, which results from penetration of the skin by schistosomal cercariae from fresh water (swimmer's itch) or from coastal water (digger's itch). Acute schistosomiasis, known as Katayama fever, typically occurs several weeks after exposure to freshwater in an endemic area (typically sub-Saharan Africa) and presents with high fever, urticaria, and eosinophilia. Long-term travelers returning from Africa may develop a pruritic, papular rash due to onchocerciasis (caused by *Onchocerca volvulus*).

Papular/Nodular/Ulcerative Lesions

Cutaneous larva migrans is the most frequent serpiginous lesion among travelers. It results from the migration of animal hookworms (e.g., *Ancylostoma braziliense* and *A. canium*) in superficial tissues. It is typically acquired after direct contact of the skin with soil or sand that has been contaminated with dog or cat feces. The lesions, which may initially be papular or vesicular, are pruritic and commonly found on the foot or buttock. *S. stercoralis* larvae may be rapidly mobile (moving approximately 5 cm per hour) and produce a cutaneous track (larva currens) that is often perianal. These are often acquired in travelers to Mexico or the Caribbean islands.

Furuncular myiasis, also known as Tumbu fly or botfly (*Dermatobia hominis*), are commonly found in Central and South America (mainly in wooded and forest margins of the lowlands and river valleys). The larvae are parasitic and undergo their development in the skin of animals such as cattle, dogs, swine, and, inadvertently, humans. When the female botfly is ready to lay eggs, she captures other *Diptera* (and less commonly ticks) and "glues" the eggs to the bottom of their abdomen. The embryos hatch in 5 to 15 days and abandon them while in contact with a warm-blooded host. If the carrier is a blood-sucking fly or mosquito, the botfly embryo can utilize the puncture site to gain entry into the host tissue; otherwise, the embryo penetrates the host through a hair follicle or a break in the epidermis. Once in the skin, the larva develops a boil-like pocket that has an opening to the outside (punctum) that allows the larvae to breathe. Conditions that may mimic botfly infestation include cellulitis, sebaceous cyst, folliculitis, cutaneous leishmaniasis, staphylococcal boil, and less commonly atopic dermatitis. Treatment is centered on the removal of the larva. The most common and invasive method is surgical excision. The main difficulties include risk of dissecting the larvae during the excision, which can result in an incomplete removal. Another option involves injecting each individual larval cavity with lidocaine and then removing the parasite with forceps once they appear at the punctum.

Similar to the botfly, tungiasis is an infestation by the burrowing flea *Tunga penetrans* or related species. It is also known as chigoe flea, jigger, pigue, nigua, pico, and bicho de pie (bug of the foot). Tungiasis was first reported in crewmen who sailed with Christopher Columbus. The flea is indigenous to the West Indies/Caribbean region, but has spread to Africa, India, Pakistan, and Latin America. Travelers to endemic areas may import cases to other countries, including the United States. To reproduce, the flea requires a warm-blooded host. In addition to humans, reservoir hosts include cattle, sheep, horses, mules, rats, mice, dogs, pigs, and other wild animals. The main habitat is warm, dry soil and sand of beaches, stables, and stock farms. Upon contact, the fleas invade unprotected skin. The most common site of involvement is the feet (interdigital skin and subungual area). Both the male and the nonfertilized female flea feed intermittently on warm-blooded hosts. Once impregnated, however, the female flea anchors herself to the skin by using biting mouthparts and painlessly burrows into the epidermis. The flea expands, often reaching 1 cm in diameter. The head is down into the upper dermis feeding from blood vessels, whereas the caudal tip of the abdomen is at the skin surface, often forming a punctum or an ulcer. The flea breathes through this opening. In many cases, this is described as a white patch with a black dot.

Over 1 to 2 weeks, more than 100 eggs, which fall to the ground, are individually released from this exposed orifice. Afterward, the flea dies and is slowly sloughed by the host. The eggs hatch on the ground in 3 to 4 days, go through larval and pupal stages, and become adults in 2 to 3 weeks. The complete life cycle lasts approximately 1 month. Reported topical treatments include cryotherapy or electrodesiccation of the nodules. Topical ivermectin, metrifonate (not available in the United States), and thiabendazole have also been reported as effective. Occlusive petrolatum may suffocate the organism; however, these organisms breathe infrequently and the effectiveness of this modality has been questioned. Topical treatments do not remove the flea from the skin and therefore do not result in relief from painful lesions. The flea may be gently removed with a needle or forceps. A number of surgical treatment methods are available, including removal of the flea from its cavity with sterile instruments, but this is more difficult when the flea is engorged. The orifice needs to be enlarged, and the entire nodule should be curetted or excised. An antibiotic ointment may be applied, along with systemic antibiotic therapy when indicated for superinfection. Aggressive treatment of secondary infection and tetanus prophylaxis are important.

Ulcers and Eschars

Ecthyma (pyoderma) is the most frequent cutaneous ulcer among travelers. These lesions are shallow, painful, and purulent ulcers of ecthyma often as a result of skin trauma or bites that have become secondarily infected with pyogenic organisms such as *Staphylococcus aureus* or group A streptococci. Less commonly, ulcers may be due to cutaneous leishmaniasis; however, these are important to recognize. These ulcers are painless and typically enlarge slowly and have a granulomatous or crusted base with raised margins. New World leishmaniasis, caused by *Leishmania* (*Viannia*) *braziliensis*, may progress to form destructive localized recrudescences on mucosal surfaces. New World leishmaniasis refers to infections acquired in Latin America, whereas Old World leishmaniasis is associated with travel to Central Asia. Leishmaniasis is occasionally manifested as isolated lymphadenopathy or as lymphocutaneous changes that can also resemble sporotrichosis or *M. marinum* infections. Eschars may be seen in rickettsial disorders such as Mediterranean spotted fever, scrub typhus, and African tick typhus. An eschar at the site where a rickettsia-transmitting arthropod has fed is usually small (less than 1 cm in diameter), asymptomatic, and is often overlooked by the patient or family.

The ill returning pediatric travel poses a number of diagnostic issues for the clinician. These can be addressed by taking a stepwise approach toward the chief complaint. Important clues to consider regarding the ill returning pediatric traveler include where they traveled to, how long they were there, when the symptoms began relative to their travel, and whether the patient was seen for pretravel counseling by a travel medicine specialist. Travel medicine specialists make recommendation for vaccinations and prophylactic medications based on the proposed travel itinerary. Vaccinations commonly used for travel prophylaxis include hepatitis A, hepatitis B, typhoid (both oral and Vi polysaccharide), meningococcal, Japanese encephalitis, inactivated poliovirus, and yellow fever. In addition to pretravel vaccination, prophylactic medications for malaria (either weekly chloroquine or mefloquine or daily atovoquone/proquanil) should be considered in the evaluation of the febrile returning patient. If appropriate vaccinations were given and chemoprophylaxis was complied as prescribed, the diagnosis may possibly be narrowed.

CHAPTER 104 ■ AN APPROACH TO THE INJURED CHILD

LOIS K. LEE, MD, MPH, AND GARY R. FLEISHER, MD

Injuries are commonly seen in the emergency department (ED), and clinicians taking care of children and adolescents in the emergency setting should be prepared to manage these patients who may present with a range of injuries. Although pediatric trauma victims have needs distinguishing them from adults, it is only since the mid-1990s that investigators have begun to systematically look at the care of the injured child. The goal of this chapter is to help prepare ED clinicians for the triage, assessment, and initial management of pediatric trauma patients from the spectrum of minor to life-threatening injuries.

The leading cause of death in children 1 to 19 years old in the United States is injury, which account for more than 50% of all childhood deaths. In 2005, more than 15,000 children and adolescents younger than 19 years died from unintentional and nonaccidental trauma in the United States. Injuries also lead to more than 10 million primary care office visits, more than 9 million ED visits, and more than 500,000 hospitalizations yearly in the United State. Injuries are the leading cause of ED visits and account for approximately one-third of all visits for children younger than 15 years. It has been estimated that the cost of unintentional pediatric injuries is $347 billion every year: $17 billion in medical costs, $72 billion in future work lost, and $257 billion in lost quality of life.

Motor vehicle crashes continue to be the most common cause of death due to injury resulting in more than 6,000 deaths in 2005. Homicide and suicide remain the second and fourth leading causes of death in children and adolescents 1 to 19 years old in the United States. In black teenagers, homicide from firearms is the leading cause of death. Although less fatal, falls, drowning, poisoning, and fire/burn injuries are significant causes of morbidity.

This chapter provides a framework for secondary prevention, after the "impact" has occurred causing the injury, with the goal of decreasing morbidity and mortality. Secondary prevention is performed in the field by emergency medical services providers or after arrival to the hospital. General principles of management are outlined for patients with multiple and local injuries ranging from mild to severe. Although most of the injuries are mild to moderate in severity, the ED clinician caring for these patients should be prepared to rapidly and systematically evaluate and manage those who present with serious and life-threatening injuries.

SPECTRUM OF TRAUMA AND INITIAL TRIAGE

Trauma causes injuries that range from minimal to fatal, from the splinter lodged in the sole of the foot to a victim of a motor vehicle crash with multiple injuries. To assist in the initial triage and diagnostic process, several categorizations of injury are useful: (1) extent—multiple or local; (2) nature—blunt or penetrating; and (3) severity—mild, moderate, or severe (Table 104.1).

Trauma can be multiple or local. From a surgical point of view, *multiple trauma* is defined as significant injury to two or more body areas (e.g., the head and abdomen, the chest and extremities, or other combinations). Although this definition serves a useful purpose in comparing outcomes retrospectively among various centers, it does not suit the needs of emergency physicians who must evaluate and treat children before all diagnostic information has become available. For the purpose of triage in the ED, *multiple trauma* is defined as apparent injury to two or more body areas. Thus, the child who fell from a bicycle, sustaining a forehead laceration and a forearm fracture, would be classified in the ED as having multiple trauma (head and extremity), even though the completed evaluation may not uncover any additional or serious injuries. Multiple trauma is common, given the child's small and immature body habitus. Localized trauma involves only one anatomic region of the body: head, neck, chest, abdomen/pelvis, back, or extremities. Again, during ED triage, the designation of local trauma is assigned initially on the basis of even superficial injuries in a given anatomic area, despite the fact that subsequent evaluation might not detect any deeper involvement.

The initial diagnostic task confronting the emergency physician is to decide whether trauma is local or multiple. In some cases, the distinction between local and multiple trauma is obvious. The 13-year-old boy who twisted his ankle coming down with a rebound has a local musculoskeletal injury. The 2-year-old boy who is cyanotic, pulseless, and apneic after a plunge from a ninth story window has sustained critical multiple trauma.

At times, however, the distinction between local and multiple trauma may not be straightforward. A 7-year-old girl who flies over the handlebars of her bicycle onto the sidewalk and is brought to the ED covered with blood, thrashing and screaming

TABLE 104.1

CATEGORIZATION OF TRAUMA

Extent: local or multiple
Nature: blunt or penetrating
Saverity: mild, moderate, or severe

at every touch, may be judged initially to have serious multiple trauma. After complete and rapid assessment, she may instead have only a superficial forehead laceration and an acute anxiety reaction. The next child with the same history and a constellation of symptoms may have a concussion and a ruptured spleen. A third child in a similar scenario may have a rib fracture leading to a pneumothorax; a fourth child may have a buckle fracture of the radius and a depressed skull fracture.

The distinction between local and multiple trauma may be difficult to ascertain initially because (1) some serious injuries are occult in their early phase; (2) some children are difficult to examine because they are nonverbal, uncooperative, frightened, or in pain; (3) some parents might have played a role in the trauma (i.e., child abuse) and will try to conceal the extent of the injury; and (4) some children, particularly adolescents, may be under the influence of drugs or alcohol. Differentiation between local and multiple trauma is thus a dynamic process, and the emergency physician's first impression may change as new evidence accumulates. Generally, it is best to consider trauma as multiple until proven otherwise; when the skin is contused over several body parts, the patient is categorized as having multiple trauma until it is known that all the injuries are superficial.

Once it has been decided that multiple trauma has or has not occurred, the emergency physician should then focus on the specific anatomic region(s) involved. For each region, it is important to ascertain whether the injury is the result of blunt or penetrating trauma and to determine the severity of the wound. Trauma may be caused by either blunt or penetrating forces. Although most civilian injuries, particularly during childhood, result from blunt trauma, some trauma centers have seen as much as 15% of serious trauma related to gunshots, stabbings, and other penetrating wounds. The distinction between these two mechanisms of injury is important because it will determine the evaluation based on the expected internal injuries. In this chapter, the management of blunt and penetrating trauma is reviewed for each specific anatomic region.

Finally, the seriousness of injury may vary from mild to severe. Table 104.2 provides a review of a classification of severity based on history and physical examination, as well as a general schema for disposition of the child with trauma, based on the general extent of the evaluation with laboratory tests and imaging required to diagnose or manage the trauma. Whereas only a few patients with penetrating injuries are considered to have mild wounds, most of the more common blunt injuries seen in the ED are minor. The first categorization by severity depends initially on the history of the incident and the physical examination. An important factor is that a history of a significant or critical force applied during impact increases the index of severity. The schema varies somewhat for each anatomic region; thus, Table 104.2 provides only a general overview. Assessment of severity is essential in the ED because it will determine whether the child requires immediate intervention, undergoes a diagnostic evaluation, is discharged after an examination, or receives further observation. The more laboratory and imaging studies required for the assessment and management of the trauma victim, the more likely a child will need admission.

GENERAL PRINCIPLES OF MANAGEMENT

The child who has sustained more than a trivial injury must be considered at risk for decompensation; therefore, an immediate decision must be made regarding the severity of the trauma (Table 104.2). The American College of Surgeons has standardized and disseminated an approach to the initial management of the trauma patient through the Advanced Trauma Life Support (ATLS) program. The goals of the initial trauma management for the trauma victim are to rapidly assess the injuries, determine the management priorities, and provide critical interventions. A systematic and logical approach to the trauma patient is required to assess and address any physiologic threats to life, followed by a complete evaluation. The clinical approach includes the following: (1) primary assessment; (2) resuscitation of vital functions (initial treatment); (3) more comprehensive secondary assessment; and (4) transition to definitive care. The assessment and management may occur simultaneously in patients with significant injuries. For example, while the primary assessment is being performed, an intravenous (IV) catheter can be placed and fluid resuscitation initiated. This approach provides a set of principles for

TABLE 104.2

CLASSIFICATION AND DISPOSITION OF TRAUMA BY SEVERITY

Category	History	Physical examination		Laboratory radiographic studies	Probable disposition
		Vital signs	Local findings		
Mild	Minimal force	Normal	Superficial only	Few	Discharge
Moderate	Significant force	Normal	Suspicious for internal injury	Intermediate	Evaluate
Severe	Critical force	Abnormal	Indicative of internal injury	Many	Immediate therapy; admit

efficiently diagnosing and treating life-threatening conditions without neglecting less severe but important injuries.

The primary assessment includes evaluating the vital signs and quickly reviewing the essential functions of all organs. The emphasis is on discovering treatable injuries and preventing complications (e.g., paralysis from an unstable cervical spine fracture). Concomitantly, resuscitation (initial treatment) is attempted to normalize vital functions and prevent further deterioration from conditions such as hypoxia or blood loss. Primary assessment and resuscitation occupy the first 5 to 10 minutes of the encounter in most cases. As soon as possible, a thorough reassessment of the patient (secondary assessment) should take place to fine-tune the details of management. The secondary assessment is the head-to-toe, front-to-back physical assessment that includes the screening radiographs and stat laboratory tests. To be effective, physical examinations must be repeated serially and then compared. Although resuscitation of unstable patients is critical and requires a strong team approach, the close surveillance of the apparently stable patient at risk of single or multiorgan trauma is paramount and may be even more challenging in terms of the early detection of occult injuries. Definitive care includes stabilization of specific local injuries, preparation of the patient for the operating room, and surgery, as indicated. At the completion of care for trauma patients, a tertiary survey is performed. This is a last thorough check for occult injuries. It is done prior to discharge from the ED, when a patient either goes home after being assessed and treated or moves to the next stage of care in the hospital.

MULTIPLE TRAUMA

Classification

Multiple trauma (see Chapter 105), as defined for the emergency physician, may vary from mild to severe (Table 104.3). The child with a history of injury caused by minimal force and a physical examination that shows only superficial lesions in two or more areas of the body would be assigned to the mild category—for example, a 7-year-old child who fell while running and is found to have abrasions on the forehead and right elbow and tenderness of the right flank. On examination, signs suggestive of deeper injury would place the child in at least the moderate category. Detection of a serious injury or abnormal vital signs (unrelated to anxiety alone) elevates the classification to severe. Unfortunately, the classification of injury by mechanism alone is not a uniformly useful predictor in blunt trauma in children or adults.

Management

Mild Multiple Trauma

The major goal in the management of a child with apparent mild multiple trauma is to confirm the initial impression of lack of severity of the injuries. If there is any question of more severe injury, a large-bore peripheral IV catheter should be inserted and appropriate laboratory studies obtained. However, in cases that obviously seem to involve minimal trauma, the physician can proceed directly to the examination. Initially, the vital signs should be obtained. Subsequent examination includes a complete assessment with special attention to the level of consciousness; tenderness or limitation of motion of the cervical spine; auscultation of the heart and lungs; palpation of the abdomen, back, and pelvis; and tenderness of the extremities. The complete physical examination should include vital signs with capillary refill; Glasgow Coma Scale (GCS) score; inspection and palpation of the head for injuries, pupillary reactions, extraocular muscle function, nasal tenderness and/or septal hematoma, and dental/oral trauma; cervical spine motion (if the child is alert, not in a cervical collar, and without complaint of tenderness); neck vein distension; auscultation of the breath and heart sounds; inspection and palpation of the chest; evaluation of bowel sounds; inspection and palpation of the abdomen; palpation and inspection of the back, flank, and pelvis; rectal and genital examination; evaluation of extremities for deformity or tenderness; palpation of peripheral pulses; neurologic evaluation; and careful survey of the skin and soft tissues.

A child with a history of minimal multiple trauma and a normal examination may require no laboratory or radiographic studies. If there is any concern for intraabdominal injury, a complete blood cell (CBC) count and urinalysis should be obtained.

Moderate Multiple Trauma. The child with multiple trauma categorized as moderate requires immediate intervention and a thorough diagnostic evaluation. A child in this category has an obvious history of involvement of several areas of the body but initially may only have evidence of musculoskeletal or several superficial local injuries. A 3-year-old child who has been hit by an automobile and has a significantly deformed femur and a few ecchymoses on the upper extremities, or an older child who fell off a second-story roof but appears well, may fit this group. As a first step, a minimum of one large-bore peripheral IV catheter should be placed. If the child is in respiratory distress, supplemental oxygen should be administered. Any suggestion

TABLE 104.3

SEVERITY OF MULTIPLE TRAUMA

		Physical examination	
Category	History	Vital signs	Local findings
Mild	Minimal force	Normal	Abrasions/contusions
Moderate	Significant force	Normal	Refer to Tables 104.7–104.9 by anatomic region
Severe	Critical force	Abnormal	Refer to Tables 104.7–104.9 by anatomic region

of cervical spine injury mandates immobilization of the neck with a semirigid collar or foam head immobilizers. If the vital signs and primary survey are normal for age, the physician should then proceed with a thorough examination, as outlined in mild multiple trauma.

Most patients with moderate multiple trauma require ancillary studies as part of their evaluation. These might include a CBC count, urinalysis, amylase/lipase, and/or liver function tests and radiographs of the chest, cervical spine, and/or pelvis. A type and screen for red blood cells (RBCs) is indicated. Depending on the history and physical examination, computed tomographic (CT) scans of the head, abdomen, pelvis, and/or spine may be indicated. In fully awake patients, a completely normal examination may be relied upon to exclude the need for all screening studies. Many patients in this category require admission to the hospital. However, an older child with a history of a moderately severe impact, who has an unremarkable examination and normal studies, may be discharged from the ED after observation for several hours.

Severe Multiple Trauma. The management of the child with severe multiple trauma demands immediate action. The initial approach assumes either obvious life-threatening injury or a reasonable likelihood that such an injury exists. An alteration of vital signs (hypotension, tachycardia), diaphoresis, or depressed consciousness automatically categorizes the injury as severe. Although helpful as an initial guide, mechanism alone (e.g., a fall from a two-story building) is not a highly accurate predictor of the risk of sustaining significant injuries. To adequately manage the child with severe multiple trauma, the physician must understand the need to institute treatment before completing a full examination and to continually intersperse detailed reassessments into an intensive treatment protocol. Table 104.4 provides an outline for organizing the initial approach to severe multiple trauma in the ED. It uses a four-pronged strategy: assessment, treatment, monitoring, and diagnostic testing. The protocol is laid out over time in an idealized fashion; obviously, limitations in the number of personnel or unusually difficult technical procedures may slow the progression of the evaluation and management.

LOCALIZED HEAD TRAUMA

Classification

Head trauma (see Chapters 38 and 105) can be divided into penetrating and nonpenetrating. Cases that involve penetration of the cranial vault entail severe injuries and often require operative intervention. Nonpenetrating (blunt) head trauma can be classified as mild, moderate, or severe (Table 104.5).

Management

Penetrating Trauma

Wounds limited to the scalp and not entering the cranial vault are appropriate for primary repair in the ED. Minor wounds from sharp objects, when the likelihood of penetration is high, should have radiologic evaluation and local exploration before primary closure. All other penetrating injuries require initial stabilization and neurosurgical consultation, as discussed in the "Blunt Trauma—Severe" section. Protruding objects should be left in place until definitive management.

Blunt Trauma—Mild

Most children seen in the ED have sustained mild head trauma, arrive awake, and primarily in need of a thorough physical examination. The head should be palpated for evidence of local injury, assessing for evidence of a depressed fracture. Bruises around the eyes or behind the ear or a hemotympanum suggest a basilar skull fracture. The pupils will be equal and reactive and the extraocular muscle function intact, unless the severity of injury has been misjudged. Although the finding of focal neurologic abnormalities is unlikely, a careful neurologic examination is mandatory. Skull radiographs and CT scans are generally unnecessary but may be indicated in selected situations such as palpation of a potentially depressed fracture or in infants in the first year of life (see Chapter 38). Although uncommon, misclassification of a patient as mild may occur in selected situations, such as when children sustain a significant direct impact to their temporoparietal skull, which is not readily appreciated, or when the history is either not available or deliberately misrepresented, as in cases of child abuse.

Patients with minor head trauma may be discharged from the ED with specific instructions to watch for changes indicative of increased intracranial pressure (ICP) or hemorrhage. Albeit unlikely, these symptoms include depression of mental status, progressive vomiting (more than 4 to 6 hours from the trauma), worsening headache, visual disturbances, ataxia, or seizures. Postconcussive seizures are unusual but may occur within a few days of mild head injury. In general, they are not prognostic for recurrent seizures.

Blunt Trauma—Moderate

Moderate head injury includes any clear-cut prolonged loss of consciousness (1 to 5 minutes) or a history suggesting a severe injury, even without specific physical findings to confirm it. This category would include those who have sustained a concussion with an alteration in their level of consciousness but not necessarily loss of consciousness. Once again, a thorough examination is required to search for signs of intracranial hemorrhage. The most important feature of the examination is a serial evaluation of the neurologic status, including the GCS score or AVPU testing (A, alert and spontaneous responsiveness; V, responds to voice; P, responds to painful stimuli; and U, unresponsive). The initial score serves as the baseline for the detection of subsequent deterioration. Radiographs are reserved for the same indications as for mild trauma. CT scanning is often, but not necessarily, performed in awake patients on arrival, however, it becomes mandatory upon deterioration in mental status, in the presence of focal abnormalities, or with more than a brief loss of consciousness (more than 1 to 5 minutes). Because of the small chance of subsequent intracranial hemorrhage or worsening cerebral edema, prolonged observation in the ED or admission is warranted in many cases with moderate injury.

Blunt Trauma—Severe

The child with severe head trauma is at risk for sudden intracranial catastrophe, acute respiratory insufficiency, or a secondary insult (e.g., brain swelling) to the central nervous system. After initial steps to assess the adequacy of the airway,

TABLE 104.4

MANAGEMENT OF SEVERE MULTIPLE TRAUMA

Time (min)	Phase	Action	Phase description
0	1	A	Airway, respiration, pulse, active hemorrhage, capillary refill, level of consciousness (AVPU or GCS score)
		T	Airway management with stabilization of cervical spine (bag-valve-mask, endotracheal intubation) (Surgical airway PRN)
			Ventilation with F_{IO_2} = 1.00, mild hyperventilation
			Cardiac compression (cardiopulmonary resuscitation) as needed
			Intravenous access/volume infusion
			Decompress pneumothorax/thoracostomy, tube placement as needed
			Relieve tamponade, control major hemorrhage
			Elevated head of bed to 30 degrees if no signs of shock
			Exposure—remove all clothing
			Wrap/bind pelvis
		M	Respiratory rate, pulse oximetry
			Heart rate (electrocardiogram)
			Blood pressure (mercury or Doppler)
		D	Complete blood cell count, type and cross-match, chemistries (glucose, amylase, alanine transaminase, aspartate transaminase)
5	2	A	Adequacy of airway, breathing, and circulation
			Level of consciousness (AVPU or GCS score)
			Temperature
			Penetrating wounds
		T	Nasogastric tube (orogastric if suspected midface fracture)
			Intravenous access, intraosseous, central catheter, or cut down as needed
			Thoracotomy or thoracostomy tube as needed
			Pericardiocentesis as needed
			Drug therapy (e.g., epinephrine)
			Blood transfusion/volume
			Prevent or treat increased ICP
		M	Heart rate, respiratory rate, pulse oximetry, blood pressure
			ET_{CO_2} if intubated
			Temperature (especially infants)
		D	ABGs PRN
10	3	A	Adequacy of airway, breathing, and circulation
		T	Additional venous access PRN/volume
			Urinary catheter (except in suspected urethral disruption)
			Arterial access as needed
			Thoracotomy as needed
			Drug therapy, including for pain management
			Avoid hypothermia
			Operating suite as needed
		M	Heart rate, respiratory rate, pulse oximetry, blood pressure
			ET_{CO_2} if intubated
			Temperature (especially infants)
		D	ABGs PRN
20	4	A	Adequacy of airway, breathing, and circulation
			GCS score, neurologic assessment
			Repeat full examination
		T	Cervical traction as needed
			Splint fractures
			Drug therapy (e.g., tetanus toxoid or tetanus immune globulin, antibiotics)
		M	Heart rate, respiratory rate, pulse oximetry, blood pressure
			Consider ICP bolt if severe head injury
		D	Repeat laboratory studies PRN

SEVERITY OF BLUNT HEAD TRAUMA

		Physical examination	
Category	History	Vital signs	Local findings
Mild	Minimal force No/momentary LOC	Normal	GCS score = 15 Abrasions/contusions
Moderate	Significant force LOC 1–5 min	Normal	GCS score ≥ 13 Drowsiness
Severe	Critical force LOC >5 min	Abnormal	GCS score ≤ 12 Focal neurologic abnormalities

GCS, Glasgow Coma Scale; LOC, loss of consciousness.

breathing, and circulation, these functions should be supported as necessary. The cervical spine should managed as if there is a presumed injury and should be stabilized with a semirigid collar or foam head immobilizers. Gentle opening of the airway with maintenance of the head in the neutral position allows the patient's passive ventilation to become adequate in many instances. If intubation is required immediately, extension of the neck should be avoided and an assistant should stabilize the cervical spine during the procedure. In less urgent situations, intubation may be deferred until a cross-table lateral radiograph of the cervical spine is obtained. In all cases, supplemental oxygen should be administered and two large-bore IV cannulas inserted. Most children with serious head injury will hyperventilate spontaneously if their airway is patent, and this will decrease their cerebral blood flow, helping to maintain normal ICP. Intubated, apneic children should be hyperventilated manually to achieve a $Paco_2$ of 30 to 35 mm Hg. Ideally, continuous, noninvasive end-tidal CO_2 monitoring with an arterial blood gas analysis obtained to assess CO_2 correlation should be the goal in the ED. An arterial catheter can be placed as needed. Corticosteroids have not been shown to be beneficial and are not recommended by most authorities. Osmotic agents are not used prophylactically, but mannitol (0.5 to 1 g per kg of a 20% solution) is occasionally necessary to decrease ICP when acute herniation is suspected or proven.

Standard skull radiographs provide little useful information for the patient with serious head injury. More efficient management calls for an immediate CT scan to evaluate the intracranial space. Rarely, neurosurgical intervention must precede imaging of the cranial contents. See Chapter 105 for more specific management.

LOCALIZED NECK TRAUMA

Classification

The larynx and trachea, carotid arteries, jugular veins, spinal cord, and esophagus all pass within the confined anatomic space of the neck. Thus, both penetrating and nonpenetrating insults can cause devastating injuries. All penetrating trauma, with the exception of tangential wounds superficial to the platysma muscle, should be considered serious and be referred promptly for surgical evaluation and possible exploration. Weapons or objects protruding from the neck should be left in place. Children with neck trauma (see Chapter 115) should be carefully examined in the ED for thoracic injuries such as pneumothorax.

Isolated blunt trauma to the neck does not occur often in children. However, the potential for major disruptions of the airway or large vessels demands a thorough evaluation. The examiner should palpate for crepitus, unequal carotid pulses, an acute hematoma that carries a risk of expansion, and cervical spine tenderness. On the basis of the history and physical findings, an estimate of the severity of the injury can be made (Table 104.6). A thorough neurologic examination, with

TABLE 104.6

SEVERITY OF BLUNT NECK TRAUMA

		Physical examination	
Category	History	Vital signs	Local findings
Mild	Minimal force	Normal	Abrasions/contusions
Moderate	Significant force	Normal	Refusal to move head Cervical spine tenderness
Severe	Critical force	Abnormal	Crepitus Expanding hematoma Unequal carotid pulses Paralysis or sensory loss

particular emphasis on determining if there may be spinal cord injury, is essential.

Management

Penetrating Trauma

Wounds clearly superficial to the platysma muscle are appropriate for repair in the ED. Children with penetrating injuries deep to the platysma require stabilization and subsequent surgical evaluation. Initial measures are directed at establishing a patent airway, providing adequate ventilation, controlling hemorrhage, and restoring the circulation. Protruding objects should be left in place by the physician in the ED. Neck exploration is recommended for the following: continued bleeding from the wound, blood in the aerodigestive tract, subcutaneous emphysema, stridor, hoarseness/aphonia, or neurologic deficits.

Blunt Trauma—Mild

If the history is one of a minimal force and no physical findings are indicative of trauma to the deeper structures, the child may be symptomatically treated and discharged from the ED. Exceptions may include patients with underlying illnesses, such as hemophilia, who are at potential risk for delayed complications. Follow-up after discharge should be clearly defined to ensure intervention if symptoms indicate a worsening situation, before compromise to internal structures occurs.

Blunt Trauma—Moderate

The child with an apparent moderate injury to the neck by definition has no evidence of respiratory or vascular compromise. However, either the history of the amount of force involved or the local findings may raise the possibility of cervical spine or other injuries. Such patients require immobilization of the cervical spine with a semirigid collar or foam head immobilizers and a meticulous neurologic examination. As a first step, a cross-table lateral radiograph of the cervical spine should be obtained with the child immobilized, often in the ED. If this first radiograph shows all seven cervical vertebrae to be intact and properly aligned, a complete radiologic evaluation of the cervical spine can be performed, which may include anteroposterior, oblique, and open-mouth views. The discovery of a bony or ligamentous injury requires consultation with appropriate specialists. A focused CT scan over the suspected area of injury may be considered for further evaluation of vertebral injury. Spinal cord injury without radiographic abnormality (SCIWORA) may be present and should be pursued when symptoms or signs are suggestive. A magnetic resonance imaging may be required to evaluate injuries to the spinal cord or adjacent soft tissues. The neurologically intact child with a normal cervical spine evaluation and no other neck trauma who remains well on repeat physical examination may be discharged after observation. If there are particular concerns, the child should have follow-up scheduled within several days with a specialist to assess for ligamentous neck injury.

Moderate trauma to the anterior neck requires careful evaluation for possible disruption of the major vessels, trachea, and esophagus. Cervical spine radiographs may outline the airway adequately. However, it is important to pay attention to the alignment of the larynx and trachea and to check for air in the soft tissues resulting from a tear in the airway or esophagus. The carotid triangle must be palpated carefully. If there is a hematoma or abnormality of the pulse, referral for possible a CT angiogram should be made.

Blunt Trauma—Severe

Classification of blunt neck trauma as severe indicates concern for overt injury to the airway, the major vessels, or the spinal cord. The initial goals of management are establishment of a patent airway, stabilization of the cervical spine, and IV access. The first choice for the establishment of the airway is orotracheal intubation, with maintenance of the patient's head in the neutral position. The inability to intubate a critical airway requires an immediate surgical approach to the trachea. Blood should be sent for a type and cross-match; if vascular injury is suspected, multiple units of blood should be made available. A surgical consultant should decide whether to proceed with an exploration in the operating room or to rely on further diagnostic studies such as bronchoscopy, CT angiography, and/or esophagoscopy.

LOCALIZED THORACIC TRAUMA

Classification

Penetrating chest injuries (see Chapter 118) are extremely relevant to physicians in the ED because they may be rapidly life threatening if untreated, yet usually respond to fairly straightforward therapeutic maneuvers. Any object that enters the thoracic cavity will result in significant injury. Patients with large open wounds or with instability of vital signs should be considered to have sustained life-threatening trauma.

Blunt chest trauma is seen more often than penetrating injury in civilian practice in general and in children in particular. Although there are no studies on the percentage of chest injuries classified as mild in childhood, statistics are available for older patients. Newman et al. found that 53% of chest injuries sustained by adults in motor vehicle accidents were merely bruises or abrasions. As with trauma to other anatomic regions, blunt thoracic trauma can be divided into mild, moderate, and severe categories (Table 104.7).

Management

Penetrating Trauma

Patients with mild injury, in which the wound clearly entered only the superficial tissues and not the thoracic cavity, may need only ED management. However, for any knife or gunshot injuries, it is advisable to have an experienced physician explore the wound and to obtain radiographs to determine the extent of injury.

Patients with deeper wounds require chest radiography, a CBC count, and blood type and cross-match. A CT angiogram may be necessary in the stable patient with a suspected aortic injury. An open pneumothorax should be covered with an occlusive dressing sealed on three sides and then a chest tube thoracostomy should be placed away from the dressing. A tube thoracostomy should also be performed to drain a hemothorax. Hemorrhage can be managed starting with crystalloid, followed by blood replacement. For the child sustaining a

TABLE 104.7

SEVERITY OF BLUNT CHEST TRAUMA

		Physical examination	
Category	History	Vital signs	Local findings
Mild	Minimal force	Normal	Abrasions/contusions
Moderate	Significant force	Tachypnea Normal pulse and blood pressure	Splinting Bony tenderness Decreased breath sounds
Severe	Critical force	Abnormal pulse or blood pressure	Flail chest Distant heart tones Absent breath sounds

cardiopulmonary arrest while in the ED after a penetrating thoracic injury, immediate resuscitative thoracotomy may be lifesaving.

Blunt Trauma—Mild

The child with a history of a minimal blow to the chest, normal vital signs, and no local signs of trauma other than abrasions or contusions has sustained a mild injury. The combination of absent or minimal bony tenderness, a normal respiratory rate, symmetric breath sounds, and normal heart rate obviates the need for radiologic evaluation of the thoracic cage or its contents.

Blunt Trauma—Moderate

If the history indicates significant force, significant bony tenderness is elicited, or there is a question of abnormal breath or cardiac sounds, a chest radiograph, an electrocardiogram (EKG), and a CBC count are indicated. Particularly in children, a pneumothorax may follow blunt injury with or without a rib fracture. Widening of the mediastinum on chest radiograph suggests disruption of the aorta. The detection of a solitary rib fracture is not important per se because no specific treatment is necessary. However, it raises the suspicion of visceral or vascular disruption, given the force required to cause a rib fracture, particularly in a younger child. Fracture of the first rib is correlated in adults with injuries to the great vessels. Although the data are scant in pediatrics, an injury to the first rib may require the patient to have a CT angiogram. The chest radiograph may provide a clue to the diagnosis of pericardial hemorrhage (by showing a slightly enlarged cardiac silhouette), but it is more often normal in this condition. Bleeding into the pericardial space leading to tamponade will invariably manifest on the physical examination at some point; findings include tachycardia, followed by pulsus parodoxus, hypotension, distended neck veins, and muffled heart tones. A pulmonary contusion or aspiration may produce a consolidation on chest radiograph. The EKG is obtained as an aid in the diagnosis of myocardial contusion; elevated ST segments are characteristic of this entity. A troponin level may be considered in the evaluation of cardiac injury. Although it may be elevated in patients with minor injury, a normal troponin level and EKG indicate that a significant myocardial injury is unlikely.

In the setting of moderate blunt chest injury, it is advisable to achieve venous access and order a blood type and crossmatch. Sophisticated diagnostic studies, such as CT angiogram, are reserved for children with abnormal findings on the preliminary evaluation. Admission for observation is often warranted; however, the child who shows improvement on examination over the observation interval with normal vital signs and does not have an abnormal chest radiograph, EKG, or CBC may often be discharged.

Blunt Trauma—Severe

The child with abnormal vital signs or local findings indicative of internal injuries has sustained an immediate life-threatening injury. Initial therapy includes airway management, the institution of two large-bore IV catheters, and the administration of supplemental oxygen. Depending on the condition of the child, chest tube insertion may be necessary for the treatment of hemopneumothorax before radiographic studies are obtained. In selected circumstances, resuscitative thoracotomy in the ED may be beneficial, although in blunt trauma to the chest, the outcome is almost uniformly poor if there has been cardiopulmonary arrest. Admission to the hospital is mandatory, and a full diagnostic evaluation should be performed to ascertain the need for surgical intervention.

LOCALIZED ABDOMINAL TRAUMA

Classification

Penetrating abdominal injuries (see Chapters 107 and 112) often cause moderate to severe trauma. However, the physician may cautiously define a small category of mild injuries, depending on the weapon involved.

All gunshot wounds must be considered at least moderate because almost all penetrate the peritoneum. Of those that penetrate the peritoneum, most cause visceral injury. If the vital signs are abnormal after a gunshot, the trauma should be considered severe.

Stab wounds, in contrast, may be superficial to the peritoneum. The patient with stable vital signs and an apparent superficial stab wound may be judged to have a mild injury if local exploration confirms the clinical impression. Stab wounds that violate the peritoneum should be considered moderately serious, and the patient should be referred for immediate surgical consultation. By definition, stab wounds that lead to unstable vital signs have produced severe trauma.

Overall, blunt abdominal trauma is much more common than penetrating injury in children. Most children evaluated in

the ED for blunt trauma to the abdomen will have relatively minor injuries.

Management

Penetrating Trauma

All gunshot wounds are of at least moderate severity. Thus, these children require two large-bore IV catheters (preferably inserted above the diaphragm); a nasogastric tube; radiographs of the abdomen and chest; and laboratory studies, which may include CBC count, urinalysis, amylase, aspartate transaminase (AST), and alanine transaminase (ALT) concentrations, and blood type and cross-match. In the child with unstable vital signs, appropriate resuscitation should be initiated and laparotomy urgently considered. A decubitus or upright abdominal radiograph may be obtained to evaluate for free air under the diaphragm. Otherwise in a stable patient, an initial CT scan may be preferable to delineate the extent and location of internal injury. All patients will require hospitalization.

Stab wounds produce variable degrees of internal injury, and the approach to management differs among institutions. Patients with abnormal vital signs require stabilization in the ED, including appropriate resuscitative measures, IV access, a nasogastric tube, radiographs, and laboratory studies. Transfer to the operating room may be necessary on an urgent basis. Patients whose vital signs are stable are evaluated further by local exploration or laparotomy.

Blunt Trauma—Mild

Mild blunt abdominal injuries often occur when there is contusion of the abdominal wall from local trauma (e.g., a punch from a fist, a short fall). After a careful history and physical examination, the patient may be discharged home if there is no abdominal tenderness and no emesis. If there is suspicion for kidney injury, usually only a urinalysis for RBCs is required.

Blunt Trauma—Moderate

Moderate blunt abdominal trauma is often seen in patients with multiple injuries or those in whom there has been an isolated but forceful blow to the abdomen. These patients should have laboratory studies that include a CBC count, amylase, AST and ALT, and blood type and cross-match. At least one IV catheter should be inserted, preferably in veins of the upper extremities that are above the level of the injury. A CT scan for the evaluation of intraabdominal injury may be indicated for patients with abdominal tenderness, low systolic blood pressure, elevated ALT and/or AST, hematocrit less than 30%, or urinalysis with more than 5 RBCs per high-power field. In addition, a CT scan of the abdomen may be considered for patients with a GCS score of 13 or less. In many cases, hospitalization or prolonged observation in the ED is indicated. Other imaging studies, such as IV pyelography, are obtained in selected situations (see Chapters 107 and 112).

Blunt Trauma—Severe

Severe blunt abdominal trauma often warrants prompt surgery after an initial stabilization of the vital signs. In general, patients who have stable vital signs after initial fluid resuscitation may be evaluated with CT scanning to define intraabdominal injuries and bleeding. The scans help define the need for surgery, especially if a hepatic or splenic injury producing limited hemorrhage is identified. A Focused Assessment Sonography for Trauma (FAST) examination may be useful, especially in the hypotensive trauma patient who may be too unstable for immediate CT evaluation of the abdomen. The FAST examination may also be used in the setting in which an unstable patient with a decreased level of consciousness requires a CT scan of the brain, and potential operative intervention, to determine the presence of possible intraabdominal bleeding that may require laparotomy.

In the presence of significant hematuria or strong suggestion of renal injury, a CT scan should be performed (see Chapter 112). In symptomatic patients with severe blunt trauma, the absence of RBCs in the urine is not by itself sufficient evidence of an intact genitourinary tract. Avulsion of the renal pedicle may occur without hematuria.

EXTREMITY TRAUMA

Classification

Most injuries to the extremities of children (see Chapter 115) seen in the ED are mild. A few injuries are of moderate extent, and occasionally, extremity trauma may be life or limb threatening. Both penetrating (Table 104.8) and nonpenetrating (Table 104.9) trauma can range in their severity. With penetrating

TABLE 104.8

SEVERITY OF PENETRATING EXTREMITY TRAUMA

		Physical examination	
Category	History	Vital signs	Local findings
Mild	Minimal force	Normal	Laceration
Moderate	Significant force (e.g., stab)	Normal	Laceration of tendon or nerve Significant venous hemorrhage
Severe	Critical force (e.g., gunshot)	Abnormal	Partial/complete amputation of arm or leg Arterial hemorrhage Open fracture

TABLE 104.9

SEVERITY OF BLUNT EXTREMITY TRAUMA

		Physical examination	
Category	History	Vital signs	Local findings
Mild	Minimal force	Normal	Contusions/point tenderness
Moderate	Significant force	Normal	Obvious dislocation of major joint
	Crush injury		Displaced fracture
Severe	Critical force	Abnormal	Decreased or absent pulses

wounds, the major immediate concern is hemorrhage, although impairment of neurovascular or musculoskeletal integrity with concomitant loss of long-term function is also a consideration. In contrast, nonpenetrating trauma may cause vascular insufficiency without external bleeding.

Management

Penetrating Trauma

The child with mild penetrating trauma requires appropriate wound care and tetanus prophylaxis (see Appendix D) in the ED. A radiograph is indicated if a radiopaque foreign body (including glass) is suspected in the wound. Moderate injuries require careful physical examination and often local exploration to define the extent of the trauma and the degree of functional impairment. At times, prompt surgical consultation or follow-up with a specialist is indicated. Some injuries require repair in the operating room; however, others—even extensive lacerations or extensor tendon disruptions—may be handled, time permitting, in the ED by an experienced physician. Surgical referral is mandatory for children in the severe category, and it is important to proceed as rapidly as possible when vascular damage is suspected.

Blunt Trauma—Mild

Children with mild nonpenetrating injuries often require a radiograph to detect underlying fractures. Particularly, when there is tenderness at the end of long bones, careful consideration should be given to radiologic evaluation for growth plate (physeal) injuries, keeping in mind that a normal radiograph does not exclude a nondisplaced Salter-Harris type I fracture.

Blunt Trauma—Moderate

Obvious dislocations should be repositioned as expeditiously as possible, usually after radiographs confirm the diagnosis. Dislocations of large joints, such as the knee, hip, and elbow, can impeded the vascular supply if not promptly reduced. Depending on the joint involved, discharge is acceptable after reduction and radiologic reevaluation (e.g., shoulder, patella, metacarpal-phalangeal, or interphalangeal joints). Crush-type injuries may initially manifest with pain and swelling. Of particular concern is the possibility that crush injury may lead to a compartment syndrome over the ensuing 6 to 24 hours, necessitating observation. Fractures with an obvious deformity should be treated with the appropriate pain medications, and the extremity should be splinted in a position of comfort as long as there is no vascular compromise. If vascular compromise is apparent with decreased pulses in the injured extremity, the fracture should be reduced and then splinted.

Blunt Trauma—Severe

Extremity injury associated with hemodynamic disturbances or disruption of the vascular supply is categorized as a severe injury. These include degloving and crush (i.e., wringer-type) injuries, as well as some long-bone fractures with high-energy transfer (i.e., femur fractures in pedestrians struck by high-speed automobiles). Patients with severe extremity injuries should receive a rapid but thorough overall assessment, followed by prompt surgical consultation.

SUMMARY

Injuries, ranging from mild to severe, frequently present to the ED, and the challenge lies in executing a thorough evaluation so that injuries are not missed while obtaining the appropriate radiologic and/or laboratory studies. The approach to the injured child requires great care and clinical acumen to establish the extent of the trauma and institute appropriate treatment. Loss of life from occult internal hemorrhage or neurologic sequelae from a missed unstable cervical spine injury is devastating. Yet, physicians in the ED must also know when children need only a careful physical examination and when laboratory testing or admission is unwarranted. This chapter describes a brief schema for providing appropriate care to children with trauma in such a way that specific issues about management can be approached reasonably by the emergency physician. The subsequent chapters in this section further describe the specific management of traumatic injuries for each anatomic area of the body.

CHAPTER 105 ■ MAJOR TRAUMA

MARK L. WALTZMAN, MD, AND DAVID P. MOONEY, MD

It's not the speed which kills, it's the sudden stop.

A. L. Moseley, Crash Investigator, Harvard University

Between the years 1950 and 1993, the overall annual death rate for children in the United States younger than 15 years declined substantially owing to the decreases in deaths associated with pneumonia, influenza, cancer, and congenital anomalies. In 2005, in the United States, unintentional injury, homicide, and suicide were the first, second, and fourth leading causes of death among persons aged 1 to 19 years, respectively. Injury continues to account for nearly one-half of all deaths in children from the ages of 1 to 14 years, with more than 7,000 fatalities per year in the United States. Nearly 22 million children are injured each year in the United States, surpassing all major diseases in children and young adults. Two of three childhood injuries occur in males. The peak age range is between 4 and 12 years, with the highest frequency at age 8 years. In the year 2000 alone, there were 37,115 injury-related emergency department (ED) visits by children being struck by a moving motor vehicle while in the street. Unintentional injury also accounts for approximately 30% of infant deaths. Data from the National Electronic Injury Surveillance System All Injury Program (NEISS-AIP), during July 2000 to June 2001, estimate 4.3 million sports- and recreation-related injuries treated in U.S. hospital emergency departments. This comprises 16% of all unintentional injury-related ED visits. Rates were highest among children 10 to 14 years of age. In 1996, the Consumer Products Safety Commission reported 116,800 nonfatal, toy-related, unintentional injuries requiring ED care; 56% involved children aged 0 to 4 years. The societal impact of years of life lost from childhood unintentional injury is staggering.

Along with unintentional injuries, data have demonstrated that between 1950 and 1993, the rates for childhood homicide tripled and the rates for childhood suicide quadrupled. In 2005, among children aged 1 to 4 years, homicide was the fourth leading cause of death, responsible for 375 deaths. In children 5 to 14 years of age, homicide was once again the fourth leading cause of death and suicide was the fifth. Data from 26 high-income countries with populations of 1 million or more contain 2,872 deaths among children younger than 15 years for a period of 1 year. Homicides accounted for 1,995 of those deaths (59% in males). The homicide rate was five times higher for children in the United States than in the other 25 countries combined (2.57 per 100,000 compared with 0.51).

Firearms were reported to be involved in 2,154 deaths among children in 2005. Sixty-five percent were reported as homicides, 27.8% as suicides, and 7.1% as unintentional.

The mortality rate for children hospitalized after an accident is less than 1% in many pediatric trauma centers, but that is in part because 80% of all childhood trauma deaths occur either at the scene or in the hospital ED. The most common preventable cause of death in injured children is failure to secure the airway. As many as 18% of hospital trauma deaths are avoidable if a correct diagnosis is made and a treatment regimen is instituted. The most common cause of death in injured children is brain injury, which alone or in association with other injuries is responsible for 80% of trauma mortality. More than 50% of major injuries have associated injuries of the head, chest, and musculoskeletal system. Such multisystem injuries require the use of multiple medical disciplines, with varied diagnostic and treatment modalities, to achieve optimal care. These problems clearly place a large burden on the emergency physician to effect an improvement in outcome from childhood trauma.

A critical factor that influences outcome for the pediatric trauma patient is the recognition that a child's physiologic needs are not the same as those of an adult. Although the child will usually mount an appropriate physiologic and endocrinologic response to stress, the difference in response, such as enhanced peripheral vasoconstriction, may mask significant underlying derangement, such as impending circulatory collapse. Also, the greater surface area relative to body size results in greater susceptibility to body heat loss and insensible fluid loss. Water, minerals, trace elements, fat, and vitamins are all needed in greater maintenance portions in the child. Critically, the growing child has a significantly higher energy requirement than that of an adult. Equally important to proper tissue repair are greater total protein and essential amino acid nitrogen requirements, which are age dependent. Whether reversal of the malnourished state will influence morbidity and mortality in childhood trauma is speculative and the nutritional requirements during the acute phase on injury remain much less well defined in children than in adults. However, if data examining this question for adults are applicable to the child, attention to the patient's nutritional status is certainly important.

CAUSES OF MAJOR TRAUMA

The predominant mechanism of major injury in children is blunt trauma, with only 10% to 20% of children suffering a penetrating injury. Motor vehicle crashes accounted for more than 60% of all trauma deaths from ages 1 to 18 in 2005. Motor vehicle occupant death rates begin to climb steeply at age 13 years and peak at 18 years. Falls from heights and falls against fixed objects are the most frequent reasons for hospital admission; however, in 2005, it accounted for only 1.3% of deaths while drownings accounted for 11% and burns 5%.

Societal violence as a cause of death in children is increasing at an alarming rate. An estimated 8,625 child maltreatment fatalities occurred in the 50 states and the District of

Columbia from 1999 to 2002. Homicide rates in children have two peaks: from age 0 to 3 years and from 14 to 18 years. Death by homicide afflicts African-American citizens most severely. Presently, 1 of every 28 African-American males born today will die as a result of homicide.

In infancy, the most common causes of unintentional death are aspiration, suffocation, and motor vehicle crashes. In a 10-year period, more than 50,000 unintentional deaths will be reported in children younger than 5 years. Annually, there will be more than 70,000 injuries as a result of automobile crashes in the same population. Crash mortality statistics show that the youngest occupant in an automobile is the most vulnerable to injury.

Children from 5 to 9 years of age are most likely to be pedestrian injury victims. Overall, pediatric pedestrian injury accounts for 46% of motor vehicle fatalities. Boys in densely populated urban areas represent the largest group at risk. Injury from bicycle crashes is particularly common in children 6 to 16 years. There were 203 bicycle crash deaths, principally from head injury, in this age group alone in 1998.

Because the United States is a nation in which vehicles are driven on the right side of the road, injuries to the left side of the pedestrian are the most common. The resulting frequency of injured organs includes, in order, the spleen, genitourinary tract, gastrointestinal tract, liver, pancreas, pelvis, and major vessels.

ORGANIZATION OF THE TRAUMA SERVICE

The regionalization of trauma care in the United States has progressed but is still in an evolutionary stage. In many areas hospitals have been stratified on the basis of both their capability and their desire to care for the multiply injured child, but in other areas, no such stratification has occurred. The goal of trauma center verification, under the guidance of the American College of Surgeons' Committee on Trauma, is the triage of injured children to appropriate, qualified facilities. Because of the relative scarcity of pediatric trauma centers, approximately 70% of injured children still receive their care in adult facilities. The availability of rapid pediatric transport services may accelerate the regionalization of pediatric trauma care.

The effective management of pediatric trauma requires the integration of a multidisciplinary team, including surgeons, emergency physicians, critical care physicians, emergency and intensive care nurses, respiratory therapists, radiologists, and various subspecialty services (neurosurgery, orthopedic surgery, etc.), as well as the ready availability of laboratory and operating room facilities. Each institution must develop its own organizational response plan for pediatric trauma with a well-established chain of command with an appropriately designated leader, a responsibility that may change hands as additional personnel arrive for resuscitation in the ED. The role of this leadership position in a hospital trauma service is to accept responsibility for patient care and organize the multiple specialists needed to care for the patient with multisystem injury. Such organization begins at the scene of an injury and includes transport, patient triage after initial evaluation, and care once the patient arrives in the hospital ED. Subsequently, the decision to transfer the child to a hospital with a higher level of capability, admit the child to the ward or to the intensive care unit, or take the child straight to the operating room will be made by the team leader after consultation with the specialists involved. If it becomes clear that the predominant injury is to a single-body system, it may be appropriate for the team leader to transfer patient care responsibility to the designated head of a given subspecialty. Figure 105.1 demonstrates a flow diagram of a response to the traumatized child, an example of organizational schema put into action when or before a victim of serious trauma arrives in the ED. The trauma team should conduct mock resuscitations to be prepared for the unusual critically injured child.

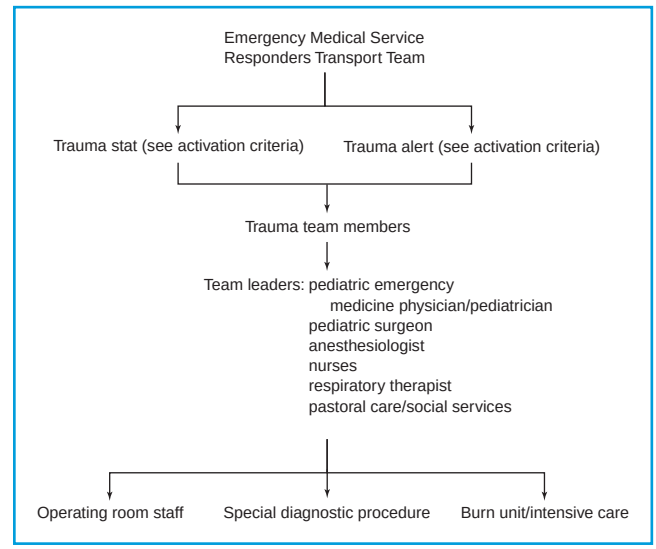

FIGURE 105.1 Sample flow diagram of a response from the emergency medical services team that is placed into action when or before a victim of serious trauma arrives in the emergency department.

ASSESSMENT AND MANAGEMENT

Initial Evaluation

Guidelines for the evaluation and management of trauma victims have been well established by the American College of Surgeons. A list of priorities needs to be established in advance for the logical approach to the trauma victim—priorities that are similar to those for severely ill ED patients. It is also imperative that during injury assessment, a simultaneous patient management protocol be initiated in a logical sequence. After prehospital evaluation and care, the injured child is transported to the hospital. A rapid and reproducible schema of immediate, simultaneous, and subsequent evaluation and treatment principles should be applied to every child who may potentially have major or multiple trauma (Table 105.1). This initial assessment includes a primary survey,

Venous access	

TABLE 105.2

CRITERIA FOR TRAUMA ACTIVATION

Trauma stat
Physiologic
Cardiopulmonary arrest
Hypotension per age
Respiratory distress
Neurologic failure (Glasgow Coma Scale score <8)
Trauma score <12
Anatomic
Penetrating (gunshot or stab) wound to head, chest, or abdomen
Facial/tracheal injury with potential airway compromise
Burn >30% BSA; inhalation airway burn
Major electrical injury
Trauma alert
Mechanism
Ejected from motor vehicle
Extrication time of >20 min
Fatality of another passenger in motor vehicle accident
Intrusion of vehicle ≥20 in by collision
Vehicle traveling at ≥20 mph in pedestrian accident or passenger unrestrained in motor vehicle accident (≥35 mph restrained)
Fall >20 ft
Run over by vehicle
Lightning
Anatomic
Significant injuries both above and below the diaphragm
Two or more proximal long bone fractures
Burn of 15%–30% BSA (second/third degree)
Traumatic amputation of limb proximal to wrist or ankle
Crush injury of torso
Spinal injury with paralysis

BSA, body surface area.

resuscitation, secondary survey, and subsequent triage. Two key principles must be followed in the initial assessment of the trauma patient. First, if any physiologic threat to the patient is identified, this threat must be treated immediately. The order of priority is airway, breathing, and then circulation (ABC). For example, a problem with breathing, such as relief of a tension pneumothorax, is addressed before proceeding with intravenous (IV) access. Second, if at any point in the patient's secondary survey or subsequent care there is unexpected physiologic deterioration, the primary survey is rapidly repeated in order of priority (ABC). An organized team of trained responders, when available, should be activated on notification of the impending arrival or simultaneously on the unexpected arrival of a child with multiple injuries. All participants of the trauma care team should fulfill their role in this initial evaluation and treatment of the patient (Fig. 105.1). The indication for team activation may vary depending on local personnel but should minimally include all children with anatomic or physiologic signs of significant injury, as listed in Table 105.2. Trauma team activation based solely on mechanism of injury criteria has been proven inaccurate and may lead to high rates of unnecessary activation. The principles of crisis resource management should be utilized to guide the flow of the evaluation and resuscitation.

Primary Survey

The first priority in assessment and management is to secure an adequate airway while concomitantly stabilizing the neck to protect the cervical spinal cord, using the chin-lift or jaw-thrust maneuver and clearing the oropharynx of accumulated foreign debris and secretions. A cervical spine injury should be assumed to be present in all patients with major trauma, especially those injured above the clavicle. Therefore, the neck should be neither hyperextended nor hyperflexed while securing the airway. All patients with major trauma should receive supplemental oxygen therapy. Before any effort at intubation, artificial ventilation should be established using a bag-valve-mask device (see Chapter 1). Cricoid pressure should be performed while preparations are made for an artificial airway. This maneuver prevents possible aspiration of gastric content caused by passive regurgitation and/or increased intragastric pressure. It is imperative to anticipate the "difficult airway" before attempting intubation. Findings suggestive that endotracheal intubation may be difficult include patients with a small mouth, inability to open the mouth, temporomandibular joint abnormalities, narrow receding mandible, protuberant maxilla (overbite), large tongue, less than 6-cm distance between the mandible and thyroid prominence, inability to place in the "sniffing position" (such as with suspected cervical spine injury), or patients with a short, full, or bull neck, or those patients with the presence of a neck mass such as a large hematoma. If the airway is deemed "highly" difficult, airway management with bag-valve-mask ventilation may be preferred until a definitive airway can be established more safely. In patients with significant facial trauma, the laryngeal structures are often surprisingly preserved and at least one attempt at visualization of the airway should be attempted prior to a surgical airway. In children younger than 8 years, the choice of surgical airway is most often a needle cricothyroidotomy.

Breathing is evaluated once a patent airway has been secured and comprises adequate air exchange with normal oxygen saturation and carbon dioxide excretion. The early use of oxygen saturation monitoring is important. Compromise of ventilatory function in an injured child most often occurs secondary to a depressed sensorium. It may also be caused by airway occlusion, restriction of lung expansion, and direct pulmonary injury (see Chapter 18). Ventilatory function in both the intubated and nonintubated patients may be accurately assessed via end-tidal CO_2 detection and the evaluation of the capnogram. Compromise of diaphragmatic excursion is a special hazard in children because of the increased importance of their diaphragms in ventilation. Gastric distension, a common event in an injured child, may significantly limit diaphragmatic excursion. Therefore, the early use of a nasogastric or an orogastric tube to decompress the stomach may be considered. If the child is obtunded or comatose, ventilation may require the use of a bag-valve device that is connected to a mask or an endotracheal tube to produce an appropriate rise in the chest and adequate oxygen saturation. Prompt recognition of and attention to a hemothorax or pneumothorax, especially with mediastinal shift secondary to tension, is essential for the management of breathing (see "Secondary Survey" section). Thoracic subcutaneous emphysema in an injured child should be considered a sign of a pneumothorax until determined otherwise.

Circulation is initially assessed by examining the pulse, skin color, and capillary refilling time. From this information, the peripheral perfusion and oxygenation may be estimated. A palpable peripheral pulse will generally correlate with a pressure greater than 80 mm Hg; an absent peripheral pulse but a palpable central pulse indicates a pressure greater than 50 to 60 mm Hg. In a normovolemic patient, the capillary refilling time, as assessed by color return after blanching, will be within 2 seconds. External hemorrhage should be controlled by direct pressure or pneumatic splints, but the application of an extremity tourniquet to bleeding, while becoming more common in adult trauma patients, remains to be evaluated in children.

TABLE 105.3

AVPU METHOD FOR ASSESSING LEVEL OF CONSCIOUSNESS

A—*A*lert	P—*P*ainful stimuli, responds to
V—*V*oice, responds to	U—*U*nresponsive

To assess patient disability, a rapid neurologic examination is completed to establish the level of consciousness, as well as pupillary size and reaction. Table 105.3 provides a list of the AVPU (*a*lert, *v*erbal stimuli response, *p*ainful stimuli response, *u*nresponsive) method of assessing the level of consciousness, in addition to pupillary assessment as previously mentioned. The Glasgow Coma Scale (GCS; Table 105.4) provides a quantitative measure of the level of consciousness and may be useful for following the progression of the injury.

To facilitate both assessment and treatment, the patient should be fully undressed and exposed; however, careful attention must be paid to the maintenance of body heat. Radiant warmers, air shields, and IV fluid warmers are useful tools in maintaining adequate temperature control in the pediatric patient.

Resuscitation

Vascular access is an early necessity in resuscitation. Percutaneous cannulation of bilateral upper extremity veins with two large-bore cannulas is ideal. However, the size of the available veins may guide the choice of cannulas. In a hypovolemic child, the visible veins may be small. Successful placement of a 22- or 20-gauge cannula is preferable to a failed attempt to place a larger cannula. In a small child, one can give

relatively large volumes (per kilogram body weight) of fluids and blood through a small cannula. Improvement in vascular volume may then permit the placement of a larger cannula at an alternative site. Early resuscitation may also be begun by intraosseous infusion into the tibial marrow space by a transtibial needle, which has been simplified by the development of intraosseous insertion devices. Cannulation of antecubital veins is preferred, but the greater saphenous vein at the ankle offers a reasonable alternative. In a hypotensive child in whom peripheral access is quickly found to be unsuccessful, the femoral vein provides a safe site for the insertion of a central catheter, often accomplished rapidly using the Seldinger guide wire technique. However, a long, narrow, standard central catheter may be less effective than a large peripheral IV catheter for fluid resuscitation. Rapid cutdown access is best done on a basilic vein at the elbow or the saphenous vein either at the ankle or in the groin just below the saphenofemoral junction. Central vein cannulation above the diaphragm, although necessary at times, is not a preferred emergency access route and, in children, should be done only by experienced personnel.

At cannulation, blood should be sent for a type and crossmatch and a hematocrit, and a tube of blood should be held for chemical parameters if they are needed on the basis of physical findings (Table 105.5). Shock after major trauma usually occurs secondary to the acute loss of a 40% or more of the blood volume, although it may less often be cardiogenic or secondary to spinal cord injury. Shock secondary to an isolated brain injury is more common than previously believed, but other etiologies must be excluded first. The presence of shock must be assessed by appreciating whether inadequate organ perfusion exists. Any injured patient who has cold skin and tachycardia is in shock until proven otherwise. Reliance on the hematocrit alone may prove unreliable because an initial near-normal hematocrit level does not exclude the possibility of significant blood loss.

To quantify the extent of the problem and decide on treatment priorities, hemorrhagic shock can be classified according to severity (Table 105.6). Class I hemorrhage occurs with an up to 15% acute blood volume loss (up to a 250-mL blood loss in a 20-kg child), and physiologic changes will be minimal. A single 20 mL per kg IV fluid bolus should stabilize the circulation. Class II hemorrhage, 15% to 30% blood loss (approximately 250- to 500-mL blood loss in a 20-kg child), is associated with tachycardia and tachypnea along with a fall in pulse pressure, as catecholamine release produces elevation in peripheral vascular resistance. Such patients may have impaired capillary refilling, and they may develop early signs of poor mentation. These patients would typically be stabilized by one or two 20 mL per kg boluses of IV crystalloid. Class III hemorrhage is physiologically more significant, with 30% to 40% blood loss corresponding to 500 to 650 mL of blood in a 20-kg child. These patients have obvious signs of shock with altered mental status, tachycardia, tachypnea, and measurable diminution in systolic pressure.

Crystalloid resuscitation should begun promptly, and some patients will also require blood products. Class IV hemorrhagic shock, involving more than 40% blood loss, is immediately life threatening. Patients are mentally depressed, cold, and pale; they have profound tachycardia and tachypnea, the pulse pressure is narrow, and there is no urine output. After rapid transfusion, such patients often require prompt operative intervention to stop ongoing blood losses.

Cardiogenic shock after major childhood injury is rare, but it could be a result of cardiac tamponade or myocardial contusion. Dilated neck veins in a patient with a decelerating injury, sternal contusion, or penetrating thoracic trauma should arouse such suspicion (see Chapters 84 and 118). Neurogenic shock classically presents with hypotension without tachycardia or vasoconstriction. Also, isolated head injuries may produce shock, though other causes of hypovolemia should always be sought in such patients. Septic shock rarely occurs immediately after injury, even in the face of abdominal contamination.

Crystalloid isotonic solution, preferably Ringer's lactate or normal saline solution, is the initial resuscitative fluid of choice for the patient in hypovolemic shock. The American College of Surgeons has specific recommendations for the management of hemorrhagic shock resulting from trauma. The initial crystalloid infusion is given as rapidly as possible in a dose of 20 mL per kg with careful monitoring of patient physiologic response. Table 105.6 emphasizes the anticipated fluid needs, depending on the degree of shock, and the formulation is based on the premise that the patient will require 300 mL of crystalloid for each 100 mL of blood loss. A simplified rule of thumb would be if shock is present, give 20 mL per kg of crystalloid; if no response, give another 20 mL per kg of crystalloid; and if there is no response, give a third 20 mL per kg of crystalloid or 10 mL per kg of packed red blood cells (RBCs). In adults with hemorrhagic shock, this resuscitation strategy is inferior to a blood plus fresh-frozen plasma resuscitation, though this therapy has not yet been evaluated in children. No response to three-bolus infusion in children suggests the need for operative intervention. The restoration of perfusion may be clinically assessed, although in unusual situations, invasive monitoring with elective placement of a central venous catheter may be helpful. A most useful practical guide is the monitoring of urinary output; 1 mL per kg per hour is optimum, although for children younger than 1 year, preferred output should approach 2 mL per kg per hour.

There are currently a number of published studies on "low-volume" fluid resuscitation (LVFR). In patients with *uncontrolled hemorrhagic shock* (which refers to an injury that can only be managed operatively, such as intrathoracic or intraabdominal trauma), the use of LVFR appears indicated. Several animal studies have confirmed the intuitive arguments raised for LVFR. These arguments include the one that, because internal hemorrhage cannot be controlled by external means, the body effectively tamponades (especially venous injuries) hemorrhage. IV fluid boluses, under these circumstances, raise central venous pressure, disrupt clots, dilute clotting factors, and worsen hemorrhage. As a result, end-organ oxygen delivery suffers. A prospective clinical trial by Bickell et al. randomized 598 adults older than 15 years with prehospital systolic blood pressures of 90 mm Hg to immediate versus delayed fluid resuscitation. They concluded that delaying aggressive administration of IV fluids to hypotensive patients with penetrating injuries to the torso until the time of operative intervention may improve outcome. Teach et al. retrospectively studied

TABLE 105.5

RAPID APPROACH TO PEDIATRIC TRAUMA PATIENTS

Time interval patient priority	System assessment	Initial therapy	System monitor	Diagnostic study
First 5 min Primary survey	Respiration	Cervical spine stabilization (sand bags, collar) Airway (bag-valve-mask, intubation) Ventilation with 100% oxygen	End-tidal CO_2 monitor Pulse oximetry	Arterial blood gas Arterial blood gas
	Pulse	Cardiac compression	Heart rate (electrocardiogram) Blood pressure	
	Ventilation	Needle/tube thoracostomy—tension pneumothorax Dressing to sucking chest wound		
	External hemorrhage	Compression		
Second 5 min Resuscitation	Perfusion	Intravenous/intraosseus needle access; 20 mL/kg crystalloid Needle pericardiocentesis Thoracotomy, aortic cross clamping	Perfusion Pulse Blood pressure PO_2, PCO_2, pH	Type and cross-match Complete blood cell count
	Level of consciousness	Nasogastric tube Urinary catheter Drugs	Temperature	Blood gas Urinalysis
Third 5 min Secondary survey	Ventilation Perfusion Head Neck Chest	Venous access Type specific blood Crystalloid Tube thoracotomy—pneumothorax, hemothorax	Perfusion Pulse Blood pressure Arterial line Foley catheter	Lateral neck film Chest radiograph
	Abdomen	Nasogastric tube		Plan for abdominal pelvic CT scan

CT, computed tomography.

prehospital fluid therapy in 50 pediatric trauma patients and assigned them to one of three groups: (i) IV therapy detrimental, (ii) IV therapy inconsequential, and (iii) IV therapy beneficial. The authors found that IV therapy was inconsequential in 47 of 50 cases, potentially beneficial in 2 cases (children with external stab wounds whose bleeding was controlled at the scene), and potentially detrimental in 1 case (a child with a head injury). Data from the Iraq conflict reveal that delay in high-volume resuscitation may be beneficial in patients with a normal sensorium and a palpable peripheral pulse.

Blood transfusion preferably is done with fully cross-matched, warmed blood passed through a 160-m macropore filter. In the face of a transient or absent response to a rapid crystalloid infusion, fully cross-matched, type-specific, or type O-negative blood should be given as a whole-blood transfusion. In summary, fluid and blood are given rapidly enough to maintain stable vital signs and adequate urine output. Vasopressors, steroids, and sodium bicarbonate do not play a role in the initial treatment of hypovolemic shock. In massive transfusion situations in adults, resuscitation with a ratio of fresh-frozen plasma to packed RBCs of 1:1 leads to the best survival.

TABLE 105.6

THERAPEUTIC CLASSIFICATION OF HEMORRHAGIC SHOCK IN PEDIATRIC PATIENT

	Class I	Class II	Class III	Class IV
Blood volume loss[a]	Up to 15%	15%–30%	30%–40%	≥40%
Pulse rate	Normal	Mild tachycardia	Moderate tachycardia	Severe tachycardia
Blood pressure	Normal/increased	Normal/decreased	Decreased	Decreased
Capillary blanch test	Normal	Positive	Positive	Positive
Respiratory rate	Normal	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Urine output	1–2 mL/kg/h	0.5–1.0 mL/kg/h	0.25–0.5 mL/kg/h	Negligible
Mental status	Slightly anxious	Mildly anxious	Anxious/confused	Confused/lethargic
Fluid replacement (3:1 rule)	Crystalloid	Crystalloid	Crystalloid % blood	Crystalloid % blood

[a]Assume blood volume to be 8%–9% of body weight (80–90 mL/kg).

While resuscitation is underway, a urinary catheter should be placed in patients who need ongoing close monitoring of organ perfusion. Urethral injuries are rare in children. However, urinary catheterization should not be attempted before a retrograde urethrogram has proven urethral integrity if blood has been noted at the urethral meatus or in the scrotum, or if there is abnormal prostate placement on rectal examination. The urinary specimen should be immediately analyzed for the presence of gross or microscopic blood. Patients with significant abdominal injury and those with inadequate airway protection should have a nasogastric or orogastric tube placed. In the presence of a basilar skull fracture, care must be taken in inserting a nasogastric tube to avoid passage into the brain through a cribriform plate fracture. An orogastric tube is preferred in such patients.

Secondary Survey

A rapid, systematic assessment of organ systems must be performed after securing the ABC. A pertinent history should at least include allergies, medications, past illnesses, time of last meal, and events preceding the injury.

A head examination includes evaluation of pupillary size and reactivity, a conjunctival and fundoscopic examination for hemorrhage or penetrating injury, and a quick assessment of visual acuity. Visualization of blood in the external auditory canal or behind the tympanic membrane raises suspicion for a basilar skull fracture. Thorough palpation of skull and mandible may detect fractures and dislocations, but if the airway is secure, further evaluation of maxillofacial bony trauma is of lesser priority in the total treatment plan.

Injury to the cervical spine is uncommon in children (see Chapter 115), but risk of injury must always be considered. This is especially true for any child with trauma above the clavicles. It is also true for young children who fall one or more floors, are hit by a motor vehicle at 30 mph or more, and who are unrestrained or poorly restrained occupants of a motor vehicle involved in a significant crash. In older children, sports injuries are the second most common cause of cervical spine injury. In a child with low risk for cervical spine injury (e.g., a fall when running), the "neck can be cleared" with a normal clinical examination in the fully awake, cooperative patient, similar to the adult NEXUS criteria. In the patient who is neurologically intact and has no tenderness over the cervical vertebrae, the clinician should actively maneuver the neck in controlled flexion, extension, and rotatory motion. If there are no symptoms or signs of spasm, guarding, pain, or tenderness, a decision can be made with a high degree of certainty that there is no fracture, ligamentous instability, or cord injury. Otherwise, adequate cervical spine radiographs are required to evaluate for a bony injury. Ligamentous disruption and dislocations of the cervical spine without radiographic evidence of bony injury are not uncommon in children because of the weakness of the soft tissue of the neck and the incomplete development of the bony spine. In approximately 30% of children with a spinal cord injury, no radiologic abnormality is present (SCIWORA). In patients with a high-risk mechanism of trauma, it is best to obtain anteroposterior, odontoid (in older children), and lateral views before "clearing" the neck. If the patient has an altered sensorium, a semirigid cervical collar should be left in place even if the three survey radiographs show negative findings. When the patient recovers sufficiently to permit a full evaluation of the neck, the collar can be removed. For unconscious patients not expected to awaken, the following should be performed: normal plain radiographs and the addition of either a normal cervical spine magnetic resonance imaging within 48 hours or normal flexion and extension views with simultaneous brain stem evoked potentials may serve to clear the spine and allow removal of the cervical collar.

Two situations require further discussion. First, if a seriously injured child has had an endotracheal tube placed, one can get a computed tomographic (CT) scan of C1 and C2 when getting a head CT scan, in place of the standard odontoid view. Second, if a patient is brought to the hospital with a helmet on (e.g., football or motorcycle) and there is no respiratory distress or other problem requiring immediate intubation, an initial cervical spine radiographic series can be performed before helmet removal (these helmets are designed to allow for adequate penetration of the x-ray beam). If it is necessary to remove the helmet before the neck is cleared, a two-person technique ensuring neck immobilization should be used.

Visual inspection of the chest may identify a rare sucking chest wound, best treated by immediate application of a sterile occlusive dressing; even more rarely, a major flail component, treated by splinting or endotracheal intubation; or a penetrating wound (see Chapter 115). Auscultation may not reveal a pneumothorax or hemothorax secondary to the broad

transmission of breath sounds in a child. A prompt chest radiograph may be helpful in disclosing these conditions in stable patients. They should be treated by tube thoracostomy. Cardiac tamponade may be detected by muffled heart sounds, distended neck veins, and a narrow pulse pressure and should be relieved by prompt pericardiocentesis (see Section VII: Procedures). If the patient is stable, echocardiography may be used in making the diagnosis and in performing the procedure. A diagnosis of tension pneumothorax is supported by observing a contralateral tracheal shift and distended neck veins, in addition to diminished breath sounds. Anterior needle thoracostomy should provide relief, but tube thoracostomy should follow, with the placement of the tube to suction. If an impaled object is protruding from the chest or any part of a patient, it is best debrided from surrounding clothing and left in place until definitive operation. If the history suggests a severe deceleration injury and the chest radiograph demonstrates a widened mediastinum with or without a fractured first rib, a thoracic aortic injury is suggested. In the stable patient, a thoracic CT angiogram is promptly indicated.

The secondary abdominal examination establishes whether visceral injury exists (see Chapters 104 and 107); it is not meant to provide an exact diagnosis. Visceral injury should be suspected in the presence of abdominal wall contusion, distension, abdominal or shoulder pain, signs of parietal peritoneal irritation, gross hematuria, and/or shock. Hemodynamically stable patients with the previous findings should undergo an abdominal CT scan as soon as possible. Gastric distension may lead to left upper quadrant tenderness, even in patients with injuries remote to their abdomen. The passage of a nasogastric or orogastric tube may relieve this condition and prevent the need for imaging. Diagnostic peritoneal lavage (DPL), previously a mainstay of emergency trauma evaluation, should be considered only with blunt trauma in the patient who remains unstable despite resuscitation and in whom the diagnosis of abdominal injury is unclear. However, DPL has been supplanted by focused abdominal sonography for trauma, the focused abdominal sonography for trauma (FAST) examination, which may sensitively demonstrate intraperitoneal free fluid. The large majority of children with documented intraabdominal or retroperitoneal injury who remain stable or rapidly become so do not require surgery, rendering the findings of peritoneal RBCs much less helpful. The performance of a DPL prior to abdominal CT scan may introduce air, decreasing the ability of CT to diagnose this life-threatening condition.

A rectal examination is still essential, assessing sphincter tone, rectal integrity, prostatic position, pelvic fracture, and the presence of gross blood in the stool. The finding of microscopic blood on rectal examination adds little to the evaluation, and guaiac testing need not be performed.

A thorough extremity examination should assess deformity, contusions, abrasions, penetration, and perfusion, including pulse palpation. Although the presence of a distal extremity pulse does not exclude a concomitant proximal arterial injury, the presence of equal Doppler blood pressures makes it much less likely. Soft-tissue injuries should be thoroughly inspected both for wound foreign bodies and for the presence of devitalized tissue. Long bones should be palpated with rotational or three-point pressure for tenderness, crepitance, or abnormal movement, and pressure should be applied to the pubis and anterior iliac spines to assess for the presence of pelvic instability. Sensation should be assessed in all limbs. Severe extremity angulations should be straightened and immobilized, and traction splints should be applied after an examination of distal neurological function and perfusion. Compound fracture sites should be covered with sterile dressings. Generous irrigation and debridement of open wounds not associated with fractures or joint injuries are beneficial in early wound care to minimize contamination before considering primary or delayed wound closure (see Chapter 124).

Hypothermia is a special risk in injured children, since a child has relatively more surface area than an adult. Hypothermia can develop in the prehospital setting and then worsen in the ED, where proper assessment and treatment may require full exposure of the patient. The dangers of hypothermia are impaired circulatory dynamics, impaired coagulation, increased peripheral vascular resistance, and increased metabolic demand. The use of overhead radiant warmers, warm blankets, and warmed IV solutions are important measures in combating the deleterious effects of hypothermia. These measures should be used as soon after arrival in the ED as possible when hypothermia is a concern. There has been increasing literature on the use of "controlled" mild hypothermia (32°C to 35°C) in the first hours after an ischemic event, which may prevent or mitigate permanent injuries. This effect has been shown most clearly for postanoxic brain injury but could also apply to other organs such as the heart and kidneys. Hypothermia has also been used as a treatment of traumatic brain injury, stroke, hepatic encephalopathy, myocardial infarction, and other indications.

The child with burn injury needs to have an initial appraisal of burn severity, including the depth, location, and type of burn (Table 105.7); an appraisal of the extent of the burned area, using the percentage of surface area for children up to or older than 10 years as defined in Table 105.8; and a determination of whether the injury also includes pulmonary, soft-tissue, or bony damage. Burns may be classified in the following categories:

- *Critical:* an inhalation injury; second-degree burns exceeding 30% of body surface area (BSA); third-degree burns exceeding 10% to 20% of the BSA; a complicating fracture or soft-tissue injury; extensive electrical burns; or extensive deep acid burns.

TABLE 105.7

BURN WOUND ASSESSMENT: BODY SURFACE ESTIMATION (ADULT VS. CHILD)

Anatomic area	Percentage adult surface (age >10 yr)	Percentage infant surface
Head	9	16
Right upper extremity	9	9
Left upper extremity	9	9
Right lower extremity	18	13
Left lower extremity	18	13
Anterior trunk	18	18
Posterior trunk	18	18
Neck	1	4
Total	100	100

TABLE 105.8

BURN INJURY

Classification	Morphology	Appearance	Cause
First degree	Superficial epidermis devitalized; vasodilation and vasocongestion	Erythema: blanches on pressure	Ultraviolet exposure; short flash
Second degree	Epidermal destruction; coagulation necrosis with congestion and fluid collection; skin elements remain viable for regeneration	Painful, erythematous, weeping, blisters, bullae; skin elements white, soft, and dry	Short flash or spill scald
Third degree	All skin elements destroyed; coagulation necrosis of subdermal plexus; capillary thrombosis	Dry, hard, inelastic with visible vein thrombosis	Flame, scald immersion; contact electrical

- *Moderate:* 10% to 30% BSA second-degree burns; from 1% to 10% BSA third-degree burns and no involvement of the hands, feet, or genitalia.
- *Minor:* less than 10% BSA second-degree burns and less than 1% BSA third-degree burns.

The burn victim should be undressed, and sterile covers should be placed over the burn wounds. IV fluid resuscitation is necessary promptly if the burn exceeds 20% of BSA (see Chapters 1 and 108). Referral to a burn center should be considered in critical burns, burns of the hands, feet or perineum, or cases with the possibility of devastating cosmetic and functional deficits.

Neurologic assessment includes a reevaluation of the level of consciousness, a repeat pupillary examination, and a thorough sensorimotor examination. Not only is serial reassessment critical but also quantification of the findings using a GCS is of benefit to detect early changes (Table 105.4; see Chapter 116). Any evidence of paralysis or paresis suggests a major neurologic injury and should be carefully documented. Until spinal cord injury is determined or ruled out in any patient with signs of central nervous system injury, maintain the patient in a semirigid cervical collar and immobilize him or her on a firm surface.

Supplemental studies (including regular and contrast imaging studies; biochemical analyses of liver, pancreatic, and renal function; and electrocardiographic analysis of cardiac function) may be performed after the secondary survey, as indicated by a history and physical examination. The routine use of a broad laboratory "panel" is unlikely to add to patient evaluation. Tetanus prophylaxis should be considered (see Chapters 92 and 104), and antibiotics should be administered if specifically indicated.

Imaging the Pediatric Trauma Patient

In any child with major trauma caused by a blunt mechanism, a basic radiographic survey series should be considered. Traditionally, this survey included cervical spine, chest, and pelvic radiographs. More recent studies have demonstrated that patients with a GCS score of 15, no distracting injury, no pain in the pelvic region, and a normal physical examination of their pelvis have a low incidence of pelvic fractures. In these patients, the routine use of pelvic radiographs is not necessary and is also rarely helpful in the short-term initial management of the traumatized child. In a stable, cooperative patient, the clinician examines the cervical spine and then proceeds with radiographs as necessary. Additional survey radiographs of the thoracolumbar spine and extremities depend on clinical findings and the mechanism of trauma.

The primary or secondary survey may suggest a need for more definitive imaging studies. For example, any patient who is normotensive but has an abnormal GCS score should undergo a CT scan of the head. Other indications for a head CT scan include a history of posttraumatic seizures, prolonged lethargy or loss of consciousness, or an underlying medical risk factor such as hemophilia. A CT scan of the abdomen is indicated in a hemodynamically stable victim of blunt trauma who has physical signs of intraabdominal injury, gross hematuria, or a worrisome mechanism of trauma in the presence of neurologic compromise. Most CT scans of the abdomen for trauma should be performed with IV contrast alone. Double contrast (enteral and IV) may delay the process and increase the risk for aspiration. If a Foley catheter is in place, it should be clamped during the abdominal CT scan to provide information about the bladder. Because of the potential for injury to the liver or spleen in children with blunt abdominal trauma, an abdominal CT scan is more comprehensive in evaluating a patient with significant hematuria than an IV pyelogram.

The likelihood of positive findings in abdominal CT scans is significantly increased if three or more of the following indicators are present: (i) gross hematuria, (ii) lap belt injury, (iii) assault or abuse as a mechanism of trauma, (iv) abdominal tenderness, and (v) trauma score 12 or less. However, certain indicators alone, such as positive abdominal findings, worrisome mechanism of trauma (e.g., ejected from a motor vehicle), and neurologic compromise (e.g., GCS score of less than 10), warrant obtaining an abdominopelvic CT scan to document possible intraabdominal or retroperitoneal injury. In general, the accuracy of CT scans in diagnosing intraperitoneal or retroperitoneal injuries is 95% or better. The use of ultrafast and multiplanar CT scans increases the diagnostic accuracy of CT scans because of less motion artifact and better contrast enhancement. Ultrasound has been used successfully in the evaluation of the adult trauma patient using the FAST examination. In the hands of an experienced examiner, it can be performed in the ED and will document approximately 70% of the injuries to the liver, spleen, and/or kidneys

TABLE 105.9

PEDIATRIC TRAUMA SCORE[a]

Component	Category		
	+2	+1	−1
Size	>20 kg (40 lb)	10–20 kg	<10 kg
Airway	Normal	Maintainable	Unmaintainable
Systolic blood pressure	>90 mm Hg	50–90 mm Hg	<50 mm Hg
Central nervous system	Awake	Obtunded/loss of consciousness	Coma/decerebrate
Skeletal	None	Closed fracture	Open/multiple fractures
Cutaneous	None	Minor	Major/penetrating sum (pediatric trauma score)

[a]Pediatric trauma score for prehospital and in-hospital use.

through the demonstration of free intraperitoneal fluid. This may be an alternative when emergency CT scans of the abdomen are not available; however, its utility in the pediatric trauma patient has not been fully evaluated.

The major limitations of CT scans of the abdomen in trauma patients are in the diagnosis of hollow viscus injuries such as perforation of the bowel and bladder. Free intraperitoneal air is seen in only 25% of patients with a bowel perforation. Other signs, free fluid in the abdomen without solid organ injury, bowel wall thickening, and a mesenteric hematoma are also seen on CT scan in a minority of patients with documented bowel injury. In alert patients, serial abdominal examinations and serial CT scans may be helpful. In unconscious patients, DPL may be useful, although false-negative studies have been reported if this maneuver is done early after injury.

Finally, selective urologic contrast studies are indicated in two situations. First, a patient with gross blood at the meatus, especially if clinical and radiographic studies suggest a pelvic fracture, should undergo a retrograde urethrogram. Gross blood at the meatus often correlates with clinical and/or radiologic evidence of a pelvic fracture. If the urethra is damaged, a surgical or urologic consultation is essential. If the urethra is not damaged, a cystogram may be performed after carefully advancing the catheter into the bladder. Second, if a patient with blunt or penetrating abdominal trauma is too unstable for a CT scan, a one-shot IV pyelogram may be performed in the operating room during laparotomy. After IV administration of a bolus of 2 to 4 mL per kg of 50% diatrizoate sodium (Hypaque; Winthrop Laboratories), the clinician should obtain a survey film of the abdomen 5 minutes after injection. This study will usually confirm the function or malfunction of both kidneys and occasionally the upper ureters.

Triage

Definitive care may occur in the prehospital setting (e.g., endotracheal intubation), in the ED (e.g., chest tube placement), or in the intensive care unit or operating room. Triage is a process of patient assessment, prioritization of treatment, and selection of appropriate treatment location. In the early stages of patient assessment, the precise diagnosis of anatomic injury is often impossible. To identify patients with a potential for major morbidity or at risk of dying, various physiologic scoring systems have been developed. In pediatric trauma, the most useful are the GCS score, the trauma score (TS), which uses the GCS (Table 105.4), and the pediatric trauma score (PTS) (Table 105.9). For the purposes of prehospital triage, admission to a designated pediatric trauma center is indicated in any patient with a GCS score of 12 or less, a TS of 12 or less, or a PTS of 8 or less. Field studies of the TS showed that at night, it is difficult to assess capillary refill and respiratory effort. Therefore, the most common tool used in prehospital triage is the revised trauma score (RTS), which deletes these two variables. Admission to a pediatric trauma center is then indicated for any of the following criteria: (i) GCS score of 12 or less, (ii) low systolic blood pressure per age, or (iii) abnormal respiratory rate per age. In the ED setting, a complete TS or PTS is usually obtained, but for trauma outcome studies, the RTS is the most commonly used tool.

The PTS is designed to give added emphasis to the importance of patient size and airway control in injured children. Indeed, studies confirm the validity of the PTS as a predictor of outcome: 9% mortality for PTS above 8 and 100% mortality for PTS of 0 or less. From 8 to 0, there is a linear relationship between decreased PTS and an increasing potential for mortality. Nevertheless, studies comparing TS, RTS, and PTS do not show any statistical advantage of PTS over the other two for the purposes of triage. In addition, many children with significant solid organ injuries were found to have a normal PTS. Therefore, whichever physiologic scoring system is selected, it should be used consistently and sequentially. For example, a repeat TS 1 hour after baseline TS shows how the patient is responding to treatment. Alternatively, it may reveal any delayed deterioration of the patient's condition and may suggest the need for more urgent intervention.

SUMMARY

Tables 105.5 and 105.10 describe a rapid approach to the patient. Over a 20- to 40-minute interval, the patient may be

TABLE 105.10

EMERGENCY DEPARTMENT ASSESSMENT AND MANAGEMENT PLAN FOR INJURED CHILD

Assessment	Diagnosis	Management	Evaluation study
Airway/breathing		Clear airway Ventilate Intubate	
Cardiac function		External cardiac massage	Cardiorespiratory monitor

sequentially and simultaneously assessed, treated, monitored, and subjected to further diagnostic study while the format of primary survey, resuscitation, secondary survey, and triage is followed. Each physician dealing with the injured child should have such a format within his or her armamentarium. With these treatment formats well in hand, the clinician can optimize the subsequent care of the patient.

CHAPTER 106 ■ MINOR TRAUMA—LACERATIONS

STEVEN M. SELBST, MD, AND MAGDY W. ATTIA, MD

LACERATIONS

Each year an estimated 12 million wounds are treated in emergency departments (EDs) in the United States. Lacerations account for 30% to 40% of all injuries for which care is sought in a pediatric ED. Broken glass, wooden furniture, asphalt or concrete, or other sharp objects cause most of these lacerations. Animal bites also account for many lacerations. More than 40% of the wounds involve a fall. Boys are injured twice as often as girls. The mechanism of injury varies with the patient's age. Household items, fences, and trees most likely injure preschoolers; older children sustain injuries in violent encounters.

Two-thirds of the injuries occur during warm weather months, although half of the injuries in an urban environment occur indoors. Deaths from minor lacerations are rare; however, complications occur in about 8%. Complications include infection, hypertrophic scarring or keloid formation, and poor cosmetic results.

Pathophysiology

Wound Healing

Normal skin is under constant tension, produced, in part, by underlying joints and muscles. The amount of tension varies by anatomic location and position of a body part. For example, skin overlying a joint will vary in tension, depending on whether the joint is flexed or extended. Lacerations that run parallel to joints and normal skinfolds usually heal more quickly and with better cosmetic results. Wounds under a large amount of tension, crossing joints, or perpendicular to wrinkle lines often heal with wide, unattractive scars. When skin is injured, sutures may be placed to provide temporary support until the skin can regenerate and overcome tension to allow wound closure.

A wound such as a laceration regains about 5% of its previous strength 2 weeks after injury and 30% after 1 to 2 months. It reaches full tensile strength 6 to 8 months after the original injury. Many factors, such as infection, tissue edema, and poor nutrition, may delay this progression.

All wounds deeper than the dermis have the potential for scar formation. Scar formation involves the laying down of collagen, which is a complex process essential in restoring tensile strength of the skin. Collagen synthesis begins within 48 hours of the injury and reaches a peak within the first week afterward. Anything that interferes with collagen synthesis, such as infection, may lead to wound dehiscence at this time. Wound contraction is expected with all healing wounds through the action of fibroblasts. Therefore, eversion of suture lines is desired at the time of repair so that the skin will contract to a flat wound during healing. Remodeling may occur for up to 12 months. Thus, the scar may fade and recede over the first 3 months, and the final appearance of the scar may not be apparent until 6 months after injury.

Wound Infection

Wound infection plays a major role in wound healing. Bacteria inhabit normal intact skin. This is the usual source of infection when skin tissue is disrupted. The amount of bacteria on the skin varies by anatomic location. High counts of bacteria are in moist areas such as the axilla and perineum. Low counts of bacteria are in dry areas such as the back, chest, and abdomen. High bacteria counts can also be expected in areas of exposed skin such as the hands, face, and feet. Areas colonized with high bacterial contamination are most prone to infection. Wounds in regions of high vascularity, such as the scalp and face, more easily resist bacterial infection despite the high bacteria count. Certainly, the oral cavity is highly contaminated with bacteria, and this is an important source of infection when a child sustains a bite wound.

Wounds inflicted by shearing forces with a sharp object such as a knife cause minimal devitalization of adjacent areas and thus are less likely to lead to infection. Wounds caused by a blunt object striking the skin at an angle of less than 90 degrees result in a tension injury such as an avulsion or flap. These injuries involve a larger force applied to the skin than that of a shearing injury, and there is more devitalized tissue. They are more likely to become infected than shearing injuries and are often more difficult to repair. Finally, compression injuries from blunt trauma to the skin at about a 90-degree angle cause the most tissue disruption and devitalization. They are characterized by ragged edges and lead to the highest infection rates and unacceptable scarring.

Clinical Manifestations

History

In the evaluation of a laceration, it is important to learn the *mechanism* of the injury because this may radically change management plans. For instance, if the wound is caused by an animal bite, the likelihood of devitalized tissue and infection is higher and repair may be omitted (see Chapter 83). Also, a wound caused by a blunt object may be associated with an underlying fracture or crush injury. Certain crush injuries, such as wringer injuries, are inherently more complicated and may require surgical consultation and hospital admission. A wound caused by a sharp object may have injured deeper tissues. Determine the *age* of the wound, as well as the possibility of a *foreign body*, in the wound.

Also, consider the *location* of the wound. If the wound is in the neck area, the physician should consider possible extension through the platysma muscle, with potential for a serious injury to underlying structures. If the wound involves the chest, the physician should look for crepitance in the subcutaneous tissue, suggesting injury to the underlying lung. An injury to the lower extremities is more likely to result in infection because of the relatively poor blood supply. Likewise, a wound overlying a joint space can be complicated if the joint cavity is violated. Injury to distal body parts such as the ear, nose, and fingers may threaten the viability of more distal tissues because of vascular compromise. Conversely, in areas where the vascular supply is good, such as the face, scalp, and tongue, the infection rate is low regardless of the mechanism of injury.

Assess the *environment* in which the injury occurred. If the injury occurred on the street, it is possible that small particulate matter may be embedded in the wound. If this debris is left in place, tattooing of the skin could result, leaving an unfavorable appearance to the healed wound. Injuries that occurred in a field, farm, or a wet, swampy area may have high bacterial loads.

The patient's *health status* should be addressed. If the patient has diabetes, immunosuppression, malnutrition, or other chronic conditions such as cyanotic heart disease, chronic respiratory problems, or renal insufficiency, higher infection rates may be anticipated. Bleeding disorders and current medications should be determined because some drugs, such as ibuprofen and corticosteroids, may affect the wound. Ascertain *allergies* to latex, antibiotics, and local anesthetics, as well as the child's *tetanus status*.

Physical Examination

A careful physical examination is essential before local anesthesia is given. First, determine whether there is an associated injury distant from the obvious wound. Wound management should not preempt care of more life-threatening injuries. It is important to assess the wound for *vascular damage* and to control bleeding if present. Brisk flow of blood may indicate injury to a major vessel. These vessels can usually be safely tamponaded and later ligated or sutured. The bleeding site must be identified, although it is often obscured by profuse bleeding. Pressure applied to the site or temporary use of a tourniquet or inflated blood pressure cuff (less than 2 hours) controls hemorrhage and allows identification of the bleeding vessel. Blind clamping of an artery should be avoided except in the scalp. Palpation of pulses and capillary refill distal to the site of injury must be checked.

Next, potential *nerve damage* must be assessed. In an older, cooperative child, the physician should always test the median and ulnar nerves of an injured upper extremity. If a young child does not permit this, pinprick sensation may be tested. Fortunately, when sensation is intact, motor function of the nerve is also usually intact.

Next, the wound must be evaluated for possible *tendon injury*. The superficial location of extensor tendons of the dorsum of the hand predisposes them to injury. Tendon injuries are sometimes visible if the wound is wide and deep. For example, a torn tendon on the flexor surface of the forearm may be seen when the patient with a laceration to the wrist is asked to flex the hand and wrist. Unless the tendon injury is obvious, wounds over joints and tendons should be put through a full range of motion. A young patient may be too uncooperative to flex and extend the fingers on command. Therefore, it is important to inspect the resting position of the injured hand in a young child to note a flexor tendon injury to the finger. One digit may be found extended at rest, while the other uninjured digits are flexed (Fig. 106.1). Applying a noxious stimulus and noting inability to withdraw the finger that is tested may show injury to the extensor tendons.

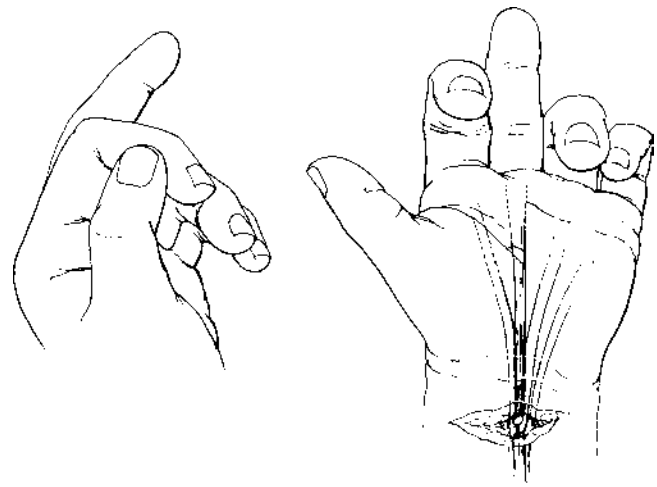

FIGURE 106.1 A seemingly superficial laceration at the wrist might be treated simply by closure of the subcutaneous tissue and skin, unless one appreciates the abnormal posture of the middle finger when the hand is at rest. The loss of normal flexor tone as a result of a divided superficial tendon results in the involved finger lying in a position of relative extension.

Determine whether there is *foreign material* in the wound. If the history or physical examination suggests a radiopaque foreign body, consider obtaining a radiograph or an ultrasound of the area for confirmation. This is especially important in assessing a wound caused by glass. A deeply embedded piece of glass may be missed without radiographs or ultrasound. Some recommend obtaining plain radiographs in all cases in which glass is involved, except for the most superficial wounds. Ultrasound is sensitive in detecting and localizing foreign bodies and is most helpful for those which are nonradiopaque, such as plastic and wood. Further inspect for foreign material after the wound is anesthetized.

Finally, *bones* near the wound should be palpated for crepitance, tenderness, or deformity, which may suggest a fracture. Obtain radiographs to confirm suspicious findings. Wounds overlying a fracture may constitute an open fracture and deserve consultation with a specialist for possible repair in the operating room. Table 106.1 summarizes general principles of wound assessment.

Patients with vascular, nerve, or tendon injury or deep, extensive wounds to the face merit consideration for referral to a surgical specialist for possible repair in the operating room.

Decision to Close the Wound

Children are less likely to get wound infections than do adults. In children, the infection rate is about 2% for all sutured wounds. Thus, most wounds may be closed primarily, meaning that the wound edges are approximated as soon

TABLE 106.1

WOUND ASSESSMENT—GENERAL PRINCIPLES

  - Foreign material
- Laboratory
  - Consider radiographs or ultrasound if a foreign body or fracture is suspected

after the injury as possible to speed healing and improve the cosmetic result. If primary closure is long delayed, the risk of subsequent infection increases. However, the length of time before the risk of infection becomes significant is variable. Some authors suggest that the "golden period" for wound closure is 6 hours. However, wounds at low risk for infection (e.g., a clean kitchen knife injury) can be closed even 12 to 24 hours after the injury. In a study from a developing country where patients presented with wounds after variable delays in care, it was found that wounds of the face and scalp heal well in more than 90% of cases, regardless of the time from injury to repair.

Most wounds of the face are best closed, primarily, even up to 24 hours after injury to achieve an optimal cosmetic effect. If the wound is extensive or has a high potential for infection (e.g., a dog bite on the face), thorough irrigation is essential. On the contrary, wounds at high risk for infection such as those in anatomic locations with poor blood supply, contaminated or crush wounds, and those involving immunocompromised hosts should be closed promptly within 6 hours of injury. Some contaminated wounds (animal or human bites or those occurring in a barnyard) in an immunocompromised host should not be sutured, even if the patient presents immediately for care. Thus, the decision to close a wound must be individualized.

Some wounds should be allowed to heal by *secondary intention* (secondary closure), although scar formation may be more unsatisfactory. Infected wounds, ulcers, and many animal bites are best left to heal by granulation and reepithelialization. Human bites over the metacarpophalangeal joints (clenched-fist bites) are especially prone to infection and should not be closed. Puncture wounds to the foot, with only a small laceration and a low concern for cosmetic results, may also be left open. A small sterile wick of iodoform gauze may be placed inside the wound to separate the edges. This gauze can be removed after 2 to 3 days, and the subsequent granulation tissue will aid healing.

If a wound is not closed initially, *delayed primary closure* (tertiary closure) should be considered after the risk of infection decreases, about 3 to 5 days later. This is recommended for selected heavily contaminated wounds and those associated with extensive damage, such as high-velocity missile injuries, crush injuries, explosion injuries of the hand, and selected bite wounds. The wound should be cleaned and debrided and covered at the time of initial presentation and then reassessed in a few days for infection. It is believed that a contaminated but healing wound gradually gains sufficient resistance to infection to permit uncomplicated closure at a later time. This may still reduce discomfort and lead to a better cosmetic result than that with no repair. Tertiary closure is used rarely in pediatrics because children have few severely contaminated wounds from farm or industrial injuries.

Management of Lacerations

Preparing the Child and Family

It is important to reassure the child and the family that everything will be done to care for the wound appropriately and to relieve the patient's pain and anxiety. In many cases, early removal of blood and foreign material from the surface of the wound is reassuring. Also, carefully chosen words will reduce fear and pain from the procedure. The physician must honestly warn the patient of an impending painful stimulus but may leave open the possibility that it may not hurt as much as the child thinks. Appearing unhurried and confident, giving the child some control of the situation, and explaining the upcoming procedure seem to help reduce anxiety and pain. The parent(s) and the child should be informed that steps would be taken to make the procedure as quick and painless as possible, such as with the use of topical anesthetics. The clinician should provide an age-appropriate empathic explanation, rather than give cold, impersonal instructions about a painful procedure to reduce anxiety. Prepare frightening instruments, such as needles and scalpels, away from the child. Allow the child to listen to music or view age-appropriate, entertaining videos during the procedure because this may serve as a distraction (see Chapter 4).

When parents are inclined to remain in the room during the procedure, they should be encouraged to do so. Inviting the parent to be in the room increases their level of confidence in the physician and can improve their overall satisfaction with the visit. Most parents want to be present during wound repair in the ED, and most can be a stabilizing force if properly oriented. The parent can reassure or distract the child with a story while maintaining physical contact under necessary drapes and restraints. It is usually best if the parent is sitting down and focusing on the child, rather than directly observing the procedure.

Appropriate use of *sedation* and *local anesthetics* is essential for successful repair of lacerations in children and will reduce the need for restraint devices (see Chapter 4). Not all children will receive sedation and some children younger than 4 years will need to be placed in a restraining device, such as a papoose board, for better immobilization. Restraint is needed to ensure the child's safety, protect him or her from self-injury, and allow for more rapid completion of the procedure. Because the child may get excessively warm while in the papoose board, it is important to ensure proper ventilation and assess the child's comfort during the restraint process. A caring, but firm, nurse or assistant is often needed to further immobilize the injured body part and complete the procedure successfully. It is better to use such hospital personnel instead

of parents to immobilize a child. A school-aged child can usually cooperate without restraint.

Preparing the Wound

Hair near the wound usually creates minimal difficulty during repair and generally does not need to be removed. In any case, nearby hair should not be closely shaved because this may damage hair follicles and increase infection. Instead, the hair should be clipped with scissors when necessary. Alternatively, petroleum jelly can be used to keep unwanted scalp hair away from the wound while suturing. Hair over the eyebrows should not be removed because this may lead to abnormal or slow regrowth.

It is essential to *clean the wound periphery* at the time of wound evaluation. Povidone-iodine solution (a 10% standard solution) is often used because it is a safe and effective antimicrobial agent with little tissue toxicity. This solution may be diluted with saline 1:10 to create a 1% solution. Use of chlorhexidine or povidone-iodine surgical scrub preparations, hydrogen peroxide, or alcohol in the wound itself is not recommended. These may irritat tissues and may increase infection by damaging white blood cells.

Wound irrigation is extremely important to reduce bacterial contamination and prevent subsequent infection. It is often necessary to anesthetize the wound before thoroughly cleansing. Taking universal precautions, the wound should be irrigated with normal saline, about 100 to 200 mL for the average 2-cm laceration. More may be needed if the wound is unusually large or contaminated. Use a large syringe (20 to 50 mL) with a splash-guard (20-gauge bore) attached to the end to reduce splatter during the irrigation. With the splash-guard almost touching the skin surface and the tip of the syringe about 2 cm from the wound, the clinician should apply firm pressure to the plunger. This technique is usually capable of generating 5 to 8 lb psi of pressure, which is considered the ideal pressure for wound irrigation. Consider warming the saline before irrigation because this may be more comfortable. Tap water has been used instead of saline and is equally effective at irrigating wounds without increasing the risk of infection. Soaking the injured body part should be avoided because this may lead to maceration of the wound and edema.

Scrubbing the wound should be reserved for particularly "dirty" wounds in which contaminants are not effectively removed with irrigation alone. Use topical or infiltrative anesthetics for pain control before scrubbing. It may be necessary to extract some foreign material with fine forceps if it remains adherent after copious irrigation. This will avoid tattooing of the skin and reduce the risk of infection.

In rare cases, the wound must be extended with a scalpel to allow proper exploration and cleaning. The physician should trim irregular lacerations and excise necrotic skin but should not make dramatic changes in the wound on a routine basis. Devitalized tissue should be removed only if it looks ischemic or is otherwise clearly indicated. Only an experienced physician should attempt to remove more than a small amount of tissue. Subcutaneous fat can be safely and easily removed if it seems to interfere with wound closure. It is wise to remove such fat carefully, in small quantities, to avoid disruption of small vessels and cutaneous nerve branches. Debridement is advantageous because it creates well-defined wound edges that can be more easily apposed. However, excessive removal of tissue can create a defect that is difficult to close or may increase tension at the wound margin such that scarring is more likely. Avoid removal of facial fat because this may leave an unsightly depression.

Examine the wound further after cleansing and debridement. After exploration, it is wise to reevaluate the decision to close the wound primarily. When proceeding further, the clinician should wash hands carefully before donning sterile gloves. Although some studies report no increased risk of infection with nonsterile gloves, most still recommend using latex-free, nonpowder, sterile gloves for wound repair. Sterile masks are not helpful in reducing wound infections, but a facial splash-shield is useful to protect the clinician. The area surrounding the wound should be appropriately draped before surgical repair. However, if a young child is particularly upset by facial drapes, they can be omitted. Proper cleaning of the wound is more important to uncomplicated healing than meticulous attempts to avoid introduction of small numbers of bacteria by preserving a sterile field.

Wound Closure

Equipment

Suture material must have adequate strength while producing a little inflammatory reaction. Nonabsorbable sutures such as monofilament nylon (Ethilon) or polypropylene (Prolene) retain most of their tensile strength for more than 60 days and are relatively nonreactive. Thus, they are appropriate for closing the outermost layer of a laceration. With monofilament nylon, it is important to secure the knot adequately with at least four to five throws per knot. Polypropylene is useful for lacerations on the scalp or eyebrows because it is more visible and thus easier to remove, although it is somewhat more difficult to control while suturing. Silk is rarely used now because of increased tissue reactions and infection.

In many cases, it is appropriate to use fine, absorbable (synthetic) sutures such as Dexon®, Monocryl®, or Vicryl® in deeper, subcuticular layers. These materials may elicit an inflammatory response and may extrude from the skin before they are absorbed if they are placed too close to the skin. When subcuticular sutures are used, they should be placed on the deeper surface of the dermis and epithelial margins may be approximated with tape strips. Synthetic absorbable sutures are less reactive than chromic gut and retain their tensile strength for long periods, making them useful in areas with high dynamic and static tensions. Absorbable sutures are advantageous for intraoral lacerations. Some recommend using rapidly absorbable sutures (fast-absorbing gut) for skin closure of facial or scalp wounds in children because suture removal is avoided. Equally acceptable cosmetic results are found with absorbable sutures compared with nonabsorbable sutures in pediatric facial laceration repair.

A 3-0 suture is recommended for tissues with strong tension, such as fascia, and a 4-0 suture is recommended for deep tissues with light tension, such as subcutaneous tissue. Skin is best closed with 4-0 to 7-0 sutures and oral mucosa with 3-0 to 4-0 sutures. The physician should use the finest sutures (6-0) for wounds of the face; heavier sutures for scalp, trunk, and extremities (4-0 or 5-0); and 3-0 or 4-0 for thick skin, such as the sole of the foot, or over large joints, such as the knee.

Needles are available in various forms, including cuticular, plastic, and "reverse cutting." The reverse cutting needle is used most for laceration repair. Its outer edge is sharp so as to allow for atraumatic passage of the needle through the relatively tough dermis and epidermal layers; this minimizes cutting of the skin where suture tension is greatest. A higher-grade plastic needle (designated P or PS) should be used for repairs on the face. A small needle (e.g., P3) should be used for wounds that require fine cosmesis. Needles come in various sizes such as 3/8 and 1/2 circle. Clinicians may develop a preference for a specific needle. However, in general, a 3/8 reverse cutting needle satisfies most needs.

General Principles

Perhaps, the two most important goals of suturing are to match the layers of the injured tissues and to create eversion of the wound margins so that they will flatten as the wound heals. Layers on one side of a wound should be sutured to the corresponding, matching layers on the other side. First, all layers of skin that have been injured should be identified. Then, an attempt should be made to appose each layer (muscles, fascia, subcutaneous tissue, and skin) as nearly as possible back to its original location. This is achieved by carefully matching the depth of the bite taken on each side of the wound when suturing.

Proper *suture placement* should result in slight eversion of the wound so that there is no depressed scar when remodeling takes place. Eversion may be achieved by slight thumb pressure on the wound edge as the needle is entering the opposite side. Sutures should take equal bites from both wound edges so that one margin does not overlap the opposite margin when the knot is tied. Wound-edge eversion is best achieved by taking proper bites while suturing, not by pulling the knot tightly (Fig. 106.2).

Suture placement may be deep or superficial. Deep sutures reapproximate the dermal layers of skin and do not penetrate the epidermis. They help relieve skin tension and improve the cosmetic appearance by reducing the width of the scar. They should be avoided in wounds prone to infection because they will further increase the risk of infection. To secure a deep suture, the needle is placed at the depth of the wound and removed at a more superficial level. The needle is then inserted superficially into the opposite side of the wound and exit out deeply so that the knot is buried within the wound. The needle end and free end of the suture should be on the same side of the loop before the knot is tied (Fig. 106.3). The simple interrupted technique (described next) with absorbable suture material should be used.

Superficial or percutaneous sutures are passed through the dermis and the epidermis and leave the knot visible at the skin surface. Skin should be closed with a minimal amount of tension. Sutures should be pulled tightly enough to approximate the wound edges but not so tightly that they cause tissue necrosis. Sutures that seem well placed initially may begin to cut into the tissue in the next few days because of swelling and inflammation. There is no need to tightly close the skin if other layers have been well sutured. Scalp wounds are an exception. They are under considerable tension, and the knots in this location should be pulled firmly to keep the skin together. The wound will be hidden by hair, so the skin can be pulled more tightly than elsewhere. Firm, but not strangulating, apposition of the wound will also help with hemostasis.

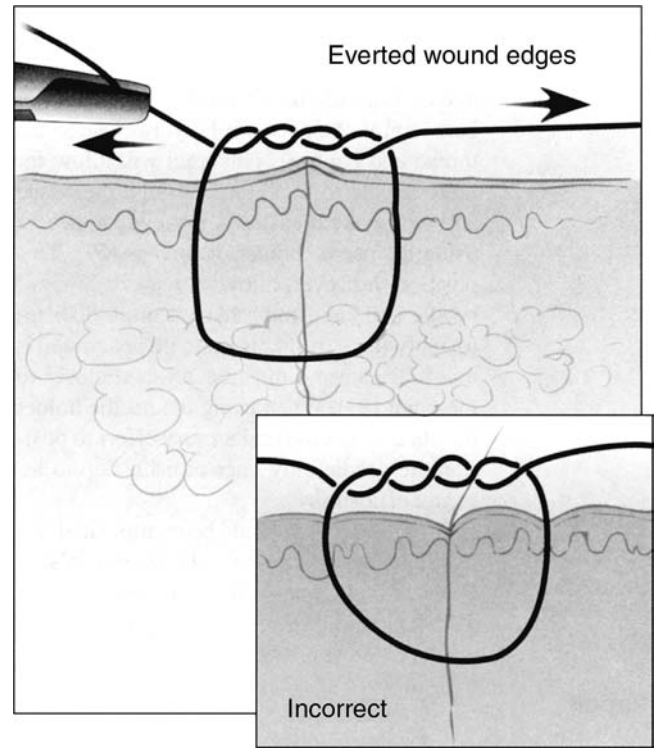

FIGURE 106.2 Suturing technique for wound-edge eversion.

To ensure proper alignment, the first suture may be placed at the midpoint of the wound, with subsequent sutures then placed in a bisecting fashion lateral to the midpoint. Use of forceps to hold tissue should be encouraged because this allows the operator to precisely pass the needle through the desired points alongside the wound edge. However, forceps use should be kept to a minimum during the repair to avoid tissue damage.

Suture Technique

Skin wounds can generally be repaired using interrupted suturing. To place a *simple interrupted suture*, the needle is held upside down and the wrist is pronated as the needle enters the skin at a 90-degree angle. The needle tip will then move farther away from the wound margin and penetrate deeply. Thus, more tissue is at the depth of the wound, and this causes the wound to evert. Sutures should be placed about 2-mm apart and 2 mm from the wound edge on delicate areas such as the face. More sutures placed closer together decrease wound tension and leave a less noticeable scar. Larger bites should be used for body parts where cosmesis is less important.

Use an instrument tie to secure the suture (Fig. 106.4). The knots should ideally be placed on one side of the wound. Knots placed directly over the wound increase inflammation and scar formation. On the first throw, the physician should wrap the needle holder twice to create a surgeon's knot and then wrap subsequent throws a single time. The first and second throws should be snug enough to approximate the wound edges but not so tight that tissue is strangulated. All subsequent knots are squared to maintain the closure. Four or five throws are usually required to keep the knot from unraveling.

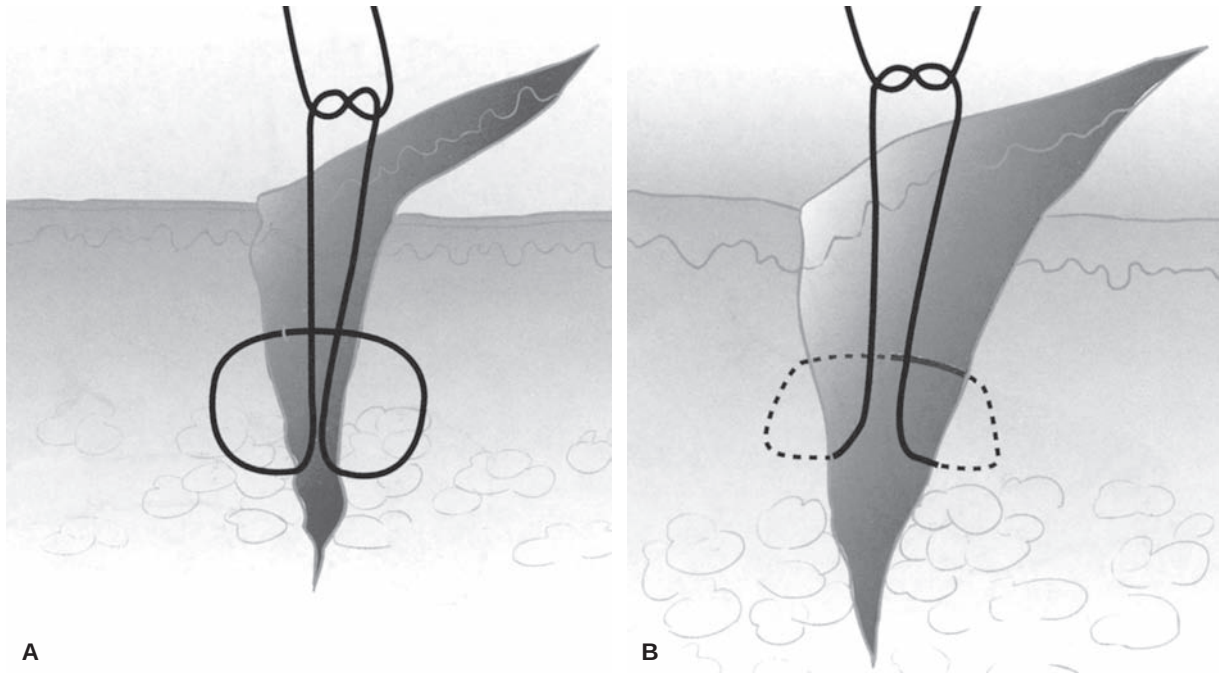

FIGURE 106.3 **A:** The buried subcutaneous suture. **B:** The horizontal dermal stitch.

A "loop knot" is effective in apposing the wound edge with minimal tension. This involves placing a surgeon's knot, using the instrument tie, followed by a loop. The surgeon's knot will "give" slightly should edema develop subsequently. The loop knot allows easier, painless removal of sutures because it creates a free space between the suture and the skin (Fig. 106.5).

Running or *continuous sutures* can be applied rapidly to close large, straight wounds or multiple wounds. In this technique, the suture is not cut and tied with each stitch. The first suture is placed at one end of the wound and a knot is tied, cutting only the end of thread not attached to the needle. The next loop is placed a few millimeters away and continuous loops of equal bites are made to close the wound. On the final loop, because the suture is not completely pulled through, a small loop remains on the opposite side of the wound. Now, the knot can be tied using the preceding loop of suture (Fig. 106.6). This type of stitch is more likely to leave suture marks if not removed in 5 days. Apposition of the edges and eversion are more difficult to achieve with this stitch, and the entire suture line can unravel if the suture breaks anywhere along the repair. However, the technique gives the advantage of having equal tension on the wound edges.

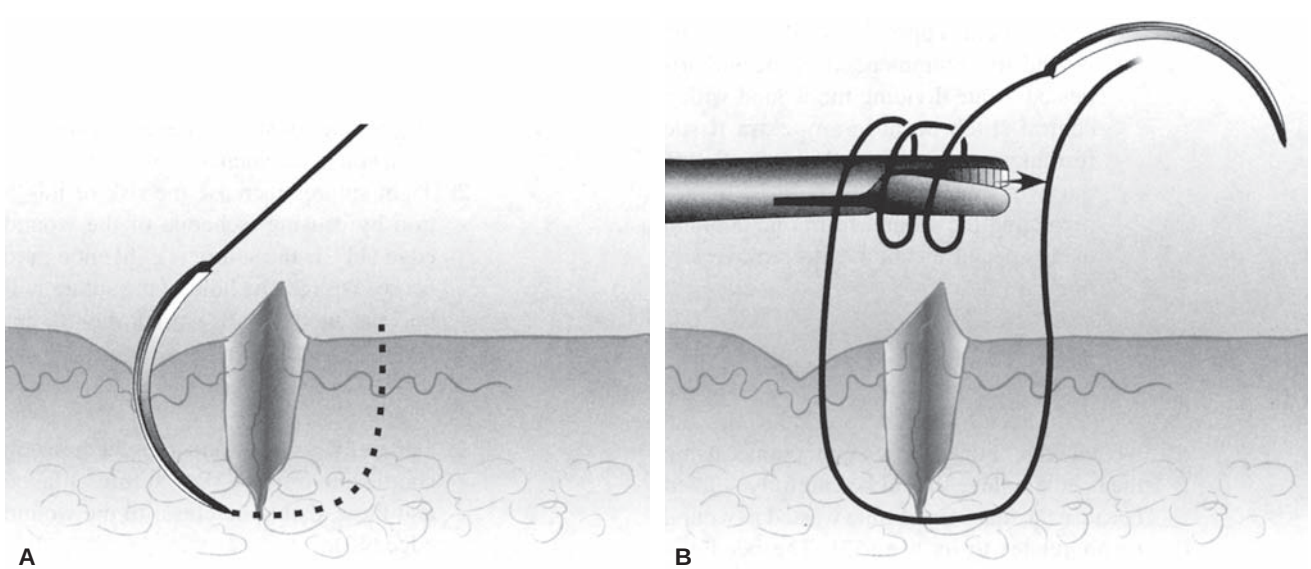

FIGURE 106.4 Simple interrupted skin suture secured with instrument tie.

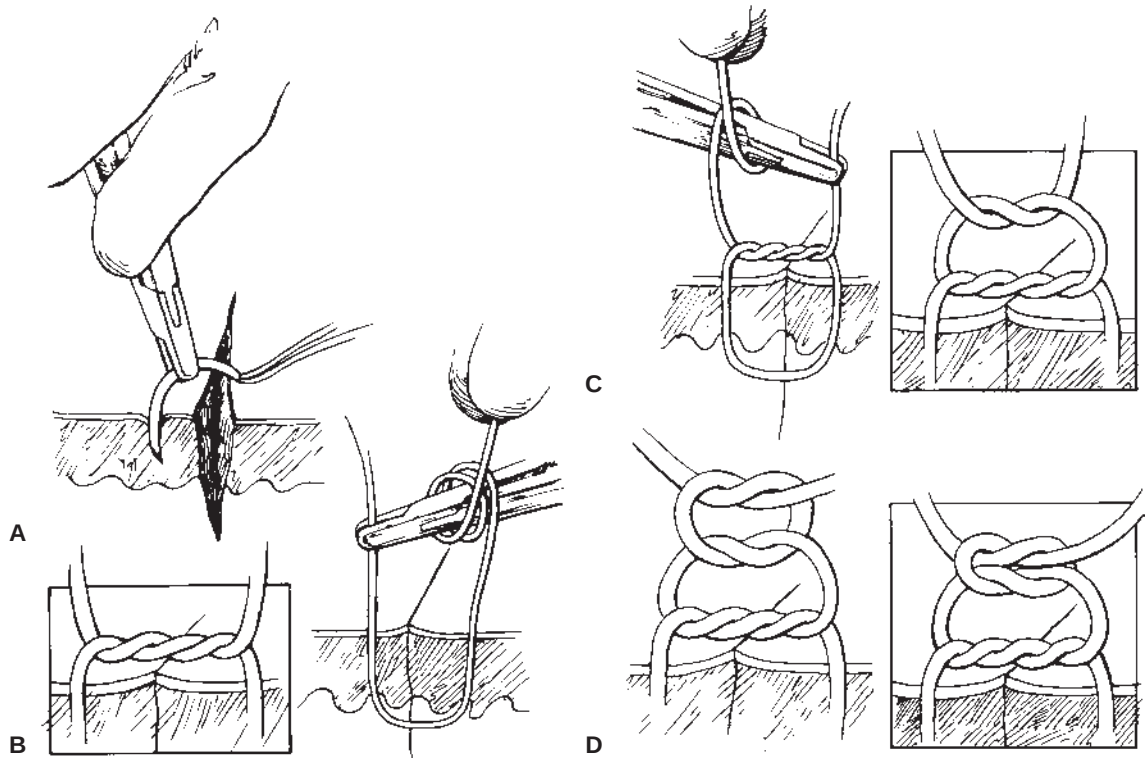

FIGURE 106.5 Placement of a "loop knot" in conjunction with simple sutures of the skin using an eversion technique. **A:** The needle enters the skin at a right angle in a way that allows somewhat less skin and more subcutaneous tissue to be caught in the passage of the needle. The needle should incorporate the same amount of skin and subcutaneous tissue on each side. The ideal suture material for placing a "loop knot" is 4-0 nylon. One can also use 5-0 nylon. **B:** The first knot should be a surgeon's knot drawn down gently to barely coapt the skin edges. **C:** The second tie should be placed to produce a square knot but should be drawn to produce an approximate 2- to 3-mm loop. **D:** The third tie should be placed to produce a square knot. This third tie can be secured tightly against the second tie, preserving the loop and allowing for some spontaneous loosening of the surgeon's knot as later edema develops.

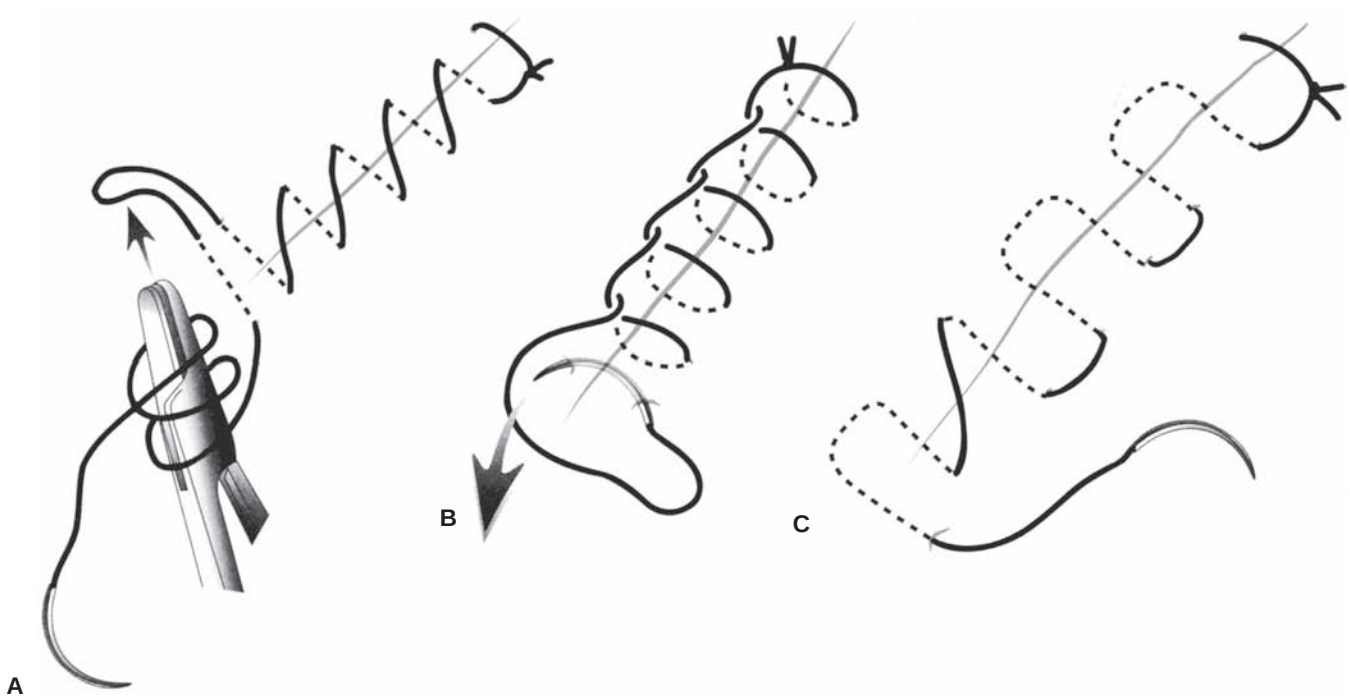

FIGURE 106.6 Continuous skin sutures. **A:** The simple continuous running stitch. **B:** The continuous interlocking skin stitch. **C:** The running lateral mattress stitch or continuous half-buried horizontal mattress stitch.

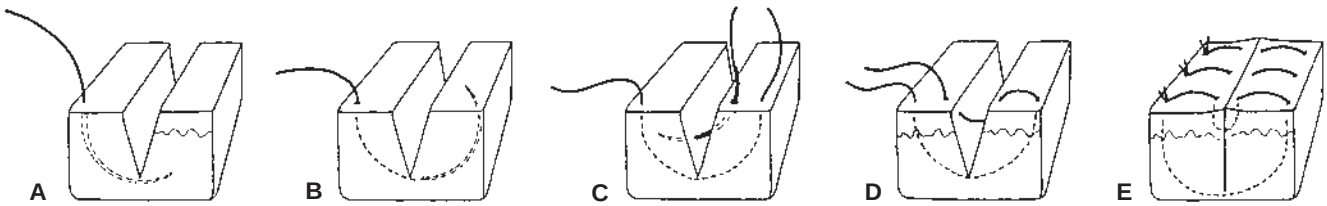

FIGURE 106.7 **A–E:** The vertical mattress suture. After initially placing a simple interrupted stitch with a somewhat larger bite, make a backhand pass across the wound, taking small, superficial bites. When the knot is tied, the edges of the laceration should evert slightly. (Adapted from Grisham J. Wound care. In: Dieckmann RA, Fiser DH, Selbst SM, eds. *Illustrated textbook of pediatric emergency & critical care procedures*. St. Louis, MO: Mosby, 1997:676. Reprinted with permission.)

The *vertical mattress stitch* is useful for deep wounds in which it may be difficult to tie a simple, deep, interrupted suture. It reduces tension on the wound and may close dead space within the wound. It essentially combines a deep and superficial stitch in one suture. The needle is placed deep within the wound (about 3 mm from the wound edge) and brought out to the opposite skin surface. It is then brought across the epidermis to approximate the epidermal edges (Fig. 106.7). This stitch takes more time to accomplish and produces more cross marks, but it provides excellent wound eversion and apposition of the wound edge. Too tight a knot will pucker the wound.

The *horizontal mattress stitch* reinforces the subcutaneous tissue and effectively relieves tension from the wound edges. It does not provide wound-edge approximation as well as the vertical mattress stitch. The needle is passed 0.5 to 1 cm away from the wound edge deeply into the wound. It is then passed through the opposite side and reenters the wound parallel to the initial suture. To avoid "buckling" and to provide some eversion of the wound edges, the skin must be entered perpendicularly and the wound must be entered and exited at the same depth (Fig. 106.8).

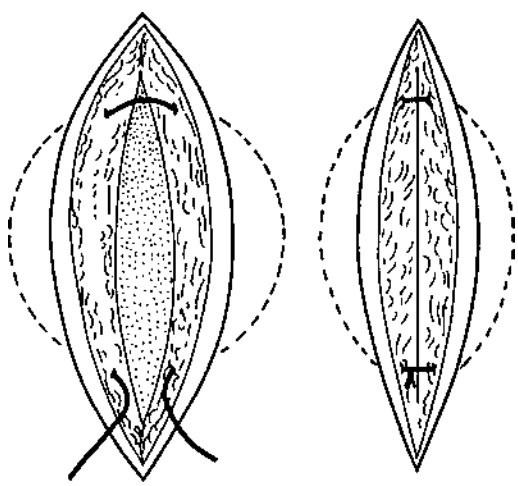

FIGURE 106.8 The horizontal mattress stitch is useful for closing the deep layer in shallow lacerations and in body areas with little subcutaneous tissue. Certain dyed suture materials may cause a tattooing of the skin if placed in such a shallow position. (Adapted from Grisham J. Wound care. In: Dieckmann RA, Fiser DH, Selbst SM, eds. *Illustrated textbook of pediatric emergency & critical care procedures*. St. Louis, MO: Mosby, 1997:678. Reprinted with permission.)

The *modified horizontal mattress stitch* (half-buried) is often used to close a flap. It is also called the corner stitch. It relieves intrinsic tension and vascular compromise when approximating the tip of the flap. Using 5-0 or 6-0 nylon, the needle should enter the intact skin across from the apex of the flap and exit the wound just below the subcuticular plane. The needle should be brought to the tip of the flap, entering and exiting at the subcuticular plane. Then, the needle is brought across the edge of the flap in the subcuticular plane and exit out of the skin. A knot should be tied in the usual manner and the tip of the flap brought to the apex of the wound (Fig. 106.9).

Placing the needle in the flap edge first can also repair wounds with flaps. The edge of the flap can then be moved back and forth until proper alignment with the opposite fixed side is obtained. After the tip of the flap is sutured, the sides of the flap are brought together. For wounds with several stellate flaps, subcuticular or subcutaneous sutures should be used to hold the tips of the flap together. Then, a single suture at the tip will provide good apposition without further damaging the tip of the flap. Other interrupted sutures can be placed on the lateral margins of the wound to provide further support. If the wound has many narrow-base stellate flaps or necrotic flap tips, the wound may be better managed with excision and simpler repair (Fig. 106.10).

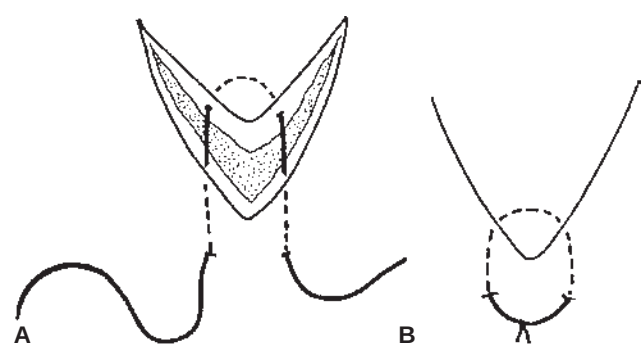

FIGURE 106.9 **A** and **B:** The corner stitch. Also called the half-buried horizontal mattress stitch, this technique allows repair of flap-type lacerations without further compromising blood flow. Place additional simple interrupted sutures along the sides of the flap if necessary. (Adapted from Grisham J. Wound care. In: Dieckmann RA, Fiser DH, Selbst SM, eds. *Illustrated textbook of pediatric emergency & critical care procedures*. St. Louis, MO: Mosby, 1997:676. Reprinted with permission.)

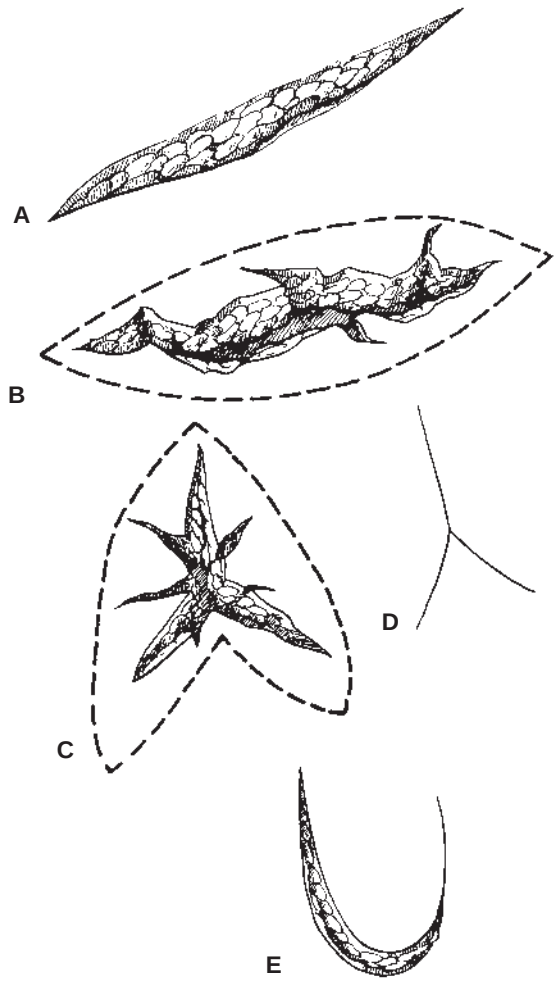

FIGURE 106.10 Variation in laceration injuries and suggestions for management: simple laceration (**A**), elliptical excision of damaged wound margins (**B**), excision and closure of stellate laceration (**C** and **D**), and flap-type laceration (**E**).

Alternative Wound Closure Techniques

Tape causes no suture marks, minimal tissue reaction, and fewer wound infections than do sutures. Tape strips, cut to size, can be used to take up tension at the wound margins and can be placed between sutures. These strips are also useful as the only means to close simple lacerations that barely extend through the dermis and they may be as useful as tissue adhesives for facial lacerations in children. Multiple tangential, triangular skin flaps (e.g., those created when an unrestrained passenger hits the windshield of a car) are closed well with tape strips. Likewise, old or contaminated wounds, such as dog bites on the extremities, can be loosely approximated with skin tape.

When tape is used, the wound should be cleansed as any other wound. Care must be taken to properly realign the dermis and the epithelium. If the tape is pulled too tightly, the margins of the wound may overlap, causing the wound to heal with a raised ridgelike area where the overlap occurred. The tape is applied perpendicularly across the wound with some space between to allow the wound to drain. In some cases, an adhesive such as benzoin is applied to the adjacent skin (not the wound) to keep the tape strips more securely in place. Some recommend leaving the taped wound uncovered because a bandage may increase moisture and cause the tape to fall off prematurely.

Tape strips should not be used on wounds subject to tension, such as those over flexor surfaces of joints. They should not be applied in areas of the body that are moist, such as the palms or axillae, because they will not adhere. They may be impractical for small children, who may inadvertently remove them from the face.

Staples can be applied more rapidly than sutures and have a lower rate of infection, with less of a foreign-body reaction. They are best for wounds of the scalp, trunk, and extremities when saving time is important. Therefore, they are particularly helpful when treating mass casualties. Staples are left in place for the same length of time as sutures. They are somewhat more painful to remove and should be removed with a specially designed instrument to avoid tissue damage. Staples do not allow for meticulous cosmetic repair, as do sutures. Thus, they should not be used for lacerations of the face, neck, hands, or feet. They should not also be used if the patient requires magnetic resonance imaging or computed tomographic scanning.

Tissue adhesives, or skin glues, such as octylcyanoacrylate, have been used to close wounds for many years. They allow rapid and painless closure of wounds. Anesthesia is unnecessary, unless painful irrigation or exploration of the wound is anticipated. No removal is needed because the adhesives slough off after 7 to 10 days. They provide an excellent cosmetic result in comparison with sutures. One study using plastic surgeons blinded to the method of repair ranked the wounds repaired with tissue adhesives to be cosmetically equal to sutured wounds at 2-month and 1-year follow-up visits.

Tissue adhesives act to decrease wound infections because they have antimicrobial effects against gram-positive organisms. Dehiscence rates (1% to 3%) are similar to that of sutured wounds. They are less expensive than sutures because little equipment is needed and personnel time is reduced. Studies have noted that patients and families of small children prefer them to sutures. Routine follow-up is not needed for uncomplicated wounds, and no long-term complications have been reported. Newer products such as high-viscosity octylcyanoacrylate tissue adhesives are less likely to migrate during repair, making wound repair easier to accomplish.

Before application of the tissue adhesive, the wound is cleaned and hemostasis is achieved with dry gauze and pressure. The wound edges are held together manually or with forceps while the tissue adhesive is applied along the surface of the wound. The tissue adhesive should not be applied to the inside of the wound because it will act as a foreign body and inhibit healing. The wound is then held in place for about 20 to 30 additional seconds to obtain adequate bonding. One study reported that if malalignment is noted, the adhesive could be removed with forceps and reapplied without further complication. The wound is then covered carefully so that bandage removal will not pull off the tissue adhesive. Avoid routine application of antibiotic ointments by parents, as these will dissolve the adhesive and cause dehiscence. However, this interaction is beneficial when adhesive (available over the counter) is inadvertently applied to areas such as the eyelashes. Any antibiotic ophthalmic ointment can be used to dissolve the adhesive when needed.

TABLE 106.2

COMMON TECHNIQUES OF WOUND CLOSURE

Technique	Advantages	Disadvantages
Sutures	Greatest tensile strength Meticulous closure Low dehiscence rate	Painful Removal needed Slow application Increased tissue reaction Risk of needle stick (clinician)
Staples	Rapid application Low cost Low tissue reaction	Not for use on the face (less meticulous closure)
Tissue adhesive	Rapid application Painless No removal needed Low cost No risk of needle stick (clinician)	Lower tensile strength Not for use on joints
Tape strips	Rapid application Painless Low cost Low infection risk Least tissue reaction	High risk of dehiscence Not for use in moist areas, young children

Tissue adhesives should be used only to close skin of superficial wounds. For many lacerations, deep absorbable sutures will also be needed because the glue has less strength than most sutures. Skin glues should not be used for wounds subject to great tension, such as on the hands or joints.

Table 106.2 summarizes advantages and disadvantages of several techniques available for wound closure.

Dressings

Dressings protect the wound from further injury and contamination. They also help absorb secretions (not likely with small wounds) and immobilize the injured part. Some use a nonadherent sterile dressing (e.g., Telfa, Xeroform) to cover the wound. This prevents the wound edges from sticking to the dressing. Then, a second layer of absorbent gauze is applied and a third layer of gauze wrap or tape is used to stabilize the other two. This protects and immobilizes the area while absorbing exudate from the wound surface.

For most simple wounds, it is adequate to cover the wound with dry sterile gauze after applying topical antibacterial ointment. Some studies indicate that topical antibiotic ointments may reduce infection and prevent scab formation by lubricating the wound edges. This allows for more rapid epithelialization of the wound.

For the face and trunk, a large bulky dressing is not practical. Thus, for small wounds in these areas, a clear plastic adhesive such as Tegaderm should be used to secure the bandage. Rolls of cotton or stretchable tube gauze can be used for larger wounds to keep the sterile dressing in place. This keeps young children from touching the wound. Scalp wounds are usually not dressed. Patients can generally wash their hair gently after 24 hours.

For children who are active, it may be best to keep the wound covered until sutures are removed. The dressing should remain in place for 24 to 48 hours after which epithelialization is usually sufficient to keep the wound from gross contamination. Then, the bandage should be changed daily and the wound inspected. Any dressing should be changed if it becomes soiled, wet, or saturated with drainage because the wet dressing may be a source of infection.

It may be advisable to splint the wound if it overlies a joint. This is most important for active children who will likely resume full activity soon after the injury. Some even recommend splinting nearby joints for any large laceration of an extremity to reduce stress across the wound even if it does not involve a joint itself. This should be done for no more than 72 hours to facilitate function. The injured extremity should be elevated to provide comfort and reduce edema.

Systemic Antibiotics

Use of prophylactic systemic antibiotics for wound management is controversial. Studies demonstrating proven benefit to the use of antibiotics are lacking. They may lead to allergic reactions, growth of resistant organisms, and unnecessary expense. Thus, they are not recommended for routine use. Decontamination with proper irrigation is more efficacious than the use of antibiotics to prevent wound infection. Consider antibiotics for heavily contaminated wounds that are at greater risk for infection. They are often used for human and cat bites (see Chapter 83), crush injuries, stellate lacerations, and very large wounds (exceeding 5 cm). Other high-risk wounds include intraoral lacerations and wounds of the hands, feet, and perineum. Similarly, open fractures, exposed joints and tendons, and any tetanus-prone wound may benefit from antibiotics. Likewise, wounds that result in exposed cartilage of the nose or ears or extensive facial wounds that may involve contamination from adjacent nasal passages are often treated with antibiotics. It may also be reasonable to use

TABLE 106.3

TETANUS PROPHYLAXIS, CHILDREN ≥ 7 YEARS OLD

Prior tetanus toxoid immunization (doses)	Clean minor wound	All other wounds
Uncertain (or <3)	Td or Tdap	Tdap or Td and TIG
Three or more (most recent >10 yr ago)	Td or Tdap	Td or Tdap
Three or more (most recent within past 5 yr)	None	None
Three or more (most recent between 5 and 10 yr)	None	Td or Tdap

Tdap, tetanus toxoid, reduced diptheria toxoid, and acellular pertussis; Td, adult formulation of diphtheria, tetanus toxoid; TIG, tetanus immunoglobulin (dose: 250–500 units intramuscularly).

antibiotics for wounds (other than scalp lesions) when repair takes place more than 12 hours after injury. They may be justified for wounds that occurred in a contaminated environment, such as a farm or roadside. Injured immunocompromised patients may warrant antibiotics.

Usually, a first-generation cephalosporin or penicillinase-resistant penicillin is used to cover staphylococci and streptococci. Amoxicillin-clavulanic acid is recommended for wounds created by mammalian bites (see Chapter 83). Additional coverage for gram-negative organisms with an aminoglycoside may be worthwhile for heavily contaminated open fractures.

Tetanus

Immunization status of all injured patients should be documented in the medical record. If the wound is clean and minor and the patient has received three previous doses of tetanus toxoid, a booster of tetanus toxoid is given only if 10 or more years have passed since the last dose. If a patient has received three or more previous tetanus immunizations but the wound is not a clean, minor laceration, tetanus toxoid is indicated if the last dose was given more than 5 years earlier.

In many cases, the tetanus immunization record is unknown. If tetanus status is unknown and the wound is not clean or minor, tetanus toxoid and tetanus immunoglobulin (TIG) are indicated. Wounds involving massive tissue destruction and contamination may also require TIG. Patients with such wounds should be admitted to the hospital (Table 106.3).

Discharge Instructions and Suture Removal

Careful discharge instructions, regarding wound care, covering the wound, when to get the wound wet, and how to dry it, are extremely important. The family should be warned about signs of infection. Specifically, they should be told to return for medical care if the wound develops increasing pain, redness, edema, and/or wound discharge, or if the child develops a fever. Analgesics may be given for minor pain, but worsening pain should always prompt a wound check. The family should also be informed that the wound was inspected for a foreign body but that there is still a possibility of a retained foreign body or an undetected injury that may require further treatment. Parents should be told that no matter how skillful the operator is, every laceration leaves some scar. The appearance of the scar will change during the next several months, and the scar's appearance will not be complete for about 6 to 12 months. Patients and parents should be advised to keep the injured part elevated when possible. A sling can be provided to accomplish elevation of the upper extremities. Some recommend that healing skin should not be exposed to sunlight for 6 months after injury because this could lead to permanent hyperpigmentation.

Follow-up care should be arranged for 24 to 48 hours in all but very simple wounds. The wound can then be reinspected for signs of infection, and healing can be assessed.

Wounds closed with tape strips do not require removal of the tape because these will fall off spontaneously. Skin glue also sloughs spontaneously. However, nonabsorbable sutures should be removed at the appropriate time, depending on the location of the injury. The importance of timely removal should be stressed to the patient and the family. Sutures should be removed when fibroblastic proliferation at the wound interface is strong enough to take the place of sutures. Removing sutures too early may lead to dehiscence and widening of the scar. Sutures left in too long may create an unnecessary tissue reaction and result in visible cross-hatching ("railroad ties").

Wounds on the scalp or face are nourished by a better blood supply and generally exhibit more rapid healing. Sutures in these areas are removed more quickly than those at other locations to avoid unsightly tracts.

When sutures are subject to considerable tension (over joints and on the hands), they should be left in place longer (Table 106.4). After the removal of sutures, it is often necessary to reinforce the healing wound with tape strips to prevent dehiscence.

In the first 24 to 48 hours, wound dressings should be changed only if wet or soiled. After that, bathing can be permitted as long as the wound is present and then patted dry and

TABLE 106.4

TIMELY SUTURE REMOVAL

Wound location	Time of removal (days)
Neck	3–4
Face, scalp	5
Upper extremities, trunk	7–10
Lower extremities	8–10
Joint surface	10–14

TABLE 106.5

REDUCING RISK IN WOUND MANAGEMENT

1. Take thorough history
2. Perform a careful examination
3. Obtain a consult for complex wounds
4. Obtain radiographs if a foreign body or fracture is suspected
5. Document carefully (inspection, irrigation, and function)
6. Communicate with parents (likely scar)
7. Arrange follow-up, recheck

covered again. There is no proven harm to exposing the sutures to soap and water for short periods.

Table 106.5 summarizes an approach to reduce risk in managing wounds in the ED.

CARE FOR COMMON WOUNDS

The principles of wound care discussed earlier should be applied in repairing any of the wounds discussed in this section. These principles include evaluation of the wound by history, physical examination, and when indicated, radiographic examination. After the wound is evaluated, the feasibility of closure and the possible need for consultation with a surgeon should be addressed. The following section discusses some of the commonly encountered wounds in children.

Facial and Oral Wounds

Forehead Lacerations

Forehead lacerations are common in early childhood. Most of these injuries occur secondary to falls on objects or furniture such as coffee tables. Most of these lacerations are simple and not associated with any other significant injuries. However, complete evaluation of the head and neck should be carried out. Superficial transverse lacerations of the forehead are easy to manage, and the outcome is usually favorable. Closure with simple or continuous cuticular sutures using 6-0 nonabsorbable material is recommended. Deeper transverse lacerations involving the deep fascia, the frontalis muscle, or the periosteum should be repaired in layers. Absorbable 5-0 material such as coated Vicryl or catgut can be used. If the deeper tissue plains are not closed, the function of the frontalis muscle, eyebrow elevation, may be hampered. Other facial expressions can also be affected because the skin may tether to the scar tissue, bridging the unrepaired gaping tissues.

Vertical forehead lacerations tend to have a wider scar because they traverse the tension lines. Complex forehead wounds, such as stellate lacerations from windshield impact and those with tissue loss, particularly secondary to animal bites, may require consultation with a plastic surgeon. Forehead lacerations are rarely associated with skull fractures, but facial or intracranial injuries should be ruled out.

Lacerations of the Eyebrow

Eyebrow lacerations are common. Repairing an eyebrow laceration is complicated by the presence of hair. It is advisable not to shave the eyebrow for wound preparation because it serves as a landmark during repair. Also, eyebrow regrowth is unpredictable; it may be either slow or incomplete, potentially leading to poor cosmetic outcome. Debridement, if required, should be minimal and along the same axis of the hair shafts to avoid damage to hair follicles; otherwise, alopecia of the brow will result. Closure with simple interrupted stitches using nonabsorbable material is usually sufficient. Attention must be paid to avoid inverting the hair-bearing edges into the wound. It is also important to pay attention to proper alignment of both ends along an eyebrow wound.

Lacerations of the Eyelid

Most eyelid lacerations are simple transverse wounds of the upper eyelid just inferior to the eyebrow. Repairing these wounds does not require any special skills. Some lacerations in the transverse crease of the eyelid will heal just fine if left alone. However, recognizing complicated eyelid lacerations is crucial for proper repair and good outcome. Vertical lacerations involving the lid margin require precision in approximation to avoid deformity and malfunction of the eyelid. Injuries potentially involving the levator palpebrae muscle, medial canthal ligament, or lacrimal duct should be considered for ophthalmologic referral. A high index of suspicion for lacrimal duct injury is particularly important when evaluating a medially positioned lower eyelid laceration. If not repaired, inferior duct injury may lead to chronic tearing, as the lower lacrimal duct is the main drain of tears from the conjunctival sac. Evaluation for an associated injury of the globe is a must, particularly if periorbital fat is exposed or tarsal plate penetration is present.

Lacerations and Blunt Trauma of the External Ear

Although the ears are subject to trauma because of their exposed position, lacerations involving the ears are rather rare. To obtain the best results in caring for injuries involving the external ear (auricle or ear lobe), attention must be paid to certain anatomic and physiologic facts. The auricle contains a cartilaginous structure that provides the framework for the complex shape of the ear. The pericondrium covering the cartilage provides it with nutrients and oxygen. Separation of the cartilage from the pericondrium because of trauma may lead to necrosis of the cartilage, leaving the auricle deformed. The overlying skin, although thin and with no or little subcutaneous tissue, is well vascularized. Skin flaps with small pedicles often survive and should not be hastily debrided.

Simple auricular lacerations can be repaired without difficulty. To avoid chondritis, approximation of the skin is important so that no cartilage is exposed. Occasionally, debridement of the cartilage is needed to obtain complete coaptation of the wound; however, cartilage debridement should be kept to a minimum. It is imperative to avoid catching the auricular cartilage with the needle tip because the skin and the pericondrium are in close proximity to each other.

Complex auricular lacerations with significant skin damage and involvement of the auricular cartilage can be difficult to repair and may require consultation with a plastic surgeon. In general, when repairing auricular cartilage, a few 5-0 absorbable sutures should be used to approximate the edges. Landmarks of the auricle should be used for proper alignment. The pericondrium should be included in the sutures so that the suture material does not tear through the friable cartilage and also to

ensure restoration of nutrient and oxygen supply. For the same reason, excessive tension should be avoided. Closure of the skin should follow as described previously. If the laceration involves the anterior and posterior aspects of the ear, closure of the posterior aspect first is recommended.

To avoid a deep scar line (notching) in repairing the ear lobe or the auricular rim, the skin edges should be everted at the time of closure because fibrotic tissue will eventually pull the scar line down, leading to notching.

For *partial avulsion* or *total amputation of the ear*, make every effort to reattach the amputated part because tissue survival and cosmetic outcome are usually favorable. Furthermore, blunt ear trauma can lead to a simple contusion or a significant *subperichondrial hematoma* that can compromise the auricular cartilage. Classically, a significant perichondrial hematoma is tense and appears as smooth ecchymotic swelling that disrupts the normal contour of the auricle. This injury is particularly common among wrestlers. Auricular hematoma should be promptly drained to avoid necrosis of the cartilage and deformed auricle or cauliflower ear.

After repair of ear lacerations or evacuation of an auricular hematoma, a pressure dressing should be applied. Follow-up in 24 hours to evaluate vascular integrity to the area is recommended.

Lacerations of the Nose

Unlike blunt injuries, lacerations to the nose are unusual. When a laceration results from blunt trauma, careful evaluation of underlying nasal bones and examination for a nasal septal hematoma are essential. Other associated injuries, such as facial bone fractures or injuries to the orbit, should also be ruled out.

The skin overlying the nose is taut and stiff. Approximating the edges of simple, nongaping nasal wounds, mostly along the upper half of the nose, is usually straightforward. Wounds with any gaping, commonly in the lower part of the nose, can be difficult to coapt because of the nature of the skin in this location. The suture material can tear through the skin easily. Absorbable subcutaneous stitches are recommended before skin closure to relieve tension and prevent tearing through the wound edges. Skin closure should be with simple interrupted 6-0 nonabsorbable material. Early removal of the sutures is advised for the same reason.

Full-thickness nasal lacerations involving the alae nasi or entering the vestibule require layered closure. The procedure should begin with the nasal mucosa, using absorbable material, and finished with the skin, preferably using continuous subcuticular intradermal suture technique.

The nasal cartilage, when involved, rarely requires sutures. When alignment is difficult, a few fine sutures (Vicryl or plain catgut) will help hold it in place. When the free rim of the nares is involved, precise alignment is imperative for good cosmetic outcome. For complex nasal lacerations, lacerations associated with fractures, or when there is tissue loss, consultation with an otolaryngologist or a plastic surgeon is recommended.

Lacerations of the Lip

Lip lacerations are a particular concern because of the importance of the lip as a facial landmark. The lip is a vascular structure with multiple layers. The vermilion border, the junction of the dry oral mucosa and the facial skin, serves as an important landmark for proper repair when involved. The relative pallor of the vermilion border to the lip and to the skin easily identifies it. Therefore, the use of epinephrine with local anesthesia should be avoided so the landmark is not obscured. When parted, the vermilion border should be precisely reapposed using a 6-0 suture. The buccal mucosal surface is then closed with 5-0 absorbable material, followed by the skin, using 6-0 nonabsorbable sutures. The parents should be warned that, while the lip is still anesthetized, there is a chance that the child will bite the sutures off and that they should distract the child from doing so. Typically after the local anesthesia has worn off, the site is sore enough so that the child will not attempt to manipulate the area.

In general, lip lacerations should be closed in layers, depending on the depth of the wound. In full-thickness lip lacerations, a three-layer repair is required. The physician should begin with the oral mucosa, using 5-0 absorbable material, followed by the orbicularis oris muscle layer to include the inner and outer fibrofatty layers, and finish with the skin, using 6-0 nonabsorbable interrupted sutures. Small wounds, less than 2 cm in length, on the inner aspect of the lip without communication to the skin surface need not be repaired. External lip wounds not communicating with the mucosal surface can be sutured by single- or double-layer closure, depending on the depth and degree of gaping of the wound. Absorbable sutures (5-0) for the subcutaneous layer and nonabsorbable (6-0) sutures for closure of the skin can be used.

Extensive lip injuries with tissue loss or those caused by electric burns, especially those that involve the angle of the mouth, should be referred to a plastic surgeon. Associated injuries such as dental trauma, mandibular fractures, and closed head injuries should be ruled out.

Lacerations of the Cheeks

When managing lacerations involving the cheeks, the physician must evaluate the integrity of the underlying structures. The parotid gland and duct, the facial nerve, and the labial artery are in close proximity of the surface of the skin and can be injured often as a result of an animal bite. If parotid gland or duct injury is identified, consultation with a surgeon is advised. Puncture wounds resulting from animal bites should be debrided and irrigated thoroughly. Some of these puncture wounds are better off left without closure to reduce infection rate, especially if the cosmetic outcome is not compromised. Otherwise, simple interrupted 6-0 nonabsorbable sutures can be used to close uncomplicated lacerations of the cheeks.

Lacerations of the Tongue

The tongue is a vascular and muscular organ. Tongue lacerations often hemorrhage excessively in the beginning, but the bleeding usually ceases quickly as the lingual muscle contracts. Lacerations of the tongue can pose a challenge to repair not only because of their inaccessibility but also because of the controversy surrounding the indications for closure.

Most tongue lacerations can be left alone with good results. However, large lacerations involving the free edge may heal with a notch causing dysfunction of the tongue. Generally, this type of laceration should be repaired. Large flaps and lacerations that continue to bleed should also be repaired. Assess patients with tongue lacerations requiring repair for potential airway problems, as well as the need for sedation or even

general anesthesia. Often, local or regional anesthesia is sufficient. The mouth should be retained open by using a padded tongue depressor placed on the side between the upper and lower teeth or by using a Denhardt-Dingman side mouth gag. The tongue can be maintained in the protruded position by a gentle pull using a towel clip or by placing a suture through the tip. Interrupted 4-0 absorbable suture, with full-thickness bites to include the two mucosal surfaces and the lingual muscle between, will close the tongue wound and provide hemostasis. Multiple knots and inverted sutures are recommended to prevent the untying of the sutures. Some authors suggest that only deep muscle closure is required because the mucosal surface heals rapidly. As in lip lacerations, children may chew off the stitches. Parents must be warned of this possibility and should attempt to distract the child at least until the local anesthesia wears off.

Lacerations of the Buccal Mucosa

Small, isolated lacerations of the buccal mucosa, mostly from impaction of teeth following falls, require no suturing. Lacerations 2 to 3 cm in length or with flaps are best closed with simple interrupted absorbable material. Coated Vicryl (4-0) on a round needle is preferred because it is less irritating to the child and is easier to work with than with chromic gut. Closure of the mucosal surface in through-and-through lip lacerations should be carried out before closure of the muscle and skin layers. After repair, a soft diet and avoidance of irritating foods should be advised, as well as vigilant mouth hygiene. Evaluation for associated injuries of the teeth or the alveolar margin is imperative.

Fingertip Injuries

Fingertip Avulsions

Fingertip injuries are rather common in children. In young children, most of these injuries are blunt and secondary to entrapment of the finger in closing doors. Most of these injuries are contused lacerations or partial avulsions. Complete amputation of the fingertips is not as common. Sharp injuries are more common in older children and less likely to be associated with fractures. Fingertip injuries should be evaluated clinically for an associated nail bed injury and radiographically for possible fractures of the phalanges. In general, this type of injury is manageable by the emergency physician, especially in preadolescent children, because tissue regeneration is remarkable and management is mostly conservative.

The management of amputations of fingertips (distal to the distal interphalangeal joint) can be approached on the basis of the absence or presence of bone exposure. If no or minimal bone is exposed, conservative management is advised. The wound should be cleansed, dressed in nonadherent gauze, and splinted for protection. Frequent dressing changes and appropriate follow-up should be planned. Antibiotic coverage is recommended. When a significant amount of bone is exposed, consultation with a surgeon should be considered. The treatment of choice usually involves shortening of the distal phalanx and covering the tip with volar skin flap. However, some hand surgeons advocate for various skin-grafting procedures to avoid permanent shortening and deformity. Consider microscopic reimplantation by a surgeon for amputations proximal to the distal interphalangeal joint.

Nail Bed Injuries

Trauma to the distal fingers is often associated with nail and nail bed (matrix) injuries. Nail avulsion can be partial or complete and may or may not be associated with nail bed laceration. An underlying fracture of the distal phalanx may also be present. Injury to the fingertip is often associated with subungual hematoma. In evaluating these injuries, the emergency physician should determine the need to explore the nail bed for a laceration. Unrepaired nail bed lacerations may permanently disfigure the growth of the new nail from the cicatrix nail bed. If the nail is partially avulsed but is firmly attached to its bed, exploring the nail bed is difficult and is probably not warranted. Good outcome is expected because the nail holds the underlying lacerated nail bed tissues in place.

If a subungual hematoma exists, it should be drained (see the following text). When the nail is completely avulsed or is attached loosely, remove the nail and assess the nail bed for laceration. If the nail bed is lacerated, repair it using 6-0 absorbable material. After cleansing and trimming its soft proximal portion, replace the nail between the nail bed and the nail fold (eponychium) and then anchor it in place with a few stitches. This will splint the nail fold away from the nail bed, which will prevent the obliteration of the space between the nail bed and the nail fold. By preserving this space, the new nail is allowed to grow undisturbed. Some have used tissue adhesive (skin glue) instead of sutures to secure the nail. The preferred method of local anesthesia for nail bed repair is digital block, and the use of a finger tourniquet during the repair allows a bloodless field. Application of a finger splint or a bulky dressing after repair, especially if there is an associated fracture, is recommended.

Subungual Hematoma

Subungual hematoma is the collection of blood in the interface of the nail and the nail bed. It is commonly seen with blunt fingertip injuries. The usual presentation is throbbing pain and discoloration of the nail. Subungual hematoma may be associated with nail bed injury or fracture of the distal phalanx.

Usually, drainage of the hematoma provides relief from the symptoms. Generally, no local anesthesia is required for a simple trephination by cauterization of the nail. After drainage, care for simple subungual hematoma includes elevation of the hand and warm soaks for a few days. Inform the family about the possibility of nail deformity in the future. When the injury is more involved, digital block is advised. If the hematoma is large and extends to the tip of the nail, consider separating the nail from the nail bed using a sharp or blunt method to allow drainage. Outcomes with nail trephination and nail removal are similar. In the presence of a distal phalangeal fracture, the physician has to be concerned about transforming a closed fracture to an open one by communicating the subungual, and hence the fracture hematoma, to the exterior surface of the nail. If there is a possibility of an underlying fracture, consider antibiotic coverage and ensure close follow-up.

CHAPTER 107 ■ ABDOMINAL TRAUMA

RICHARD A. SALADINO, MD, AND DENNIS P. LUND, MD

Trauma is the most common cause of death in children between 1 and 18 years of age in the United States; more than 10,000 children die each year from injuries. Blunt trauma accounts for more than 90% of childhood injuries; the most common associated mechanisms are falls and motor vehicle–related trauma. Although injury to the abdomen accounts for only 10% of injuries in children with trauma, it is the most common unrecognized cause of fatal injuries. Therefore, a compulsive and systematic approach to identification and treatment is necessary.

Children are at greater risk than adults for intraabdominal injuries after blunt trauma because of their immature musculoskeletal system. The overlying muscles and associated skeleton is much weaker than for adults and, therefore, less protective. In addition, children have a higher abdominal organ-to-body mass ratio. A given force delivered to the abdomen is distributed over a smaller body surface area, increasing the likelihood of injury to the underlying structures.

APPROACH

The assessment of any trauma patient always begins with the ABCs (airway, breathing, and circulation). Priorities in evaluation and treatment include recognition and relief of airway obstruction, appropriate protection of the cervical spine, and management of life-threatening chest injuries and shock. Once resuscitation and cervical spine stabilization have begun, evaluation of the abdomen is included in both the primary and secondary surveys.

The evaluation for intraabdominal injuries in children starts with a determination of the mechanism of trauma, elicited from witnesses, caregivers, and emergency medical personnel. Blunt injuries account for most of the morbidity and mortality of childhood trauma, although the frequency with which penetrating injuries occur is increasing. Penetrating trauma is usually evident on careful inspection of both the anterior and posterior torsi. In contrast, blunt abdominal trauma must be suspected from both historical information and careful physical examination. Children with severe multiple trauma are obviously at risk for intraabdominal injuries, but sufficient energy to injure may also be present in apparently minor falls, direct blows to the abdomen from balls, bats, bicycle handlebars, and countless toys, and during contact sports.

Life-threatening abdominal injuries may be occult or manifest in several ways: abdominal ecchymoses or distension, shock, or external hemorrhage (e.g., from a penetrating injury). Historical information or physical examination findings are often subtle or lacking. Children have the capacity to maintain a normal blood pressure level in the face of significant blood loss and hence may mask major intraabdominal bleeding. The examining physician must always keep in mind that the abdomen is a large potential reservoir for blood loss.

Physical Examination

A traumatized child is often difficult to examine; pain associated with extraabdominal injuries may obscure abdominal findings. In addition, the results of physical examination may be subtle or unreliable in an unconscious, intoxicated, agitated, or fearful child. Vital signs, including blood pressure and pulse, may be normal for age, especially in children with isolated injuries of the liver and spleen. Furthermore, external signs of injury, abdominal tenderness, and absent bowel sounds seldom differentiate pediatric patients who require laparotomy from those who do not.

Careful serial examinations are critically important in maintaining the index of suspicion necessary to proceed with more sophisticated testing when appropriate. Inspection should note abrasions, lacerations, ecchymoses, penetrating wounds (including missile entry and exit sites), and telltale markings (e.g., seat belt marks, tire tracks). Attention should be paid to the anterior and posterior abdomen and to both flanks, as well as to the lower thorax, when considering abdominal injuries. Abdominal distension may be caused by hemoperitoneum or peritonitis but most often results from gastric distension from air swallowed by the crying child. Early gastric decompression may assist the abdominal examination and prevent vomiting with aspiration of gastric contents. The presence or absence of bowel sounds is generally not of much significance in the initial evaluation, but prolonged ileus may be a sign of intraabdominal pathology. Tenderness upon palpation, percussion, or shaking may be caused by abdominal wall contusion or may indicate intraabdominal injuries. Pelvic stability is evaluated by gently compressing and distracting the ileac wings.

Digital rectal examination should be performed; the presence of blood may indicate perforation of the bowel. A boggy or high-riding prostate, blood at the urethral meatus, or a distended bladder may be present with urethral disruption and preclude bladder catheterization until a retrograde urethrogram has been performed (see Chapter 112). Diminished or absent rectal sphincter tone may indicate a spinal cord injury.

Laboratory Data

Blood should be obtained and sent for immediate baseline hemoglobin measurement and typing and cross-matching, not only in all instances of multiple trauma but also if isolated

intraabdominal injury is suspected. The blood bank at a trauma center not only should be able to provide type-specific blood in a short time frame but must also have O-negative packed red blood cells (RBCs) ready for resuscitation if needed.

Routine multipanel laboratory testing (so-called "trauma panels") has historically been standard for patients with trauma, but more recent studies have called into question this undifferentiated approach. Nonetheless, common additional laboratory studies include measurement of liver transaminases, amylase, and lipase and urinalysis.

Many recent studies indicate that, in combination with the presence of physical examination findings, abnormal laboratory findings contribute to the identification of children with intraabdominal injuries. Elevated serum liver transaminase levels may be associated with intraabdominal trauma, especially hepatic injuries. Screening for intraabdominal injuries by evaluating transaminase levels is not universally accepted because sensitivity and specificity vary widely in the literature, but some data suggest that elevated transaminase levels [as low as aspartate aminotransferase more than 200 U per L and alanine aminotransferase more than 125 U per L] correlate well with hepatic injuries. Using thresholds such as these may allow for more judicious use of computerized tomographic (CT) scan of the abdomen for children with blunt abdominal trauma.

Examination of the urine may also play a role in an increased suspicion for intraabdominal injury after blunt force trauma to the abdomen. Grossly bloody urine indicates likely injury to the kidneys and has been shown to be associated with nonrenal intraabdominal injuries in pediatric patients with trauma. The predictive capacity of microscopic hematuria is controversial. In one study, microscopic examination of urine that revealed more than 50 RBCs per high-powered field (hpf) was 100% sensitive and 64% specific for the presence of an intraabdominal injury (see Chapter 112). A more recent study suggests consideration of CT scan of the abdomen in the context of a urinalysis demonstrating as few as 5 or more RBCs per hpf when the history indicates a significant force has been applied to the abdomen. In addition, clinicians must remember that major trauma may cause complete disruption of a renal pedicle without any hematuria.

Hyperamylasemia may be present with pancreatic injury, but its absence does not preclude injury. In one study, elevations of amylase level more than 200 U per L and lipase level more than 1,800 U per L were markers of possible major pancreatic ductal disruption. In a more recent retrospective study, elevations of amylase and lipase levels were infrequently detected in patients with blunt abdominal trauma (4% and 7%, respectively), and neither the sensitivity nor negative predictive values of elevated measurements were sufficient to be used as screening tools for pancreatic injury. Pancreatic injury is difficult to diagnose, particularly since a CT scan of the abdomen is only 60% to 70% accurate in identifying pancreatic injury.

INITIAL MANAGEMENT PRINCIPLES

Basic Principles of Management

Airway management and cervical spine stabilization are first priorities (Fig. 107.1). Supplemental oxygen should be administered to any child with significant injuries, regardless of whether obvious signs of shock are present. Intravenous or intraosseous access should be obtained while the primary survey is completed. Immediate life-threatening injuries should be treated promptly. Hemorrhagic shock should be addressed with rapid infusion of isotonic crystalloid solution. A first intravenous administration of a bolus of 20 mL per kg may be given rapidly, followed by a second bolus of 20 mL per kg, if the pulse and blood pressure remain outside the physiologic range. If hemodynamic instability persists after 40 mL per kg of crystalloid, ongoing bleeding should be suspected and administration of blood strongly considered. Large-bore catheters are preferable, whether in the upper or lower extremities, to allow rapid infusion of large volumes of fluid during resuscitation. Accessing the femoral vein is acceptable and in fact is a preferred site in children for central access.

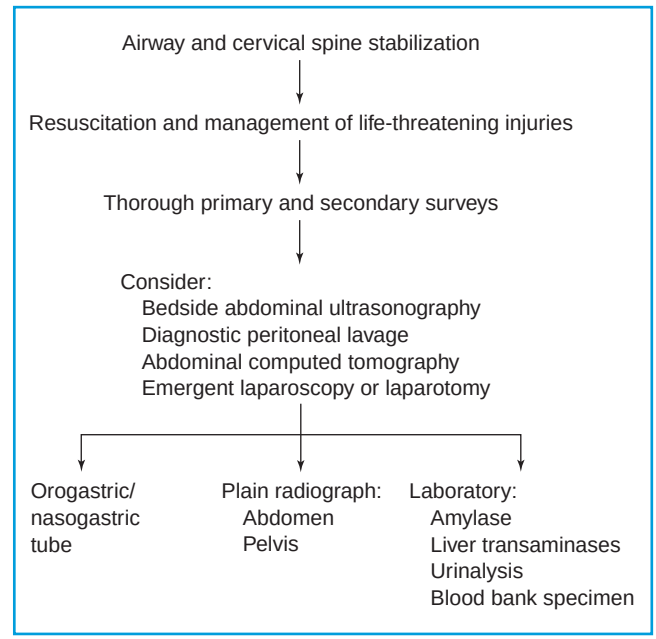

FIGURE 107.1 Initial evaluation and treatment of the child with abdominal trauma.

The American College of Surgeons currently recommends that aggressive fluid resuscitation be pursued. Although some animal data and a single clinical study suggest that less rigorous (hypotensive) fluid resuscitation may improve survival by limiting hemorrhage into the peritoneal space, application to the management of children is still controversial and not part of the approach to the injured child with hypotension.

As the initial evaluation proceeds, the priorities of management depend on the extent of multisystem injuries and the condition of the patient (Fig. 107.2). Patients who are unstable as a result of ongoing blood loss or an expanding intracranial hemorrhage require operative intervention early in the evaluation phase.

The Unstable Patient

Immediate life-threatening injuries, such as airway obstruction, tension pneumothorax, pericardial tamponade, and obvious sources of external blood loss, must be treated promptly upon detection. The role of emergency department (ED)

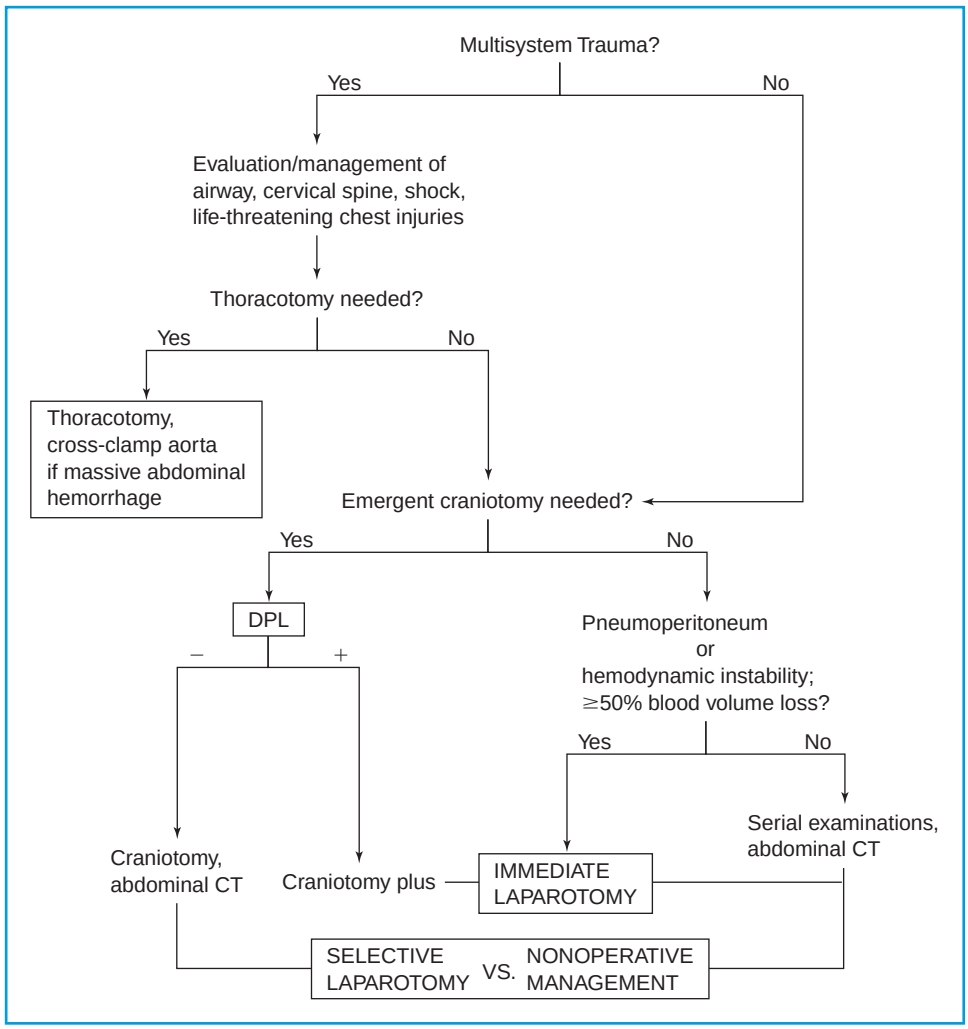

FIGURE 107.2 Management of blunt abdominal trauma. DPL, diagnostic peritoneal lavage; CT, computed tomography (see Table 107.2).

thoracotomy is controversial in children; its use should be confined to situations in which control of intrathoracic bleeding is needed (e.g., with lung or heart lacerations) or in patients in whom previously detected vital signs are lost. If emergent thoracotomy is performed in the latter instance for presumptive intraabdominal hemorrhage, the aorta is cross-clamped at a level just above the diaphragm.

If significant head trauma has occurred, a determination must be made regarding the need for immediate neurosurgical intervention. A rapidly performed CT scan of the head is usually sufficient to determine the presence of a hematoma, which can be evacuated surgically. If hemodynamic instability or the need for immediate craniotomy exists and does not allow for CT evaluation of the abdomen (Table 107.1), a diagnostic peritoneal lavage (DPL) should be performed either in the ED or in the operating suite. In the presence of a positive DPL finding (Table 107.2), laparotomy and craniotomy proceed simultaneously. Finally, if neither thoracotomy nor craniotomy is indicated, emergent laparotomy is performed when pneumoperitoneum is noted on a plain radiograph or when the patient remains hemodynamically unstable in the face of historical or physical evidence of abdominal trauma (Fig. 107.2).

The Stable Patient

Commonly, the injured child can be stabilized in the ED with proper airway and cervical spine management, and with intravenous fluid therapy and blood transfusion. A careful secondary survey should then be performed. On the basis of history and careful, serial abdominal examinations, CT is indicated when intraabdominal injuries are suspected (Table 107.1). Children who have had only moderate injuries should be examined serially in the ED. At times, an abdominal CT scan is merited based

solely on severe force inherent in a particular mechanism of injury, despite an unremarkable physical examination or the absence of abnormal screening laboratory values.

Additional Management

Children with abdominal trauma often need decompression of the stomach; this procedure facilitates examination, may provide information concerning gastric or diaphragmatic injury (bloody aspirate, radiographic evidence of the nasogastric tube in the thoracic cavity), and relieves the discomfort of an ileus. Major maxillofacial trauma precludes nasogastric tube placement, but an orogastric tube suffices in these instances. Urinary bladder catheterization may provide evidence of genitourinary system injury and is helpful in monitoring urinary output. Bladder catheterization is contraindicated when urethral disruption is suspected on the basis of the findings described previously.

Focused Abdominal Sonography for Trauma

Ultrasound screening (FAST: focused abdominal sonography for trauma) of the abdomen has been routinely utilized in adult trauma patients for many years with excellent sensitivity and specificity. FAST is typically performed in the ED during the secondary survey. The operator looks at four windows in the abdomen: the left upper quadrant, the right upper quadrant, the pericardium via a subxiphoid window, and the pelvis. The purpose of the scan is simple: the identification of free fluid. Free fluid in any of these areas indicates the need for further evaluation and treatment.

Review of several studies of adults with blunt abdominal trauma suggests that the immediate use of FAST may reduce the use of CT for unstable patients with a positive ultrasound finding. The predominance of the more recent literature suggests that FAST may support a decision to proceed to laparotomy without the need to undergo DPL or CT. In the unstable patient, free fluid points toward the need for operative intervention, whereas in the stable patient, further evaluation with CT scan is indicated.

The utility of FAST in the management of pediatric patients remains controversial. The literature for pediatric patients with intraabdominal injuries suggests that, to date, FAST is not sufficiently sensitive and CT scanning remains the gold standard for the radiologic evaluation in children. Nonetheless, there is a role for FAST in pediatric populations, particularly in unstable children or children who need immediate transfer to the operating suite for an emergent procedure, such as cranial decompression. Although a negative FAST finding does not exclude injury, a positive FAST finding is evidence enough to warrant exploration of the abdomen, either with laparoscopy or with laparotomy, in such a patient.

Diagnostic Imaging

Radiographic evaluation of children with abdominal trauma includes plain radiographs, contrast studies, ultrasound, and CT. CT scanning of the abdomen after blunt trauma is the standard of care when suspicion of intraabdominal injury exists. Both intravenous and oral contrasts are recommended to obtain the greatest amount of information from a single study. Importantly, though, not all trauma surgeons or radiologists agree that oral contrast is required for all cases, especially if time is limited. If a nasogastric or orogastric tube is in place, it should be withdrawn temporarily into the esophagus to avoid an artifact from its radiopaque marker. Abdominal CT shows lowest sensitivity for small gastrointestinal perforations and pancreatic injury. Although CT is the most common technique used in childhood trauma, the surgeon's decision to proceed to laparotomy or laparoscopy may be based more on the clinical status of the child than on the radiologic findings. Although abdominal CT is considered the most sensitive diagnostic tool, FAST may provide important data early in the course of the management of a child with suspected intraabdominal injuries. Although FAST may assist in the early evaluation of an injured child, a negative study result is not sufficient at present to exclude intraabdominal injury. Judicious use of the combination of physical examination, laboratory screening values, and CT scanning is indicated for the stable patient.

Diagnostic Peritoneal Lavage

DPL is occasionally a helpful adjunct to the management of children with abdominal trauma. The disadvantages of DPL include the introduction of air and fluid into the abdomen (subsequent radiologic evaluations are less helpful) and peritoneal irritation caused by the procedure (subsequent physical examinations are less reliable).

It is rarely necessary to perform laparotomy on children with free intraperitoneal blood. DPL, which effectively detects small volumes of blood, is often too sensitive in children. The primary indication for DPL in children is an urgent "need to know" with regard to the status of the peritoneal cavity, such as in the child who is hemodynamically unstable or requires immediate craniotomy and cannot be delayed for abdominal CT. If the technology is available, however, this need can be met with FAST or laparoscopy.

The technique for DPL in children is similar to that in adults, although in young children, a small supraumbilical incision is preferred over the usual infraumbilical approach to avoid the bladder. If a nasogastric tube and a urinary bladder catheter have not been placed, they should be inserted before peritoneal lavage is performed. Warm Ringer's lactate solution (10 mL per kg, maximum 1,000 mL) is instilled into the peritoneal cavity over 10 minutes and then removed for analysis.

TABLE 107.3

INDICATIONS FOR IMMEDIATE LAPAROTOMY FOR CHILDREN WITH ABDOMINAL TRAUMA

Multisystem injuries with indications for craniotomy in the presence of a positive diagnostic peritoneal lavage, free peritoneal fluid on ultrasonography, or strong historical, physical, or radiographic evidence of abdominal injury
Persistent and significant hemodynamic instability with evidence of abdominal injury in the absence of extraabdominal injury
Penetrating wounds to the abdomen
Pneumoperitoneum
Significant abdominal distension associated with hypotension

Criteria for the presence of a positive lavage are shown in Table 107.2.

Emergent Versus Selective Laparotomy

The indications for immediate laparotomy are limited in blunt abdominal trauma (Table 107.3). In most cases of childhood trauma (Fig. 107.2), emergency laparotomy is not necessary and further diagnostic studies direct either elective (selective) laparotomy or observation and monitoring. Most children with blunt abdominal trauma require only in-hospital observation and monitoring after delineation of the site and extent of their injury by abdominal CT.

The indications for emergent laparotomy in children with penetrating trauma are illustrated in Fig. 107.3. Any gunshot wound to the abdomen mandates immediate exploration. Other types of penetrating wounds in the presence of unexplained hemodynamic compromise, evisceration, pneumoperitoneum, or any evidence of violation of the peritoneum require prompt laparotomy.

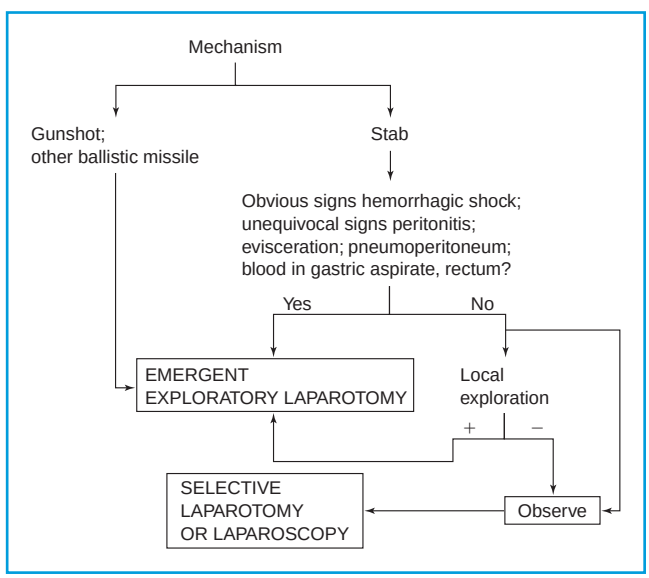

FIGURE 107.3 Management of penetrating abdominal trauma.

BLUNT ABDOMINAL TRAUMA

Abdominal Wall Contusions

Many children have minor trauma to their abdomen in the course of play and as a result of minor accidental events. Balls, bats, swings, toys, and contact with other children may cause contusions of the abdominal wall.

Children subjected to minor forces without signs of intraabdominal pathology (e.g., distension, tenderness on deep palpation, peritoneal irritation) can be sent home. Those with a troubling history or any worrisome signs should receive a diagnostic laboratory evaluation and should be observed in consultation with a surgeon. Suspicion for more serious intraabdominal injuries is based on the mechanism of injury and careful abdominal examination. Bilious or bloody vomiting, persistent vomiting, abdominal distension, any signs of peritoneal irritation, and rectal blood or hematuria suggest possible visceral injury, as does an elevation in amylase or liver transaminase levels in cases in which a clinical decision is made to obtain these studies. A low threshold for the use of abdominal CT should be maintained. Children with even minor contusions of the liver, spleen, pancreas, or hollow viscera should be hospitalized.

Solid Organ Injuries

The spleen is the most commonly injured intraabdominal organ, followed by the liver. Most of these injuries are the result of automobile-pedestrian trauma, although falls and bicycle accidents are also common mechanisms. The potential morbidity and mortality result from the highly vascular anatomy of this organ and hemorrhage into the large potential space of the peritoneal cavity.

Patients who have splenic injuries may present with either diffuse abdominal pain or localized tenderness. Subphrenic blood may cause referred left shoulder pain (Kehr's sign). Percussion and palpation tenderness is usually of greatest magnitude in the left upper quadrant of the abdomen. Abdominal radiographs occasionally reveal a medially displaced gastric bubble. CT scan will identify the extent of injury (Figs. 107.4 and 107.5).

Management of splenic injuries has evolved during the last three decades since the recognition of the postsplenectomy sepsis syndrome, resulting from the influence of both clinical and diagnostic advances. Nonoperative management of splenic injuries has largely replaced the traditional treatment, which included splenectomy or splenorrhaphy. The safety measure in nonoperative management for most childhood spleen injuries has been well documented, and the incidence of postsplenectomy sepsis has declined. The availability of noninvasive diagnostic CT also has allowed for greater confidence in the nonoperative approach to splenic trauma.

Blunt liver trauma is the most common fatal abdominal injury (Fig. 107.6). Mechanisms of injury are those that are common to splenic trauma. Diffuse abdominal tenderness may be a result of hemoperitoneum, but maximal tenderness is elicited in the right upper quadrant of the abdomen. Right shoulder pain is an occasional complaint.

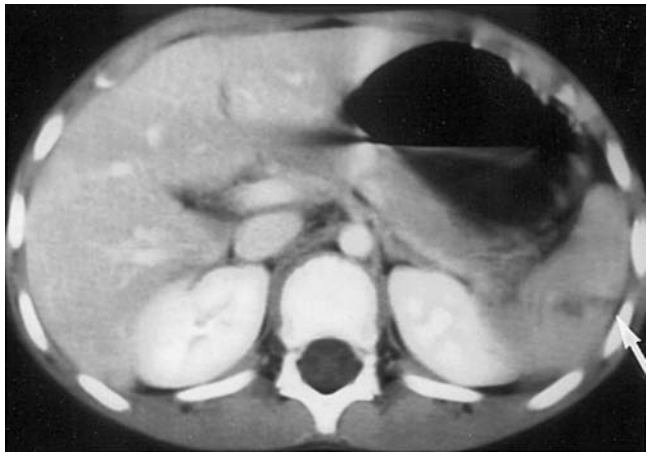

FIGURE 107.4 Abdominal computed tomography of a 13-year-old girl who fell from a horse onto her left side, showing a splenic laceration.

As with trauma to the spleen, nonoperative management of blunt hepatic injuries has become more common and is now the rule rather than the exception. Nonoperative management of isolated spleen and liver injuries without blood transfusion is the standard of care in pediatric trauma care facilities and is successful in 95% and 90% of cases, respectively. The American Pediatric Surgical Association Trauma Committee has published the guidelines for the nonoperative management of isolated solid visceral injuries in children, as listed in Table 107.4. These recommended practices are the result of a retrospective analysis of surgeon practices, national data on outcomes, and a prospective multicenter trial.

Pancreatic Injuries

Blunt abdominal injuries, particularly from bicycle handlebars, are the most common cause of pancreatic pseudocyst formation in children, although this injury is infrequent. Diagnosis is often delayed because of the nonspecific nature of subjective complaints and physical examination findings.

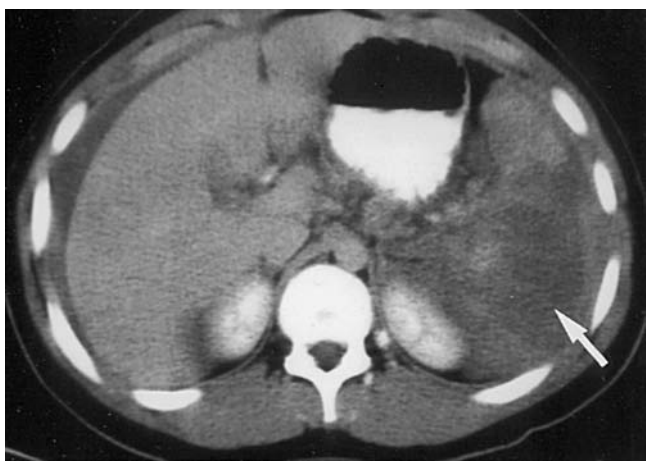

FIGURE 107.5 Abdominal computed tomography of a 10-year-old boy struck by a motor vehicle while crossing a street, showing massive splenic rupture and hemoperitoneum.

FIGURE 107.6 Abdominal computed tomography of an unrestrained 13-year-old girl in a rollover motor vehicle collision. A liver fracture is evident with differential perfusion of the lobes of the liver. Additional injuries included lung contusion.

The classic triad of epigastric pain, a palpable abdominal mass, and hyperamylasemia are detected only rarely in children and may develop slowly. The pancreas is relatively well protected and associated trauma such as hepatic and intestinal injuries is commonly present when injury to the pancreas has occurred. Abdominal ultrasound and contrast CT (often serial examinations) are used to make the diagnosis (Fig. 107.7); however, acute pancreatic injuries may not be apparent on the initial CT scan.

Severe injury of the pancreas is rare, but when it occurs, blood loss and leakage of enzyme-laden secretions may result in hypovolemia and peritonitis. Blunt abdominal trauma may also injure the ductal elements of the pancreas, and diagnosis depends on a high index of suspicion, consideration of the mechanism of injury, physical examination, serum amylase determination, and diagnostic imaging. Of note, however, is that the absence of hyperamylasemia does not preclude pancreatic trauma. Serum amylase level may be normal in 30% of patients with complete transaction, whereas elevated serum

TABLE 107.4

GUIDELINES FOR MANAGEMENT IN CHILDREN WITH ISOLATED SPLEEN OR LIVER INJURIES

Computed tomography grade	I	II	III	IV
Intensive care unit days	None	None	None	1
Hospital days	2	3	4	5
Predischarge imaging	None	None	None	None
Postdischarge imaging	None	None	None	None
Time of restricted activity (wk)	3	4	5	6

amylase level is detected in 14% to 80% of cases of blunt injury. Elevated serum amylase level should suggest the possibility of pancreatic involvement, but the absolute value does not correlate with the degree of injury. Elevation of the amylase level in fluid returned from DPL suggests injury to bowel or pancreatic ductile elements.

Nasogastric decompression and bowel rest are indicated when pancreatic injury is suspected. Nonoperative therapy is normally used initially for children with isolated pancreatic pseudocyst caused by blunt trauma. Maturation of the pseudocyst may necessitate surgical drainage, although spontaneous resolution may occur in 25% of children. Experience with percutaneous drainage of pancreatic pseudocysts in children is increasing, but the traditional approach has been to use surgical internal drainage once a pseudocyst has persisted beyond 6 weeks. When severe pancreatic crush or transection is suspected, the surgeon may elect to perform immediate exploration and resection or drainage.

Hollow Abdominal Viscera Injuries

Intestinal perforation caused by blunt abdominal trauma is rare in the pediatric age group, but the most common causes of this injury are automobile-pedestrian trauma, automobile lap belt injuries, and child abuse. The mechanisms of injury usually involve rapid acceleration or deceleration of a structure near a point of anatomic fixation (e.g., ligament of Treitz), or trapping of a piece of bowel between two unyielding structures such as a lap belt and the spine. Hollow visceral injury may be difficult to diagnose because physical findings may be minimal and/or nonspecific for the first few hours, and abdominal CT is not particularly sensitive in this situation. However, succus entericus, bile, and activated pancreatic enzymes are extremely irritating to the peritoneum over time. The development of fever or worsening peritonitis on serial physical examinations should alert the examining physician to the possibility of bowel perforation.

Plain radiographs of the abdomen demonstrate free intraabdominal air in only 30% to 50% of cases. Similarly, pneumoperitoneum or leakage of gastrointestinal contrast is only rarely seen on the CT scan. DPL, which is rarely performed because of limited indications, may demonstrate bile or amylase in the effluent and is sensitive for bowel perforations (see Fig. 107.2 and Table 107.2). Most perforations or transections of bowel are found during laparotomy, which the surgeon has chosen to perform because of advancing peritonitis or unexplained persistent fever. Management depends on the site and extent of structural injury.

A significant percentage (up to 25%) of hollow visceral injuries may not be apparent on the initial CT scan of a child with blunt injury. Therefore, evaluating the mechanism of injury should lead to a high index of suspicion for this type of injury. A significant lap belt sign is a harbinger of possible bowel injury. Similarly, free fluid in the abdomen on CT scan should be very carefully evaluated and consideration should be given for laparoscopy or laparotomy.

Late Presentations of Intraabdominal Trauma

Some children with abdominal trauma do not have evidence of intraabdominal pathology on initial evaluation but may return days or weeks later with abdominal distension and/or pain, persistent emesis, or hematochezia. In particular, three injuries are characterized by late presentations: (i) pancreatic pseudocyst (previously discussed), (ii) duodenal hematoma, and (iii) hematobilia.

Intramural duodenal hematoma is an uncommon injury that results from a direct blow to the epigastrium (blunt force delivered by a small-diameter instrument such as a broom handle or the toe of a boot) or from rapid deceleration (e.g., in the lap belt syndrome) and may cause partial or complete gastric outlet obstruction. Bleeding into the wall of the duodenum causes compression and therefore symptoms of intestinal obstruction, including pain, bilious vomiting, and gastric distension.

Diagnosis is made by ultrasonography or a contrast upper gastrointestinal study, revealing the "coiled spring sign." Injury of the pancreas must be suspected when duodenal hematoma is considered. Nonoperative management includes nasogastric decompression and parenteral nutrition for up to 3 weeks.

Rupture of the gallbladder is rare and is almost always associated with severe blunt trauma to the liver. Likewise, hematobilia is associated with hepatic trauma and is a result of pressure necrosis from an intrahepatic hematoma or direct injury to the biliary tree. Children with hematobilia present several days after a blunt abdominal trauma with abdominal pain and upper gastrointestinal tract bleeding. Cholangiography confirms the diagnosis. Embolization is used to achieve hemostasis, but partial hepatic resection is necessary when this treatment fails.

PENETRATING ABDOMINAL TRAUMA

Penetrating abdominal trauma is much less common than blunt trauma in the pediatric age group and accounts for less than 10% of pediatric trauma injuries. However, the evolution of a more heavily armed society has resulted in a worrisome increase in the frequency with which children sustain penetrating injuries.

The high morbidity and mortality associated with penetrating trauma to the abdomen is a result of the destructive force of ballistic missiles and fragments, rapid hemorrhage of vascular structures and solid organs after missile and stab injuries, difficulty in surgical repair of grossly injured intraabdominal organs, and postoperative complications. Intraabdominal organs are at risk for penetrating trauma, depending on their size and location. The colon and small bowel are large in volume and are the most commonly injured structures, followed by the liver, spleen, and major vessels. Hypovolemia and/or signs of peritonitis are then the result of brisk hemorrhage and spillage of enteric contents into the peritoneal space.

The approach to these patients includes management of all life-threatening injuries and treatment of hemorrhagic shock. The need for laparotomy must be determined quickly, and broad-spectrum antibiotics, such as cefoxitin 25 mg per kg, should be given.

Gunshot Wounds

The destructive energy of ballistic missiles and fragments is related to mass and velocity (kinetic energy = $\frac{1}{2}MV^2$, where M is the mass and V is the velocity), and more than 90% of gunshot wounds to the abdomen are associated with significant injuries. Hollow viscera and large vessels are often involved, and solid organs such as the liver and the spleen may demonstrate burst injuries. Therefore, laparotomy is mandated in virtually all gunshot wounds to the abdomen.

Stab Wounds

Stab wounds to the abdomen carry potential for devastating injury, depending on which intraabdominal structures are involved. The extent of the injury also depends on the type, size, and length of the weapon and on the trajectory. Major vascular injuries pose the greatest threat; commonly injured vessels include the intraabdominal aorta, the inferior vena cava, the portal vein, and the hepatic veins.

Anterior stab wounds are explored via laparotomy if hemodynamic instability or signs of peritonitis are present, if blood is noted in the gastric aspirate or on rectal examination, or if pneumoperitoneum or evisceration is noted (Fig. 107.3). Local exploration is needed to rule out penetration of the peritoneum, even in minor stab wounds. In cases in which the exploration cannot rule out peritoneal penetration, laparoscopy will delineate the injury and many minor injuries can be repaired without open surgery.

Stab wounds to the flank or back are less readily and less quickly diagnosed than do anterior wounds; the retroperitoneal structures are more protected by paraspinal musculature, and bleeding is often tamponaded in this area. Dorsal stab wounds are sometimes managed nonoperatively unless hemodynamic instability or signs of peritonitis are present, although selective laparotomy is a common surgical strategy.

LAP AND SHOULDER BELT AND AIR BAG INJURIES

Children who are too small for adult seat belts are at increased risk for injuries. In particular, children restrained only by lap belts in motor vehicles involved in rapid deceleration crashes are at risk to sustain Chance fractures (compression or flexion-distraction fractures of the lumbar spine) in association with intraabdominal injuries (the lap belt complex). As many as one-half the children with Chance fractures have intraabdominal injuries, including duodenal perforation, mesenteric disruption, transection of small bowel, and bladder rupture (Fig. 107.8). Therefore, a high index of suspicion must be maintained to detect such injuries. The hallmark of the lap belt complex is abdominal or flank ecchymosis in the pattern of a strap or belt (Fig. 107.9). This is accompanied by abdominal and back pain. A normal abdominal CT scan does not rule out ruptured viscus, and laparoscopy or laparotomy should be considered for children in whom the lap belt complex is suspected strongly (Fig. 107.10). Carotid injuries caused by high-riding shoulder restraints in motor vehicle collisions are much less common.

Although it is well publicized that children younger than 12 years or less than 5 feet in height should not ride in the front seat of a vehicle that has functioning air bag restraints, significant injuries and deaths continue to occur. Life-threatening injuries caused by air bag deployment are typically related to cervical spine injuries and closed head trauma. Less severe air bag injuries include abrasions to the face, neck, and chest;

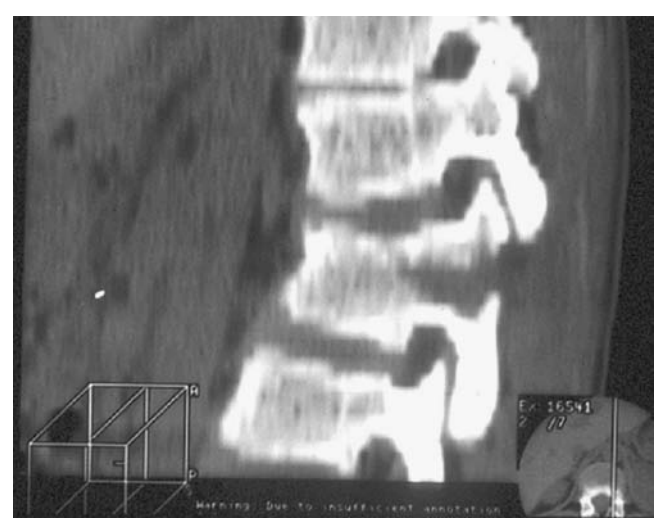

FIGURE 107.8 Magnetic resonance imaging scan of the lumbar spine of a 12-year-old girl involved in a high-speed motor vehicle collision. An anterior compression of L2 is seen, with disruption of the posterior elements. The lap belt complex in this patient also included loss of her small bowel secondary to thrombosis of the superior mesenteric artery.

FIGURE 107.9 Eleven-year-old girl with classic abdominal and flank ecchymosis in the pattern of a lap belt. Her injuries included colon perforation and a Chance fracture.

minor burns to the upper extremities; blunt ocular trauma; and chemical keratitis.

CHILD ABUSE

At least 1.6 million children are abused or neglected every year in the United States. Major blunt abdominal trauma resulting from physical abuse is uncommon but highly fatal in children; mortality rates are as high as 50%. This high fatality rate is the result of the unfortunate but typical delay with which parents or caregivers who abuse children seek treatment.

Children who are seriously injured because of physical abuse commonly have more than one site of trauma; some of the injuries can be occult, and others may have been inflicted at different times. Abdominal injuries are usually inflicted by fists, feet, or small handheld objects and are rarely penetrating. The diagnosis of blunt abdominal injury caused by battering is difficult to make unless a high index of suspicion for child abuse is maintained. An important clue is often an implausible historical account for the seriousness of the injury. As with abdominal trauma caused by other mechanisms, physical examination findings may not be obvious. Laboratory analyses and abdominal CT may be necessary to confirm the diagnosis. Less obvious intraabdominal injuries may be suspected by the use of a Wood lamp. Enhanced visualization of bruising not otherwise seen in normal light may be apparent under ultraviolet (Wood lamp) illumination. Such bruising on the abdomen or flanks should increase the suspicion for occult intraabdominal injuries.

Severe injuries may present with obtundation and shock, abdominal distension, and tenderness. Intraabdominal injuries most commonly involve the liver and the spleen, as well as the pancreas-duodenum-jejunum region. In all such cases in which child battering is suspected, a child protection consultant should be involved early.

FIGURE 107.10 Intraoperative photograph of a segment of small bowel of a 15-year-old boy who was a lap and shoulder belt–restrained back seat passenger in a motor vehicle collision. Initial examination revealed ecchymosis below the umbilicus and significant tenderness upon palpation of the lower abdomen. Findings at laparotomy included near transaction of the terminal ileum with devitalized tissue at the edges of the injury.

CHAPTER 108 ■ BURNS

MARK D. JOFFE, MD

BACKGROUND

Children in modern society will inevitably be exposed to thermal energy that has the potential to cause injury. While preventive efforts are paramount in importance, all clinicians who care for injured children must be able to assess and begin treatment of both minor and severe burns. Burns and related injuries are the third leading cause of death in childhood, killing approximately 2,500 children per year. Children suffering morbidity from serious burns are three times as numerous as those who die. Medical care is sought for burn injuries more than 250,000 times per year in the United States, generating costs that exceed $1 billion per year. Competent management of minor burns can optimize cosmetic results and minimize functional morbidity for children, a benefit that is difficult to express in dollars.

The past 40 years has seen major advances in burn treatment and improved outcomes. A recent study reported a mortality rate of only 39% for children with burns of more than 80% of body surface area (BSA). Factors associated with hospital care were much more predictive of survival than injury characteristics or time to resuscitation, so every child, regardless of the extent and severity of burns, should be aggressively resuscitated by prehospital and emergency care providers.

Only 3% to 5% of all burns in children are life threatening. Most burns are minor scalds, accounting for about 80% of all thermal injuries. Flames produce 13% of burns and with associated smoke inhalation result in the majority of deaths. Electrical or chemical burns account for 2% to 3% of injuries and pose special challenges in management.

Males and children younger than 5 years are at highest risk of thermal injury. Bathing-related scalds are a particular risk during infancy. Hot liquid spills are common in toddlers. School-aged children are often injured as a result of playing with matches, with high morbidity and mortality to the child and his or her family. Burns related to high-voltage electrical lines are seen primarily in teenagers.

Several preventive strategies can reduce the risk of thermal injury to children. Lowering the temperature of water heaters from more than 130°F (54.4°C) to 120°F (48.9°C) increases the time for full-thickness scalding from less than 30 seconds to 10 minutes. Burn centers have noted a decrease in full-thickness flame burns since the introduction of flame-resistant children's sleepwear. Cigarette misuse is responsible for more than 30% of house fires. Childproof lighters and "fire-safe" cigarettes have the potential to reduce the frequency of these often-deadly events. Smoke detectors and sprinkler systems can greatly reduce deaths, but only if installed and maintained properly. Advances in burn prevention can have a far greater impact on public health than refinements in burn management.

PATHOPHYSIOLOGY

The skin is a complex organ performing many vital functions that are often unappreciated until it is severely injured. Skin preserves body fluids, efficiently regulates heat loss to the environment, and acts as a barrier to infectious pathogens. It is composed of an outer, mostly nonviable epidermis, and a dermis. The outer layer of the epidermis, the stratum corneum, prevents passive water loss and is lethal to most viruses and gram-negative bacteria. It has a fatty acid film that is fungistatic and bacteriostatic. The dermal–epidermal junction prevents loss of macromolecules through the skin. Eccrine sweat glands in the dermis secrete fluid to increase evaporative heat loss. Vasodilation and vasoconstriction of blood vessels in the dermis regulate radiant heat loss, affecting a 100-fold variation in skin perfusion. Therefore, children with extensive burns have difficulty retaining body fluids and regulating temperature (Fig. 108.1).

Major systemic physiologic effects are seen in children with burns of more than 20% of BSA. Burn injury causes increased capillary permeability and the release of osmotically active molecules to the interstitial space resulting in extravasation of fluid. Protein is lost from the vascular space to the interstitium during the first 24 hours. In patients with large burns, vasoactive mediators are released to the circulation and result in systemic capillary leakage. Edema develops in both burned and noninjured tissues. Circulating factors that depress myocardial function decrease cardiac output. Acute hemolysis of up to 15% of red blood cells may occur both from direct heat damage and from a microangiopathic hemolytic process. The profound circulatory effects of severe burns can result in life-threatening shock early after injury.

Hair follicles, sweat glands, and sebaceous glands in the dermis play a crucial role in the healing of partial-thickness burns. After an inflammatory phase characterized by leukocyte infiltration, cytokine release, and complement activation, epithelial cells in these structures undergo metaplasia to produce a stratified squamous epithelial cell layer that is required for healing of skin. Neovascularization and fibroblast migration occur 1 to 3 weeks after partial-thickness burns. Overproduction of collagen can result in hypertrophic scarring. In full-thickness and deep partial-thickness burns, the absence of sufficient dermal appendages precludes reepithelialization by this mechanism and necessitates skin grafting.

Thermal energy damages the skin structures in proportion to the intensity and duration of exposure. Hot grease and

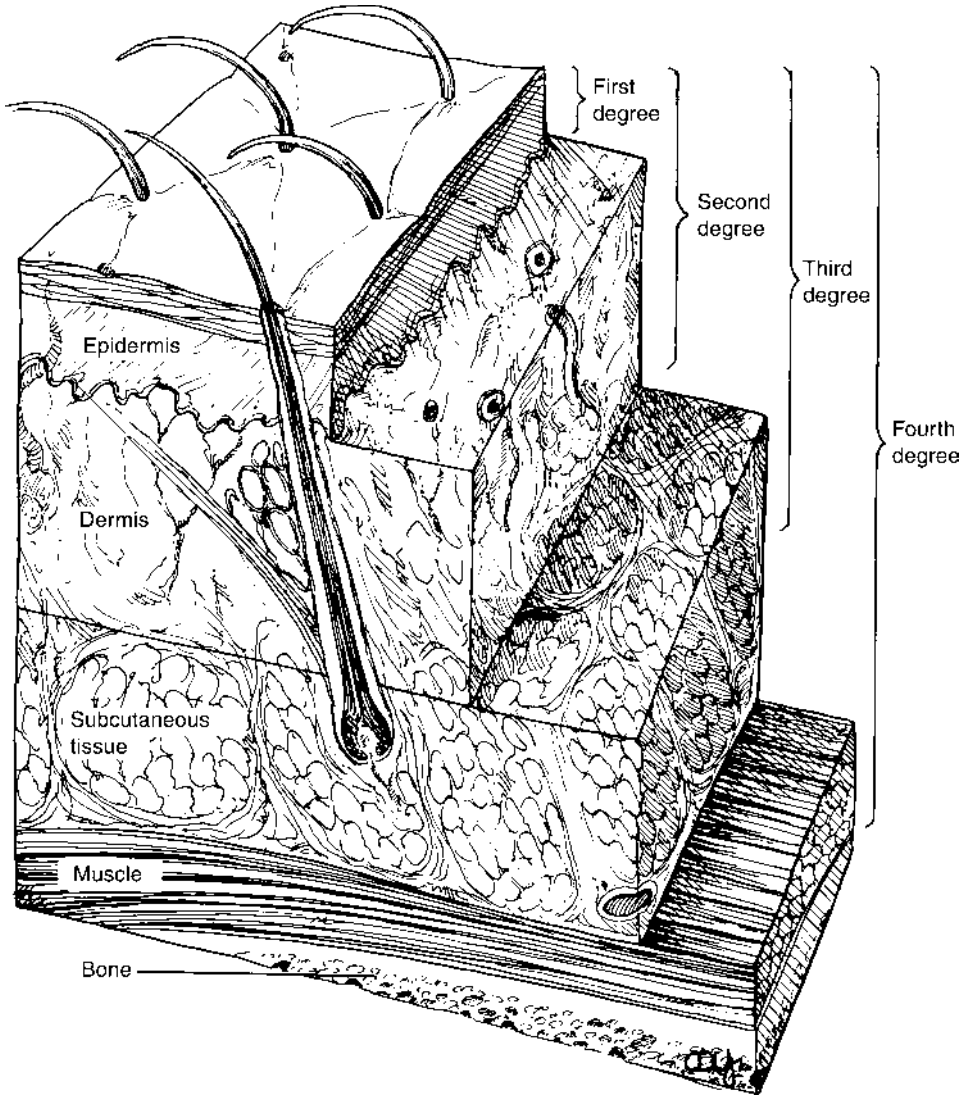

FIGURE 108.1 Degree of burn wound depth. First degree involves only the epidermis, second degree extends into the dermis, third degree into subcutaneous tissue, and fourth degree to muscle, tendons, or bone.

thick soups and cereals cause deeper injuries because they cling to the skin longer than scalding water, affording more time for transfer of the thermal energy. Ignition of synthetic fabrics often causes melting and adherence to the skin, resulting in more serious burns than ignition of cotton garments. Skin thickness is also a variable in the severity of injury with a given thermal exposure. Submersion of the hand may result in deep burns of the dorsum, with relative sparing of the thick skin of the palm. The thinner skin of young children accounts for deeper burns than those in adults with similar heat exposure.

A first-degree burn is characterized by redness and a mild inflammatory response confined to the epidermis, without significant edema or bulla formation. First-degree burns are not included in the calculation of burn surface area used for therapeutic decisions. These minor burns may be painful and resolve in 3 to 5 days without scarring.

Most burns treated in emergency departments (EDs) are partial-thickness or second-degree burns. Superficial second-degree burns involve destruction of the epidermis and less than half of the dermis. Blistering is often present. Increased capillary permeability, resulting from direct thermal injury and local mediator release, results in edema. These injuries are usually painful because intact sensory nerve receptors are exposed. The capillary network in the superficial dermis gives these burns a pink-red color and moist appearance. Healing occurs in about 2 weeks, and scarring is usually minimal.

Deep partial-thickness burns involve destruction of the epidermis and most of the dermis. Edema can lessen the exposure of sensory nerve receptors, making some partial-thickness burns less painful and tender. Deep partial-thickness burns have a paler, drier appearance than superficial injuries, at times making them difficult to distinguish from full-thickness injury. Thrombosed vessels often give deep partial-thickness burns a speckled appearance. Burns evaluated immediately may appear to be partial-thickness injuries and subsequently become full-thickness injuries, especially if secondary damage from infection, trauma, or hypoperfusion ensues. Deep

partial-thickness burns can take many weeks to heal completely. Unacceptable scarring is common and skin grafting may be necessary to optimize cosmetic results.

Full-thickness or third-degree burns involve destruction of the epidermis and the entire dermis. They usually have a pale or charred color and a leathery appearance. Destruction of the cutaneous nerves in the dermis makes them nontender, although surrounding areas of partial-thickness burns may be painful. Full-thickness burns cause a loss of skin elasticity. The burned skin cannot expand as tissue edema develops during the first 24 to 48 hours of fluid therapy. Circumferential or near-circumferential burns can therefore cause respiratory distress, abdominal compartment syndrome, and vascular insufficiency of the distal extremities. Full-thickness burns cannot reepithelialize and can heal only from the periphery. Most require skin grafting. Fourth-degree burns are those full-thickness injuries that also involve underlying fascia, muscle, or bone.

Heat causes coagulation necrosis of tissue, producing a protein-rich medium that nourishes bacterial growth. Burns become colonized with potentially pathogenic organisms, primarily from the skin and intestinal flora of the patient with burn injury and not from exogenous sources. Cleansing and debridement reduce substrate for bacterial proliferation and topical antimicrobial therapy reduces the number of microorganisms, but burns are never completely sterilized so that the risk of secondary infection is always present.

FIRST AID AND PREHOSPITAL CARE

Emergency physicians may be consulted about the immediate care of minor burns. Early cooling is accomplished by running cold water over the injured area. If performed in the first 30 minutes after injury, it not only stops ongoing thermal damage but also prevents edema, reducing progression to full-thickness injury. Applying ice directly to the wound is painful, and the extreme cold can worsen the injury. Parents should be reminded not to put grease, butter, or any ointment on the burn because these substances do not dissipate heat well and may contribute to the contamination. Intact blisters should not be broken during the prehospital phase. The burn should be covered with a clean cloth or bandage.

Small burns from mechanisms unlikely to cause full-thickness injury can be managed at home with a topical antibiotic and a bandage. Burns of larger size and burns involving the face, hands, feet, or perineum should be evaluated promptly by a physician. Telephone advice, without the benefit of physical examination, should always err on the side of caution with recommendation for a medical evaluation.

The concerns for children with major burns are different. Prehospital care providers should initially forget about the burn and focus on airway, breathing, and circulation, as they would for any other trauma victim. Rapid transport to a hospital setting is crucial. Oxygen should be administered. The trachea should be intubated if there are signs of upper airway obstruction, apnea, or severe hypoventilation. If transport time is likely to be prolonged, intravenous fluids should be started. Inadequate prehospital fluid resuscitation has been associated with preventable deaths in children with burns.

MAJOR BURNS

Evaluation and Management

During the first few seconds after arrival, the physician must determine if a patient with burn injury requires aggressive therapy for major burns (more than 20% of BSA) (Fig. 108.2). In children with severe injuries, the evaluation and initial management take place simultaneously. Smoldering clothing or other sources of continued burning must be removed. Information about the circumstances of the burn and the potential for associated injuries should be sought from prehospital care providers, police, or family members, but this should not delay the initial treatment.

Airway

Improper airway management has been implicated in some deaths of children with severe burns. Most life-threatening burns are the result of house fires. The inhalation of hot gases can burn the upper airway, leading to progressive edema and airway obstruction. Any child with burns of the face, singed facial hairs, or hoarseness is at high risk, but airway burns can occur in the absence of these signs. Edema of the burned airway will worsen over the first 24 to 48 hours. Knowledge of the time course of airway swelling justifies intubation of the trachea for subtle signs of airway compromise that occur shortly after the injury. Early intubation may circumvent a difficult intubation later in the course of a child with severe pharyngeal and airway edema. Endotracheal tubes of smaller diameter than expected for age should be available in anticipation of a narrowed airway. Increasingly, cuffed endotracheal tubes are used to decrease air leaks, even in children younger than 8 years.

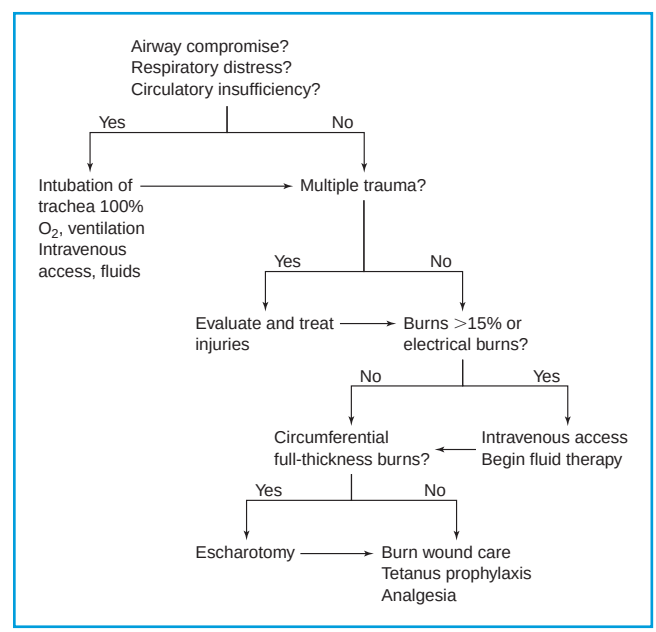

FIGURE 108.2 Diagnostic approach to the patient with burn injury.

Children who have jumped or fallen in house fires, been burned in motor vehicle accidents, or been burned by explosions are at risk for associated cervical spine and other traumatic injuries. A history of trauma may not be available at the time of airway management. Physicians should manage the airway with the neck in a neutral position, avoiding any flexion or extension. Radiographs can be obtained later to help exclude cervical spine injury (see Chapter 115). Children with severe burns may have depressed levels of consciousness for many reasons. Airway obstruction from the loss of pharyngeal tone is not uncommon. A chin-lift maneuver is now recommended for all lay rescuers, but the jaw-thrust maneuver is preferred in patients with possible cervical spine injury.

Breathing

A rapid assessment of ventilation includes respiratory effort, chest expansion, breath sounds, and color. Pulse oximetry is useful, but patients with significant levels of carboxyhemoglobin will look pink and have "normal" oxygen saturation as measured by a pulse oximeter. Children with severe burn injury should receive 100% oxygen. Arterial blood gases with CO-oximetry should be obtained promptly. Careful assisted ventilation is recommended for patients whose ventilatory status is questionable. Avoidance of high inflating pressures and application of cricoid pressure can minimize gaseous distension of the stomach and reduce the risk of regurgitation with pulmonary aspiration.

Children burned in house fires or in any closed space are at high risk of inhalation injury. Facial burns, singed facial hairs, and carbonaceous sputum are not always present in children with significant inhalation injury. Chest radiographs may be normal initially, even if pulmonary injury has occurred. Smoke is responsible for most of the lower airway abnormalities in patients with burn injury, and management of smoke inhalation is covered in Chapter 87. The efficient heat-exchange function of the upper airway can dramatically reduce the temperature of inspired dry gases, protecting the lower airway from thermal injury. Inhalation of steam, with its higher heat capacity, is more likely to result in burns of the lower airway.

Extensive full-thickness burns of the thorax may restrict expansion of the chest and impair ventilation. Respiratory embarrassment in this setting is an indication for escharotomy of the chest. Incision through the depth of the eschar should be performed along the anterior axillary lines to allow adequate chest expansion. If the deep burns extend to the abdomen, the escharotomies should be extended downward and connected by incision along the costal margin.

Circulation—Burn Shock

The physiology of circulatory impairment in patients with severe burn injury is complex. Burn shock occurs in adults with burns over 30% of BSA but may occur in children with burns over 20% of BSA.

The rapid assessment of circulation includes skin color, capillary refill time, temperature of the peripheral extremities, heart rate, and mental status. Blood pressure is often maintained until decompensation occurs, making it an unreliable measure of early circulatory impairment. Hypertension from increased systemic vascular resistance has been reported immediately after severe burns, particularly in pediatric patients, and must not discourage proper fluid therapy.

Vascular access should be obtained soon after arrival of the child with severe burn injury. Peripheral, large-bore intravenous catheters are favored because they have the lowest resistance. Catheters placed in the upper extremity through intact skin are preferred because they are easier to secure, but access through burned areas may be necessary. Anticipating the need for hyperalimentation, sites for central catheter placement should be saved, if possible. Attention to aseptic technique when starting intravenous catheters in the ED can prevent infectious complications during subsequent care. Circumferential taping is dangerous because the swelling that occurs during the first 24 hours can cause circulatory insufficiency distal to the constriction. Urine output is the most important means of monitoring fluid status, but in patients with severe burns with associated inhalation injury, central venous pressure monitoring may be useful in the first few hours.

An initial bolus of 20 mL per kg of Ringer's lactate solution is recommended while assessment of the extent of the burns takes place. Fluid volume from initial boluses should be counted when calculating fluid volumes during the first 24 hours of treatment. A urinary catheter should be placed early in the management because there are often several hours of monitoring during transport or in the ED during which urine production can provide clinicians with information about fluid status. Major burns cause decreased splanchnic blood flow and ileus. After ensuring that the airway is protected by an endotracheal tube or an adequate gag reflex, the clinician should place a nasogastric tube. Hypothermia can occur rapidly in small children, especially in those whose skin injury impairs normal thermoregulation. Core temperature should be monitored and the child kept covered, except as necessary for examination and burn assessment. Children younger than 7 years who are not fully immunized, or if immunization status is unknown, should receive DTap patients 7 years and older who require tetanus prophylaxis should receive Td or Tdap (not immunized, unknown status 5 years or longer since last tetanus-containing vaccine dose); unimmunized and underimmunized patients also require tetanus immune globulin.

Peripheral circulation may require assessment with a Doppler device because the usual methods of assessment, including capillary refill and temperature, are difficult in a child with severe burn injury. First, all jewelry and watches should be removed because these may restrict distal flow of the blood. For extensive, deep upper extremity burns, the radial, ulnar, and palmar arch pulses should be checked by Doppler ultrasound. Posterior tibial and dorsalis pedis pulses are assessed when the lower extremity is involved. Absence of flow or progressive diminution of the pulse is an indication for escharotomy through the depth of the eschar on the medial and lateral aspects of the extremities, including the hands. Finger escharotomies are seldom necessary and should be undertaken only after consultation with a burn center surgeon. It is especially important to extend escharotomy incisions across the joints because at these locations, the skin is tightly adhered to the underlying fascia where vascular obstruction is likely to occur. The procedure does not require anesthesia because the wounds are full thickness and therefore insensate. Pulses assessed by Doppler ultrasound should immediately improve after escharotomy. If improvement is not immediate, hypovolemia should be suspected. Reperfusion of the extremities after escharotomy may abruptly reduce intravascular volume and require prompt adjustment of fluid therapy.

Assessment

After stabilization of vital functions in the primary survey, a systematic evaluation of the surface area and depth of burns follows. The rule of nines used to estimate burn surface area in adults cannot be applied to children because they have different body proportions. Young children have relatively larger heads and smaller extremities. Areas of partial- and full-thickness injuries should be recorded on an anatomic chart (Fig. 108.3) and then total percentage burn surface area computed using age-appropriate proportions. First-degree burns are not included. A child's palm including the fingers is approximately 1% of BSA and can be used to estimate the extent of scattered, smaller burns (Fig. 108.3).

BSA calculations are inexact, and some first-degree burns may progress to second-degree burns over time, so BSA estimates should be reassessed.

Fluid Therapy

Rapid treatment of the hypovolemia that occurs early in children with severe thermal injuries is of prime importance. The fluid status of children with burn injury is a dynamic process that requires careful reevaluation and therapeutic adjustments. Extravasation of water, sodium, and protein through abnormally permeable capillaries continues for about 24 hours after injury. Capillary integrity then improves and intravascular volume stabilizes. Most burn centers recommend crystalloid during

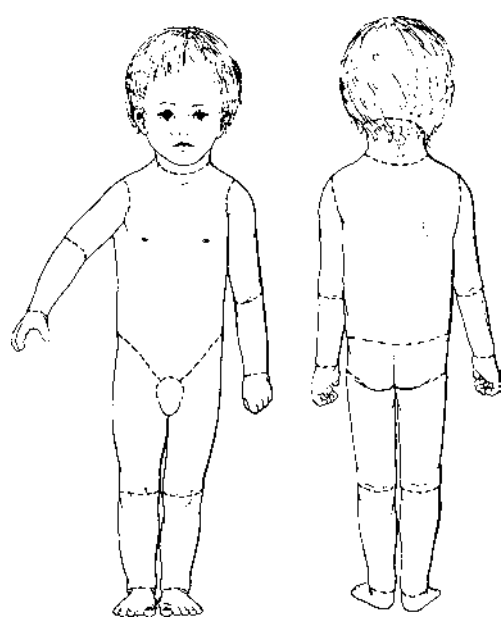

FIGURE 108.3 Estimation of surface area burned on the basis of age. This modification by O'Neill of the Brooke Army Burn Center diagram shows the change in surface of the head from 19% in an infant to 7% in an adult. Proper use of this chart *(above)* provides an accurate basis for subsequent management of the child with burn injury.

TABLE 108.1

FLUID RESUSCITATION FORMULAS

Parkland: 4 mL/kg/% of BSA second- and third-degree burns, half in the first 8 h following injury, half in the next 16 h. Add maintenance with 5% dextrose in children <5 years old

Galveston Shriners: 5,000 mL/m^2/% of BSA second- and third-degree burns, half in the first 8 h, half in the next 16 h. Add 2,000 mL/m^2/day maintenance with 5% dextrose

the first 24 hours because colloid may extravasate through the leaky capillaries and worsen interstitial edema. Once capillary integrity is restored, colloid is useful for volume expansion and for restoration and maintenance of serum oncotic pressure. The sodium ion is critical for maintaining adequate intravascular volume, so isotonic crystalloid solutions are recommended in the resuscitation phase. Hyperosmolar therapy with 3% saline appears to have little benefit and increased risk. Potassium is released from damaged cells and may elevate measured serum levels shortly after injury; therefore, potassium replacement is not recommended during the early phase of fluid therapy.

Several formulas for the calculation of initial fluid therapy exist (Table 108.1). The Parkland formula recommends 4 mL per kg/% of BSA of crystalloid over the first 24 hours, half during the first 8 hours from the time of injury and half during the next 16 hours. This formula underestimates the fluid needs of young children, who are also at greater risk for hypoglycemia. Maintenance requirements are added for patients with burns who are younger than 5 years using isotonic solutions with 5% dextrose. The Galveston Shriners formula uses BSA rather than weight to calculate fluid therapy. Galveston Shriners recommends 5,000 mL per m^2/% of BSA, half during the first 8 hours from the time of injury and half during the next 16 hours, plus 2,000 mL per m^2 per day as maintenance. The calculated volume requirements are useful in choosing an initial rate of fluid infusion. Adjustments of infusion rates are the rule, not the exception. Most pediatric burn centers follow urine output rather than central venous pressure to assess the adequacy of fluid therapy. Children should produce approximately 1 mL per kg per hour of urine. A study of burns in adults showed that most patients receive more fluid volume than that prescribed by the Parkland formula, and almost half are "overresuscitated" as defined by excessive urine output. Overresuscitation, or excessive fluid administration, is to be avoided because it may cause tissue edema that compromises local blood supply. Hyperglycemia may cause an osmotic diuresis and complicate care of the patient with burn injury. Before infusions are decreased in response to excessive urine output, a measurement of blood glucose should be made.

Inadequate fluid resuscitation is usually manifested by oliguria. Rarely, intrinsic renal disease is responsible for oliguria, as may occur after electrical injuries because of myoglobinuria.

Trauma associated with burns may increase fluid requirements. Additional fluids may also be necessary when burns are associated with an inhalation injury. Fractures or other traumatic lesions causing blood loss and edema also increase the need for fluids. Neurogenic shock from unrecognized cervical spine or head injury may cause hypotension, usually with a relative bradycardia. Toxins, such as cyanide, ingested before the burn or inhaled during the fire can depress myocardial function or vascular tone. Any patient with shock that appears out of proportion to the extent of the burn injury, or who is poorly responsive to fluid therapy, should have an aggressive diagnostic workup for concurrent problems.

Antibiotics

Burn sepsis continues to be the major cause of mortality after the period of resuscitation despite improvements in topical and systemic antimicrobials. Meticulous antiseptic techniques can lessen colonization of burns with potential pathogens. Topical antibiotics further reduce bacterial number. Early streptococcal cellulitis is less common than in years before the development of topical antibiotics for burns, and most burn centers do not routinely treat patients with prophylactic penicillin. Pediatric patients, however, may have greater risk than adults, and some pediatric burn centers administer intravenous penicillin for the first 3 to 5 days after injury.

Broad-spectrum antibiotics should not be used prophylactically because of the increased likelihood of inducing resistant organisms. Frequent examination of healing burns for signs of infection and cultures to monitor colonization can direct specific antibiotic therapy for documented infections.

Care of the Burn Wound

Early surgical management of some partial-thickness and most full-thickness burns with excision and grafting has been an important advance in burn treatment. Initially, burns should be covered loosely with clean sheets during the resuscitation phase in severe injuries. Once cardiorespiratory status is stabilized, the wounds are uncovered and assessed for size and depth. The goals of burn wound care are to promote rapid healing and prevent infection. Cleansing with large volumes of lukewarm sterile saline or chlorhexidine gluconate reduces contamination. Loose tissue can often be wiped away with sterile gauze, simplifying and expediting burn debridement. Bullae larger than 2 cm and those at locations that are likely to rupture should also be debrided. Smaller bullae may be left intact to preserve the barrier to bacterial invasion. Application of temporary skin substitutes may reduce pain, expedite healing, and reduce length of hospitalization compared with topical antibiotics and conventional dressings but are usually not applied in the ED. It is not necessary to apply topical antimicrobials to burns prior to transfer to a burn center or children's hospital.

Pain Management

Safely reducing pain is an important consideration in the management of children with burns of all sizes. Pain is a subjective experience influenced by the preceding events. Children rescued from house fires, separated from their parents, transported in ambulances, and brought to EDs are usually extremely anxious. Calm, developmentally appropriate verbal reassurance, even to preverbal children, can reduce anxiety and dramatically reduce the perception of pain.

The exposure of sensory nerve receptors in partial-thickness burns makes them sensitive to environmental stimuli. Movement of cool air across burned tissue increases pain significantly. The simple measure of covering burns with a clean sheet, only exposing them when necessary for burn assessment, is an extremely effective and safe analgesia.

Many children will still have significant pain after nonpharmacologic measures are taken. Narcotic analgesics are useful when administered appropriately. Morphine may reduce the blood pressure, especially in patients who are hypovolemic. Fentanyl causes less cardiovascular effect than morphine but has a short half-life. Clinicians should be reluctant to use narcotics until adequate circulation is reliably established.

Analgesic medications administered intravenously are preferred in patients with severe burns because they are more effective and predictable. Intramuscular injections or oral doses should not be given to patients with significant burns because circulation to muscle and gut is reduced, and absorption of medication will be delayed and unpredictable. Morphine (0.1 to 0.15 mg per kg (2.5 mg–5 mg max)) is the drug of choice for most patients with severe burns. In children who do not respond well to the initial dose of morphine, a careful assessment for other causes of pain or agitation should be sought. Compartment syndrome, hypoxemia, early shock, and occult injuries should be excluded before repeating doses of analgesics. Analgesic administration just before debridement of the burn wound is recommended.

Disposition

Guidelines for admission must be individualized when treating children with burns. Hospitals, physicians, and parents have varying capabilities for managing pediatric patients with burns. In general, admission is recommended for children with burns of smaller percentages of BSA than adults, especially patients younger than 2 years.

Children with partial-thickness burns of more than 5% to 10% of BSA should be considered for admission to a hospital. Partial-thickness injury over 10% of BSA warrants admission to a children's hospital or burn center. Full-thickness burns over 2% of BSA require inpatient treatment. Burns in certain locations are at higher risk for disability or poor cosmetic outcome and should be considered for treatment in the hospital. These include more than 1% of BSA burns of the face, perineum, hands, and feet; circumferential burns; or burns overlying joints. Children with inhalation injury or associated trauma require admission with burns involving lesser percentages of BSA. Any time the physician suspects that the burns cannot be adequately cared for in the home, admission to the hospital is warranted.

OUTPATIENT MANAGEMENT OF BURNS

A small minority of all burns in children require therapy in the hospital. Once a careful assessment has led to a decision to manage a burn as an outpatient, preparations for treatment at home should begin. Parents become the physician's partner in this context and need to be instructed carefully.

A first-degree burn usually does not require therapy. Moisturizers and acetaminophen or ibuprofen can be given as needed. Partial-thickness burns are first cleansed with mild soap and water, povidone-iodine solution at one-fourth strength, chlorhexidine gluconate, or saline alone. Devitalized tissue can usually be removed by wiping with gauze. Bullae larger than 2 cm are likely to rupture and should be debrided. Clean partial-thickness burns less than 2% of BSA can be dressed with petrolatum gauze. Topical antibiotics are recommended for larger or more contaminated burns. Silver sulfadiazine cream (Silvadene) and bacitracin are the topical antibacterial agents of choice at most burn centers. A $\frac{1}{16}$– to $\frac{1}{8}$– in layer of silver sulfadiazine is applied to the burn with a sterile tongue blade or gloved hand. Silver sulfadiazine is soothing to the burn, has few side effects, and kills many gram-positive and gram-negative bacteria and *Candida* species. Mild bleaching of the skin may occur with silver sulfadiazine, so bacitracin is often chosen for burns of the face. About 5% of children are allergic to sulfa drugs and can be treated with bacitracin or povidone-iodine ointment. Leukopenia has also been reported in patients treated with silver sulfadiazine. Mafenide acetate (Sulfamylon) is a topical antimicrobial agent that is more penetrating than silver sulfadiazine. It causes pain when applied, cannot be used in sulfa drug–sensitive patients, and inhibits carbonic anhydrase, which can cause a metabolic acidosis. Some experts recommend mafenide acetate for burns overlying cartilaginous structures such as the ear and nose.

A loose gauze dressing should be placed over the burn and secured with tape. Burns of the face can be treated with an open technique. Dressings should be changed twice each day. The parent should rinse off residual antibacterial cream with warm water and inspect the wound. Signs of infection, such as redness and tenderness around the margin of the burn, warrant immediate evaluation by a physician. A gray-greenish material formed by serous drainage from the burn mixing with the silver sulfadiazine cream is often mistaken for purulence. If the burn is healing well, the parent should reapply the antibiotic cream and dress the wound as demonstrated by the physician or nurse in the ED. Burns should be examined by a physician every 2 or 3 days until healing is well under way. Large burns or burns of the hands, feet, perineum, or overlying joints that are managed as an outpatient should be referred for follow-up to a burn specialist and evaluated more frequently. Prophylactic antibiotics are not recommended.

A new method for managing burns as an outpatient involves dressings composed of carboxymethylcellulose fibers impregnated with silver. Fluid from the burn surface interacts with the dressing to form a firm bandage with an antimicrobial contact layer. These dressings continue to release antimicrobial agent to the burn surface for 1 to 2 weeks and do not require daily dressing changes. They are as effective as silver sulfadiazine at reducing microbial counts and greatly simplify the management of outpatient burns, but long-term data on outcomes are not yet available.

INFLICTED BURNS—CHILD ABUSE

Child abuse must be considered in patients with specific patterns of burn injury. Between 10% and 20% of burns in children are inflicted, accounting for 10% of child abuse cases. Most inflicted burns are scalds. Forced submersion of the hands or feet often causes burns that are deep, have a clear line of immersion, and are symmetric. Scald burns of the buttocks and thighs in toddlers are frequently the result of forcible submersion in a tub of hot water as punishment for toilet-training mishaps. Inflicted contact burns also have characteristic patterns. Small, round, deep burns result from cigarettes intentionally applied to the skin. Deep injuries with distinctive patterns

may be noted in children held against portable heaters or burned with irons.

In many children with inflicted burns, the pattern of injury is nonspecific and a history of abuse is not offered. A deep wound with a geometric pattern and sharply demarcated borders suggests a contact burn. Scald burns usually have scattered splash lesions. In burns from spilled hot beverages, there is often a pattern of injury spreading downward from the falling liquid. Physicians should make a judgment whether the characteristics of a burn correspond with the reported mechanism in a plausible way. Identifying suspicious injuries and notifying the appropriate authorities can prevent subsequent injuries.

ELECTRICAL BURNS

Burns that result when electrical current passes through the body have unique characteristics. Each year there are more than 4,000 ED visits caused by electrical injuries mostly in children (see Chapter 87). Electrical burns account for 3% of burn center admissions and are increasing in number. Most injuries occur in young children from contact with low-voltage (less than 120 V) alternating household current, often from mouthing plugs or extension cords. Severe high-voltage (more than 500 V) injuries are also seen, often in adolescent boys as a consequence of risk-taking behaviors.

Thermal energy is released in proportion to the amount and duration of electrical current that passes through tissue. Current flows preferentially through tissues of low electrical resistance, such as blood vessels, nerves, and muscles. Moisture on the skin decreases resistance, accounting for the greater severity of injury in the antecubital, axillary, popliteal, and inguinal areas in patients of electrical burns. Current arcing through the skin can ignite clothing and cause severe thermal burns in addition to the electrical injury. In some direct current electrical burns, a depressed entrance wound and a blown out exit wound can be identified. If the current traverses the heart, which occurs more often when the flow is arm to arm, a myocardial injury may occur. Current through the heart at certain points of the cardiac cycle can induce ventricular fibrillation or asystole. Electrical injury, especially by alternating current, can cause tetany of the musculature that may prolong the contact with the high-voltage source. Tetany of the respiratory muscles can lead to suffocation.

The initial approach to patients of electrical burns is similar to that in other children with severe burns. Electrical burns are usually more severe than they appear. Significant deep and internal injuries may occur in patients with relatively small external burns. Fluid requirements are higher than those predicted by formulas based on percentage of BSA because a larger portion of the injury is internal. Destruction of muscle often causes myoglobinuria, so serum creatine kinase and urine for myoglobin should be tested. Renal failure can usually be prevented with forced diuresis and alkalinization. Electrical injury and edema within fascial compartments can cause a compartment syndrome requiring fasciotomy. Patients with a normal electrocardiogram (rate and rhythm) in the ED do not appear to be at significant risk for later development of arrhythmias. Severe electrical injuries require extensive evaluation for internal injuries, which should be done at a children's hospital or regional burn center.

A common electrical injury occurs to the lips and mouth of toddlers who suck on plugs or extension cords. Deep burns at the corner of the mouth require specialized attention to prevent severe scarring and contracture. Bleeding from the labial artery 1 to 2 weeks after injury, when the eschar separates, can result in a significant blood loss. In previous years, children with electrical injuries were hospitalized for 2 weeks, but some burn specialists now manage these children as outpatients after giving careful instructions to children's caregivers. See Chapters 87 and 109 for additional discussion of electrical burns, including lightning strikes.

CHEMICAL BURNS

More than 25,000 different caustic products are in use in the United States. Most are either acidic or alkaline. Acids cause coagulation of tissue proteins, which limit the depth of penetration. Alkali results in liquefaction and deeper injury. Some organic compounds, including petroleum products, damage tissue by dissolving the fats in cell membranes. Caustic chemicals on the skin cause a prolonged period of burning compared with most thermal burns, making immediate irrigation especially important in limiting the extent of injury. Edema of the underlying tissue can make full-thickness injuries appear deceptively superficial. Treatment of caustic burns, regardless of the substance involved, requires copious irrigation to dilute and remove the chemical to stop the burning process. Attempts at neutralization are usually ineffective and should be avoided. The pH of the effluent can be monitored to help determine whether irrigation has been adequate. A thorough examination is necessary to identify other areas of skin exposed from splashes or contact that also require irrigation. Consultation with a burn specialist and admission are recommended at smaller percentages of BSA with chemical burns than with thermal injuries. Chemical burns to the eye can threaten vision and, after starting irrigation, require prompt consultation with an ophthalmologist (Chapter 127).

CHAPTER 109 ■ DENTAL TRAUMA

LINDA P. NELSON, DMD, MSCD, HOWARD L. NEEDLEMAN, DMD, AND BONNIE L. PADWA, DMD, MD

ASSESSMENT OF TRAUMATIC DENTAL EMERGENCIES

The care of pediatric patients with oral and maxillofacial and dental trauma should follow the basic tenets of emergency medicine. An initial general assessment includes evaluation of airway, breathing, and circulation (ABCs). Control of bleeding, assessment of the degree of shock, evaluation of neurologic status, and notation of other injuries must be done sequentially.

Life Support

The most common cause of airway obstruction in a child with facial injuries is the accumulation of blood in the oral cavity and pharynx. Unconscious children may be unable to clear their airway by coughing or swallowing. A tooth aspirated by a child can block the airway. A fractured mandible may cause the tongue to fall posteriorly and create obstruction. The mouth should be gently suctioned clean. If the tongue of an unconscious child is causing obstruction, the mandible can be pulled forward by pressure at the angles or an oropharyngeal or nasopharyngeal airway can be placed. Chapter 1 details the procedures for establishing a patent airway. If endotracheal intubation fails, a surgical airway must be obtained with either a cricothyrotomy or a tracheostomy.

The soft tissues and bones of the lower and midface are well vascularized and bleed profusely when injured. Hemorrhage is best controlled both by direct pressure and by ligating any vessels that are easily seen. However, vessels of the face often retract when severed, making them difficult to visualize. If there is extensive blood loss, the patient should be assessed for signs of shock (see Chapter 3).

History

A thorough history and physical examination are important to any treatment considerations. Traumatic orofacial injuries can be dramatic, making the history difficult to obtain, and informants other than the patient may have to be questioned. The practitioner should always be alert to the possibility of "nonaccidental" trauma (i.e., child abuse) if the history is not consistent with the observed injury. Many traumatic facial injuries occur with concomitant soft-tissue injuries, and the need for tetanus prophylaxis is based on the history of immunization. Antibiotics may be indicated before treatment is indicated in children with congenital heart defects to prevent bacterial endocarditis (see Chapter 84 and Table 84.25) and in children who have certain hematologic, oncologic, or endocrine disorders (e.g., sickle cell disease, leukemia, diabetes). The history should also give the physician an indication of the preinjury and postinjury neurologic status. A thorough neurologic assessment must be made as early as clinically possible because the concurrent risk of neurologic injury is high in patients with head and neck trauma.

Physical Examination

Children with facial injuries are usually frightened and apprehensive, requiring an authoritative and reassuring manner during the initial contact. The examination should be organized to include inspection and palpation of extraoral and intraoral structures.

Extraoral Examination

Inspection. The extraoral examination should start with noting the symmetry of the face in the anterior and profile views. A loss of symmetry is often associated with swelling as the result of trauma. The clinician should carefully note the location and nature of any swollen or depressed structures, the color and quality of the skin, and the presence of lacerations, hematomas, ecchymoses, foreign bodies, or ulcerations. The child should be asked to open and close his or her mouth while facing the clinician to see whether the mandible deviates during function. If the child is unable to open or close his or her mouth because of pain, the action should not be forced because it may increase the extent of injury. The clinician should inspect for lip competency (the ability of the lips to cover the teeth) because loss of competency may indicate displacement of the teeth from trauma.

Palpation. Gentle bilateral digital palpation of the temporomandibular joints (TMJs) should be the next point of the examination. The clinician should feel the TMJs as the child opens and closes his or her mouth. There should be equal movement on both sides without major deviations. The infraorbital rims should be palpated to ensure it is continuous and intact all the way to the inner canthus of the eye. Examination continues across the zygoma to the nose, palpating for crepitus or mobility. Attention should focus on the mandible, feeling along the posterior border of the ramus and moving anteriorly along the body to the symphysis, palpating for any discontinuity, mobility, swellings, or point tenderness. The child should be questioned and examined for any evidence of paresthesia or hypoesthesia (numbness) of the lips, nose, and cheeks, which may indicate a fracture through the bony foramen in which the nerve exits. Figure 109.1 shows the main nerve supply to facial structures.

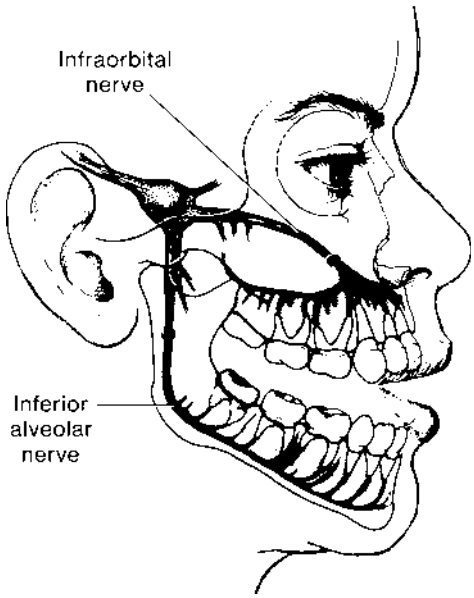

FIGURE 109.1 Infraorbital and inferior alveolar main nerve supplies the teeth.

Intraoral Examination

Inspection. A good light is essential for the intraoral examination to inspect the color and quality of the lips, gingiva (gums), buccal mucosa, floor of the mouth, tongue, and palate. The gingiva should be pink, firm, and stippled (like a grapefruit skin). The mucosa of the cheeks and floor of the mouth should be pink, moist, and glassy in appearance. Any soft-tissue swelling that is blue as a result of ecchymoses and/or hematoma should be noted. Hematomas or mucosal ecchymoses at the floor of the mouth or vestibular area are highly suggestive of mandibular fractures. Any inflamed, ulcerated, or hemorrhagic areas, as well as any foreign bodies or denuded areas of bone, should be documented.

Teeth are labeled according to their position. For older children with secondary dentition, the examiner begins on the upper right at the third molar with #1, precedes clockwise across the top to #16, and then continues on the lower left with the third molar from #17 across the bottom to #32. A similar process in young child with primary teeth starts with A in the upper right and proceeds clockwise across the top to J picks up on the bottom left from K to T.

Traumatically displaced teeth often result in malocclusion (complaint that the child's teeth do not fit together when he or she bites on the back teeth). This should not be confused with a similar complaint, which may be expressed by a child when a primary tooth is mobile and about to exfoliate. Figure 109.2 shows key eruption times for primary and secondary teeth. Exfoliation of primary teeth can be confused with traumatic dental injuries, and clarification can be made with an intraoral radiograph if necessary. The child should be examined for any damaged teeth and if a tooth is chipped or missing, the clinician should check for any fragments of teeth or foreign bodies in the adjacent soft tissues. If the child's teeth are missing yet no bloody socket is present, the eruption/exfoliation timetables (Tables 109.1 and 109.2) can be helpful in determining whether the loss

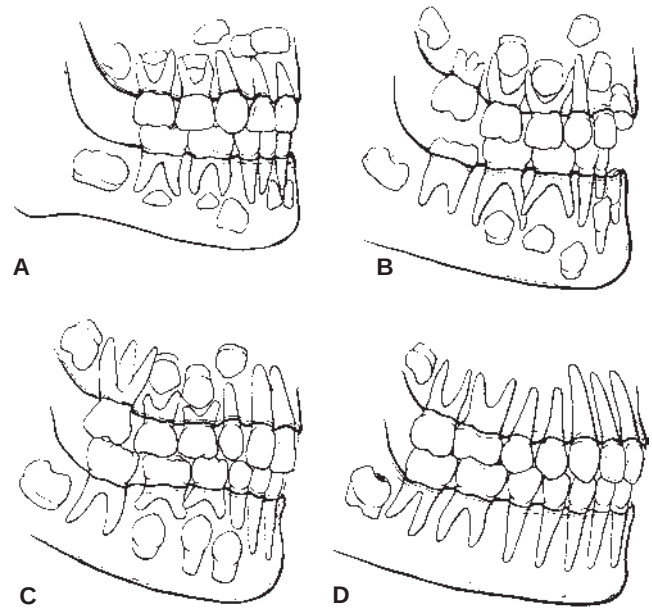

FIGURE 109.2 **A:** At age 3 years, 20 primary teeth should be erupted. The permanent teeth are in various stages of calcification underneath and behind the primary teeth. **B:** At age 6 years, 16 primary teeth should be present. The permanent 6-year molars should be erupting distal to the last primary molars. The permanent anterior central incisors should be erupting. **C:** At age 9 years, 8 to 12 primary teeth should still be present. The permanent 6-year molars should be totally erupted and in occlusion. The permanent anterior central and lateral incisors are totally erupted and are most prone to fracture at this time. **D:** At age 12 years, 28 permanent teeth should be present. Only teeth not present should be third molars (wisdom teeth).

TABLE 109.1

CHRONOLOGY OF ERUPTION OF PRIMARY AND PERMANENT DENTITION

	Maxillary	Mandible
Primary[a]	**Mean age (mo)**	**Mean age (mo)**
Central incisor	10 (8–12)	8 (6–10)
Lateral incisor	11 (9–13)	13 (10–16)
Canine	19 (16–22)	20 (17–23)
First molar	16 (13–19 boys) (14–19 girls)	16 (14–18)
Second molar	29 (25–33)	27 (23–31)
Permanent[b]	**Mean age (yr)**	**Mean age (yr)**
Central incisor	7–7.5	6–6.5
Lateral incisor	8–8.5	7.2–7.7
Canine	11–11.6	9.7–10.2
First premolar	10–10.3	10–10.7
Second premolar	10.7–11.2	10.7–11.5
First molar	6–6.3	6–6.2
Second molar	12.2–12.7	11.7–12.0
Third molar	20.5	20–20.5

[a]Mean age in months ±1 standard deviation. (From Lunt RC, Law DB. *J Am Dent Assoc* 1974;89:878. Reprinted with permission.)

TABLE 109.2

SEQUENCE OF PRIMARY TOOTH EXFOLIATION

Rank	Mandibular arch	Maxillary arch	Mean age[a] (yr, mo) Boys	Girls
First	Central incisors		6.0	5.7
Second		Central incisors	6.10	6.7
Third	Lateral incisors		7.2	6.10
Fourth		Lateral incisors	7.10	7.5
Fifth	Canines		10.5	9.7
Sixth	First molars		10.8	10.2
Seventh		First molars	10.11	10.6
Eighth		Canines	11.3	10.7
Ninth	Second molars	Second molars	11.9	11.5

[a]Ages are for the right side of the mouth; however, exfoliation is generally bilaterally symmetric.
From Ripa LW, Lesks GS, Sposanto AL, et al. Chronology and sequence of exfoliation of primary teeth. *J Am Dent Assoc* 1982;105:641. Reprinted with permission.

is normal. In addition, intraoral and/or extraoral dental radiographs, such as a panoramic view, can be diagnostic.

Palpation. Using the thumb and index finger, the clinician should palpate the alveolar ridge in all four quadrants for any swelling, discontinuity, or mobility of the soft tissues, and underlying bone. The palate should be examined for any swelling or tenderness. The masseter muscle should be palpated with fingers placed intraorally and extraorally, and rolling the muscle between the two. Using a gauze pad, the clinician should hold the tongue and lift it gently to better view and examine its dorsal, ventral, and lateral surfaces and the floor of mouth. The lips should be palpated for any swelling or nodules, and the quality of the swelling should be noted (i.e., fluctuance vs. induration). The teeth should be assessed for mobility, tenderness, or fracture, and the gums should be palpated for erupting teeth, noting any purulent exudate.

Percussion. The teeth should be percussed individually with the end of a mouth mirror handle or tongue depressor. Mobile, abscessed, vertically fractured, or traumatized teeth may be sensitive and sound dull on percussion.

Radiographs are a valuable supplement to the clinical examination. However, obtaining a diagnostic radiographic survey in a child with acute orofacial/dental injuries may be difficult.

OROFACIAL/DENTAL TRAUMA

Dental trauma occurs in various forms that can be confusing to the primary care provider. The emergency physician needs to know which injuries can be managed without dental consultation, which need follow-up care with a dentist, and which need emergency dental care. In a survey at an urban pediatric emergency department, trauma represented 21.7% of the chief complaints and 29.2% of the diagnoses. Several factors, including age, occlusion, and agility in sports, predispose pediatric patients to orofacial trauma. Traumatic dental injuries occur as the toddler becomes ambulatory (ages 1 to 3), as the child enters school (ages 7 to 10), and as the older adolescent (ages 16 to 18) engages in athletic activities. In addition, proclined or prominent maxillary anterior teeth are more susceptible to being displaced or fractured. Early orthodontic treatment to retract prominent incisors can reduce the risk of trauma to these teeth. Also, the use of a preformed ("boil and bite") or custom-made mouth guard in children with prominent maxillary incisors is helpful in reducing the chance of these accident-prone teeth sustaining traumatic injuries. This section details the management of dental injuries that are most commonly seen in the pediatric emergency patient.

Soft-tissue Lacerations

Management of soft-tissue injuries of the oral cavity follows the same emergency care principles used for injuries at other sites. Injuries to the lip result in significant swelling after minor trauma. Lacerations of the tongue and frenum bleed profusely because of the richness of their vascularity. However, ligating specific vessels is usually unnecessary because bleeding almost always stops with direct pressure and careful suturing. Frenum lacerations heal spontaneously and, therefore, do not require suturing. The injured area should be thoroughly examined for a foreign body, including obtaining a radiograph before suturing when a foreign body is suspected. If chipped teeth are present, radiograph examination is imperative to rule out the presence of the missing piece in the soft tissues. When a laceration in the oral cavity is more than a few hours old, primary closure depends on the relative risk of secondary infection (see Chapter 122).

Suturing the lip must be done carefully to achieve a precise approximation of the edges of the vermilion border to avoid a disfiguring scar. If necessary, the lip must be sparingly debrided and the skin closed with 5-0 or 6-0 nylon sutures. Deep lip lacerations require closure in multiple layers, beginning with approximation of the obicularis oris muscle using 4-0 chromic and then 5-0 or 6-0 nylon for the skin and vermilion. If the lip laceration is through and through, debridement may be necessary. In children younger than 5 years, 4-0 chromic on the deeper mucosal aspects of the lip and 6-0 chromic on the superficial

aspects are preferred. In children older than 5 years, 4-0 chromic is used on the deeper mucosal aspects of the lip and 5-0 or 6-0 nylon on the superficial edges. Most superficial tongue lacerations heal without suturing; however, deep lacerations or those that create a flap need to be sutured. When necessary, tongue lacerations are usually sutured with 4-0 chromic in superficial wounds and with 3-0 chromic in deeper wounds. With tongue lacerations, it is important to consider the excessive muscular movements that pull at the sutures; therefore, tongue sutures should be made deep into the musculature.

Injuries to the Teeth

Traumatic dental injuries can be categorized into two groups: (i) injuries to the teeth—hard dental tissues and pulp; and (ii) injuries to the periodontal structures—periodontal ligament and alveolar bone. Figure 109.3A indicates the relative positions of these structures. Injuries to the teeth can be further categorized into complicated and uncomplicated fractures.

Injuries to Hard Dental Tissues and Pulp

Uncomplicated tooth fractures are confined to the hard outer dental tissue (enamel) and the underlying (dentin). The fracture line may appear deep, but no sign of bleeding from the central core (pulp) of the tooth is apparent. The child may complain of sensitivity, especially to cold air and fluids. Emergency treatment is aimed at decreasing sensitivity of the involved tooth and protecting the pulp, even if no frank pulp exposure is noted. The child should be seen by a dentist within 48 hours to place a dressing of calcium hydroxide or glass ionomer over the exposed dentin for thermal and chemical insulation to minimize the chance of (pulpal) necrosis. A temporary restoration is then placed to prevent the insulation material from dissolving. At some later date, an aesthetic resin acid-etched restoration can be placed (Figs. 109.3B and 109.3C). The prognosis for uncomplicated tooth fractures is good.

A complicated tooth fracture involves not only the enamel and dentin but also the pulp of the tooth. Often, bleeding is noted from the central core of the tooth. To best preserve the viability of that tooth, dental pulpal treatment must be initiated immediately. Prognosis depends on the size of the exposure (less than 1 mm carry the best prognosis), the time interval between the trauma and therapy (less than 48 hours carries the best prognosis), and the maturity (root development) of the involved tooth. Thus, calling the dental consultant as soon as possible to institute pulpal therapy is important. Root fractures are generally seen after the tooth has reached full root formation, which is approximately 2 to 3 years after eruption begins (Table 109.1). Root fractures most commonly involve maxillary anterior teeth. Diagnosis depends on intraoral dental radiographs; therefore, immediate dental consultation is necessary. Treatment involves reduction if the segments are not aligned, followed by splinting. Pulpal therapy of the involved teeth may be necessary if healing of the fragments does not occur.

In any injury resulting in fragmentation of teeth, the emergency physician should attempt to account for all the fragments. Soft-tissue lacerations, especially of the lower lip and tongue, should be evaluated clinically and, if necessary, radiographically to rule out embedded tooth fragments. Infection and poor wound healing are the sequelae of such an oversight.

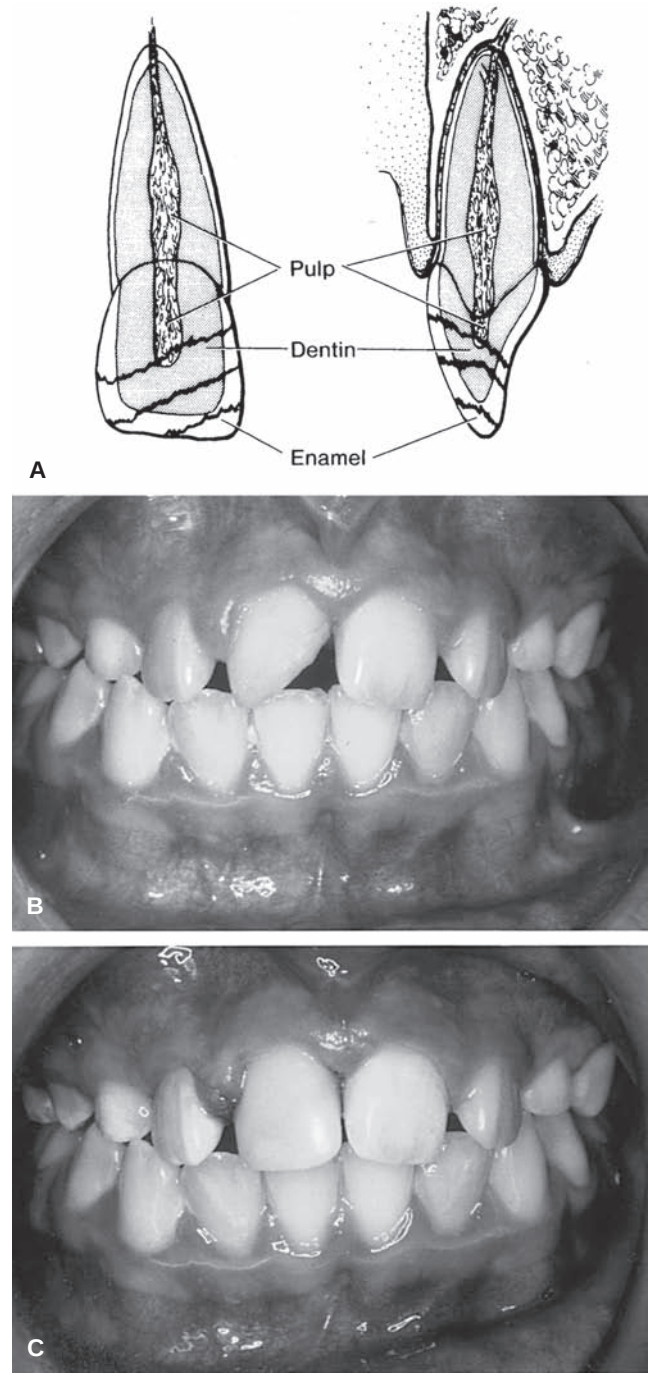

FIGURE 109.3 **A:** The anatomy of a tooth should be considered during a traumatic injury: enamel fracture, no emergency treatment; dentin fracture, emergency treatment as soon as convenient; and pulpal fracture, emergency treatment as soon as possible. **B:** Enamel and dentin fracture of a permanent incisor. **C:** The same child after bonded restoration.

Displaced Teeth

The tooth is held in the socket by slender elastic and collagen fibers collectively known as the periodontal ligament. These fibers are easily injured or severed with trauma to the teeth. Clinically, the physician may note either an increase or a decrease in mobility, depending on the extent of the cortical

plate fracture and/or displacement of the affected teeth. If asked, the child will be able to point to an injured tooth because of the tooth's heightened sensitivity. Periodontal injuries may be further subdivided into five clinical types: (i) concussion, (ii) subluxation, (iii) intrusion, (iv) extrusion/lateral luxation, and (v) avulsion, as noted in Fig. 109.4.

Concussion is usually caused by minor damage to the periodontal ligament, resulting in slight edema. Teeth sustaining concussive injuries exhibit no displacement or excessive mobility. They are, by definition, percussion sensitive when tapped with the blunt end of an instrument such as an intraoral mirror. No emergency treatment is indicated for such injuries, although baseline radiographs are needed at a subsequent dental consultation to rule out more serious involvement. The prognosis for concussion injuries is good, although pulpal necrosis is possible over time.

Subluxation is more damaging to the periodontal ligament because of increased edema. There is excessive mobility in the horizontal and/or vertical direction, but no displacement within the dental arch. The tooth is sensitive to percussion. The child may complain that his or her teeth feel like they do not meet when biting down. Because subluxated teeth, especially in the permanent dentition, may require stabilization with a bonded resin splint, this type of injury should be referred to the dental service as soon as possible.

Intrusion, although more commonly seen in the primary dentition, can be seen in the permanent dentition with high-velocity or high-force injuries. Intruded teeth are teeth displaced directly into the socket. Intruded teeth may not be visible and thus give the false appearance of being avulsed. To confirm complete intrusion and to rule out avulsion, an intraoral dental radiograph must be obtained when this condition is suspected. An intruded primary tooth must be evaluated by a dental consultant for its proximity to the developing permanent tooth. The prognosis for pulpal tissues of an intruded tooth is poor because of pulpal compression and severance, which occurs on impact. Intruded primary teeth can be either extracted or allowed to spontaneously reerupt, depending on the severity of the intrusion and condition of the surrounding bone and soft tissues. Intrusive injuries in the permanent dentition usually require repositioning and splinting. Pulpal treatment (endodontics) is almost always needed because the pulp is rendered nonvital as a result of trauma, which can cause root resorption and periapical infection. Compression fractures of the alveolar socket and anterior nasal spine may be seen radiographically.

Extrusion/lateral luxation injuries are manifested clinically as displacement of the tooth or teeth from the alveolar socket in an extrusive or lateral direction. Most commonly, the anterior maxillary teeth are involved. These teeth are extruded and displaced lingually, causing a fracture of the labial cortical plate of the alveolar socket. Luxated permanent teeth must be realigned and immobilized with a splint as soon as possible. Endodontic treatment is often needed in the long term. Extrusive/lateral luxations of the primary dentition usually necessitate extraction to allow children to fully occlude their teeth and to avoid potential injury to the permanent tooth bud during realignment or as a result of eventual pulpal necrosis.

Avulsion is the term used to describe a tooth that has been completely displaced from its socket. Radiographs may show the tooth to be actually intruded, ingested, or aspirated. The

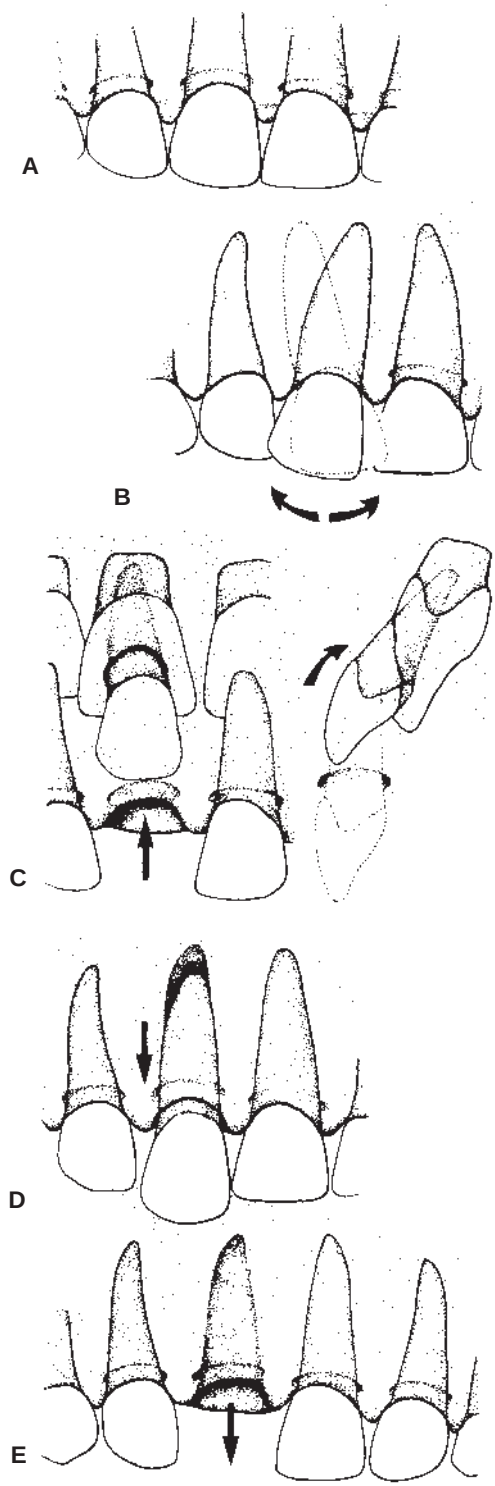

FIGURE 109.4 The various types of trauma to the periodontal structures. Concussion/subluxation (**A**); lateral luxation (**B**); intrusion (if primary tooth is intruded note location of developing permanent tooth bud) (**C**); extrusion (**D**); and avulsion (**E**). Refer emergencies (**B**) through (**E**) to the dental staff as soon as possible.

best prognosis exists if therapy is instituted within 15 to 30 minutes of the avulsion. The emergency physician or the parent should (as seen in Fig. 109.5) (i) find the tooth; (ii) determine whether it is a primary tooth by checking the child's age and the table of tooth eruption (if it is a primary tooth, do not reimplant); (iii) if it is a permanent tooth, gently rinse the tooth under running water or saline, taking care to hold the crown of the tooth and not the root (do not scrub the crown or root); and (iv) insert the tooth into the socket in its normal position (do not be concerned if it extrudes slightly).

If on-site reimplantation is impossible, the optimal storage to preserve the vitality of the periodontal ligament of the root surface is a cell culture medium such as ViaSpan or Hank's balanced salt solution. A commercial product such as the 3M Save-a-Tooth Emergency Tooth Preserving System (Smart Practice, Phoenix, AZ) containing Hank's solution is available to place the tooth into during transportation to the dental office. If none of these products are available, milk is an excellent alternative transport medium. Although saliva or saline are not ideal, they are alternative mediums that are preferred

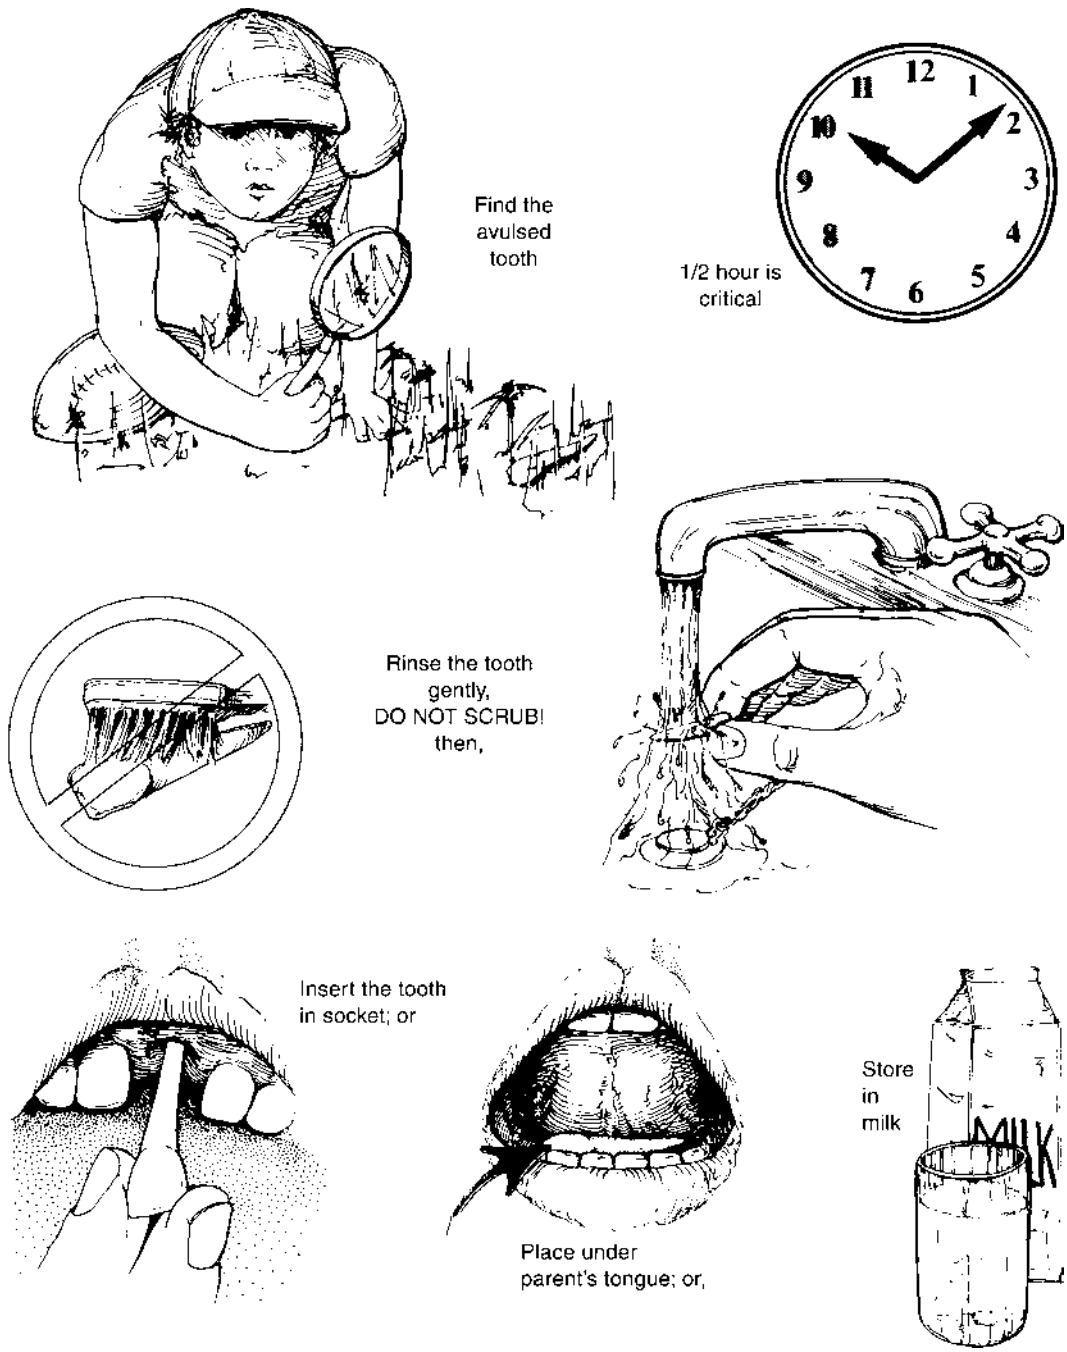

FIGURE 109.5 If a child loses or avulses a tooth, find the tooth and determine whether it is a primary or permanent tooth by checking Table 109.1. If it is a primary tooth, *do not reimplant*. Gently rinse under running water or with saline, but do not scrub the tooth. Insert the tooth back into the socket or place in milk or Hank's balanced salt solution and take immediately to the dentist. Remember, you have only 15 to 30 minutes to preserve the vitality of the tooth.

over allowing the root surface to air dry. The patient should go directly to the dentist for immobilization (splint). Dental follow-up is mandatory to prevent resorption of the root. Prophylactic pulpal therapy (endodontics) helps improve the prognosis by limiting pulpal necrosis and thus root resorption. Avulsed primary teeth are generally not reimplanted because of the close proximity of the permanent tooth and possible negative effects on development of this tooth.

Orthodontic Trauma

Young patients are frequently undergoing orthodontic treatment, and trauma results in loosening of wires or ligatures that are attached to orthodontic brackets or bands. These emergencies should be seen by the dental service as soon as possible to alleviate any discomfort and soft-tissue trauma. If dental treatment is unavailable, the physician can bend or cut the wire away from the soft tissues with a hemostat. Softened wax can be molded over the loose wire as a temporary method or to allow the traumatized soft tissues to heal. If no discomfort is noted and no loose foreign bodies are present, definitive treatment can be delayed until an orthodontic specialist can see the patient.

Mandibular Fractures/Dislocations

Although the incidence of facial fractures in children is low, the most common facial fractures are those of the nasal bones, followed by the mandible. The emergency physician should be knowledgeable in the diagnosis and management of mandibular fractures. History, physical, and radiographic examination should be used to establish the diagnosis of mandibular fracture.

The mandible can be compared with an archery bow, which is strongest at its center and weakest at its ends. Thus, most fractures occur at the neck of the condyles. Other areas of the jaw that are predisposed to fracture include the angle of the mandible where deep impacted teeth or unerupted 6-year molars make the mandible more vulnerable. The clinician should examine the teeth for any changes in occlusion and any raised or depressed fragments. Areas of bleeding, gingival/mucosal tears, or sublingual ecchymoses are also clues. Pain when opening the mouth, especially if the child is unable to open it fully, often indicates mandibular fracture. A unilateral condylar fracture should be suspected if the mandible deviates toward the affected side on opening.

A panoramic radiograph or preferably a computed tomographic scan should be obtained. In the pediatric patient, a mandibular fracture generally necessitates hospital admission. The appropriate consulting service should be called to stabilize the fracture, using either open or closed reduction.

Mandibular dislocation occurs when the capsule and TMJ ligaments are sufficiently stretched to allow the condyle to move to a point anterior to the articular eminence during opening. Dislocation can be unilateral or bilateral and often accompanies a history of extreme mouth opening (e.g., deep yawn) or occurs after a long dental appointment. The muscles of mastication enter a tonic contraction state, and the patient is unable to move the condyle back into the glenoid fossa and close his or her mouth. Gentle downward and backward pressure should be applied by the physician's thumb (wrapped in gauze) on the occlusal surfaces of the posterior teeth

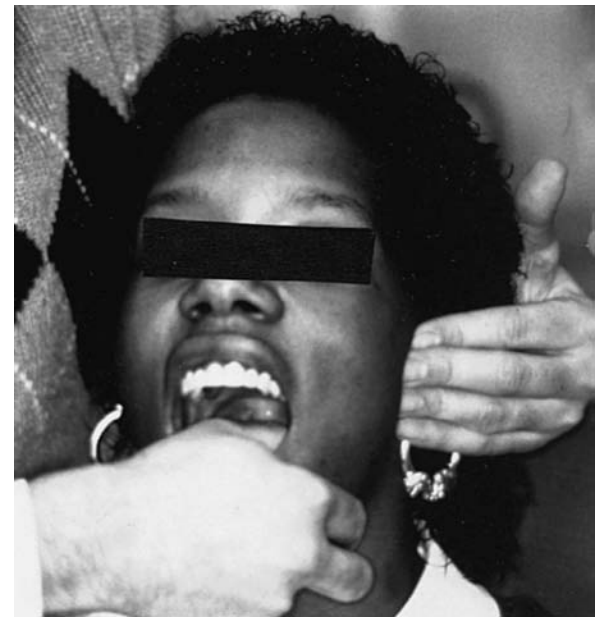

FIGURE 109.6 Position for the reduction of a dislocated mandible.

(Fig. 109.6). The downward pressure moves the dislocated condyle below the articular eminence; subsequent backward pressure on the molars shifts the condyle posteriorly into the mandibular fossa. If this approach fails, intravenous diazepam (0.2 mg per kg, maximum 10 mg) can be administered as an adjunct before relocating the condyles. Figure 109.7 shows the anatomic landmarks and repositioning of the TMJ.

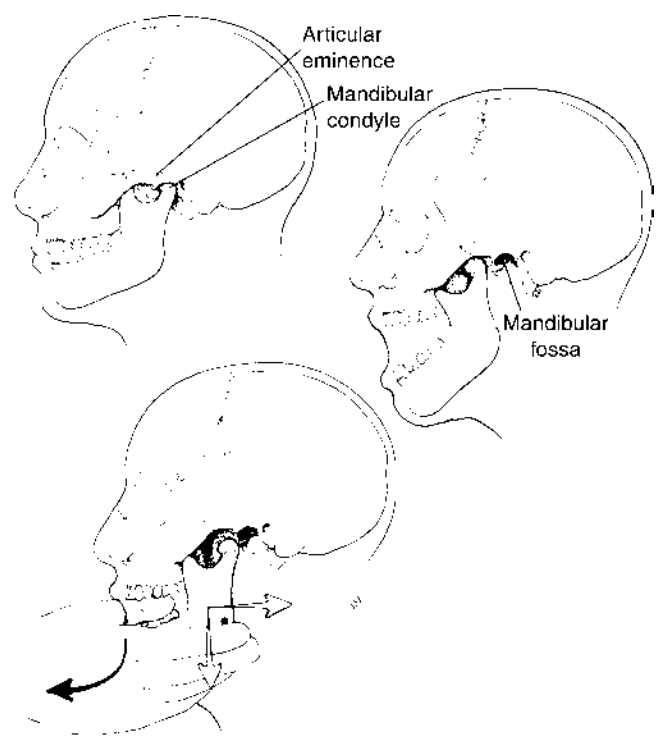

FIGURE 109.7 Dislocation of the temporomandibular joint occurs when the mandibular condyle moves to a point anterior to the articular eminence during opening. Reduction is accomplished by pushing downward and backward on the occlusal surfaces of the posterior teeth.

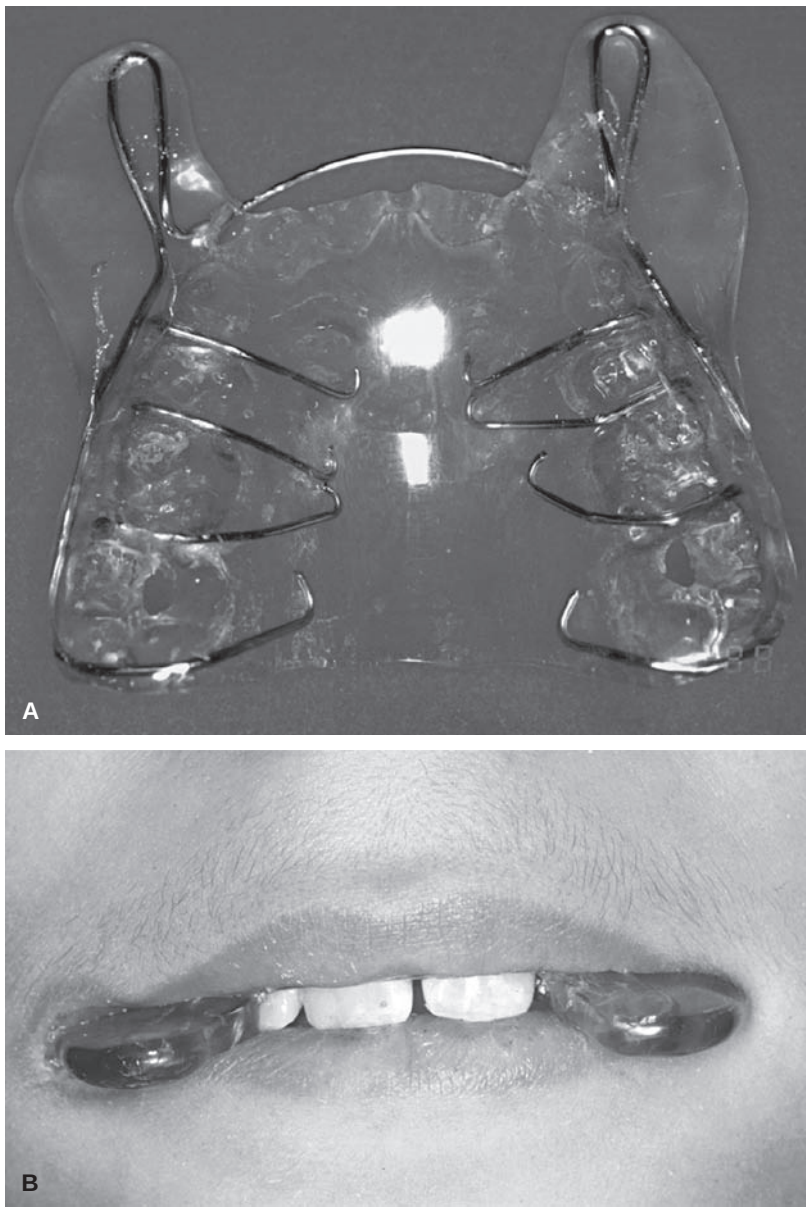

FIGURE 109.8 **A:** Removable maxillary intraoral acrylic appliance with extraoral commissure extensions. **B:** Appliance in place, separating the upper and lower lips with electrical burns at the commissure.

Maxillary Fractures

Premaxillary or anterior maxillary alveolar bone fractures are a common finding associated with the displacement or avulsion of maxillary anterior teeth. By gentle digital manipulation, the labial plate of bone can often be guided back into position under local anesthesia. Infiltration with 2% lidocaine with 1:100,000 epinephrine is commonly used. The bone fragment can be held in place temporarily by aluminum foil (three thicknesses) molded over the teeth and alveolar ridge. This emergency splint should be held in place by having the child bite down. A dental consultant should be contacted as soon as possible for fabrication of a more permanent dental splint. Splinting the loose teeth and suturing the gingival tissue holds the bone fragments in place. Mandibular and other facial fractures are covered in greater detail in Chapter 111.

Electrical Burns

Electrical burns of the mouth occur when children bite on electrical cords. The saliva in the mouth acts as a conductor to complete the circuit. In the emergency department, the first consideration is the patient's respiratory status. Next, the patient should be assessed for the presence of shock or other injuries. Although the commissure of the mouth is most likely affected, the tongue, alveolar ridge, and floor of the mouth are occasionally involved. Most children with these injuries can be managed as an outpatient. A bland, soft, cold diet is initially recommended. If refusal of food and dehydration are prob-

lems, the child requires admission to the hospital for the administration of intravenous fluids. Meticulous oral hygiene using a toothbrush with or without toothpaste must be performed three to four times per day, as well as hydrogen peroxide and water (1:1) rinses. With severe burns of the lips and mouth, arterial bleeding may occur 5 to 8 days after the injury. The clinician should instruct the parent on the method for digitally compressing the labial artery or consider admission to the hospital for wound management. To prevent scarring down of the commissure, electrical burns of this area require the fabrication of an intraoral or extraoral device to separate the upper and lower segments during healing (Figs. 109.8A and 109.8B).

CHAPTER 110 ■ OTOLARYNGOLOGIC TRAUMA

KEN KAZAHAYA, MD, MBA

In children, the head and neck regions are common sites for trauma; therefore, emergency medicine specialists must be familiar with injuries to these regions as they will often be called upon to evaluate these areas. Although the presenting complaints may seem extremely distressing to the patient and cause considerable anxiety for the parents, the conditions prompting the visit are rarely life-threatening. While many injuries may be isolated to the head, ear, nose, mouth, or throat, associated trauma (e.g., eye, dental, central nervous system, thorax) is also common and must be considered and detected when evaluating and treating patient's suffering from otolaryngologic trauma.

Evaluation of the patient with otolaryngologic trauma requires a careful and thorough examination of the head and neck. The specific methods of examination of each anatomic area are detailed in a separate chapter in this textbook.

EAR

Foreign Bodies

Foreign bodies in the external auditory canal (EAC) are common in children Solid objects, such as stones, beads, foam, silicone wax, or paper, are the most commonly encountered foreign bodies, but live insects may also enter the EAC. Foreign bodies should be removed as soon and as safely as possible. Evaluation and manipulation of the foreign body should be done with good illumination, and often, magnification, such as a microscope, is required. Most objects can be gently rolled out of the external meatus with an ear curette or grasped and removed with an otologic forceps. If a disk battery is in the EAC, it should be removed expediently to avoid caustic injury to the EAC. Round or occluding objects may be removed by irrigation of the canal with body-temperature water. The stream is directed along the side of the foreign body, forcing it to the external meatus. Irrigation, however, should not be performed if a tympanic membrane (TM) perforation is suspected or if a ventilating tube is in place. Furthermore, organic foreign bodies should not be irrigated, to avoid absorption of the fluid and expansion of the material in the EAC. If a disc battery is present in the EAC, irrigation is not recommended. Insects should be killed by filling the ear canal with alcohol or mineral oil before they are removed from the ear canal by the techniques already described. Objects resting against the TM are best removed by irrigation to avoid injury and pain from manipulation.

Care must be taken to remove the foreign material without causing pain or trauma to the external canal. The medial portion (bony portion) of the EAC and TM are exquisitely sensitive and easily traumatized. Topical anesthetic emulsions are available and have been used to decrease the sensitivity of the ear canal skin. Unfortunately, it may be difficult to get the emulsion past the foreign body, and it requires time for optimal performance. Furthermore, in the event there is a TM perforation, the anesthetic may cause nausea and vomiting as a result of direct effect upon the vestibular system. If removal of the foreign body is not easily performed, it may be prudent to seek consultation from an otolaryngologist before the child becomes averse to allowing anyone near their ear. If the removal is unsuccessful, an otolaryngologist may elect to proceed to the operating room and remove the foreign body while the patient is under general anesthesia. If an excoriation or trauma of the EAC occurs, use of an ototopical antibiotic drop, such as a fluoroquinolone, for example, ofloxacin, may prevent development of otitis externa.

Trauma

External Ear Trauma

External ear trauma is common in children because the pinna is in an exposed position on the side of the head. Reflex turning of the face to the side to avoid a blow or a fall places the ear directly in the line of injury. External blunt trauma is often secondary to an athletic injury, a fall, or a direct blow to the ear. The injury may result in ecchymosis or it may disrupt perichondrial blood vessels with subsequent hematoma or seroma formation. These collections usually form a smooth, bluish-colored mass on the lateral surface of the auricle that obscures the normal contours of the helix and antihelix. Hematomas and seromas must be evacuated expeditiously to prevent cartilage necrosis and potentially a cauliflower ear. After drainage of the collection, sutures are used through the pinna to hold bolsters in place on both sides of the pinna to prevent recollection. Lacerations of the pinna should be closed by using the same surgical principles applied to repairing lacerations in other end-organ areas of the body. Earrings in pierced ears may be torn from the lobule. These lacerations should be closed like all skin lacerations, reestablishing the normal anatomy—care should be taken to avoid notching the lobule at the laceration site. The skin edge should be everted.

Thermal injury of the external ear commonly occurs because the ear protrudes from the head and is exposed to burns and cold. The external ears frequently become exposed to environmental conditions such as excessive sun or subfreezing air. Burns of the ear should be treated in the same manner as burns of other parts of the body. Care should be taken to observe for sign of development of a chondritis. Frostbite is

suspected when the ear is pale and is usually painful on warming. The frostbitten ear should be rewarmed rapidly by applying warm soaked cotton pledgets at 38°C to 40°C (100.4° to 104°F); the ear should be completely thawed and never recooled.

Middle Ear Trauma

Perforations of the TM may result from acute otitis media. These perforations are typically small and heal readily. Traumatic perforations of the TM may also occur as a result of a slap to the side of the head (by a hand or a breaking wave) from the sudden compression of the air in the EAC; however, traumatic perforations of the drum are more often a consequence of poking an object into the ear canal. The structures of the middle ear may also be damaged by the penetrating object. The ossicles may be fractured or dislocated, resulting in a conductive hearing loss, or a perilymph fistula may be created if the footplate of the stapes is disrupted or dislodged from the oval window. A perilymph fistula typically presents with immediate vertigo, nystagmus, and sensorineural hearing loss. The facial nerve may be injured and may result in facial paralysis from injury in the horizontal portion of the facial nerve as it courses horizontally over the oval window. Traumatic perforations of the TM must be examined carefully, ideally under magnification, to be certain that the edges of the perforation do not fold into the middle ear. If this occurs, skin may grow into the middle ear and a cholesteatoma may develop. Clean perforations with margins that do not fold into the middle ear usually heal spontaneously in 2 to 3 weeks. The perforation should be kept clean and dry. If the ear is draining, topical antibiotic drops (e.g. ofloxacin or ciprofloxacin) should be used for 10 days. Systemic antibiotics are usually unnecessary. Any perforation that does not heal within 3 weeks should be referred to an otolaryngologist for evaluation and management. Traumatic perforations associated with vertigo, sensorineural hearing loss, or facial nerve paralysis requires urgent consultation and possible exploration of the middle ear by an otolaryngologist.

Barotrauma to the ear may occur any time there is a significant change in ambient pressure on one side of the TM that is not compensated by a change in pressure on the other side. This may occur during an airplane trip, while scuba diving or sometimes even diving in the deep end of a swimming pool. These injuries are more common if a child has eustachian tube dysfunction—as can occur with an acute upper respiratory tract infection. The eustachian tube provides communication between the middle ear and the nasopharynx, normally permitting prompt equalization of pressure on both sides of the TM. If the eustachian tube is obstructed or nonfunctioning, changes in ambient pressure may not be transmitted to the middle ear, and barotrauma can result. It is proposed that, as the one descends in an airplane (or during an underwater dive), the increased ambient pressure is transmitted to the cardiovascular system and thus to the vessels of the mucosal lining of the middle ear. The vessels become engorged and the mucosa becomes edematous. If the eustachian tube is obstructed and has not equalized the air pressure, a large differential pressure occurs between the middle ear mucosa and its air-filled cavity. This condition results in a rupture of the blood vessels within the mucosa and bleeding into the middle ear. Serous fluid may also accumulate in the middle ear secondary to eustachian tube obstruction. Rarely, perforation of the TM occurs. These injuries usually resolve spontaneously over several weeks. Antimicrobials may be prescribed to prevent infection of the middle ear fluid/blood. The rare case that does not respond to this regimen should be referred to an otolaryngologist for further evaluation and treatment. Persistent symptomatic fluid may require myringotomy and ventilation tube placement. Barotrauma with acute sensorineural hearing loss and/or vertigo may indicate the presence of a perilymph fistula (previously described). Persistence of these symptoms requires urgent middle ear exploration to close the fistula.

Inner Ear Trauma

Concussive injuries to the head may cause inner ear trauma by disrupting the delicate intracochlear membranes. Sensorineural hearing loss and/or vertigo may occur as a result of such an injury. Occasionally, the losses from these injuries can improve spontaneously but most are permanent. Temporal bone fractures (especially transverse) have a high incidence of otic capsule and cochlear disruption.

The presence of enlarged vestibular aqueducts (EVA's) may predispose an affected individual to sudden sensorineural hearing loss from minor head trauma, such as a blow or jarring the head or sudden dramatic pressure changes (such as scuba diving or skydiving). EVA is the most common congenital ear anomaly causing sensorineural hearing loss in children. EVA can be diagnosed with high-resolution, thin-cut computed tomography (CT) or magnetic resonance imaging scans of the temporal bones. Typical radiologic criteria consider more than 1.5 mm at the midpoint of the vestibular aqueduct or more than 2 mm at the internal opening of the vestibular aqueduct as an EVA.

Constant exposure to loud noise or amplified sound may cause a progressive high-frequency sensorineural hearing loss. Loud blasts from explosions or other sudden loud noises may cause sudden permanent sensorineural hearing loss.

Temporal Bone Fractures

Temporal bone fractures are usually the result of an impact to the head, such as from a motor vehicle collision, a fall, or an object striking the head. Typically, significant forces are required to fracture the temporal bone. Temporal bone fractures have been traditionally classified as longitudinal or transverse. Eighty percent of temporal bone fractures are usually classified as longitudinal and are most commonly the result of impact to the side of the head. Typically, longitudinal temporal bone fractures stay extralabyrinthine—the fracture line usually parallels the internal auditory canal and may disrupt the bony annulus of the TM. Hemotympanum and ossicular disruption may occur. Bleeding from an external ear canal laceration or TM disruption is not uncommon. Facial paralysis is uncommon.

Transverse fractures of the temporal bone occur less frequently and are usually the result of severe impact to the front or back of the head. There is typically disruption of the otic capsule, the internal auditory canal, the facial nerve, and the auditory-vestibular nerve (cranial nerve VIII). Fifty percent of transverse temporal bone fractures have facial nerve involvement. It is important to document the status of the facial nerve function in head trauma cases, especially in cases where a temporal bone fracture is suspected. Sensorineural hearing loss is common.

Cerebrospinal fluid (CSF) leaks are more common with transverse fractures, which may present with CSF rhinorrhea.

Cerebrospinal Fluid Otorrhea

CSF otorrhea may be secondary to a temporal bone (usually longitudinal) fracture that results in a fracture through the inner ear and ruptures the TM. Transverse fractures have a higher incidence of CSF leak; however, since there is typically an intact TM, otorrhea is usually not present. Manipulation or instrumentation of the EAC in the presence of CSF otorrhea is discouraged because it could introduce bacteria and contribute to the development of meningitis. If CSF otorrhea is suspected, the child should be placed at bed rest with the head elevated and neurosurgical consultation should be obtained. The use of prophylactic antimicrobials in CSF otorrhea is controversial. CSF in the middle ear space should be suspected in cases of temporal bone fractures and a persistent effusion. CSF leaks from temporal bone fractures may sometimes present as clear rhinorrhea or a persistent salty postnasal drip. A CSF leak should be considered if a patient develops recurrent bouts of meningitis.

Facial Nerve Paralysis

Facial nerve paralysis may occur as a result of temporal bone trauma. The functional status of the facial nerve should be documented as early as possible after head trauma, especially in cases where temporal bone fracture may be possible. Transverse fractures of the temporal bone can cause disruption of the facial nerve in its intratemporal segment. Longitudinal fractures are less likely to cause facial nerve paralysis. Usually, if facial paralysis is incomplete or delayed in onset, there is less chance that the nerve has been transected. Sudden loss of facial motion may signify disruption. Patients with traumatic facial nerve paralysis should be referred to the otolaryngologist for evaluation, management, and possible exploration and nerve repair.

NOSE AND PARANASAL SINUSES

Nasal Trauma

General Principles/Nasal Fracture

Facial trauma often occurs in children as a result of play activities, contact sports, and automobile accidents. Most of these injuries are minor. Nevertheless, any child with facial trauma should be assessed for associated, possibly more serious, injuries to the cervical spine, eyes, central nervous system, and chest.

Because of its prominent position on the face, the nose is subject to frequent trauma and accounts for most facial injuries in children. It is important, however, to realize that nasal trauma may also be associated with ocular injury, such as hyphema or retinal detachment, or orbital bony fractures. If the initial survey suggests a serious ocular injury, an ophthalmologic consultation must be obtained.

In children, the nasal architecture is different from that of adults as it is has more of a prominent soft cartilaginous portion. The cartilage will bend easily, allowing the force of the blow to dissipate across the midface, and may result in significant edema and ecchymosis. This soft-tissue swelling can make examination of the facial bones and nasal structure difficult.

A direct blow to the nose can fracture the nasal skeleton with resultant deviation and/or depression of the nasal bones and septum. The deformity may be readily apparent by clinical examination, but the postinjury edema may prevent its recognition for several days until the swelling has subsided (Fig. 110.1). A step-off or bony irregularity may often be detected in these patients. Radiographs of the nose are notoriously unreliable in the evaluation of nasal injuries and are not recommended in the routine management of simple nasal fractures. Even in cases where there may appear to be a fracture on plain radiographs, if there is no significant displacement of the nasal bones, no intervention would be warranted. Epistaxis commonly accompanies nasal trauma but usually has stopped by the time the child reaches the emergency department (ED). Persistent or severe bleeding may require local pressure, topical vasoconstrictors, or nasal packing.

In assessing the nasal injury, the emergency physician must determine the nature and extent of trauma to the overlying skin, the nasal skeleton, and the nasal septum. A septal hematoma (see below), if present, requires emergent incision and drainage. The amount of nasal deviation and/or depression should be noted. Because this condition can be masked by postinjury edema, it may be best to examine the child again in 3 to 4 days when the swelling has subsided, to allow an accurate determination of nasal deviation and/or depression. Orbital and nasoethmoid fractures should always be suspected when a child appears to have suffered from significant facial injuries.

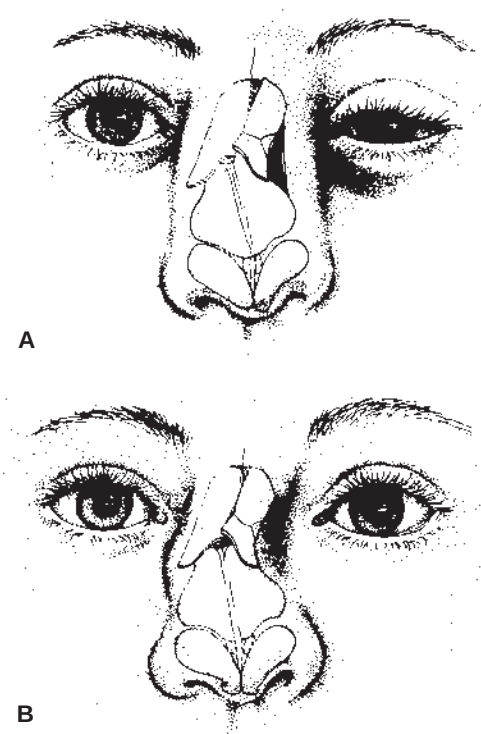

FIGURE 110.1 **A:** Postinjury edema may mask underlying nasal bone deformity. **B:** Nasal deformity manifests as edema subsides.

If no septal hematoma or associated ocular or intracranial injuries are present, then the deviated nose and septum can be reduced by the otolaryngologist when the swelling has subsided enough to permit an accurate evaluation of the nasal deformity. If more than 7 to 10 days elapse between the time of injury and the attempt at reduction, the fracture fragments begin to form a strong fibrous union in their deviated positions, making reduction difficult. Antimicrobials (such as amoxicillin 25 to 50 mg per kg per day for 7 days) are generally administered to these patients to prevent complications from occurring in what is almost always a compound fracture (i.e., open into the nasal cavity).

Septal Hematoma

The presence of a septal hematoma must be recognized as soon as possible after the injury. A septal hematoma appears as a bulging of the nasal septum into one or both sides of the nasal cavity. The septal hematoma results from the disruption of the septal perichondrium from the cartilage when it is deformed by trauma. Bleeding from the inner aspect of the perichondrium accumulates between the septal cartilage and its overlying mucoperichondrium, depriving the cartilage of its blood supply. Immediate nasal obstruction following injury should be suspect for a septal hematoma. Septal hematomas will not vasoconstrict with topical nasal decongestants. Otolaryngologic consultation should be obtained as quickly as possible if a septal hematoma is suspected. The hematoma should be drained as soon as possible and the mucoperichondrium packed back against the septal cartilage to restore its blood supply. If the hematoma is left for any duration, septal abscess may develop and cartilage destruction may occur. If there is loss of septal cartilage, a saddle nose deformity may result.

Cerebrospinal Fluid Rhinorrhea

A clear, watery rhinorrhea occurring after nasal trauma may be CSF rhinorrhea, which would indicate a skull fracture, usually through the cribriform plate. Less commonly, the CSF originates from a temporal bone fracture and enters the nasopharynx through the eustachian tube. If the patient leans forward, allowing the nasal drainage to drip onto a piece of paper, a characteristic target pattern will often appear, with a bloodstain in the center of the drop and a clear halo of CSF around it. CSF is high in glucose content, which may be detected with the use of a glucose oxidase test paper (used in urinalysis). Care must be taken in interpreting these tests because normal nasal mucus can look like CSF and the oxidizing substances present in nasal and lacrimal secretions may give a false-positive reaction. If traumatic CSF rhinorrhea is suspected by history or clinical examination, the child should be admitted and restricted to bed rest with his or her head elevated about 30 degrees in an attempt to decrease and seal the leak. Frequently, traumatic CSF leaks will heal spontaneously with rest and conservative management. If possible, some of the fluid should be collected and tested for β-2-transferrin (found specifically in CSF). Otorhinolaryngology and neurosurgery consultations should be obtained. The use of prophylactic antimicrobials in CSF rhinorrhea is controversial. Further diagnostic studies, such as CT scans and isotope scans, can be performed to confirm the diagnosis of CSF leak.

Sinus Trauma

Fractures of the paranasal sinuses may occur as isolated injuries or in association with trauma to the nose and orbital structures. Fractures of the ethmoid sinus or anterior wall of the maxillary sinus usually occur as a result of blunt trauma to the nose or cheek, respectively. The otolaryngologist should assist the emergency physician in evaluating these injuries. Subcutaneous crepitance may be felt in the cheek or around the eye. Radiographs may demonstrate air in the cheek or orbit or air-fluid levels in the sinus cavities. After determining the absence of potential associated ocular injury, the patient is usually placed on oral antimicrobials (usually amoxicillin 25 to 50 mg per kg per day for 7 days) and observed as an outpatient until the crepitance resolves. Displaced anterior maxillary sinus wall fractures rarely require intervention.

Facial Trauma

Blunt facial trauma can result in focal injuries and fractures or more generalized fractures involving much of the midface. Blunt trauma to the orbit may result in the force being transmitted through the globe to break the orbital floor (roof of maxillary sinus) or the medial orbital wall (lamina papyracea of the ethmoid sinus). These blowout fractures are discussed in detail in other chapter in this textbook.

Midface fractures include fractures of the malar bone, which affect both the orbital floor and the maxillary sinus. A complete malar (incorrectly called *trimalar* or *tripod*) fracture is present when the malar bone fractures at the infraorbital rim, zygomatic arch, and zygomaticofrontal suture line. Isolated malar fractures can also occur at the zygomatic arch or the lateral wall of the maxillary sinus. (For more detail regarding sequential steps and examination for facial fractures, see Chapter 111.) Severe midface injuries often require multidisciplinary cooperation among specialists in otolaryngology, ophthalmology, plastic surgery, oral surgery, and neurosurgery.

Sinus Barotrauma

A direct open communication between the paranasal sinuses and the nasal cavities normally permits prompt equalization of changes in ambient pressure. If a sinus ostia is obstructed, however, changes in ambient pressure may not be transmitted to the affected sinus cavity (most commonly the maxillary sinus, although the frontal sinus may be affected in older children and adolescents), and barotrauma can result. As the child descends in an airplane or during an underwater dive (even to the depth of the deep end of a swimming pool), the increased ambient pressure is transmitted to the cardiovascular system and, thus, to the vessels of the mucosal lining of the sinus. The vessels become engorged and the mucosa becomes edematous. If the sinus is obstructed and has not equalized the air pressure, a large differential pressure occurs between the sinus mucosa and its air-filled cavity. This condition results in a rupture of the blood vessels within the mucosa and bleeding into the sinus. The child usually complains of cheek pain and may have epistaxis. Treatment for this condition involves amoxicillin 25 to 50 mg per kg per day for 7 days (to prevent infection of the

blood-filled sinus), antihistamine–decongestant therapy and topical nasal sprays to restore the normal physiologic communication between the sinus and the nasal cavities, and the avoidance of further barotrauma. The rare case that does not respond to this regimen should be referred to an otolaryngologist for further evaluation and treatment.

Foreign Bodies

Nasal foreign bodies are common in children. These children are usually brought to the ED with the history of putting an object into the nose, but the presence of a foreign body may often be unsuspected and may be discovered only during evaluation of a child with persistent, unilateral, foul-smelling, purulent rhinorrhea. This mode of presentation for these problems is so common that any child with a foul-smelling unilateral nasal discharge (even without a history of placing an object in the nose) should be considered to have a nasal foreign body until proven otherwise. The foreign body is usually visible on anterior rhinoscopy. However, suctioning of purulent secretions from the nasal cavity may be required before the object is seen. If the foreign object has been present for a while, there may be granulation tissue around the object and may bleed. Radiographs are of limited value because most of the foreign bodies are radiolucent (e.g., paper, cloth, sponge, food).

If the object is located in the nasal vestibule, the emergency physician may attempt to remove it. The child should be adequately restrained, and the necessary equipment, including a nasal speculum, directed light, suction, small hooks, and forceps, should be available. Otologic instruments are often very useful in the removal of nasal foreign bodies. Vasoconstriction with a topical nasal decongestant, such as oxymetazoline, plus a few drops of 4% lidocaine, for topical anesthesia, can be placed in the nostril before attempting the removal of the foreign body. An otolaryngologist should be consulted if the foreign body cannot be removed easily.

Hygroscopic foreign bodies, such as beans, may swell with nasal secretions and become difficult to remove. Disk batteries can be extremely caustic and need to be removed emergently, as they may cause a septal perforation and/or scarring; if they cannot be easily removed, an otolaryngologist should be immediately consulted. A foreign body should never be pushed or irrigated into the nasopharynx, where it could be aspirated by the struggling child. Antimicrobials (usually amoxicillin 25 to 50 mg per kg per day for 7 days) are administered to prevent (or treat) an infection (rhinitis, sinusitis) in this already traumatized area, especially after removal of a long-standing foreign body.

ORAL CAVITY, PHARYNX, AND ESOPHAGUS

Trauma

A common etiology of oral cavity trauma is biting the inside of the cheek or tongue; this is painful and can cause result in a laceration or hematoma formation. Treatment of self-inflicted bites is rarely needed, but a laceration may require suturing if it bleeds excessively, has a significant soft-tissue flap (trapdoor flap), or is severe enough to alter intraoral anatomy or physiology (i.e., breathing, deglutition, or speech). Oral hygiene with warm saline for irrigation or over-the-counter oral rinses, such as Peroxyl™, can be considered. These lesions rarely require oral antibiotic therapy. Topical analgesic preparations can be used for pain relief.

Children may suffer oropharyngeal lacerations or puncture wounds when they fall with an object, such as a stick, in their mouths. If the injury is restricted to the central portion of the palate, damage to vascular or neural structures of the head and neck is unlikely. These children are usually safe to send home after confirmation of absence of any retained foreign body (see the following section). However, trauma to the lateral aspects of the palate or the posterior pharyngeal wall may be associated with vascular injuries of the carotid artery or the jugular vein. Expanding hematoma of the neck or pharynx, continued intraoral bleeding, diminished pulses in the neck, or neurologic changes are all signs of serious vascular injury. These children need to be admitted and have an urgent angiogram/venogram performed (such as conventional angiography, computed tomography angiogram [CTA], or magnetic resonance imaging arteriogram/venogram [MRA/MRV]), and possibly require surgical exploration. If a lateral pharyngeal or palatal puncture injury is present without signs of vascular injury, the child should be observed closely in the hospital or at home for signs of neurologic deterioration.

In treating puncture wounds of the pharynx, it is imperative to determine whether the foreign body has been recovered intact or if a portion of the foreign body may have been left in the palatal tissues. A portion of pencil lead left in the palatal tissue can cause a chronic foreign body reaction if it is not removed at the time of initial treatment and repair. Plain radiographs may not be useful in determining whether a foreign body has been left in the wound because most of the objects are radiolucent and/or too small to be seen. Inspecting the actual object that caused the wound, to make sure that it is intact, is more important. If a retained portion of the foreign body is suspected, CT scan may be required, followed by exploration of the wound, usually under general anesthesia. Clean puncture injuries or simple lacerations do not require surgical repair and usually heal by secondary intention. Large gaping injuries may require exploration, debridement, and a formal layered closure to restore normal function to the palate.

Caustic Injuries

Caustic substances (lye or acid) may be ingested, causing burns anywhere from the lips to the stomach. Burns of the oral mucosa appear as patches of erythema, blebs, or ulcerated areas. Although caustic burns are usually visible in the oral cavity and pharynx, large skip areas may exist. Therefore, the absence of oral or pharyngeal burns does not rule out esophageal injury. If a history of significant caustic ingestion exists, an esophagoscopy should be performed 6 to 12 hours later to establish the presence of esophageal burns, regardless of the condition of the oral cavity and pharynx. Because burns occur rapidly after ingestion, the child need not be given any oral antidote in the ED. In fact, emesis should not be induced because it only re-exposes the esophagus to the caustic substance; induced emesis also carries the risk of aspiration of the caustic material.

Caustic substances may burn the larynx when ingested and can cause rapidly progressive edema and respiratory distress. Endotracheal intubation for acute airway management should be performed in the ED if necessary. A tracheotomy should be considered as soon as possible after intubation to minimize the possibility of laryngotracheal stenosis.

Foreign Bodies

Foreign bodies in the oral cavity and pharynx are uncommon because of the child's protective reflexes. The tongue is sensitive and can detect sharp foreign objects that are then spat out. The gag reflex often expels foreign material from the pharynx, but sharp objects, such as fish bones, pins, and pieces of plastic, may get stuck in the oral mucosa, tonsils, or pharynx (Fig. 110.2). If a foreign body is visible and the patient is cooperative, the object may be removed in the ED with a clamp or forceps.

Objects of all types may lodge in the hypopharynx or esophagus. Esophageal foreign bodies generally lodge at the areas of natural narrowing of the esophagus. The most common sites are the cricopharyngeal area, thoracic inlet, arch of the aorta, and the gastroesophageal junction. If the child can breathe and talk, no attempt should be made to remove the object in the ED. The safest method of removal is under direct visualization while a child is under a general anesthetic. If the child is gagging and unable to breathe, the Heimlich maneuver may be used. If this method is not effective, emergency intubation or tracheotomy may be required to bypass the obstructing object.

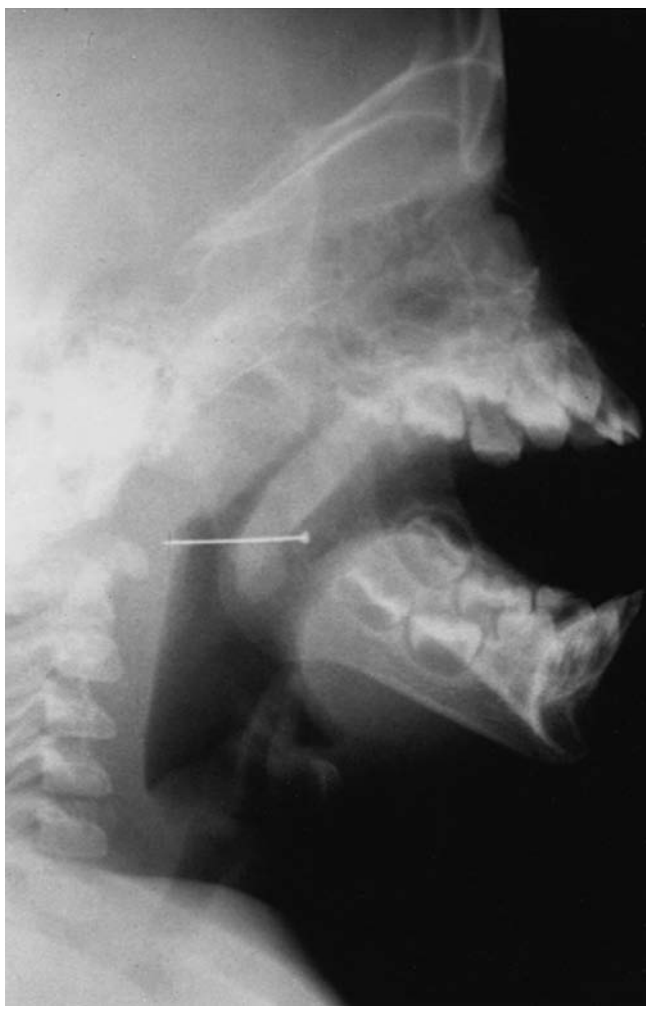

FIGURE 110.2 Lateral neck radiograph of a straight pin lodged in posterior pharyngeal wall.

Lateral neck and chest radiographs reveal radiopaque hypopharyngeal and esophageal foreign bodies. Plastic and other nonradiopaque objects cause the same foreign body sensation (something stuck in the throat) but are not visible on radiograph. Young children often have dysphagia and drooling because of painful swallowing.

Although ingestion of a foreign body usually causes gagging and choking that last for several seconds, these symptoms often subside. In addition, the initial episode may have taken place unobserved by an adult. Thus, unexplained dysphagia or drooling should initiate a search for a possible foreign body.

If a child presents to the ED with a history of swallowing an object, such as a toy or a fish bone, and complains of a foreign body sensation, a careful examination of the oral cavity and hypopharynx must be performed. If no foreign body is seen, plain radiographs of the neck should be obtained. Barium esophagrams are rarely helpful in pinpointing sharp foreign bodies in the esophagus but may be useful to confirm esophageal obstruction from an impacted foreign body such as a bolus of food. Foreign bodies easily seen in the oral cavity may be removed by the emergency physician. Consultation with an otolaryngologist (or similarly skilled specialist) should be obtained if a foreign body is detected in the pharynx or esophagus because removal usually requires endoscopic examination under anesthesia.

If the physical examination and radiographs fail to detect a foreign body, management is determined by the child's symptoms. If the child is having significant pain, the otolaryngologist should be consulted to perform esophagoscopy in the operating room. If the pain is mild, the child can swallow his or her own saliva, and no evidence of respiratory distress is present, the foreign body sensation may be secondary to a mucosal scratch from a foreign body that has passed into the stomach. In that instance, it may be appropriate to send the child home to return the next day if the sensation persists, which would indicate the potential presence of a persistent foreign body and require further evaluation.

Particular attention should be observed when there is disk-like foreign object on a plain film—it should be carefully examined to determine whether the object is coin or a disk battery. The anteroposterior (AP) and lateral views should be carefully scrutinized—looking for the presence of a double ring on the AP view and/or a step-off on the lateral view (Fig. 110.3). Disk battery ingestion must be emergently managed as disk batteries can cause significant caustic injury to the esophageal mucosa.

LARYNX AND TRACHEA

Trauma

Laryngeal trauma can occur in a variety of ways. Blunt or penetrating injuries of the larynx can result in mucosal lacerations, laryngeal hematomas, vocal cord paralysis, or fractures

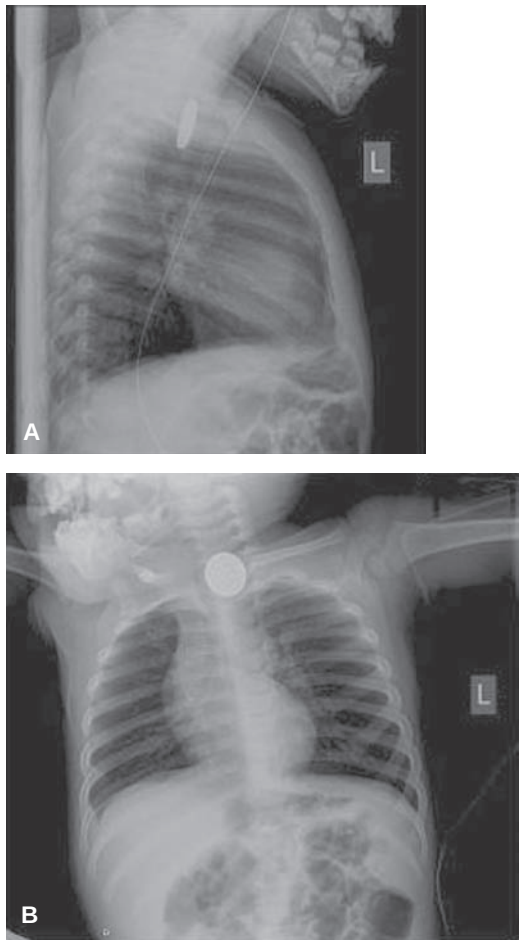

FIGURE 110.3 Chest radiographs of child with esophageal foreign body. **A:** AP film with round radiopaque foreign object—double ring makes this object suspect for a disc battery. **B:** Lateral film—note the step-off along the anterior edge of the foreign object, once again concerning for a disc battery. AP, anteroposterior.

of the thyroid and cricoid cartilages. Burn injuries can result from inhaling hot air or smoke from fires, or chemical burns may arise from caustic ingestion. Proper treatment requires prompt recognition of the presence and nature of a laryngeal injury and protection of the airway. Patients with laryngeal trauma present with varying degrees of neck pain, hoarseness, hemoptysis, and airway obstruction. Physical examination of a child with blunt trauma can reveal anterior neck tenderness, crepitance, and absence of the normal prominence of the thyroid cartilage or "Adam's apple" (Fig. 110.4). The otolaryngologist (or similarly skilled specialist) may be needed to perform an indirect examination of the larynx on the child with a suspected laryngeal injury. A direct laryngoscopy may be required when the child is in respiratory distress. The otolaryngologist should be prepared to intervene with intubation, rigid bronchoscopy, tracheotomy, and/or surgical exploration of these laryngeal injuries. If a child has a stable airway, radiologic imaging may help assess the airway for laryngeal, thyroid cartilage or tracheal injury. Penetrating neck injuries may require angiography or MRA/MRV to evaluate the vasculature of the neck for site of potential damage, including assessment for intimal damage, thrombus, or pseudoaneurysm formation. Even if the patient is stable, penetrating injuries of the central third of the neck should be considered for surgical exploration, and injuries to the upper and lower thirds of the neck should be imaged.

Home fires are the most common etiology of inhalational injury to the airway. Any child who was involved in a home fire should be assessed for possible thermal injury to the larynx and airway. Soot or carbonaceous debris at the nares or in the oral cavity and oropharynx should make one suspect of inhalation of hot gases. Typically, flexible laryngoscopy can be performed to assess the larynx, looking for soot, edema, or evidence of thermal injury to the larynx. If there is concern for thermal injury to the larynx, prophylactic intubation of airway

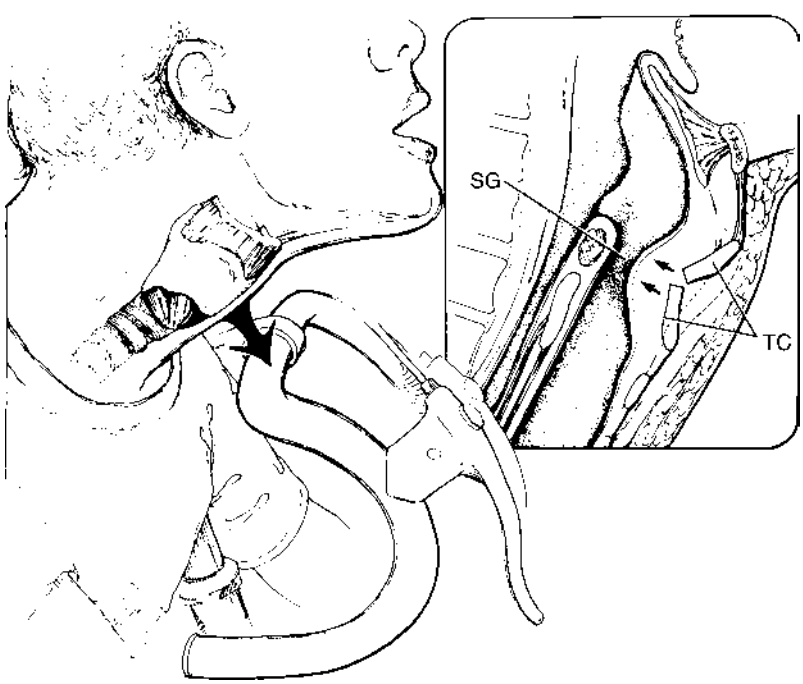

FIGURE 110.4 Loss of thyroid cartilage prominence and associated acute airway obstruction secondary to laryngeal fracture. *SG,* narrowed subglottic space; *TC,* fracture of thyroid cartilage.

may be considered to protect the airway prior to the onset of significant swelling.

Ingestion of caustic substances can cause severe burns of the larynx and pharynx; airway obstruction may occur secondary to the edema related to this injury. Laryngeal burns should be suspected in the child who has hoarseness or stridor after caustic ingestion. The child should be hospitalized, and otolaryngologic consultation should be obtained. If signs of respiratory distress (e.g., tachypnea, stridor) occur, the child should be taken to the operating room, where endoscopy can be performed and an artificial airway, usually a tracheotomy, can be established.

Foreign Bodies

Foreign bodies may become trapped in the laryngeal inlet, causing acute upper airway obstruction. The child usually presents with severe coughing, hoarseness, and significant respiratory distress. If the child is able to phonate, air is moving through his or her larynx, indicating only partial obstruction. "Back blows" or the Heimlich maneuver should not be performed in these children because this action may cause the foreign body to lodge more firmly in the larynx and convert a partial obstruction into a complete one. The child should be taken immediately to the operating room, where the otolaryngologist (or similarly skilled specialist) can perform the direct laryngoscopy necessary to remove the foreign body. In contrast, if the child is unable to speak, the foreign body may be causing total obstruction. In this case, back blows or the Heimlich maneuver may be lifesaving. Care must be taken in performing the Heimlich maneuver in young children because of the potential hazard of liver laceration. Emergency laryngoscopy, intubation, or tracheotomy is rarely required, and only if the previously described maneuvers are unsuccessful.

Foreign bodies that pass the larynx to lodge in the trachea or proximal bronchi can present problems in diagnosis and management. A history of coughing or choking on food (e.g., a peanut, raw carrot) or a toy is usually obtained. The child is often in no acute distress but may demonstrate a mild cough and/or wheezing. Inspiratory and expiratory stridors are characteristic of tracheal foreign bodies. Unilateral wheezes and decreased, or even absent, breath sounds are often seen with unilateral bronchial obstruction. Because most of the foreign bodies are radiolucent, they are not identifiable on radiographs. However, a radiographic difference in aeration of the lungs often helps detect the presence and identify the site of bronchial obstruction. Volume decrease, atelectasis, and infiltrate on the involved side may be seen on plain chest radiographs if the bronchus is completely occluded by the foreign body. Hyperaeration (air trapping) secondary to a ball-valve effect of a foreign body that is partially blocking the bronchus is best seen by comparing inspiration and expiration films (Fig. 110.5). If the child will not cooperate to obtain these views, right and left lateral decubitus films can often demonstrate the same phenomenon. Although differentiating hyperaeration and contralateral volume loss from atelectasis and compensatory contralateral lung expansion may help predict the location of a possible foreign body, this distinction is not as important as recognizing that any radiographic asymmetry signals a possible foreign body and requires endoscopy. A normal chest radiograph, however, does not rule out the possibility of a foreign body. If a foreign body is suspected (by history or clinical examination), the child should be admitted and otolaryngologic consultation should be obtained to consider performing the endoscopy necessary for the prompt and safe removal of the foreign object.

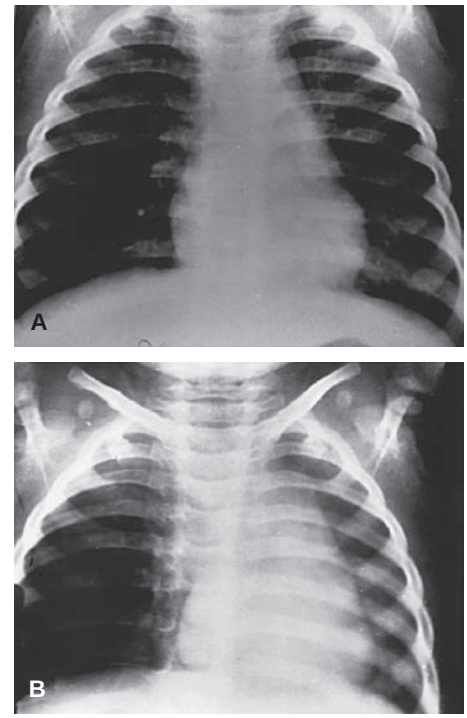

FIGURE 110.5 Chest radiograph of child with bronchial foreign body. **A:** Inspiratory film demonstrates only subtle hyperaeration of right lung. **B:** Expiratory film shows accentuated hyperaeration on the right side secondary to air trapping ("ball-valve" phenomenon) by the foreign body in the right mainstem bronchus. In addition, the mediastinum is displaced to the left.

CHAPTER 111 ■ FACIAL TRAUMA

MARK I. NEUMAN, MD, MPH

BACKGROUND

Soft-tissue injuries and lacerations account for the majority of facial trauma in children. Common mechanisms of facial injury in children include falls, sports-related injuries, assaults, and motor vehicle accidents. Children account for approximately 15% of all facial fractures, with children younger than 5 years comprising only 5% of this total. The majority of facial fractures in children occur in teenagers, with a 2.5:1 male predominance.

This low prevalence of facial fractures in children is multifactorial. The face of a child is relatively small compared with the head and thus most fractures in young children tend to involve the upper face and skull. In addition, the face is much stronger because the sinus cavities are poorly developed and the proportion of cancellous to cortical bone is greater, providing more elasticity. Young children are also afforded some protection by large fat pads, particularly the buccal fat pad in the malar region. Children are also less likely than adults to be exposed to occupational trauma, assaults, and major trauma associated with motor vehicle accidents.

INITIAL MANAGEMENT

Injuries sustained as a result of facial trauma are rarely, in and of themselves, life threatening. However, patients who have sustained enough force to cause significant facial injury may have occult injuries elsewhere and a complete trauma evaluation is usually warranted. In rare instances, these life-threatening injuries have been overlooked, likely due to the profound appearance of some facial injuries. In particular, care should be taken when examining the face and head until an injury to the cervical spine is excluded. In some series, up to 10% of patients with maxillofacial trauma have an associated cervical spine injury. Patients with tenderness of the cervical spine, impaired sensorium, focal neurologic deficits, or major distracting injury elsewhere should be placed in a hard cervical collar until an injury to the cervical spine can be excluded.

Stabilization of the airway is the primary concern in the management of facial injuries in children. Patients can have airway obstruction resulting from various factors, including blood, loose teeth, the tongue, and pharyngeal edema; therefore, the airway should be cleared and examined for patency. Loss of support of subglottic musculature can result from severe mandibular fractures, and the tongue can fall posteriorly and occlude the airway in a comatose patient. Oral or nasal airway may serve as an adjuvant to positioning in order to achieve airway patency. Tracheal intubation may be required if the airway remains unstable. Cricothyrotomy or tracheostomy may be necessary if these measures fail to secure the airway. These should be attempted only as a last resort because of the technical difficulty and complications associated with such procedures.

Difficulties in decision making in the initial management of patients with facial trauma often revolve around whether subspecialist input is warranted, and if so, which particular subspecialist to involve. Plastic surgeons, ophthalmologists, otorhinolaryngologists, and oral and maxillofacial surgeons have expertise and interest in the management of patients with facial trauma. Once it is determined that subspecialist input is warranted, the decision of which subspecialist to involve will depend largely on availability and expertise of such individuals within the institution. Although most facial injuries can be managed without involving a subspecialist, many of the injuries detailed in this chapter do require such input.

HISTORY

Special attention must be paid to the mechanism of injury in order to determine the facial injuries one is likely to encounter. In addition, the timing and location of the injury are important factors to consider when determining the course and prognosis, particularly related to infection. Often in the child with serious facial trauma, the history may need to be obtained from a bystander, emergency medical services personnel, or family members. In the alert and verbal child, key questions should include (i) Where does it hurt? (ii) Do you have blurry or decreased vision? (iii) Do you have any numbness of a particular region of your face? and (iv) Does it hurt when you open or close your mouth? Responses to these questions will help focus the examination. In the case of facial lacerations, it is important to ascertain whether the mechanism of injury was likely to result in a retained foreign body or whether it poses a high risk of infection. Finally, one must ensure the child's tetanus immunizations are up to date.

PHYSICAL EXAMINATION

Examination for specific bony injuries begins with the observation for deformity and asymmetry, which should be carried out in all projections. Malar eminences and zygomatic arches are visualized well when standing behind the patient and looking down over the forehead. Asymmetry can take the form of swelling or loss of projection or flattening.

Next, systematic palpation of the facial bones should be performed (Fig. 111.1). Tenderness, crepitus, and "step off" are signs of underlying fracture. Particular attention should be

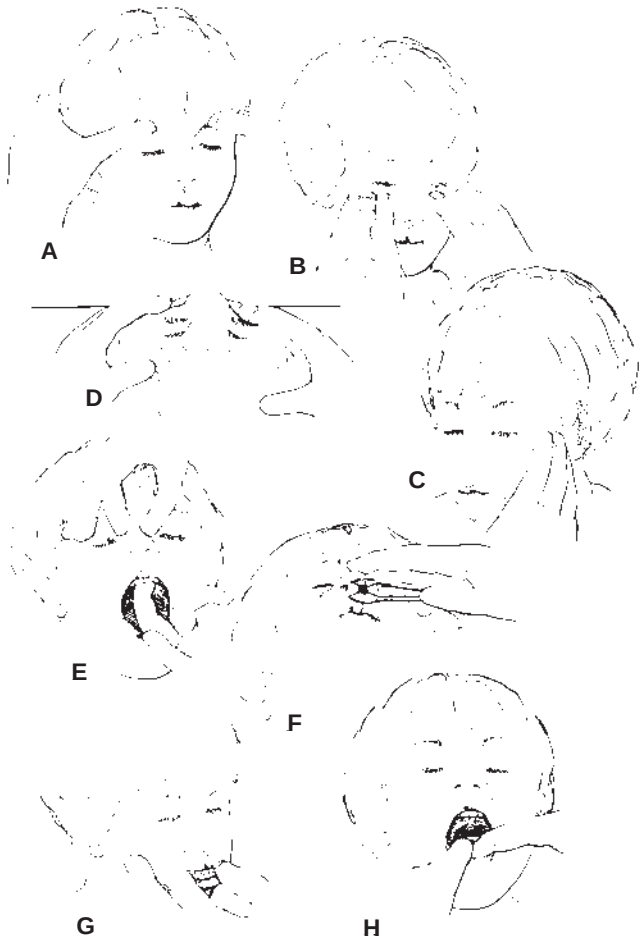

FIGURE 111.1 Sequential steps in examination for facial fractures. **A:** The supraorbital ridges are palpated while keeping the patient's head steady. **B:** The infraorbital ridges are palpated using the index, middle, and ring fingers to assess for areas of point tenderness. **C:** The zygomatic arch is palpated on each side to determine continuity and the possible presence of displaced fractures. **D:** The infraorbital rims, zygomatic bodies, and maxilla are palpated and examined from the top of the head to determine depressions and fracture displacement. **E:** The nasal bone and maxilla are examined for stability and possible fracture displacement. **F:** The nose is examined intranasally to determine the placement of the nasal septum and the possible displacement of nasal bones or disruption of nasal mucosa. **G:** The occlusion is observed to determine any disturbances of normal teeth relations. **H:** The mandible is palpated and then retracted to determine sites of discomfort and possible mandibular fractures.

paid to the malar eminences, zygomatic arches, and superior and inferior orbital rims. Assessment for a fracture of the maxilla can be performed by grasping and attempting to move the upper central teeth. Any laxity of the maxilla or crepitus is suggestive of fracture. External and intraoral palpation of the mandibular symphysis, body, angle, and ramus can help diagnose fractures in these areas.

Inspection of the mouth and oral cavity should be performed to assess for injury to the maxilla and mandible. Occlusal disharmony is an indication of mandibular and/or maxillary displacement. Older children will be able to tell the examiner if their bite "feels normal." Opposing teeth that do not come together, but that exhibit wear facets (smoothing of mamillations along the incisal surfaces of the teeth), suggest a traumatic malocclusion. An inability to hold a tongue blade between occluded teeth on each side of the mouth is suggestive of a mandibular fracture.

Examination of the eyes should include the assessment of pupillary reactivity and size and examination of extraocular movements, visual acuity, and surrounding orbital injuries. Direct trauma to the globe should be excluded. Orbital dystopia and/or enophthalmos are suggestive of a fracture of the orbit. An ophthalmologist should be consulted if any of these abnormalities are suspected (see Chapter 117). Examination of the nose should include documentation of focal tenderness, swelling and asymmetry, bleeding, or other nasal discharge, as well as the presence or absence of a septal hematoma.

Neurologic examination of the face should include evaluation of both sensory and motor functions. All three branches of the trigeminal nerve should be evaluated for sensation. Anesthesia of the cheek suggests injury to the infraorbital nerve, whereas anesthesia of the lower teeth and lower lip suggest inferior alveolar nerve involvement. The facial nerve should be evaluated by asking the patient to wrinkle the forehead, close and open the eyes fully, smile, show his or her teeth, and close the mouth tightly. Pure motor injuries to the facial nerve are quite amenable to microsurgical repair if detected and repaired in a timely fashion. Therefore, all suspected motor nerve injuries warrant appropriate surgical consultation to allow for the best functional recovery.

IMAGING STUDIES

The use of radiography in the evaluation and management of children with facial trauma should be considered if there is a concern of fracture based on history and physical examination. Because of the occult nature of pediatric facial fractures, as well as the inability of many young children to communicate, one should have a low threshold for radiographic evaluation. The complexity of bony and soft-tissue facial structures can make the interpretation of plain radiographs difficult. In addition, plain radiographs are often inadequate to determine whether a patient requires operative intervention. Computed tomography (CT) has mainly replaced plain radiographs in the definitive assessment of bony facial injuries because it has a greater ability to detect fractures and associated displacement, as well as a greater ability to visualize soft-tissue structures.

Despite their limitations, plain radiographs obtained in the emergency department during the initial evaluation can provide useful information about suspected bony injuries, are less expensive and easier to obtain than CT scans in most institutions, and do not require the use of sedation. The Waters view (occipitomental) is used to visualize the midface region—the orbital rims and floor of the orbit, nasal bones, zygoma, and maxilla. This view may be particularly useful in patients suspected of having a blowout fracture of the orbit, as well as for detecting fluid in the maxillary sinus. The Caldwell view supplements the Waters view for the evaluation of the upper two-thirds of the face, including visualization of the superior orbital rim, frontal sinuses, and nasoethmoid complex; however, the orbital floor is often obscured. The lateral view is useful for the detection of fractures to the anterior wall of the frontal sinus, the anterior and posterior walls of the maxillary

sinus, and the nasal bones. The submentovertex view provides visualization of the zygomatic body and arch. Posterior–anterior, right and left lateral oblique, and Townes views are used to detect fractures of the mandible; however, fractures of the symphysis may be difficult to discern. Panorex views provide visualization of the entire mandible and lower teeth.

With the development of high-resolution scanners, CT has become the most frequently used imaging modality for the evaluation of suspected facial fractures. Axial views demonstrate fractures of the anterior and posterior walls of the frontal sinus, medial and lateral orbital walls, posterior wall of the maxillary sinus, zygomatic arches, and mandible. Coronal views demonstrate fractures of the ethmoid, sphenoid, and paranasal sinuses; orbital floors and infraorbital rims; the nasoethmoid region; and mandibular condyles and symphyses. Coronal imaging requires hyperextension of the neck and thus requires prior exclusion of a cervical spine injury. Three-dimensional CT imaging can help guide operative repair.

SPECIFIC INJURIES

Bony Injuries

In general, fractures of the upper face are managed with the goal of restoring anatomic alignment. Unless there is evidence of nerve or muscle entrapment, most surgical reductions of facial fractures do not need to be performed immediately. Generally, repairs occur a few days after the injury to allow for proper radiographic evaluation, as well as time for the swelling to subside. Because bony healing is relatively rapid in children, anatomic reduction becomes more difficult when healing in the displaced position has occurred, and early treatment (within 4 to 5 days) is preferred. There is an increasing trend toward early repair to facilitate a rapid recovery. Patients who are unable to drink, either because of pain or because of inability to open the mouth, require hospitalization.

Mandible Fractures

Fractures of the mandible can occur in one or more of the following regions: the symphysis, body, angle, ramus, and condyle (Fig. 111.2). The mechanism of injury often determines the site of potential fracture in patients with trauma to the mandible. Motor vehicle collisions and falls tend to cause fractures of the condyles and symphysis because the force is directed against the chin, whereas assaults tend to produce injuries to the body or angle of the mandible at the point of impact. Patients with parasymphyseal fractures resulting from falls often have an associated fracture in the opposite subcondylar region. Pain and difficulty with mouth opening are usually present with mandibular fractures. Numbness of the lip and chin may also suggest a mandibular fracture because the inferior alveolar nerve courses through the center of the mandible, from the middle of the ramus, to its exit at the mental foramen. Mandibular fractures may result in airway obstruction due to hemorrhage either from the floor of the mouth or from a disruption in the bony support structure for the tongue.

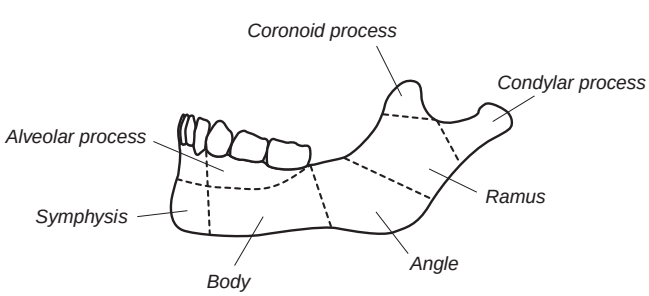

FIGURE 111.2 Anatomy of the mandible. Common sites of fracture include the condyle and subcondylar region, as well as the angle, body, and symphysis of the mandible.

Powerful muscles of mastication apply distracting forces to the fractured mandibular segments, often resulting in bony displacement and occlusal disharmony. The growth center for the mandible is located in the area of the condyle, and damage to this area from a fracture can cause significant growth disturbances, especially if sustained before the age of 3 years. Therefore, the clinical evaluation of any chin laceration should include palpation of the mandible, particularly the condyles. Malalignment of the lower central incisors (i.e., step off in dentition) suggests a mandibular fracture at the symphysis. Unilateral condyle fractures will most often result in the deviation of the jaw toward the side of the fracture upon mouth opening.

Because of concern regarding mandibular growth retardation and injury to permanent tooth buds, mandibular fractures in children are treated by more conservative measures than those in adults. A majority of fractures can be managed conservatively with closed reduction and maxillomandibular fixation. A soft or liquid diet is recommended. The remaining fractures are treated by open reduction, internal fixation, or the use of splints. Antibiotics are usually warranted because these fractures are often in communication with the oral cavity.

Temperomandibular joint dislocation may not only result from a direct blow to the chin but also occur while yawning or opening the mouth widely. With dislocation, the condyle of the mandible is displaced anteriorly and is prevented from sliding back into place by spasm of the jaw muscles. Preauricular swelling and inability to close the mouth fully are the key features on physical examination. Reduction of such dislocations often requires the use of procedural sedation and may be facilitated with a benzodiazepine to decrease muscle spasm. Downward traction is applied to the posterior aspect of the mandible. The chin is then pushed posteriorly to allow the condyle to return to its fossa.

Orbital Fractures

Knowledge of the bony anatomy of the orbit is integral to the understanding of fractures at this site. The superior portion of the orbit is composed of the superior orbital rim and orbital roof, which is part of the thick frontal bone. The medial wall is formed by the ethmoid bone, which is adjacent to the nasal bones. The lateral wall is formed by the greater wing of the sphenoid and the zygoma, which are also quite thick. The floor and the inferior orbital rim are formed by the zygoma and the maxilla, which are relatively thin, and are further weakened by the groove for the infraorbital nerve.

Fractures of the floor of the orbit, sometimes known as "orbital blowout fractures," typically occur when a medium-sized, round, hard object, such as a baseball, strikes the eye (Fig. 111.3). The volume of the globe is fixed; thus, when an

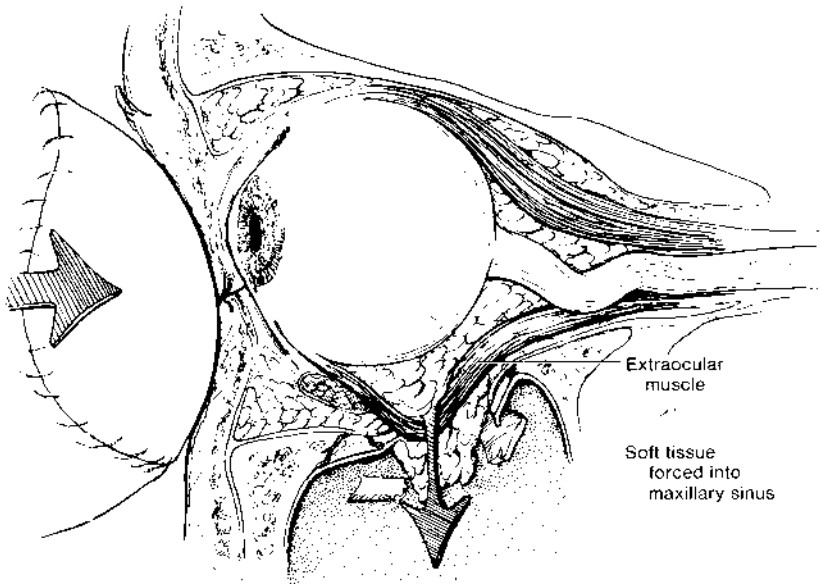

FIGURE 111.3 Mechanism of blowout fracture. In a sagittal view, a ball is shown striking the eye, deforming it, and causing increased pressure of the intraorbital contents. The periorbital fat is forced through the floor of the orbit. Retropositioning of the eye (enophthalmos), lowering of the eye, and extraocular muscle entrapment can result.

acute increase in orbital space (an opening in the floor of the orbit) occurs, the globe may be pushed posteriorly in the orbit, producing enophthalmos, a sunken appearance to the eye. A true orbital blowout fracture denotes a fracture of the floor of the orbit, with an intact inferior orbital rim. Although these fractures are quite rare in children, they are often due to direct trauma to the zygoma rather than a compression of the globe itself. Blood and orbital fat may sink into the maxillary sinus, clouding the sinus on the radiograph (Fig. 111.4). Asymmetry in the horizontal level of the eyes (orbital dystopia) may also be present. The infraorbital nerve, the terminal branch of the maxillary division of the trigeminal nerve, exits the maxilla just below the infraorbital rim. Manifestations of injury to this nerve include decreased sensation to the cheek, upper lip, and upper gingiva on the affected side.

In children, the floor of the orbit is relatively flexible. Consequently, it may fracture in a linear pattern that snaps back to create a "trapdoor" fracture. In adults, the floor of the orbit is thick and more likely to shatter when exposed to force. If the inferior rectus muscle is entrapped in the fracture gap in the floor of the orbit, voluntary upward gaze may be limited. The presence of entrapment is one indication to operate on a blowout fracture on an urgent basis.

Studies suggest that early repair of orbital fracture and release of the entrapped muscles (within 24 to 48 hours) may help avoid muscle ischemia and fibrosis and result in better functional recovery. Corticosteroids may help decrease swelling in patients with limitation of extraocular movement.

A thorough ophthalmologic examination is warranted in all patients with orbital fractures because of the high likelihood of associated eye injuries. In particular, vision should be assessed because decreased visual acuity may be an early sign of a retrobulbar hemorrhage, or injury to the optic nerve or eye itself. A retrobulbar hemorrhage can cause compression of the central retinal artery, which can threaten vision to the affected eye if not surgically decompressed. The type of eye and orbit injuries varies on the basis of the object and mechanism involved. Typically, a low-impact mechanism with a small

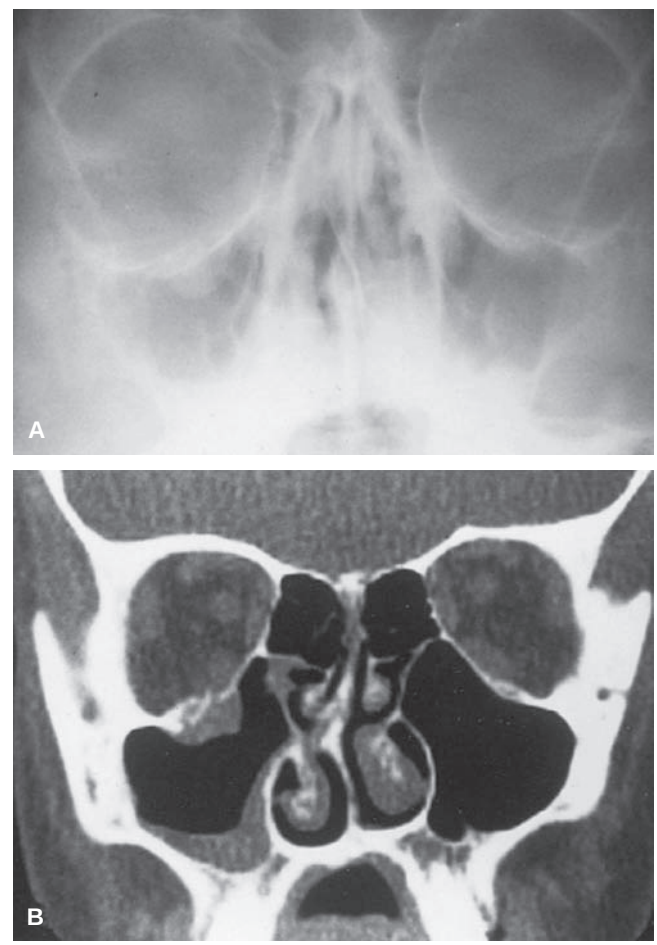

FIGURE 111.4 **A:** Blowout fracture. The sinus view shows teardrop configuration of the blowout fractures in the right orbit. Note associated fracture through the orbital floor and air–fluid level in the maxillary sinus. **B:** In the same patient as (**A**), computed tomography section more clearly demonstrates the multiple fragment fracture through the orbital floor. Teardrop and air–fluid level are evident in the right maxillary sinus. (Courtesy of Soroosh Mahboubi, MD.)

object will result in injuries to the eye itself, such as a corneal abrasion or hyphema. Injury to the eye from a high-speed soft object such as a tennis ball will often result in a hyphema. Hard objects striking the orbit at a high speed, such as a baseball or a fist, are likely to result in an orbital blowout fracture. High-impact mechanisms, such a those encountered when the face strikes the dashboard in a motor vehicle collision, are likely to result in complex orbital and midface fractures.

Nasal Fractures

The nasal bones are among the most commonly fractured bones of the facial skeleton because of their prominent location on the face. Nasal fractures may be difficult to detect clinically because of significant swelling associated with such injuries. Plain radiographs are needed only rarely in the emergent care of children with nasal trauma because, in most cases, they do not contribute to subsequent care and management. Most nasal injuries can be followed on an outpatient basis, and evaluation after the swelling subsides dictates the need for further intervention.

Two particular nasal injuries that deserve specific comment are the intractable nosebleed and septal hematomas. Because of the rich vascular network in the nose, supplied by branches of both the internal (anterior ethmoidal) and external (superior labial, palatine) carotid arteries, nasal hemorrhage can be difficult to stop despite usual conservative measures (e.g., elevation, compression). Treatment of persistent epistaxis may require anterior and/or posterior nasal packing with gauze or tampon, or the placement of an epistaxis balloon catheter. If a bleeding vessel can be identified, silver nitrate cauterization can be performed.

Septal hematomas arise because of hemorrhage from an artery beneath the mucoperichondrium, separating it from the septal cartilage. Because the septal cartilage is avascular and relies on the overlying mucoperichondrium for its blood supply, a hematoma may result in cartilage necrosis and eventual septal perforation. In most cases, septal hematomas require urgent incision and drainage (see Chapter 111 and Section VII).

Repair of nasal fractures should ideally be performed either within a few hours after the injury (prior to significant swelling) or after the swelling subsides (usually 4 to 7 days). Because of the significant swelling that often develops rapidly with such injuries, immediate repair is usually not possible. Patients suspected of having nasal fractures should be reevaluated within 4 to 5 days after the swelling subsides. Plain radiographs may be helpful at this time to determine whether malalignment exists. Patients with nasal deformity 4 to 5 days after injury require urgent consultation with a specialist to restore anatomic alignment.

Nasoorbital ethmoid fractures involve complete separation of the nasal bones and medial walls of the orbits from the stable frontal bone superiorly and infraorbital rim laterally. These injuries are usually the result of high-velocity trauma to the central midface. The bones are often fragmented and telescoped posteriorly into the ethmoid region. These patients display a characteristic flattened nose, with the loss of anterior projection on the lateral view of the face. Because the medial canthal tendons attach firmly to the medial walls of the orbits, lateral drift of the fracture segments results in traumatic telecanthus. Normal mean intercanthal distance is 16 mm at birth, which increases to 25 mm in a female and 27 mm in a male at full facial growth. A significant increase in intercanthal distance or gross asymmetry in the medial canthal to facial midline distance should raise suspicion of this fracture. Traumatic telecanthus suggests the diagnosis of a nasoorbital ethmoid fracture, which unlike a nondisplaced nasal fracture, requires urgent subspecialist input.

Zygoma and Maxilla Fractures

The zygoma is composed of a body or malar eminence and the zygomatic arch and attaches to the temporal, frontal, and maxillary bones of the facial skeleton. A complete fracture of the zygoma results in fractures at each of these sites and extends through the floor of the orbit. This may result in an inferior displacement of the zygoma because of the strong inferior forces applied by the masseter muscle, which attaches to the malar eminence. Zygoma fractures often produce a flattened appearance to the cheek, with inferior displacement of the globe, and conjunctival hemorrhage. Decreased sensation along the distribution of the infraorbital nerve is also common, as zygomaticomaxillary fractures usually include the infraorbital foramen. In isolated zygomatic arch fractures, a decrease in temporal width can be appreciated when viewing the face from the front as a result of buckling of the zygomatic arch. If this buckling is severe, the mandibular condyle may be impinged, with resultant difficulty in mouth opening.

In 1901, LeFort described three fracture patterns that occurred in patients with midface trauma (Fig. 111.5). The LeFort I fracture pattern involves only the maxilla and extends through the zygomaticomaxillary region to the base of the pyriform aperture. It allows motion of a segment of alveolar bone and teeth when examined. The LeFort II pattern, also called a pyramidal fracture, is similar but extends more superiorly to the infraorbital rims and across the nasofrontal sutures. The maxilla, nasal bones, and the medial orbital wall are separated from the facial skeleton. The nose and the upper jaw are movable, whereas the zygomas are stable. The LeFort III pattern, also called craniofacial dissociation, extends across the zygomatic arch, zygomaticofrontal region, floor of the orbit, and nasofrontal sutures, effectively separating the midface from the skull base. When the nose or upper jaw is moved, the entire midface, including the zygoma, moves with it. These fractures are quite rare in children, and when they do occur, they are most often asymmetric because impact is sustained from the side rather than head on.

Patients with midface fractures typically have significant swelling over the maxilla and severe epistaxis. Particular attention to the airway is of paramount importance in these children because significant bleeding and a disruption in the normal anatomic structures may threaten the patency of the airway. Nasal manipulation should be avoided because these fractures may be associated with cribriform plate injuries and passage of a nasogastric or endotracheal tube may result in brain injury. On examination, by grasping the maxilla at the level of the central incisors, the clinician may be able to appreciate crepitus or mobility when traction is applied. Clear rhinorrhea in the setting of midface trauma may be a sign of a cerebrospinal fluid (CSF) leak and warrants neurosurgical consultation. All patients suspected of having a midface fracture require CT imaging to determine whether surgical reduction is necessary.

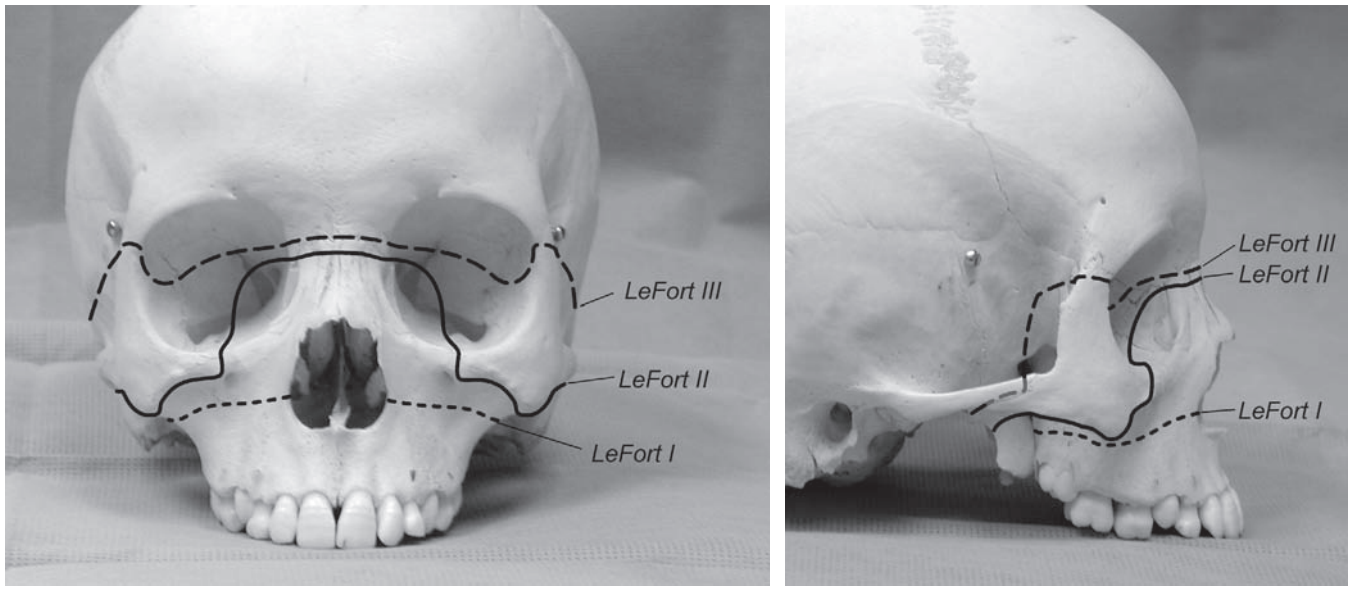

FIGURE 111.5 The LeFort classification of fractures. With type I, the maxilla is separated from its attachments. Type II (pyramidal) produces a mobile maxilla and nose. With type III (craniofacial disjunction), all attachments of the midface to the skull have been separated. Traction on the anterior maxilla produces motion up to the inferior orbital rims and zygoma. These fractures are not mutually exclusive. For example, LeFort II fracture may exist on the one side with type III on the other side.

Frontal Bone Fractures

Fractures of the frontal bone are rare in young children because the frontal sinuses do not begin to develop until 8 years of age. Injury to the frontal sinus may reveal a palpable or visible depression if the anterior wall of the sinus has been compressed. Displaced fractures of the anterior wall of the frontal sinus require surgical elevation. In patients with severe frontal sinus fractures associated with forehead lacerations, a fracture of the posterior wall of the sinus and dural tear may allow CSF to leak from the wound. Leakage of clear fluid from the wound, or clear rhinorrhea, should raise suspicion for such a leak and warrant CT imaging and neurosurgical consultation.

Soft-tissue Injuries

The approach to a child with soft-tissue injuries is discussed in the section on minor trauma (see Chapter 106). However, certain aspects of soft-tissue injuries involving the face warrant further discussion in this chapter.

Abrasions

Abrasions of the face should be evaluated for size, presence of foreign bodies, and injury to underlying structures. The severity and depth of injury may only be assessed by performing a thorough examination, which is often difficult in young children. The use of topical, local, and regional anesthetics may facilitate the examination and repair of such injuries. Deep abrasions should be irrigated to allow for optimal cleansing of the wound. Removal of debris from the wound is essential to avoid subsequent infection. Injuries on road or gravel can implant particulate matter into dermal layers. These areas require aggressive scrubbing and possible picking out of individual particles with the tip of a scalpel blade. Finally, extreme or deep wounds should be covered with sterile dressing. The use of topical antibiotic ointment on facial abrasions is controversial.

There are five general reasons to apply a dressing to a wound: protection, absorption, immobilization, compression (sometimes), and aesthetics. In most facial lacerations, the protective and aesthetic aspects of the dressing are most important. Deep abrasions should be covered with a dressing that provides controlled hydration, such as a polyurethane film, or a thicker, more absorptive dressing, such as those composed of hydrogels and hydrocolloids. These dressings help reduce pain, and studies have demonstrated that partial-thickness wounds covered with this type of dressing heal in approximately half the time it would take for an abrasion that is exposed to air or is covered with a dry dressing.

Lacerations

The goal of laceration repair is to achieve hemostasis and provide an optimal cosmetic result (Fig. 111.6, see also color plate). Although not unique to facial lacerations, cosmesis is often the primary concern among parents accompanying children with such injuries. Knowledge of the deep structures of the face, particularly the facial nerve and the lachrymal apparatus, will aid in the evaluation and management of children with deep facial lacerations. Lateral periorbital lacerations should raise suspicion of injury to the frontal branch of the facial nerve, which travels superficially along a line from just above the tragus to a point 1.5 cm above the lateral eyebrow. Lacerations in the medial periorbital region near the medial canthus should raise suspicion for lachrymal duct injury. Because 85% of tears are drained via the lower canaliculus, failure to repair a laceration to the lachrymal duct may result in excessive tearing (epiphora). If deep lacerations are present in

FIGURE 111.6 Photographs of a 3-year-old boy after an attack by a dog. The **top** photograph shows the child before sharp debridement, facial nerve exploration, and layered closure of his complex wound. The **middle** panel is a photograph of the child 1 week after his repair and demonstrates the precise reapproximation of the facial soft tissues. The **bottom** photograph was taken 8 months after the attack and demonstrates a nicely healed facial scar that will continue to fade and soften. (Courtesy of David W. Low, MD.)

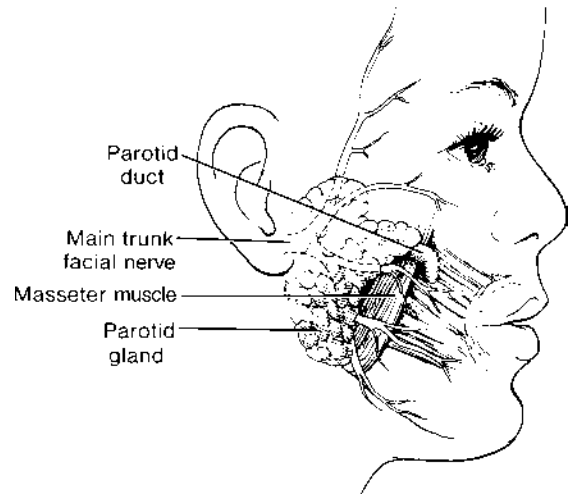

FIGURE 111.7 Deep lacerations to the cheek can injure the facial nerve, parotid gland, or parotid duct. The facial nerve becomes more superficial as it branches and proceeds distally. Distal nerve injuries can thus occur with more superficial wounds.

the cheek region, the clinician must determine whether injury to the buccal branch of the facial nerve and to the parotid duct has occurred (Fig. 111.7).

Injuries to the cheek, involving the region between the mid-cheek and the tragus of the ear, should be assessed for injury to the facial nerve. When injury to the facial nerve is suspected, patients can be tested by having them move specific muscles of facial expression. This testing should take place before infiltration with local anesthetic. The frontal branch of the facial nerve can be tested by asking the patient to frown in order to look for symmetry of frontalis action. The marginal mandibular (motor) branch may course as much as 1 to 2 cm below the border of the mandible and is responsible for the depression and eversion of the lower lip. Injury to this branch results in a characteristic inward rotation of the lower lip on the affected side as a result of unopposed orbicularis tone on that side. The buccal branches are in close proximity to Stenson's (parotid) duct, usually close to a line between the tragus of the ear and the mid-upper lip. Deep lacerations in this area raise the possibility of injury to both structures.

Examination for potential injury to Stenson's duct is accomplished by grasping the commissure between the thumb and index finger and gently everting the buccal mucosa to identify Stenson's duct, which lies on a vertical line along the maxillary second premolar. With the opposite hand, gentle massage of the parotid gland is accomplished by pressing in the preauricular region. The appearance of clear fluid from Stenson's duct suggests an uninjured duct. The absence of fluid after several minutes of inspection, or bloody fluid, suggests injury to the gland or duct. In this case, inspection of the depth of the wound may reveal salivary fluid and severed ends of the duct may be identified. A sialogram can be a useful adjunct in the diagnosis of parotid duct injuries. In wounds with substantial bleeding, clamping all but the most obvious cut ends of blood vessels should be avoided for possible injury to a facial nerve branch.

Although most lacerations should be repaired within 8 to 12 hours, clean lacerations of the face can often be reapproximated up to 24 hours after the injury was sustained. Late-presenting lacerations (48 to 72 hours after the injury) can be closed after thorough sharp debridement. The risks of infection in closing such a wound must be weighed against the benefits of reducing the facial scarring that will result if the wound is allowed to heal secondarily. Factors such as mechanism of

injury, immunocompetence, and hygiene must be considered. Similar to abrasions, anesthesia, copious irrigation, and tension-free approximation are vital to a successful closure. If in doubt regarding closure of a late-presenting or heavily contaminated wound, the clinician should consult a specialist or consider leaving the wound open to heal by secondary intention or delayed primary closure. In this case, irrigation and cleansing are still important and moist, saline-soaked sponges can be placed in the wound (to be changed several times a day).

If possible, facial lacerations should be repaired using deep sutures to reduce tension on the wound and to help with eversion of the edges. All wounds contract as scar formation occurs and thus eversion of the skin should be considered for facial lacerations, particularly those involving the nares, eyelids, helix of the ear, and vermillion border of the lower lip. Inadequate eversion of the wound edges at these sites may lead to a depressed scar or notching at the site of the laceration. The time after which sutures should be removed varies from approximately 5 days in the eyelids to 5 to 7 days in the face to 10 days in the nose and up to 14 days in the ear.

Repair of complex injuries to laminated structures (e.g., ear, eyelid, nose, lip) requires that each layer of the structure be reapproximated. For example, a full-thickness laceration to the nose at the nostril rim requires closure of three separate layers. The nasal lining is usually closed first with an absorbable suture material. Next, the cartilage must be repaired, also with absorbable material. Finally, the overlying skin of the nose can be reapproximated. Similarly, complex injuries of the ear, the eyelid, or the lip require layered closure to achieve the best cosmetic result. Careful attention should be paid to lip lacerations that traverse the vermillion border. Cosmetic outcome is predicated on successful alignment of tissue at this junction.

The mouth should be evaluated for lacerations of the mucosa or tongue, injury to the palate, and loose or missing teeth. Chapter 109 details specific oral injuries. Lacerations and soft-tissue injuries involving the external ear, as well as the nasal mucosa, may require plastic surgical evaluation and are described in detail in Chapter 110.

Verbal or written consent should be obtained from patients and families undergoing laceration repair and documented within the emergency department. The physician should provide a careful assessment and natural history of the injury if left untreated to heal on its own. The physician should also describe the recommended treatment, as well as alternative treatments, with its likely outcomes and possible complications. If, for instance, a dark-skinned child has sustained an abrasion or laceration to the face, the risk of pigment changes or excessive scarring in terms of hypertrophy of the scar or keloid formation is significant. Patients with lacerations resulting from dog bites and those who present for care after a delayed period of time should be warned of the high risk of infection.

Complicated facial laceration repair and laceration repair in young children may be facilitated by the use of procedural sedation. For properly selected superficial facial lacerations, tissue adhesives such as 2-octylcyanocrylate have demonstrated similar cosmetic outcome to sutures while offering the benefit of providing a painless procedure, often accomplished without the use of procedural sedation. For deep lacerations, skin closure should be performed only after tension is relieved from wound borders, usually through the use of buried absorbable sutures. Stapling has been shown to be a fast and cosmetically acceptable alternative to suturing for simple scalp lacerations.

Regional Nerve Blocks

Local or regional anesthesia may be used to aid in the suturing of facial lacerations in children. Regional anesthesia has the distinct advantage of allowing the physician to perform a painless procedure, without distorting the anatomic structures under repair. In addition, regional blocks, in general, require fewer anesthetics. Regional nerve blockade of the face is discussed in more detail in Section VII, 12.13E to 12.13G; however, certain aspects warrant mention in this chapter.

The supraorbital nerve exits the supraorbital rim in the medial third of the eyebrow approximately 2 to 3 cm from the facial midline. Local infiltration in this region can effectively provide anesthesia to the ipsilateral hemiforehead. The infraorbital nerve exits through the infraorbital foramen, approximately 5-mm inferior to the infraorbital rim. Effective block of this nerve can provide anesthesia to the ipsilateral medial cheek and upper lip. Anesthesia of the lower lip and chin may be achieved by infiltration of the ipsilateral mental (infraoral) nerve. This nerve exists approximately 2 to 3 cm superior to the inferior border of the mandible. The supraorbital and inferior orbital nerves, as well as the mental nerve, exit the facial skeleton from foramen, which are inline with the first premolar tooth.

GUIDELINES FOR CONSULTATION

Priority must be given to the stabilization of the patient, following the airway, breathing, and circulation (ABCs) of trauma resuscitation. When a patient is stabilized, and after other associated injuries are addressed, the physician must decide whether the facial injuries warrant consultation with a subspecialist.

For the pediatric population, the parent(s) or guardian often requests a specialist consultation for problems that may not require specialist intervention, such as the repair of simple facial lacerations. Communication is of paramount importance in this scenario. Emergency physicians have the training and expertise to repair most facial lacerations in children. The provider should convey to both the child and the caregiver that he or she has the experience and procedural skills to perform the procedure and that the outcome will likely be no different if the laceration is repaired by a plastic surgeon. Injuries that require specialist consultation include (i) lacerations with evidence of injury to deep structures (a major motor nerve or a glandular duct), (ii) cases in which a substantial amount of devitalized tissue exists or actual tissue loss has occurred, (iii) wounds in which the amount of bleeding cannot be easily controlled, (iv) full-thickness defects of the ear and nose, and (v) cases in which it is unclear exactly which tissue to approximate to restore preinjury anatomy and aesthetics (e.g., lips, eyelids, nostrils, ears).

CHAPTER 112 ■ GENITOURINARY TRAUMA

CARMEN TERESA GARCIA, MD, AND VALERIE T. THOMPSON, MD

In children who sustain multiple injuries, genitourinary trauma is second in frequency only to central nervous system trauma. Approximately 10% of patients with serious multisystem trauma have urogenital injuries. Most injuries (90%) are the result of blunt trauma that involves crush injuries and acceleration/deceleration forces. Vehicular and pedestrian accidents account for a large percentage of blunt trauma. Other mechanisms of injury include falls and sports-related incidents. Penetrating injuries are less common in children than in adults. High-velocity bullet wounds produce direct tissue injury and damage to adjacent tissue because of the energy generated by the missile. Low-velocity bullet wounds and stab wounds cause injury by penetrating the tissue directly. Iatrogenic trauma has been reported after operative procedures.

Injuries to other systems are often encountered in patients sustaining genitourinary trauma. Common associated problems include head injuries, fractures (extremities, pelvis, ribs, spine, skull), spinal cord injuries, and lacerations of the liver and spleen. Simultaneous upper and lower genitourinary tract injuries are rare and are usually incompatible with survival. Isolated urologic injuries are rarely the cause of death.

The clinical approach to the injured child should strictly follow Advanced Trauma Life Support guidelines. Figure 112.1 provides an algorithm for diagnostic evaluation of pediatric patients with genitourinary trauma. Urologic management may be temporized to permit urinary drainage in the initial phases; the patient may subsequently require operative procedures.

KIDNEY

The kidney is the most commonly injured structure in the genitourinary tract. Approximately half of genitourinary injuries involve the kidney. Children are more likely than adults to sustain renal injuries. In children, the kidney is larger in proportion to the size of the abdomen than in adults. The child's kidney may retain fetal lobations, which allow for easier parenchymal disruption. The kidney has inadequate protection due to weaker abdominal musculature, a less well-ossified thoracic cage, and less developed perirenal fat and fascia than in adults. Most pediatric renal trauma is minor, requiring no intervention.

Blunt trauma accounts for more than 90% of renal injuries. Most pediatric renal trauma is sustained in motor vehicle accidents. Falls, sports-related incidents, and direct blows are also common mechanisms of injury. Penetrating trauma accounts for the remaining cases. Approximately 10% of penetrating abdominal injuries involve the kidney. Penetrating renal trauma may occur as a complication of amniocentesis or percutaneous manipulation.

Associated injuries often occur, with head injuries being the most common. Associated intraperitoneal injuries occur in 80% of patients with penetrating renal trauma and 20% of patients with blunt renal trauma. In general, the hospital length of stay is determined by the associated injuries and not the renal injuries.

Coincidental congenital renal anomalies and intrarenal tumors have been reported in up to 20% of injuries. More accurate recent reviews show that the incidence rate is closer to 1%. Historically, preexisting anomalies have been believed to increase the risk and severity of injury to the kidney. However, it appears that in most patients, congenital genitourinary anomalies associated with renal injury are incidental findings and do not increase morbidity. Nevertheless, a high index of suspicion should be maintained in any child who presents with gross hematuria after a relatively minor trauma. Other patients may present with an acute abdomen due to intraperitoneal rupture of a hydronephrotic kidney.

Classification

Renal injuries have been described using different classification systems based on the clinical and radiologic assessment of the patient. The Organ Injury Scaling Committee of the American Association for the Surgery of Trauma has devised an injury severity score, which represents an amalgamation of previous scales. The injury severity score was developed to facilitate clinical research. This classification system is illustrated in Fig. 112.2. Grade I injuries include contusions or subcapsular, nonexpanding hematomas. Grade II injuries include nonexpanding hematomas confined to the retroperitoneum or lacerations less than 1 cm in depth without urinary extravasation. Grade III injuries include lacerations extending more than 1 cm into the renal cortex without collecting system rupture or urinary extravasation. Grade IV injuries include lacerations extending into the collecting system or renal vascular injuries with contained hemorrhage. Grade V injuries include completely shattered kidneys or avulsions of renal hilum with devascularized kidneys.

Parenchymal contusions and hematomas are the most common renal injuries, accounting for 60% to 90% of all lesions from blunt trauma. Lacerations account for up to 10% of renal injuries and may involve disruption of the capsule, collecting system, or both.

Severe injuries, such as shattered kidney or pedicle avulsions, constitute approximately 3% of renal injuries. Pedicle injuries result from lateral displacement of the kidney with stretching of the tethered renal vessels.

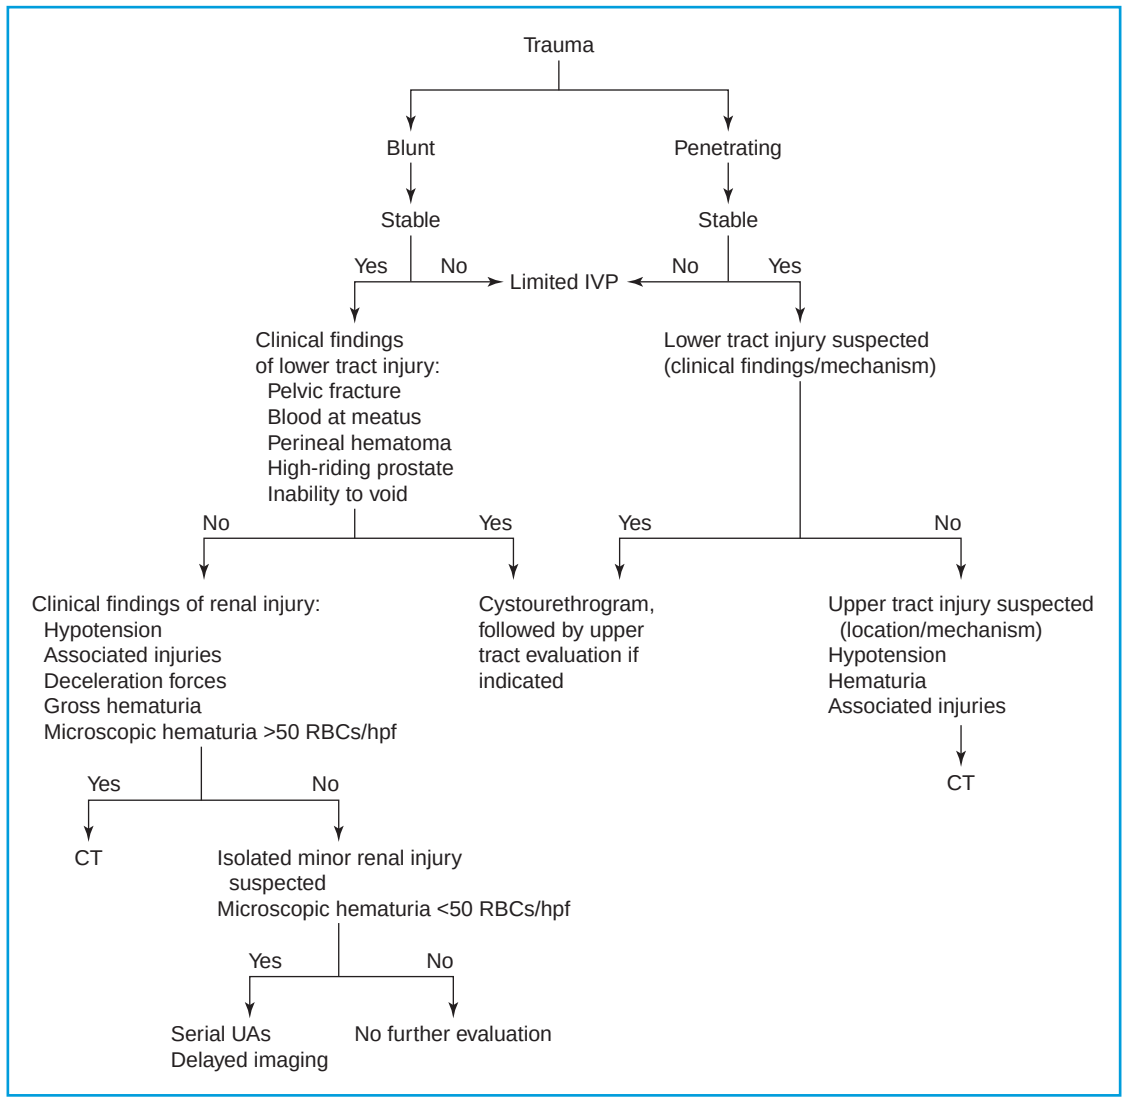

FIGURE 112.1 Algorithm for the evaluation of the pediatric patient with genitourinary trauma. IVP, intravenous pyelogram; CT, computed tomography; RBC, red blood cell; hpf, high-powered field; UAs, urinalyses.

Clinical Presentation

Children who sustain significant renal injuries usually present with localized signs such as flank tenderness, flank hematoma, or a palpable flank mass. Findings also include nonspecific signs often associated with injury to other intraabdominal organs. Generalized abdominal tenderness, rigidity of the abdominal wall, paralytic ileus, and hypovolemic shock may all be part of the clinical picture. Penetrating injuries to the chest, abdomen, flank, and lumbar regions should alert the clinician to the possibility of a renal injury.

Hematuria has long been considered the cardinal marker of renal injury. Gross hematuria is a hallmark of severe injury. It should be emphasized that the degree of hematuria does not correlate with the severity of the renal lesion. Hematuria may be absent in up to 50% of patients with vascular pedicle injuries and in approximately one-third of patients with penetrating injuries.

Hematuria with abdominal symptoms has been associated with an increased risk of nonurologic intraabdominal injuries. Injuries to other organs can be seen regardless of renal injury. Some series suggest that clinically significant liver and spleen injuries are more common in children with hematuria than are renal injuries.

Diagnostic Evaluation

All injured children should undergo a thorough evaluation based on well-established trauma protocols. Assessment of the genitourinary system can be undertaken once life-threatening conditions have been identified and the child has been resuscitated. A urinalysis should be obtained in all patients with multisystem trauma or suspected isolated renal injury.

Hypotension is not a reliable indicator of significant renal injuries in children and therefore should not be used to guide management; however, most patients with multisystem trauma

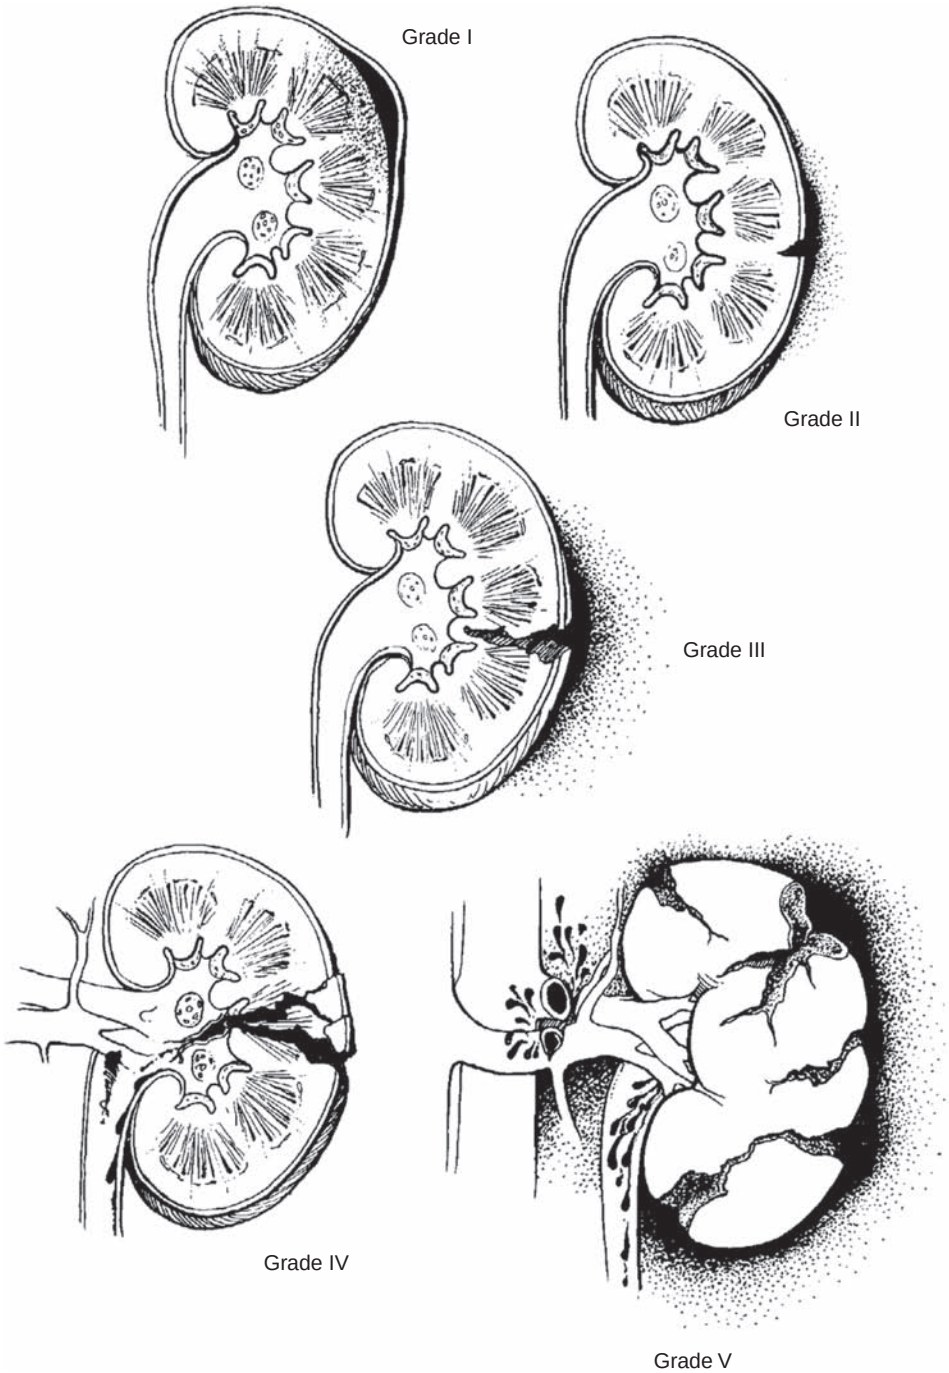

FIGURE 112.2 Classification of renal injuries as proposed by the Organ Injury Scaling Committee of the American Association for the Surgery of Trauma.

and hypotension undergo an abdominal computed tomographic (CT) scan to look for nonurologic injuries. Radiographic evaluation of the pediatric genitourinary tract is necessary in cases with clinical signs indicative of renal injury, gross hematuria, major associated injuries, or significant deceleration forces. Imaging all patients with blunt trauma and microscopic hematuria gives an extremely low yield. Detection of significant renal injury increases with hematuria of more than 50 red blood cells (RBCs) per high-power field (hpf). Children who present with this degree of hematuria require prompt radiographic studies. An isolated finding of microscopic hematuria of less than 50 RBCs per hpf does not alone fulfill the criteria for imaging. These patients are likely to have renal contusions and can be managed conservatively with serial urinalyses. Microscopic hematuria that persists for more than a month warrants radiographic evaluation.

Criteria regarding the imaging of children with penetrating trauma are less well established. In the adult population, radiographic evaluation is required in patients with hypotension, penetrating injuries in the vicinity of urologic organs, associated abdominal injuries, or the presence of any degree of hematuria.

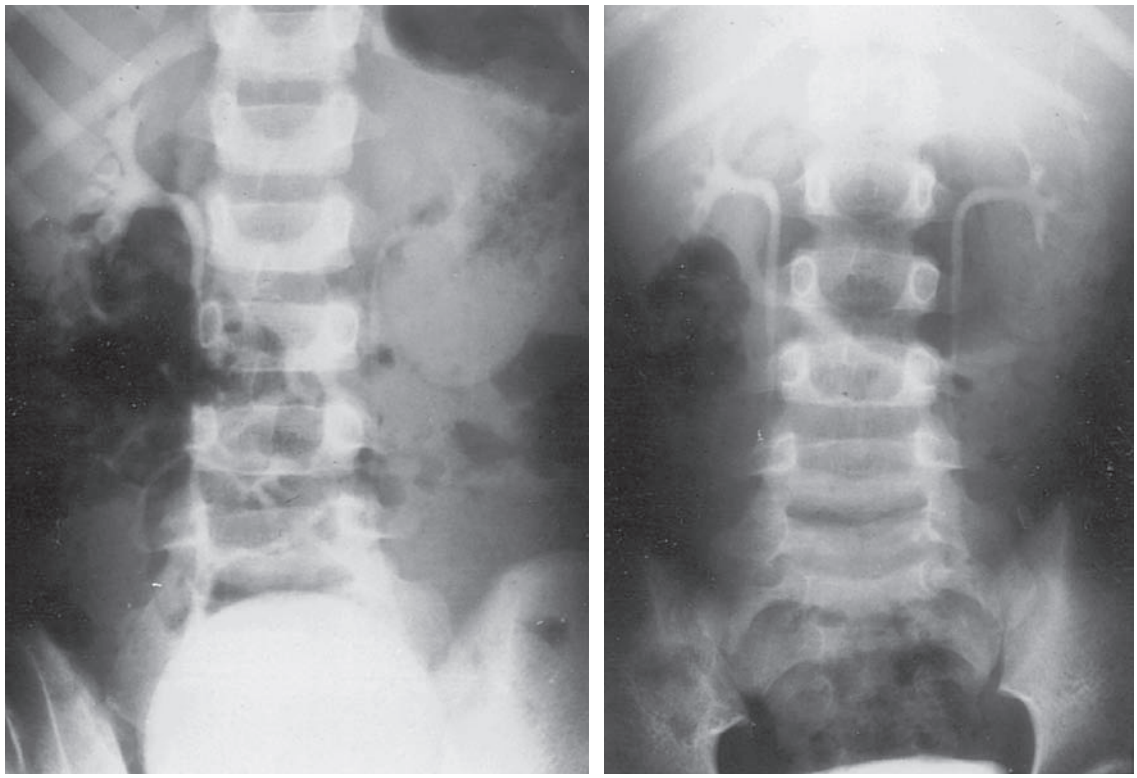

FIGURE 112.3 Renal contusion. Intravenous pyelogram (IVP) (**left panel**) shows decreased concentration of contrast material in the left kidney. Follow-up IVP (**right panel**) 1 month after the injury reveals normal renal function.

Initial evaluation of children with multisystem injuries and suspected pediatric renal trauma should include radiographs of the chest, abdomen, and pelvis. Plain radiographs may show obliterated renal and psoas shadows, scoliosis with the concavity toward the injured site, intraabdominal mass effect, or a coincident rib, spinous process, or pelvic fracture.

Traditionally, intravenous pyelogram (IVP) has been the cornerstone of evaluation in renal trauma (Fig. 112.3). The IVP is available in most institutions and provides information about the overall functional and anatomic integrity of both kidneys. It can be obtained in an unstable patient urgently in the emergency department (ED) or in the operating room before surgery. Indications of renal injury include delayed excretion of the contrast agent by the injured kidney, nonvisualization of the caliceal system, or extravasation of the contrast agent into the perinephric tissues. The presence of a normally functioning kidney contralateral to the injured kidney should be specifically noted.

Even under optimal conditions, the IVP cannot always reliably identify and stage renal trauma. The pyelogram accurately diagnoses only 5% of contusions, 50% of lacerations, and 29% of pedicle injuries. Contrast-enhanced CT is the preferred study for the evaluation of major abdominal injury, including renal injury (Fig. 112.4). CT scan has certain advantages over the IVP, the most important of which is the detection of associated injuries. In addition, CT provides three-dimensional views and imaging independent of the vascularity of the kidney. Conventional IVP should be used to evaluate major renal injuries only if CT scanning is not readily available. IVP may also be indicated in the long-term evaluation of persistent hematuria.

CT imaging can be used to determine the degree of renal parenchymal injury, to evaluate the presence of nonviable tissue, to demonstrate extravasation and perirenal collections, and to diagnose most pedicle injuries. The diagnostic accuracy of the CT scan has been reported to be as high as 98%. Helical

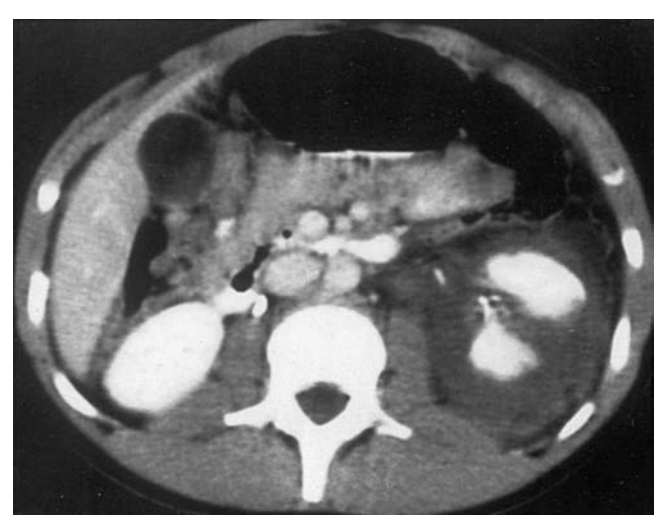

FIGURE 112.4 Renal fracture. Computed tomography section of the abdomen shows fracture of the left kidney with moderate subcapsular hematoma.

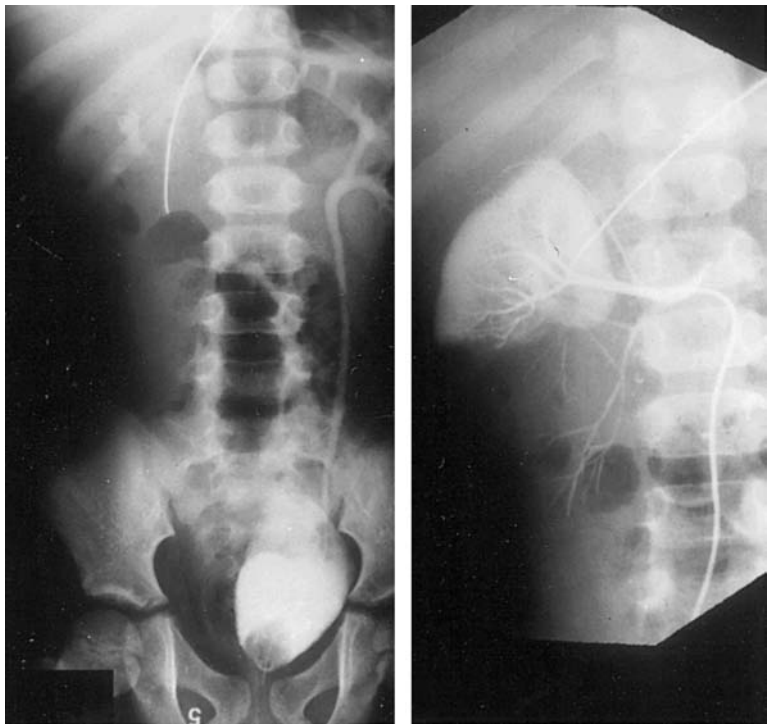

FIGURE 112.5 Renal fracture. Intravenous pyelogram (**left panel**) demonstrates nonvisualization of the lower pole of the right kidney. The arteriogram (**right panel**) confirms the diagnosis.

CT scan with immediate postcontrast and delayed imaging is the standard radiographic modality for renal trauma. CT scanning has also proven to be a useful tool for following patients after trauma.

Ultrasonography is not widely accepted for the staging of renal trauma. Its sensitivity in demonstrating renal injury is only 70% compared with CT scanning. However, ultrasound has certain advantages over CT scanning. It is readily available, can be performed at the bedside, minimizes exposure to radiation, and does not require the use of contrast material or sedation. Ultrasound can evaluate the size of the kidney and the integrity of the urinary drainage system. Pulsed-flow duplex Doppler ultrasound can assess renal arterial and venous flow and may represent the most immediate means of screening for renal pedicle injury.

Ultrasound can be particularly helpful in patients with perirenal collections who require early follow-up imaging during the hospital stay. It may be an alternative modality for the evaluation of the pregnant trauma patient. It is also often used for long-term outpatient follow-up, although its efficacy in this setting has not been proven.

Angiography (Fig. 112.5) has been largely replaced by noninvasive modalities, especially in the pediatric patients in whom technical problems with vascular access result in a higher complication rate than in adults. Arteriography does not add useful information to contrast CT scanning and may increase diagnostic delay during the preoperative workup. It is useful in patients who require therapeutic embolization of an active bleeding site.

Radionuclide imaging can assess pedicle competence, parenchymal integrity, and renal function. A nuclear scan can be obtained instead of sonography to assess change in the size of perinephric collections. Its most important role is in follow-up evaluation of renal injury (Fig. 112.6), particularly in the setting of new-onset hypertension.

Magnetic resonance imaging (MRI) has been found to be as effective as CT scanning in staging renal injuries. However, because of cost and time restraints, its role has been limited. MRI may be indicated in carefully selected patients, such as those with either equivocal findings on the CT scan or a severe renal injury.

In conclusion, hemodynamically stable patients who present with suggestive clinical findings, gross hematuria, microscopic hematuria of more than 50 RBCs per hpf, major associated injuries, or a history of significant deceleration injury

FIGURE 112.6 Follow-up renal scan of patient in Fig. 112.5 obtained 4 months after the injury. The study reveals several areas of decreased radiotracer uptake in the left kidney.

should undergo radiographic evaluation. These patients should have a CT scan. Children who remain unstable despite resuscitative measures should undergo a one-shot IVP before emergency laparotomy. This procedure is particularly important to confirm the presence of a normal contralateral kidney. Children with isolated microscopic hematuria of less than 50 RBCs per hpf do not require immediate imaging. These patients may be discharged and can be evaluated on an outpatient basis with CT, IVP, or ultrasound if hematuria persists. However, in some centers, management of these patients involves hospitalization for observation, followed by nonemergent radiographic evaluation.

Management

The principle underlying the management of pediatric renal trauma is preservation of renal tissue and function with minimal morbidity and mortality. Patients who are hemodynamically unstable or have sustained severe intraabdominal penetrating trauma require immediate surgical intervention. Management of hemodynamically stable children should proceed on the basis of staging of the traumatic lesion. Attempts should be made to manage all renal injuries conservatively.

In cases of blunt trauma, children with grade I renal injuries (contusions) can be discharged home without further imaging and followed with serial urinalyses. Patients are instructed to limit daily activity until the urinalysis is within normal limits. Outpatient radiographic evaluation is necessary if microscopic hematuria persists for more than 30 days. Grade II and III renal injuries warrant admission to the hospital for a minimum of 24 hours when the risk of bleeding is highest. Expectant treatment includes supportive care with strict bed rest, hydration, antibiotics, and serial hematocrits. Once the gross hematuria resolves, these children may be discharged home with limited activity until microscopic hematuria resolves and repeat imaging demonstrates total healing.

Management of the remaining patients (with grade IV and V injuries) evokes significant controversy. The shift from early operative intervention to a more expectant approach for most solid organ injuries has been increasingly applied to high-grade renal injuries. Advocates of early surgical exploration argue that this approach results in decreases in morbidity, hospital stay, and complications without a significant increase in the risk for nephrectomy. Opponents believe that nonoperative management of selected patients does not lead to negative consequences and may result in a higher renal salvage rate.

Nonoperative management requires time with admission to the hospital, serial examinations and hematocrits, and antibiotics. Repeat imaging should be routinely obtained at 48 hours or earlier if clinically indicated. Patients who demonstrate hemodynamic instability require surgical intervention or angiographic embolization of renal vessels. Angioembolization should be performed only in those children who have a definable segmental artery injury. Persistent urinary extravasation can be managed with percutaneous drainage or internal ureteral stenting. These procedures, as well as embolization, should be limited to institutions that can provide appropriate resources.

Operative exploration is required in 5% to 10% of cases. Absolute indications for surgery include persistent renal bleeding and expanding or pulsatile hematoma. Relative indications for exploration are urinary extravasation, nonviable tissue, segmental arterial injury, and incomplete staging. Some studies suggest that surgical intervention is more often necessary in patients with other associated nonrenal, solid organ intraabdominal injuries. Attempts to preserve the kidney are more likely to succeed in patients with grade IV injuries. Children with grade V injuries frequently require nephrectomy. In patients with vascular injuries, chances of renal salvage are improved if renal parenchyma is minimally disrupted and revascularization is achieved within a few hours of the injury. In extreme situations, such as a solitary kidney or bilateral renal injuries, surgery should be attempted even after a long delay.

Penetrating renal injuries have traditionally been managed with operative intervention. Compared with blunt trauma, far less literature is available in support of nonoperative treatment after penetrating trauma. In addition, many recommendations are extrapolated from data from adult patient populations. Careful selection of hemodynamically stable patients who can tolerate CT staging may identify a cohort of children who can be safely treated conservatively. Indications for renal exploration are similar to those for injuries caused by blunt trauma. Patients with penetrating trauma have a higher need for surgical intervention.

Complications

Short-term complications of renal trauma include delayed hemorrhage, urinary extravasation, abscess formation, and ureteral obstruction secondary to clot formation. Long-term complications include compromised renal function, hypertension, hydronephrosis, arteriovenous fistula, renal intestinal fistula, and stone formation. Children with a history of significant renal trauma require regular follow-up for at least 1 year to ensure complications are diagnosed and treated promptly.

URETER

Ureteral injuries are uncommon in children, accounting for less than 1% of all urologic trauma. These injuries can be caused by blunt, penetrating, or iatrogenic trauma.

Blunt trauma usually involves the ureteropelvic junction. Disruption of the ureter from the renal pelvis results from stretching of the ureter by sudden hyperextension of the trunk. Traditionally, this injury has been described more often in children. The degree of hyperextension necessary to cause avulsion of the ureter is believed to be fatal in adults. However, an increased number of ureteropelvic junction injuries have recently been reported in adults. In the past, many injuries in adults may have been misdiagnosed as parenchymal lacerations involving the collecting system.

Trauma to the ureter should be suspected in patients presenting with fracture of the transverse process of a lumbar vertebra. Pelvic fracture, hip fracture, lower rib fracture, splenic laceration, liver laceration, and diaphragmatic rupture have also been reported in association with ureteral injuries.

Early diagnosis of blunt ureteral injuries is critical. These injuries are often overlooked. Less than 50% of patients are

diagnosed within 24 hours of presentation. The physical examination may be unremarkable. However, an enlarging flank mass in the absence of signs of retroperitoneal bleeding suggests urinary extravasation. Hematuria is an unreliable sign. The urinalysis may be normal in 30% of confirmed cases. When the diagnosis has been delayed, ureteral injury may manifest with fever, chills, lethargy, leukocytosis, pyuria, bacteriuria, flank mass or pain, fistulas, and ureteral strictures.

Avulsion of the ureter should be suspected when the IVP demonstrates extravasation of contrast material and nonfilling of the affected ureter. Contrast-enhanced CT is an appropriate alternative to the IVP. CT findings suggestive of ureteral injury include medial perirenal extravasation of contrast material, a circumrenal urinoma, and the lack of opacification of the ureter distal to the injury. Delayed images must be obtained regardless of which diagnostic modality is used. Both CT scan and IVP have been shown to have a low sensitivity for ureteral injuries, identifying only 33% of cases. Retrograde pyelogram may be a more reliable examination, but it is rarely performed in the initial evaluation of a trauma patient.

The management of complete transection of the ureter depends on the level of the injury. Important elements include debridement of devitalized tissue and a watertight, tension-free anastomosis. Ureteroureterostomy, transureteroureterostomy, or pyeloureterostomy is recommended for mid- and upper ureteral injuries. Mid- to lower ureteral injuries are best treated with ureteroneocystostomy. Placement of a ureteral stent is indicated in most cases. Conservative treatment with stent placement alone may be adequate for patients with hematomas or minor lacerations.

If the ureteral lesion is identified within 5 to 10 days of the injury, prompt repair of the ureter is indicated. If diagnosis is delayed for more than 10 days, urinary diversion above the lesion should be performed with subsequent definitive repair 4 to 6 months later. The incidence of nephrectomy is approximately 5% when the injury is detected early, but it is as high as 30% when recognition is delayed.

Penetrating injuries may occur at any point along the length of the ureter and are associated with injuries to other intraabdominal organs in up to 90% of cases. Stab wounds rarely cause ureteral injuries. However, up to 50% of patients with gunshot wounds to the abdomen have injury to the ureter. Occasionally, the ureter may be accidentally injured during pelvic operations or ureteroscopy. Most penetrating ureteral injuries are recognized intraoperatively by direct visual inspection. Intravenous or intraureteral injection of indigo carmine or methylene blue may facilitate the diagnosis. Repair of penetrating injuries to the ureter in children follows the same guidelines as those observed in adults. Injuries caused by high-velocity missiles require wide debridement to ensure an adequate anastomosis and to preserve blood supply.

BLADDER

Bladder injuries may occur after blunt or penetrating trauma. Blunt trauma secondary to motor vehicle accidents is the leading cause of bladder injuries. More than 80% of bladder injuries are associated with pelvic fractures and penetration of the bladder by a bony fragment. However, only 10% of patients with pelvic fractures sustain lower urinary tract injury. The probability of having an associated bladder injury increases proportionally with the number of fractured pubic rami. Mortality rate associated with bladder rupture may be as high as 40%. Death is usually caused by associated head injuries rather than by bladder injuries themselves.

During childhood, the bladder has a higher abdominal location, which renders the organ more susceptible to injury than in adults. The bladder can also be more easily damaged when full. The risk for this injury is especially increased in the setting of improperly fastened seat belts and lap belts. Bladder neck injuries are uncommon, but serious. Such injuries have been reported to be more common in children than in adults because of the undeveloped prostate and are often in association with a pelvic fracture. The injury may be due to longitudinal lacerations or lacerations that extend to the proximal urethra.

Bladder injuries are classified as extraperitoneal, intraperitoneal, or combined. Extraperitoneal injuries are more frequently associated with pelvic fractures of the anterior ring and may be related to either laceration or penetration from a bone spike, irrespective of bladder volume at the time of injury. In contrast, intraperitoneal injuries, which account for approximately two-thirds of major bladder injuries, are usually caused by blunt trauma, resulting in a burst mechanism to a full, distended bladder. Combined injuries are usually seen with gunshot wounds. Bladder injuries may range from contusions to rupture. Contusions are incomplete, nonperforating tears of the mucosa. Complicated injuries may involve the bladder, urethra, sacral plexus, and supporting structures of the anorectal region.

Hematuria and dysuria are symptoms commonly seen at presentation. Nearly 100% of patients with rupture of the bladder have gross hematuria. Microscopic hematuria is associated with less severe injuries such as contusions. Inability to void may be associated with large tears. Patients with intraperitoneal ruptures may develop a palpable fluid wave from extravasation of urine into the peritoneal cavity and peritoneal irritation. Elevated levels of blood urea nitrogen out of proportion to creatinine result from more rapid peritoneal reabsorption of urea.

A large, prospective series of pelvic fractures and lower genitourinary tract injury in pediatric patients found that imaging is not required if patients are stable, have a normal genitourinary examination, do not have gross hematuria, and do not have multiple associated injuries. Diagnostic evaluation is indicated in patients who sustain pelvic or lower abdominal trauma with gross hematuria, inability to void, abnormal external genitourinary examination, or multiple associated injuries. Evaluation begins with a plain radiograph to exclude a pelvic fracture. Fracture types that have been associated with bladder injury include widening of the sacroiliac joint, symphysis pubis, and fractures of the sacrum. If a pelvic fracture is not identified, the urethra can be catheterized and a cystogram is performed. Catheterization must be avoided if physical examination reveals blood at the urethral meatus or a high-riding prostate.

Conventional cystography is still considered to be the imaging "gold standard" for the evaluation of blunt bladder trauma. CT cystography has been demonstrated to have similar sensitivity, specificity, positive, and negative predictive value as conventional cystography for the presence and type of bladder injury. However, the accuracy is lower than that reported by conventional cystography for distinguishing

intraperitoneal from extraperitoneal injury. It is important for the CT to have the ability to distinguish the specific type, as the management of the two may differ greatly. Sagittal and coronal multiplanar images may be helpful in identifying most sites of bladder rupture.

CT cystography does offer some advantages over plain cystography for patients undergoing CT scanning for the evaluation of other associated blunt injuries. CT scanning provides expeditious scanning of the head, chest, abdomen, and pelvis; interpretation is often less affected by overlying bone fragments from pelvic fractures and spine boards than in the plain radiographic cystogram, and the CT can detect small amounts of intra- and extraperitoneal fluid. The disadvantages of CT cystography include the much higher radiation exposure and cost than those of plain radiographs. Currently, the CT cystogram is recommended, when indicated, for patients undergoing CT scanning for other associated blunt trauma-related injuries.

Conservative management with or without urethral catheter drainage is the standard of care in patients with contusion. Extraperitoneal vesical rupture can be managed by urethral catheter or suprapubic drainage for 7 to 10 days. Treatment of extraperitoneal or intraperitoneal tears involves transperitoneal exploration and repair with the placement of a suprapubic or transurethral catheter, or transurethral catheter alone. Both have been shown to have similar outcomes and complication rates. Combined or penetrating injuries to the bladder require surgical exploration and direct closure.

Iatrogenic bladder injuries may occur during herniorrhaphy, cystoscopy, and umbilical artery cutdown. Patients with myelodysplasia who have undergone bladder augmentation may experience spontaneous bladder rupture in the presence of infection, bacteremia, or overdistension. Symptoms and signs of sepsis, as well as shoulder pain, may be encountered at presentation. Emergent exploration is indicated after a cystogram is completed.

URETHRA

Blunt trauma, due to motor vehicle accidents, high-velocity falls onto the perineum, and straddle injuries, accounts for most urethral injuries sustained during childhood. Injuries due to instrumentation and penetrating injuries, such as gunshot wounds, are less common. Urethral injuries occur primarily in males. In boys, the urethra is divided by the urogenital diaphragm into an anterior urethra (pendulous and bulbous) and a posterior urethra (membranous and prostatic) (Fig. 112.7). Anterior and posterior urethral injuries differ from each other by mechanism of injury, clinical presentation, and treatment.

Anterior urethral injuries result from direct trauma, are often isolated, and are associated with low mortality. The pendulous urethra may be damaged by blunt or penetrating forces. Bulbar injuries are commonly caused by straddle injuries, as the urethra is compressed between the symphysis pubis and a solid object. The major sign of acute anterior injury is bleeding from the urethra. Blood at the meatus has been reported in up to 90% of patients sustaining anterior urethral injuries. Other findings include hematuria, inability or difficulty voiding, and periurethral or perineal edema and ecchymosis. Perineal ecchymosis in the shape of a butterfly is typical for these injuries. Blind placement of a urethral catheter may convert a partial tear into a complete transection and therefore should be discouraged.

Diagnosis can be made by a retrograde urethrogram. A Foley catheter appropriate for the size of the patient is inserted into the urethra to the fossa navicularis without inflating the balloon. Contrast material is injected via the catheter into the

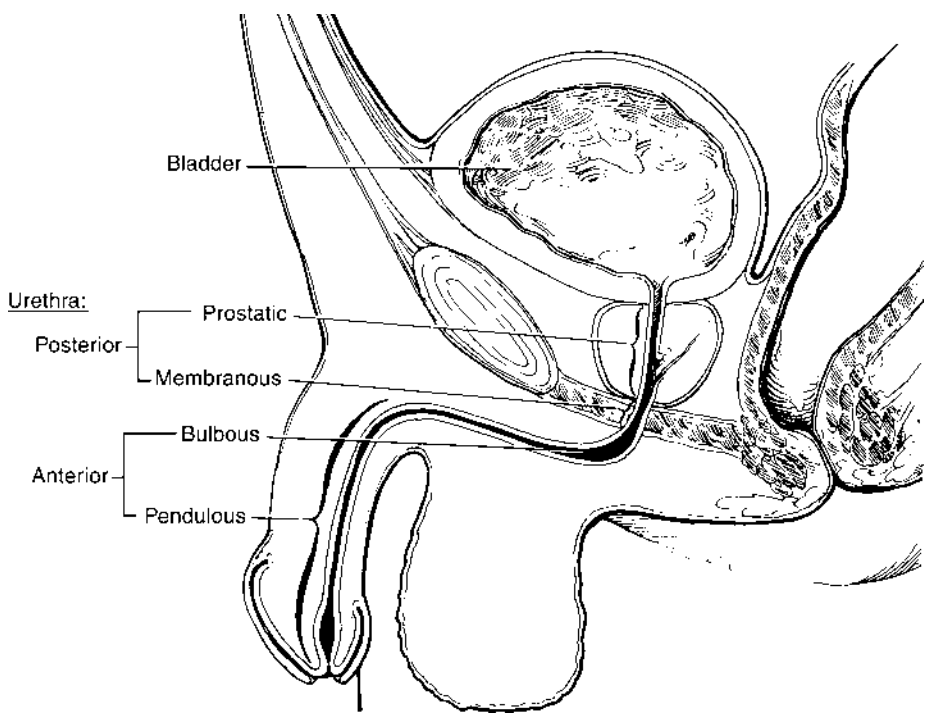

FIGURE 112.7 Sagittal section of male lower urinary tract illustrating levels of urethra.

urethra and images are obtained in an oblique position. If a Foley catheter is already in place, the urethrogram can still be performed via a small feeding tube passed alongside the catheter. An optional technique involves simple retrograde syringe injection through the urethral meatus. Retrograde urethrography should be performed under fluoroscopy with minimal pressure. Gross extravasation of the contrast agent at the site of the injury without visualization of the proximal urethra and bladder is diagnostic for complete rupture of the urethra. Partial rupture is represented by localized extravasation at the site of the injury, with contrast passing into the proximal urethra and bladder. If no extravasation is noted, the urinary catheter can be gently advanced into the bladder.

Anterior urethral injuries can be managed by 7 to 10 days of urethral catheterization and antibiotic therapy. More severe injuries require urinary diversion by suprapubic cystostomy.

Posterior urethral injuries occur with severe trauma to the body and are usually associated with other injuries, particularly pelvic fractures. The mortality rate with fractured pelvis has been reported to be as high as 30%. Many patients may not manifest the usual clinical signs of urethral injury. In such cases, urethral injury may be predicted by the location and displacement of associated anterior pelvic fractures, which may be valuable in making a decision to pursue further evaluation. There is a well-established association between pubic arch fractures and urethral injury, with higher risk as the number of broken rami increases. The high death rate in these patients is attributed primarily to associated injuries.

The urogenital diaphragm located between the pubic rami fixes the membranous urethra and makes it vulnerable to rupture when the pubic arch is fractured. Tears may also result from shearing of the prostatic urethra at the superior border of the urogenital diaphragm. Injuries to the prostatic urethra may extend to the bladder neck. Posterior urethral injuries in men almost uniformly occur distal to the prostate. In adults, the mature prostate, puboprostatic ligament, and bladder stabilize the prostatic urethra, making it less susceptible to trauma.

Proximal urethral injury should be suspected when there is blood at the meatus, hematuria, inability to void, displacement of the prostate on rectal examination, and/or perineal ecchymosis. Catheterization of the urethra is contraindicated. The diagnosis is best made by retrograde urethrography as described for anterior urethral injuries. CT scan is not adequate for diagnosing urethral injuries and is presumptive only if extravasation is detected at the bladder neck or urethra (Fig. 112.8). The IVP may demonstrate an elevation of the bladder out of the pelvis. MRI provides useful information in the determination of the need for surgical repair but is not helpful in the initial evaluation.

Initial management of posterior urethral injuries remains controversial. Therapeutic options vary from immediate exploration with primary repair to the placement of a suprapubic tube with delayed urethroplasty. Urethral rupture may also be treated by realigning the urethra over an indwelling urethral catheter. Suprapubic cystostomy and delayed repair are recommended for trauma patients who are hemodynamically unstable.

Primary realignment has become a more common treatment option. Although the incidence of urethral strictures is higher in patients undergoing primary realignment with delayed repair, impotence and urinary incontinence are more prevalent when urinary diversion is performed. Some studies suggest that long-term outcome may be determined by the location of the injury regardless of treatment method. Membranous urethral tears may have a more favorable outcome. Bladder neck injuries have the lowest rate of continence.

Penetrating wounds of the urethra demand early surgical exploration with conservative debridement and primary repair. Patients with extensive loss of urethral tissue can be managed with delayed repair and staged reconstruction.

Because the female urethra is relatively mobile and short, trauma to the urethra is uncommon. It was reported in less than 6% of cases with associated pelvic fractures in one series of women and girls. When it does occur, it is found more commonly in girls than in women. Female urethral injuries are commonly divided into avulsions and longitudinal tears. These injuries occur most often from blunt abdominal trauma in motor vehicle accidents and in association with pelvic fractures. Injuries may also occur after surgical procedures or instrumentation. The diagnosis is missed on initial assessment in up to

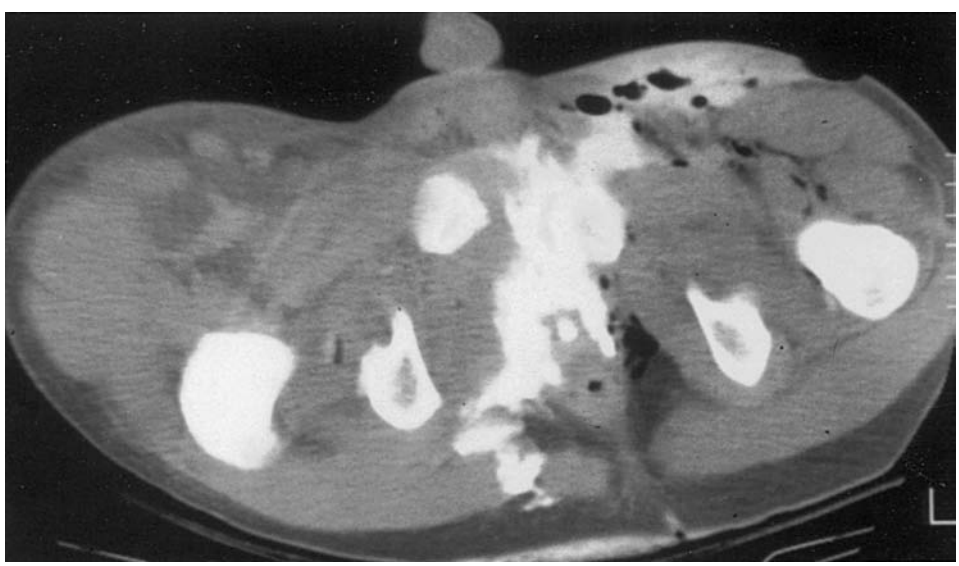

FIGURE 112.8 Posterior urethral disruption and pelvic fracture. Computed tomography of pelvis shows extravasation of contrast material from posterior urethra into the surrounding tissues.

40% of patients, emphasizing the need for careful physical examination and diagnostic evaluation. In one series, every patient with a significant urethral injury had gross hematuria or blood at the introitus and a pelvic ring fracture. Any female patient with this combination of findings should be evaluated for a urethral injury. Most serious injuries involve the vesicourethral junction and extend to the vagina. It is recommended that, whenever possible, a full speculum examination should be performed in patients in whom there is a finding of gross hematuria and pelvic ring fractures, difficulty placing a urethral catheter, and anticipated delay until the pelvic fractures is stabilized. Management of female urethral injuries relates to the location of the injury. The bladder neck and mid urethra should be repaired primarily. The distal urethra may be left open, although sutures may be required for hemostasis. Placement of a suprapubic tube and delayed repair are reserved for unstable patients, as such the placement has been associated with scarring, strictures, urethral obliteration, and fistulas. Most authors recommend some form of primary operative repair of the urethral rupture with closure of associated vaginal tears. Long-term complications of this injury include urethrovaginal fistula, vaginal stenosis, incontinence, sexual dysfunction, and urethral stricture. These patients require long-term urological follow up.

SCROTUM

Scrotal trauma may occur as a result of straddle injuries or bicycle accidents, or during sporting events. The patient may present with scrotal tenderness, edema, and ecchymosis. Potential injuries include skin or dartos ecchymoses and lacerations, intrascrotal hematomas, testicular hematomas, testicular dislocation, and testicular rupture. In addition, a testicle may torse after trauma.

When inspection of the scrotum and its contents is obscured by local swelling and pain, ultrasonography is helpful to define the extent of the injury. An intratesticular hematoma may show as an echogenic or hypoechoic testicular mass. A hematocele produces a complex extratesticular fluid collection. Sonographic findings of rupture include the presence of hematocele, mixed parenchymal echogenicity, intraparenchymal hemorrhage, and disruption of the tunica albuginea or parenchyma. If the ultrasound examination is inconclusive, radionuclide scanning may provide additional information. Both ultrasonography and nuclear scintigraphy help in the diagnosis of testicular torsion (see Chapter 124).

Patients who sustain intrascrotal hematomas, skin ecchymosis, or skin and dartos injury without evidence of injury to the testes can be managed only conservatively. Treatment consists of ice packs and scrotal support. Minor testicular injuries such as contusions or hematomas can also be treated conservatively. Large testicular hematomas may require surgical management. Delay in surgery may lead to ischemic necrosis, secondary infections, and disruption of testicular function.

Testicular dislocation may occur either as a result of an upward blow to the scrotum or, rarely, as a result of compressive displacement following severe blunt abdominal trauma. Dislocation has been described in the context of mild scrotal trauma as well.

Diagnosis of testicular dislocation can be made by thorough physical examination, including palpation of the testes, in patients with multiple trauma, especially involving the abdomen. Examination will reveal a well-developed, but empty, scrotal sac or palpation of an abnormally located testis. Severe scrotal pain, obesity, ecchymosis, swelling, or associated pelvic injuries may make examination and diagnosis difficult. In most cases, the dislocated testis lies under the abdominal wall. Color Doppler sonography has been recommended by some to aid in the assessment but may be operator dependent. Associated injuries, such as pelvic fracture, are common. Operative repair is required if closed reduction fails.

Testicular rupture is a surgical emergency. It is characterized by a tear of the tunica albuginea and extravasation of testicular contents into the scrotal sac. Such injuries require early surgical exploration and repair to avoid the potential complications of atrophy and persistent pain. Ultrasonography has been demonstrated to be sensitive in the diagnosis of testicular rupture by informing the clinician of the integrity of the scrotal contents early. The high specificity of the ultrasonography may also provide information to guide the clinician on the necessity of surgical exploration. Testicular salvage is more likely when exploration is performed within 24 hours of the injury. Ultrasonography has shown poor accuracy, however, for the evaluation of isolated epididymal lesions. Other injuries requiring surgical management include tense hematoceles and torsion after trauma.

Superficial lacerations of the scrotum can be repaired using absorbable sutures. Local infiltration with lidocaine plus epinephrine provides adequate anesthesia. Urologic consultation should be obtained if the laceration extends through the dartos. Physical examination of the scrotal contents determines the need for debridement and primary closure. All penetrating testicular injuries require surgical exploration.

Degloving injuries of the scrotum can be seen after motor vehicle (particularly motorcycle), industrial, or farm machinery accidents. Scrotal injuries are associated with varying degrees of penile skin loss. The underlying penile and scrotal structures are usually spared. Management involves debridement and coverage of the defect by skin flaps or grafting.

PENIS

The most common cause of penile trauma in infants is iatrogenic, especially at the time of circumcision. Complications include transection of the glans, urethrocutaneous fistula, deskinning of the penile shaft, and coagulation necrosis of the entire penis from electrocautery. These injuries usually require extensive surgical repair. Penile gunshot wounds are uncommon because of the position and mobility of the penis but have the potential to significantly affect quality of life. Signs that may indicate corpora cavernosa injury include uncontrolled bleeding, expanding hematoma, blood at the meatus, or a palpable corporeal defect. Urethral injury should be ruled out by retrograde urethrography if these signs are present. These injuries require urologic evaluation to determine the need and timing of surgical management.

Blunt penile trauma from toilet seats falling on the glans or distal shaft has been described in toddlers. Significant injury to the corporal bodies or the urethra is rare and patients can be managed expectantly with warm soaks. Although the child

does not commonly experience urinary retention, he may be more comfortable voiding in a tub of warm water.

Tourniquet injuries may result from bands, rings, or human hair. In the infant, strangulation with a fine hair may be difficult to recognize because of local edema. The initial diagnosis may be balanitis or paraphimosis. Local or general anesthesia may be required to expose and remove the hair. Complications include urethrocutaneous fistula or loss of the penis.

Fracture of the penis is produced by traumatic rupture of the corpus cavernosum. This injury usually occurs when the erect penis is forced against a hard surface. The patient may hear a cracking sound and develop pain, edema, and deformity of the penis shaft. The urethra is rarely involved. Most injuries require surgical treatment with evacuation of the penile hematoma, repair of the torn tunica albuginea, and a pressure dressing, but some fractures of the penis can be managed conservatively with bed rest, ice packs, and a pressure dressing.

Superficial lacerations of the penile shaft can be repaired with absorbable sutures under local anesthesia or penile block. Lacerations extending to the corporal bodies or the urethra require urologic consultation. Diagnostic evaluation includes a retrograde urethrogram to define the extent of the injury. Injuries to the corporal bodies should be repaired primarily to prevent fibrosis and impotence. Injuries to the urethra may require urinary diversion.

Zipper entrapment of the penis or foreskin is a common complaint that can be managed in the ED. Methods of emergent release have been described in relation to the zipper parts and depending on the type of zipper. The median bar of the zipper may be cut with wire cutters and thus disassembling the zipper mechanism (Fig. 112.9). This technique may sometimes prove difficult when the metal bar is sturdy and there is edema of the entrapped penile tissue within the zipper fastener, limiting access to the metal bar. Such may be the case with heavy metal zippers such as those found on jeans and dungarees, and success may depend on the strength of the operator and the availability of bone or wire cutters. Therefore, this technique may work best with plastic or lightweight zippers. Cutting the dentition of the zipper at any position, permitting unzipping of the zipper from the rear may work best for heavy-duty metal zippers. Disengagement of the fastener by inserting a flathead screwdriver between the inner and outer faceplates and applying torque toward the median bar (Fig. 112.10) may prove helpful when it is difficult to grasp the tiny median bar with bulky cutting pliers. Elliptical incision of the entrapped foreskin or emergency circumcision can be of value when less invasive methods have failed. Regardless of technique, procedural sedation may facilitate the procedure. Edema can be treated with warm soaks.

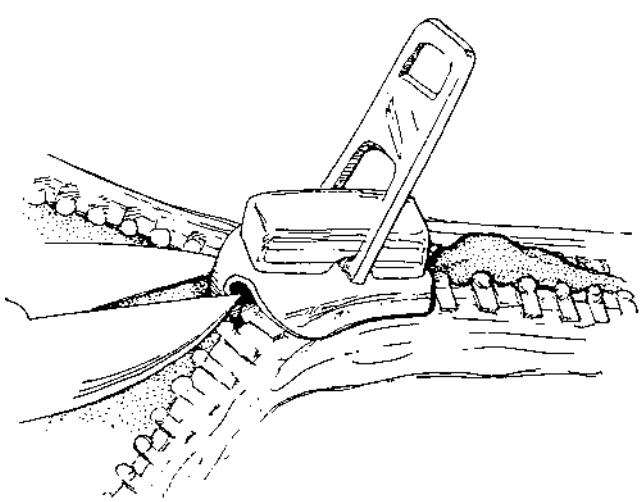

FIGURE 112.9 Penile zipper injury. A wire cutter may be used to cut the median bar of the zipper, releasing the two sides of the zipper and freeing the penis.

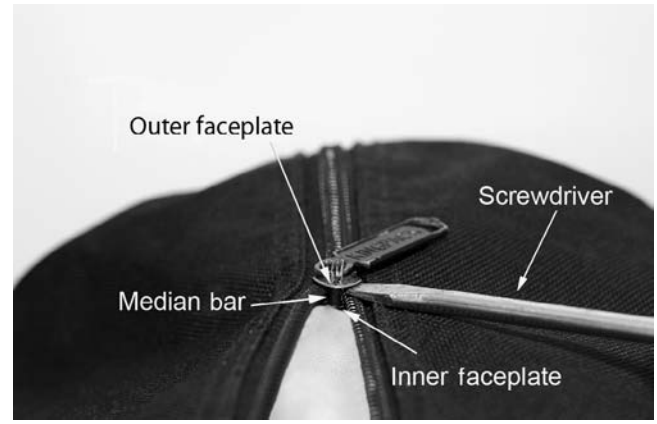

FIGURE 112.10 Screwdriver technique for the release of foreskin entrapped in the zipper. The screwdriver should be placed between the two faceplates and twisted toward the median bar.

PERINEUM

The mechanism most commonly associated with trauma to the female perineum is a straddle-type injury. These injuries may cause vulvar hematomas, which usually respond to treatment with ice packs and bed rest. Patients experiencing mild urinary retention may be more comfortable voiding in a tub of warm water. Massive or expanding hematomas may require surgical exploration and evacuation.

Superficial lacerations of the perineum can be treated conservatively at home with sitz baths. Deep lacerations may extend into the rectum or urethra and therefore require consultation by a surgeon. Rectal penetration requires a diverting colostomy. Suprapubic cystostomy or primary repair should be performed if the urethra is disrupted.

Vaginal lacerations must be suspected in patients with severe trauma to the external genitalia or penetration by foreign object. If a significant vaginal laceration is noted, endoscopy with sedation or general anesthesia is necessary for a full evaluation. The possibility of extension into the urethra, bladder, or rectum must be investigated. The vaginal laceration is debrided and repaired with fine absorbable sutures.

SEXUAL ABUSE

When common accidental situations fail to explain certain genitourinary injuries, the possibility of sexual abuse should be considered. Injuries resulting from sexual abuse include

abrasions and hematomas in the penile shaft, vaginal lacerations, and perineal hematomas (see also Chapters 76 and 132).

CHAPTER 113 ■ HAND TRAUMA

MICHAEL WITT, MD, MPH, AND DONALD S. BAE, MD

EPIDEMIOLOGY

Hand trauma is extremely common in the pediatric emergency department, with a broad spectrum of clinical presentations. Injuries include lacerations, soft-tissue injuries, nail bed injuries, fractures, and sprains. Understanding the epidemiology of these injuries helps the clinician identify patterns of injury as well as allows experts to modify risk factors to decrease the incidence of these injuries.

Hand injury rates follow a bimodal distribution of age, with the peaks seen in toddlers and in teenagers. Lacerations and soft-tissue injuries tend to predominate in the younger children (particularly involving the fingertips), whereas fractures are seen more frequently in older children primarily due to sports involvement. These injuries tend to occur around the home, particularly outdoors.

Fractures are most commonly seen in the little finger, especially the proximal phalanx, and fifth metacarpal. In these typically older children, sports such as football, basketball, and baseball cause the majority of injuries, though many nonathletic causes are also known, including fighting.

In cases of nonaccidental trauma, the hand is often the target. Bruises, burns, and other soft-tissue injuries are common, whereas fractures are less so. Nevertheless, during the skeletal survey of a child with suspected abuse, equal attention should be paid to the radiography of the hand.

EXAMINATION

The physical examination of the hand after trauma is perhaps the most important component of the emergency department visit. Proper treatment can only be instituted, including the need for specialist intervention, when all injuries are identified.

Every examination of the hand begins with visual inspection, particularly when compared with the opposite side. Obvious abnormalities such as edema, erythema, ecchymosis, as well as skin defects should be noted. Nail and nail bed injuries are often dramatic but may distract from other superficial or deeper trauma, such as tendon involvement. Examination of the general alignment of the hand and digits may demonstrate subtle abnormalities. Having the patient make a fist and observing any finger displacement can identify spiral phalangeal fractures. In the young, anxious, or uncooperative child, similar assessment of digital alignment may be seen with passive wrist extension, taking advantage of the tenodesis effect (Fig. 113.1).

Focused palpation of the area in question, as well as thorough examination of the other areas of the hand and wrist, is necessary. Identification of tenderness, temperature, induration, crepitance, edema, and fluctuance is critical. The ability to identify abnormalities as they relate to the different regions of the hand will help focus clinical suspicion and analysis of radiographs. Snuffbox tenderness specifically should raise suspicion of scaphoid injury.

Passive range of motion should be tested across all joints in the hand and wrist, with attention paid to discomfort and both increased and decreased range of motion. Active range of motion can be tested by isolating each joint and observing both full flexion and extension. Testing against resistance may also be helpful, particularly in cases of partial tendon injuries. When examining the fingers, recall that the flexor digitorum profundus (FDP) muscle inserts on the distal phalanx, allowing for active distal interphalangeal (DIP) flexion. Therefore, the FDP muscle should be tested by asking the patient to flex the DIP joint while holding the proximal interphalangeal (PIP) joint extended. Because FDP tendons to the digits share a common muscle belly, often individual DIP flexion is not possible. In contrast, the flexor digitorum superficialis muscle inserts into the middle phalanx of each digit; it is best tested by asking the patient to flex the PIP joint while holding the adjacent digits in full extension so as to avoid being misled by the FDP function. The thumb should be tested similarly by observing flexion of the interphalangeal joint due to the flexor pollucis longus muscle. If necessary, moving the hand from flexion to extension at the wrist can cause passive flexion of the muscles and may also identify some abnormalities (Fig. 113.2). Similarly, the extensor functions of the hand should be tested by isolating each joint.

The thumb is controlled by seven muscles. The abductor pollucis longus and abductor pollicis brevis muscles together act to abduct the thumb metacarpal and can be tested against resistance. The extensor pollucis brevis muscle acts to extend the proximal phalanx of the thumb. The extensor pollucis longus muscle acts to extend the distal phalanx and move the thumb dorsally and can be tested by placing the hand palm down on a flat surface and raising the thumb up. The thumb is flexed at both the carpometacarpal and metacarpophalangeal (MCP) joints by the flexor pollicis brevis muscle. Opposition of the thumb is the most important movement and is performed by the opponens pollicis muscle. Finally, the adductor pollicis muscle allows adduction of the thumb and gives strength during grasp movements.

The vascular examination may include the Allen test. After occluding both radial and ulnar arteries with direct pressure applied to the wrist over the palpable radial and ulnar pulses, the patient is asked to clench the fist, resulting in blanching of the skin. Upon releasing pressure over one artery, observation of color return confirms patency and function of the released artery. Digital capillary refill is tested

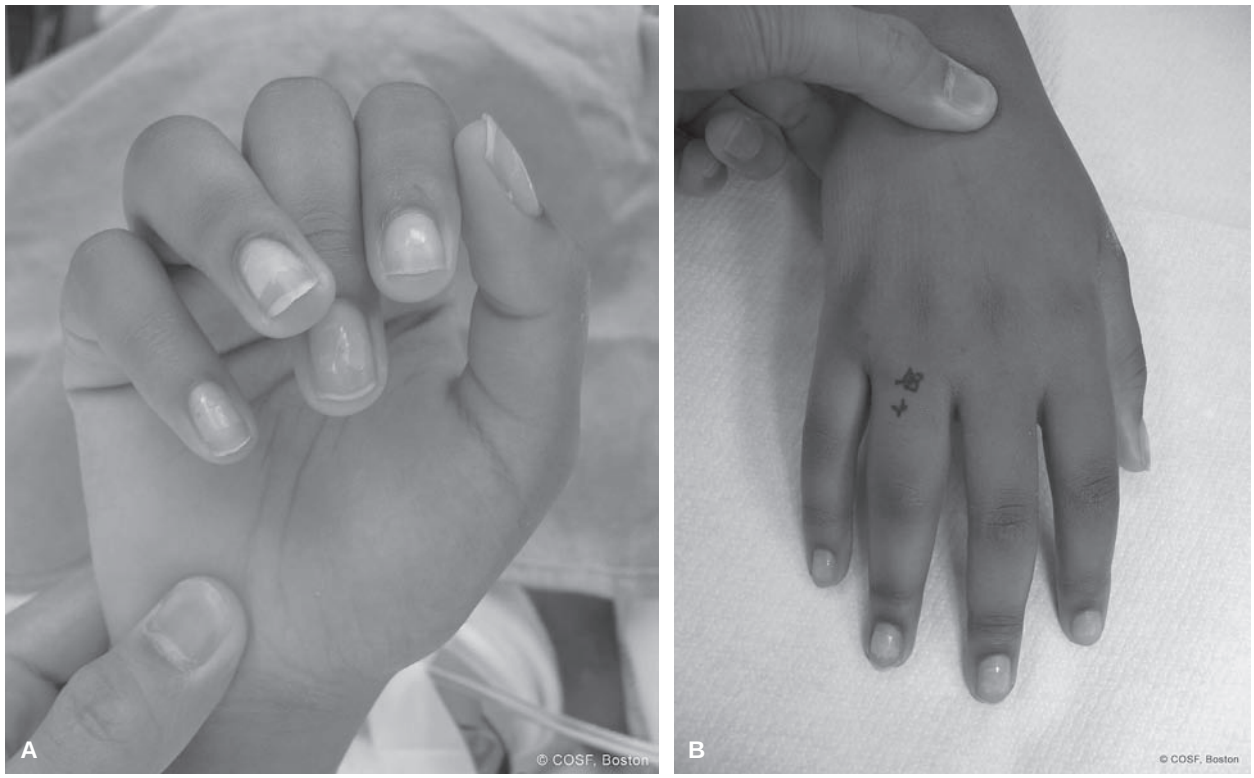

FIGURE 113.1 Abnormal tenodesis. Clinical photographs depicting abnormal rotation of the ring finger in the setting of a malrotated phalanx fracture. Note the clinical overlap of the ring finger over the long finger and increased gap between the ring finger and the small finger, with passive wrist extension (**A**) that is not clinically as apparent with the wrist in neutral position and the digits extended (**B**). (Courtesy of Children's Orthopaedic Surgery Foundation.)

by compressing the tip of the nail until blanched and then timing the return to color after releasing the pressure, generally in less than 1 to 2 seconds.

Neurologic evaluation for sensation includes light touch and pinprick, with two-point discrimination also useful in children older than 5 to 7 years who can cooperate. Motor function has effectively been tested during active range of motion, but additional attention should be paid to the ulnar innervated intrinsic muscles by asking the patient to actively abduct and adduct the fingers.

FIGURE 113.2 Clinical photograph of a patient with an isolated flexor digitorum profundus rupture of the long finger. Note the abnormal digital cascade and resting flexion posture of the long finger in relationship to the adjacent unaffected digits. (Courtesy of Children's Orthopaedic Surgery Foundation.)

CARPALS

The incidence of carpal fractures is relatively low in children, although increasing awareness has increased its recognition. In infancy, the carpals are completely cartilaginous and are nearly immune to injury. They progressively ossify beginning with the capitate bone. The scaphoid is by far the most common fractured carpal bone, with most fractures occurring in the late childhood and adolescence. Falls are the most frequent cause.

Physical examination requires attention to edema, range of motion, and point tenderness to localize carpal injuries. Snuffbox tenderness is a useful tool for scaphoid fractures. X-ray study is obviously limited in infancy and early childhood because of the lack of ossification. As the patient ages and the carpals are progressively ossifying, comparison with the contralateral side may be of benefit. An important radiologic concept is the distance between the scaphoid and lunate bones. In a true scapholunate dissociation, this space is widened and often called the Terry Thompson sign, but in children in whom the carpals are not fully ossified, this space is naturally widened.

Scaphoid fractures have different patterns depending on the age of the patient. Younger patients are more likely to fracture the distal third of the bone, whereas adolescents and adults tend to fracture at the waist. A unique fracture to young patients is the avulsion to the distal radial aspect of the scaphoid but often is not diagnosed on first presentation and is seen on radiographs 1 to 2 weeks later. Most scaphoid fractures are nondisplaced and managed with cast immobilization, though displaced fractures may require surgical reduction and internal fixation to prevent nonunion.

In addition to fractures, suspicion for ligamentous injuries should be high, particularly in late childhood and adolescence. As mentioned above, scapholunate dissociation can be identified by widened space between the two bones. Lunate dislocation is best identified with the lateral wrist radiograph, with the bone displaced from its typical midaxial location over the radius.

METACARPALS

Injuries to the metacarpals include fractures to different zones of the bones and dislocations of the MCP joint. Dislocation of the metacarpals from the carpals is possible but rare in children, although these dislocations may coexist with another injury. The metacarpals may be fractured at the base, shaft, or neck. These injuries often occur from crushing trauma in younger patients as well as from impact along the axis of the bones, such as in fighting, in older children and adolescents. Compartment syndrome in the hand can occur, particularly with multiple fractures, and thus careful physical examination and appropriate suspicion are required.

Metacarpal base fractures occur at the least common location, but most of these involve the small finger. There will be significant pain and dorsal edema, which can make accurate diagnosis challenging. Nondisplaced or minimally displaced fractures are generally managed with support via a splint or cast. Displaced fractures often require closed reduction and subsequent casting. Carpometacarpal dislocations alone or in conjunction with a fracture, however, are unstable and often require operative stabilization. Bennett fractures, or intraarticular fracture of the base of the thumb metacarpal, mandate special attention, as the thumb carpometacarpal joint is critical for full use of this digit. Similarly, Rolando fractures, comminuted fractures of the base of the thumb metacarpal, also require careful attention.

Metacarpal shaft fractures are also uncommon in the pediatric population and tend to involved the long, ring, and small fingers. They are most often spiral in nature, indicating a rotational component to the injuring force. Careful attention to the alignment of the fingers when making a fist may demonstrate subtle rotation. These injuries also result in significant edema, but significantly angulated or displaced fractures can be suspected on examination. Most nondisplaced and displaced shaft fractures can be managed with closed reduction and immobilization, though fractures with significant shortening of the length of the bone or those involved with multiple fractures may require operative repair.

The most common metacarpal fracture occurs at the neck of the bone, with the majority involving small finger (the boxer's fracture) (Fig. 113.3). Inspection for rotational displacement of the fracture is again important, as is the evidence of skin trauma that might indicate contamination from an opponent's mouth during a fight. A considerable amount of angulation of the fracture can be tolerated without limiting ultimate hand function, with increasing tolerance in the ring and small fingers. A commonly used rule is 10–20 degrees to 30–40 degrees, indicating the progression on tolerable angulation from the index to the small finger ray. Closed reduction is often all that is needed in fractures that exceed the tolerable amount of angulation, except in unstable patients.

FIGURE 113.3 Anteroposterior radiograph of the hand depicting a displaced fifth metacarpal neck fracture. (Courtesy of Children's Orthopaedic Surgery Foundation.)

MCP joint dislocations are the most common dislocation among the pediatric hand injuries and most frequently involve the thumb (Fig. 113.4). Similar to dislocations of the interphalangeal joints, these dislocations occur most often with the proximal phalanx dorsal to the metacarpal and the metacarpal head palpable in the palm. In the immature patient, these dislocations on radiographs may be difficult to clarify because of the joint consisting mainly of cartilage and thus may simply seem hyperextended. Reduction attempts should maintain or exaggerate the hyperextension while putting pressure on the volar aspect of the phalangeal head toward the palm. In general, straight longitudinal traction is not recommended in an effort to avoid soft-tissue interposition and converting a reducible injury into an irreducible dislocation. If the joint is not easily relocated, specialist involvement and likely open reduction will be required because the tendons and volar plate involved may prevent reduction with inline traction.

PHALANGES

Phalanx injuries are very common in children, as the fingers of a child are a first exploration into his or her world. Mechanisms of injury included crush, hyperextension, and "jamming" most frequently. As mentioned previously, careful examination with particular attention to rotational deformity is required. Often identifying which bone is involved in an interphalangeal joint can be challenging due to pain and edema.

Proximal phalanx injuries are some of the most common pediatric hand injuries. The base of the proximal phalanx often endures a Salter-Harris II fracture, with the little finger being most frequent. Many are managed with splinting/casting and closed reduction if necessary. Shaft fractures are also generally managed with closed reduction, though displacement or rotational deformity may require surgical stabilization. Phalangeal neck fractures can be difficult to diagnose and often oblique views on radiographs may be of assistance (Fig. 113.5). These fractures in particular require close outpatient care, as displacement and rotation may have long-term consequences on the flexion of the adjacent interphalangeal joint. Finally, condylar fractures may involve one or both condyles and long-term management may depend on the severity of the injury (Fig. 113.6). Close follow-up is also required in these injuries, as the bone may not remodel well and may require early reduction and other intervention.

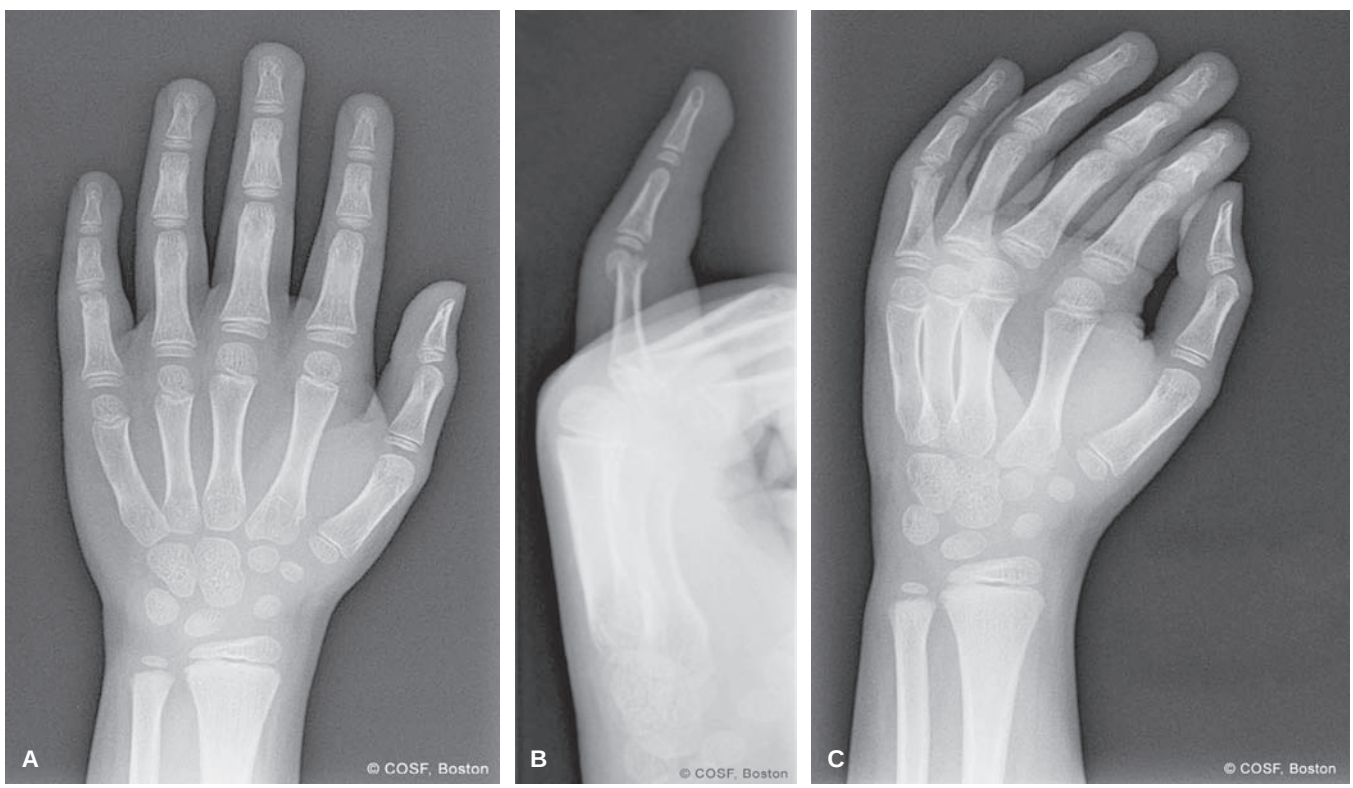

FIGURE 131.5 Radiographs of a displaced small finger proximal phalangeal neck fracture. Note the relatively subtle and benign radiographic appearance on the anteroposterior view (**A**). Fracture displacement is best seen on a dedicated lateral view (**B**) as well as on oblique projections of the small finger (**C**). (Courtesy of Children's Orthopaedic Surgery Foundation.)

FIGURE 113.6 Anteroposterior radiograph depicting an intraarticular fracture of the head of the small finger proximal phalanx involving the radial condyle. (Courtesy of Children's Orthopaedic Surgery Foundation.)

Proximal phalanx injuries to the thumb ray are unique. In adolescents and adults, a skier's thumb or gamekeeper's thumb occurs with rupture of the ulnar collateral ligament (UCL) during stress onto the thumb away from the rest of the hand. In children, a fracture of the base of the proximal phalanx is more likely than an UCL injury, with Salter-Harris I and II fractures predominating in younger children and Salter-Harris III fractures in older children. Thumb spica splinting is appropriate for the constellation of these injuries in the emergency department. Displaced fractures require operative management.

Middle phalanx fractures are generally managed similarly to proximal phalanx injuries. Most are managed by closed management, although surgical reduction and stabilization may be required in displaced fractures. Fractures of the head of the phalanx require close management by hand surgeon because of a high rate of complications. Avulsion fractures of the middle phalanx at the insertion of the volar plate or extensor central slip are not uncommon. Avulsions on the volar side generally are from hyperextension, and generally the fragment does not reattach and frequently results in chronic stiffness and has potential for permanent loss of range of motion. Splinting is performed initially, but early range of motion is often started a week later. Small avulsions on the extensor side are generally treated similarly, though larger ones are treated with longer splinting and displaced fractures may require open reduction.

Distal phalanx injuries are very common and often associated with nail and nail bed injuries, as discussed in the following text. When associated with nail bed injuries, after the nail is removed (if necessary), the open fracture should be copiously irrigated and the nail bed repaired, followed by splinting. These should be followed by hand surgeons in case a further intervention, such as pin fixation, is required. Seymour fractures comprise a special type of injury, with a Salter-Harris I or II fracture of the distal phalanx associated with exposure of the proximal aspect of the nail and damaged germinal matrix (Fig. 113.7). The distal interphalangeal joint is often held at some flexion. Discussion with a hand surgeon is useful, as the fracture healing may be prevented by tissue present in the physis.

Lacerations in the fingers and hands that involve tendons can be serious and require attentive care. In addition to routine wound care, extensor tendon lacerations proximal to the MCP joints may be amenable to repair by the emergency physician. Extensor tendon lacerations involving the MCP joints or digits, as well as all flexor tendon lacerations, require care by a hand surgeon. In consultation with the surgeon, closure of the skin and splinting may comprise appropriate care with close follow-up.

Injuries to the extensor tendon across the distal interphalangeal joint prevent extension of that joint, commonly called mallet finger. The DIP joint rests in a somewhat flexed position. This injury occurs when the finger is "jammed" longitudinally and occurs mostly in adolescents and adults. Bony mallet fingers, on the other hand, are not a DIP issue and instead represent physeal fractures at the base of the distal phalanx. They clinically appear similar and are managed identically initially with splinting but may require surgical management. A similar injury can happen across the proximal interphalangeal joint causing a Boutonniere deformity, but the care in the emergency department is the same.

Dislocations of the MCP and interphalangeal joints are generally uncommon in younger patients, although adolescents tend to have incidence similar to adults, particularly those involved in contact sports. These dislocations most often occur with the distal bone placed dorsal to the proximal. Prompt relocation after management of pain, particularly if there is any concern of neurovascular status, is performed with inline distraction and hyperextension in the interphalangeal joints. MCP dislocation is reduced by flexing the wrist to relax the tendon and then applying dorsal pressure both in the direction of the palm and toward the fingertip. Splinting all dislocations to maintain stability is required until reevaluation.

FINGERTIP INJURIES

Fingertip injuries are very common, as the tips of the fingers are often the entry point to exploration of our surroundings. Crush injuries are the most frequent cause and can result in injuries ranging from minor lacerations and subungual hematoma to complex open fractures and tissue loss. Similarly, sharp lacerations are often simple, but particularly if the mechanism also has the force to damage the nail, complete amputations can occur. Although children often recover quite well, careful attention and care to these wounds can help reduce the risk of permanent deformity to the fingertip and nail.

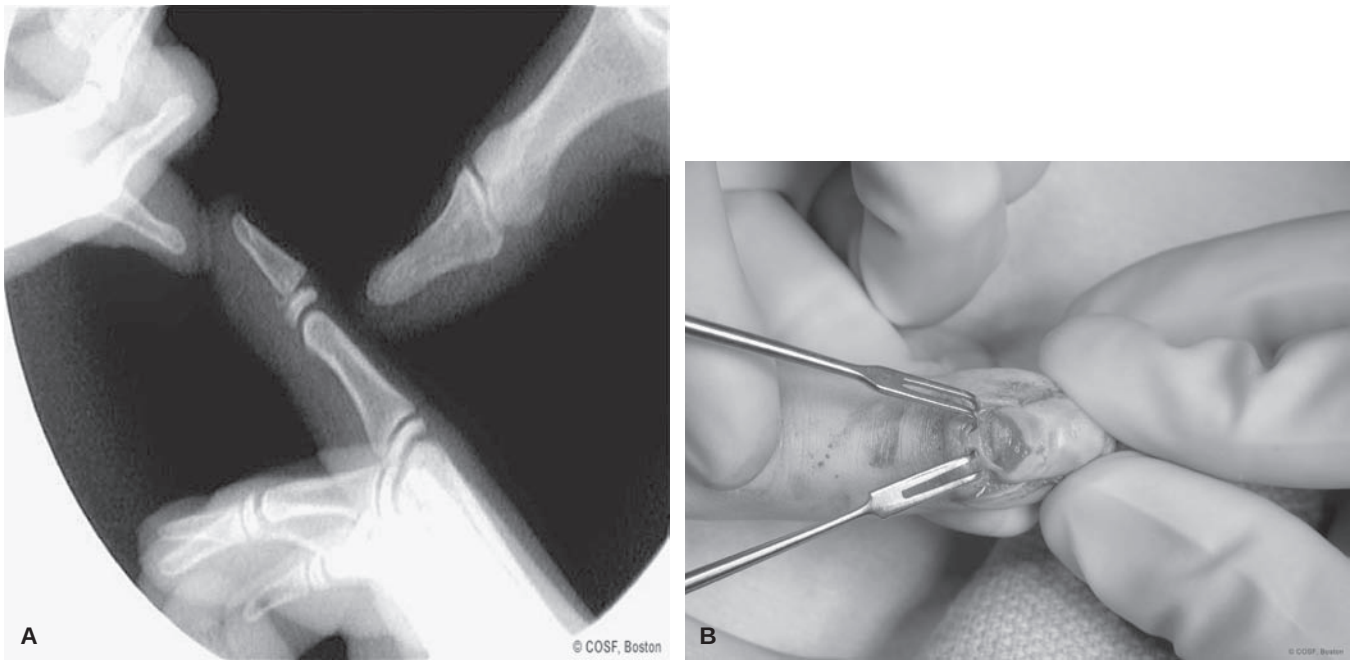

FIGURE 113.7 Seymour's fracture. **A:** Lateral radiograph depicting a displaced distal phalangeal physeal fracture in the setting of a nail bed injury. **B:** Intraoperative photograph after nail plate removal depicting the tear in the germinal matrix of the nail bed and underlying bony injury. (Courtesy of Children's Orthopaedic Surgery Foundation.)

Although the physical examination features discussed previously hold true, these injuries are often associated with significant pain and bleeding that may hamper repair efforts. Digital block of the affected digit may be required for adequate pain control. An easily removed tourniquet device is recommended if oozing from wounds precludes adequate examination and repair.

Copious irrigation is required with all wounds, with extra attention paid to open fractures. Some wound debridement may be required, though the emergency physician should hesitate before debriding the nail bed for fear of permanent effects on subsequent nail growth. When repair is complete, a nonadherent dressing should be used and splinting considered. Petrolatum-laced mesh dressings are particularly effective at optimizing healing and minimizing discomfort and damage on removal. Prophylactic antibiotics are controversial in fingertip injuries, even in open fractures. Meticulous wound care is likely most beneficial, and antibiotics should be considered in dirty wounds or those with significant devitalized tissue.

Nail bed injuries require nail removal, if not already performed traumatically, with careful wound preparation and closure of the often friable tissue with 5-0 or 6-0 absorbable suture. The nail fold must be kept open for the new nail to form and thus several placeholders are used. The salvaged nail can be placed, as can a sterile aluminum (from suture packaging), reinforced silicone sheeting, or a nonadhesive dressing. The nail should be tacked down with nonabsorbable sutures proximally and distally, though the proximal sutures should be removed early in the course at follow-up with a hand surgeon to prevent wound tracks during nail development.

Fingertip lacerations are managed similarly to lacerations in other locations with a few caveats. Wound care is performed as described above. Some literature recommends nonabsorbable suture material, though at our institution, absorbable suture is often used because the swelling and discomfort often preclude simple suture removal.

Amputations of the fingertip are not uncommon and can result in permanent deformity. When the issue of transport is concerned, the current recommendation is to transport the amputated part in saline-moistened gauze in a bag that is then kept cool in an ice–water mixture. Reimplantation has been recommended in most cases involving children if the distal piece is available and the tissues are not damaged beyond repair. Reimplantation may not be an option if the avulsed tip is too small, macerated, or grossly contaminated. If possible, the skin can be closed over the stump with sutures while taking care to protect the nail bed. Small avulsions are best cared for with local wound care and petroleum-based dressing until granulation and healing. If closure is not an option due to bone exposure, hand surgery consultation is indicated either in the emergency department or with wound care and petroleum-based dressing until seen as an outpatient.

Subungual hematomas, or the collection of blood between the nail and the nail bed, are common and generally occur with crushing injuries. Small hematomas are generally cared for without intervention, whereas hematomas involving more than 50% of the nail surface are more likely to be associated with significant nail bed injury, particularly in the setting of an associated distal phalanx fracture. Nevertheless, the literature has demonstrated that if the nail is intact and well adhered, then nail removal and nail bed reconstruction do not impart any improved outcome over simple trephination. Nail trephination can be performed with a heated paper clip, an electrocautery pen, or a large-bore needle drill rotating in a circular motion.

CHAPTER 114 ■ MUSCULOSKELETAL TRAUMA

DAVID BACHMAN, MD, AND STEPHEN SANTORA, MD

Orthopedic trauma currently accounts for 10% to 15% of emergency department (ED) visits in urban pediatric hospitals. The number and spectrum of musculoskeletal injuries sustained by children and adolescents appear to be on the rise since the mid-1990s, in part because of the rapid growth of organized sports. More recent reports in the medical literature have highlighted the range of injuries, many if not the majority of them orthopedic, stemming from active participation by youth in such activities as skateboarding, rollerblading, skiing, and snowboarding. The injuries associated with the use of scooters and trampolines have drawn particular attention. As the result of a number of anatomic and physiologic differences, the array of orthopedic injuries seen in pediatrics differs greatly from that seen in adult practice. An understanding of these differences allows the emergency physician to make accurate diagnosis and avoid complications. This chapter provides a set of principles and guidelines to be used in the initial evaluation, diagnosis, and treatment of common orthopedic injuries in children.

GENERAL PRINCIPLES OF PEDIATRIC ORTHOPEDICS

Structural and Physiologic Differences between the Musculoskeletal Systems of Children and Adults

The bony architecture in children includes a thick and active periosteum, a growth plate (physis), an epiphysis (secondary ossification center), and perichondrial rings (Fig. 114.1). The bones of a child are much more porous and thus more pliable than those of an adult. In contrast, because of this increased porosity, stiffness and overall bony strength are less, and the incidence of fractures is greater in children. During growth, the skeleton undergoes changes that cause different anatomic regions to be more susceptible to fracture at certain stages of development. In general, the ligaments attaching one bone to another have greater strength than the epiphyseal plates and perichondrial rings. As a result, although the number of fractures is greater, the incidence of sprains, ligamentous injuries, and dislocations is significantly lower in children.

The periosteum plays an important role in the reparative process of fracture healing. In children, the periosteum is thick and physiologically active, and is easily stripped from the bony cortex during injury. When injuries occur, the periosteum is often torn on the convex side of the fracture while remaining intact on the concave side. The intact periosteum on the concave aspect often aids the orthopedist in the reduction of the fracture fragments. Callus formation is exuberant in the young and declines with age as the physiologic activity of the periosteum decreases. Nonunions almost never occur in children.

Remodeling, although rare in adults, is expected to a degree in children. Significant remodeling can be anticipated in younger children and when the fracture occurs in the metaphysis of growing bones. Deformities occurring in the plane of motion of the adjacent joint remodel to the greatest degree. Fractures that occur in the diaphysis of long bones in adolescents, away from the plane of motion of the joint, cannot be expected to correct spontaneously with growth. The potential for remodeling with bowing fractures is particularly limited, with reduction generally recommended for cosmetically unacceptable deformities of greater than 10 degrees. In general, it is important to obtain as near an anatomic reduction of fracture fragments as possible in all age groups and not to rely on remodeling to align angulated fractures.

Fractures Unique to Children

The anatomic and physiologic differences between adults and children are reflected in a number of fractures and injuries unique to the pediatric age group, including physeal fractures, torus fractures, greenstick fractures, bowing deformities, and avulsion fractures.

Physeal Fractures

Fractures often occur at the physis (growth plate) in children. Most such fractures occur through the zone of provisional calcification, a relatively weak area of the germinal growth plate. Overall, up to 18% to 30% of pediatric fractures involve the physis. Physeal injuries are more common in adolescents than in younger children, with a peak incidence at 11 to 12 years of age. Most growth plate injuries occur in the upper limb, particularly in the radius and ulna.

Several classification systems have been described for physeal fractures. The most widely used is that of Salter and Harris, who described five types of growth plate fractures, each having specific prognostic and treatment implications (Fig. 114.2).

Salter-Harris Type I Fracture. It involves separation of the metaphysis from the epiphysis through the zone of provisional calcification. Diagnosis is often difficult if displacement is minimal. Type I fractures are generally benign, with little chance of growth disturbance if near anatomic reduction is achieved. Exceptions include type I injuries of the proximal radius, the proximal and distal femur, and the proximal tibia, all of which are subject to premature physeal closure and posttraumatic

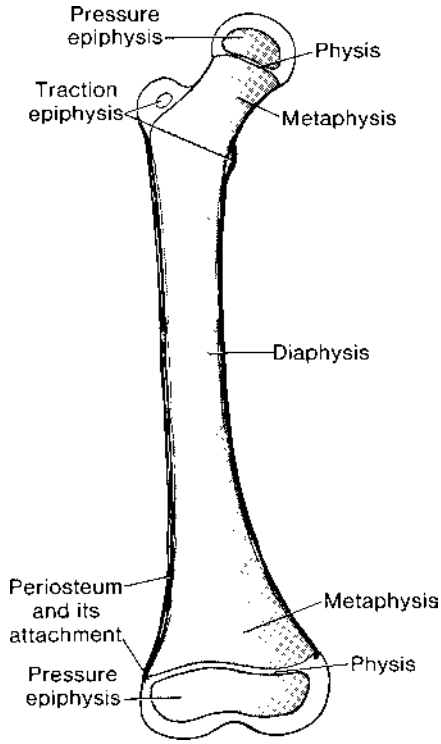

FIGURE 114.1 Diagrammatic representation of the femur in late childhood.

growth arrest. In general, when radiographic studies are negative but physical findings are suggestive of a Salter-Harris type I injury (e.g., point tenderness over a growth plate), immobilization and a follow-up examination are essential.

Salter-Harris Type II Fracture. It is the most common type of pediatric physeal fracture. It is similar to a type I fracture except that a portion of metaphyseal bone is displaced with the epiphyseal fragment.

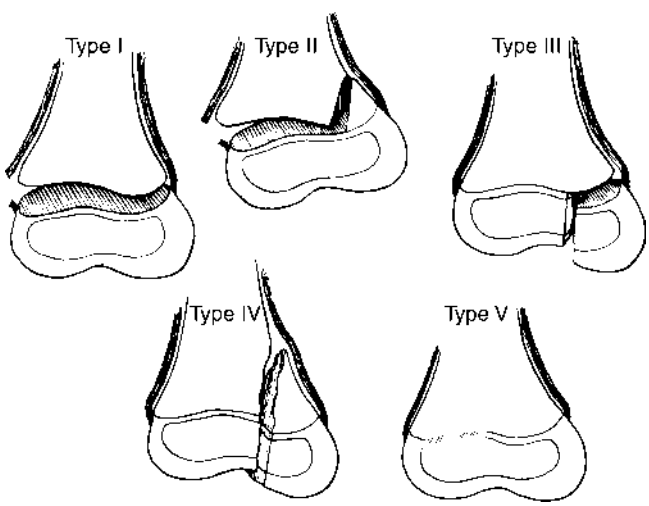

FIGURE 114.2 The Salter-Harris classification for physeal fractures. The prognosis for growth disturbance worsens from type I through type V.

The fracture line crosses the germinal growth plate as it courses toward the metaphysis. Like the type I injuries, these fractures generally carry a good prognosis.

Salter-Harris Type III and IV Fractures. These are intraarticular injuries that also involve the growth plate. Anatomic position must be reestablished to restore normal joint mechanics and prevent growth arrest. Because of the increased incidence of growth disturbance, altered joint mechanics, and functional disability following Salter-Harris type III and IV fractures, an orthopedic consultation is usually obtained for all but the most minor type III and IV injuries while the patient is in the ED.

Salter-Harris Type V Fracture. It results from axial compression of the germinal growth plate. It is often difficult to diagnose; the radiograph may be normal or may demonstrate any of the above Salter-Harris growth plate fractures. The diagnosis is often made in hindsight after a growth arrest becomes evident.

Torus Fractures

Torus (buckle) fractures are common fractures in young patients. They occur in the metaphyseal region of bone from a compressive load. The cortex of the bone buckles in a small area, resulting in a stable fracture pattern (Fig. 114.3). As the child matures, the stiffness of the metaphyseal region increases, and the incidence of this fracture pattern decreases.

Greenstick Fractures

Greenstick injuries are the most common fracture pattern in children, accounting for up to 50% of fractures before

FIGURE 114.3 Torus fracture of the proximal right tibia in a 1-year-old child *(arrow)*.

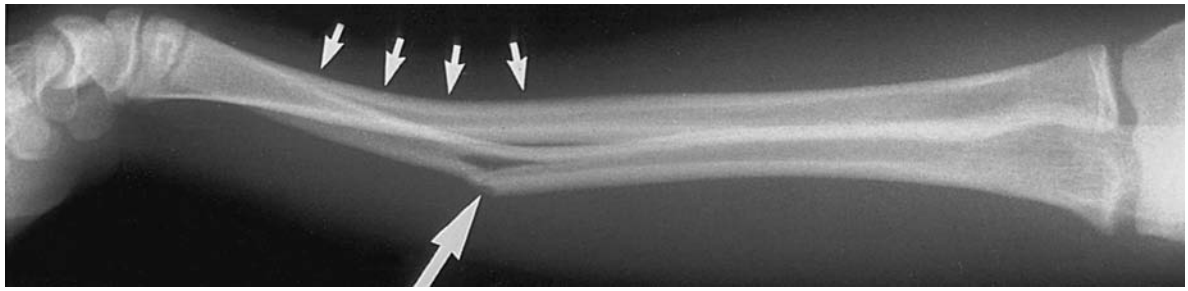

FIGURE 114.4 Greenstick fracture of the ulna *(large arrow)* and a bowing fracture *(small arrows)* of the radius. The extent of bowing can often be fully appreciated only with comparison views of the opposite extremity.

12 years of age. They are incomplete fractures that occur at the diaphyseal–metaphyseal junction and in which the cortex remains intact on one side. Angulation and rotation are common. To obtain an anatomic reduction, the fracture must often first be completed (Fig. 114.4).

Bowing Fractures

Bowing fractures occur uniquely in children. More recent evidence suggests that the force causing the deformation is longitudinal. The force stops short of creating a fracture but does cause persistent plastic deformation (bowing) of the bony structure (Fig. 114.4). Little remodeling can be expected from the injury, and both cosmetic and functional deficits are common. Anatomic reduction produces the most satisfactory result. All bowing deformities should be referred to an orthopedic surgeon.

Avulsion Fractures

Avulsion fractures are common in children. Strong muscular attachments adhere to secondary centers of ossification known as apophyses in the developing skeleton. During intense muscular contraction, fractures occur through the apophyseal plate. Most avulsion fractures occur in the pelvis and heal uneventfully. Other common sites include the tibial tubercle and the phalanges. Only infrequently do avulsion fractures require open or closed reduction. Conservative care is the mainstay of treatment.

Physical and Radiographic Examination

Approach to the Physical Examination

A systematic approach to the child with a suspected fracture is necessary to avoid overlooked injuries and undue complications. The basic principles of a history and physical examination should be followed. In all cases, it is necessary to consider the possibility of associated head and truncal injuries. Often the history is obtained from a parent or bystander who witnessed the accident. At times, no history is available. Attention to the mechanism of injury and the force causing the injury gives clues to the severity of the fracture and soft-tissue injury. The activity of the patient following the injury also helps define the likelihood and nature of orthopedic injuries. Whether the child is able to provide any details of the accident obviously depends on the child's age, as well as the extent of associated head and internal injuries.

The physical examination should begin with careful observation of the patient's behavior. Is he or she guarding or not moving an extremity? Is there pain? How is the patient's color? Is the child interacting normally with his or her parents and the environment? After observing the child and determining the area or areas of injury, the physician can look for swelling and deformity. It is best to always begin with the extremities that do not appear to be injured. An effort should be made to gain the patient's trust by gently moving all joints and extremities that appear uninjured while trying to distract the child from the examination itself. This also allows detection of unsuspected areas of injury. Attention should then be turned to the injured extremity. Swelling, ecchymosis, deformity, and the presence of lacerations and puncture wounds should be noted. When open wounds are present, the exact location, degree of contamination, presence of fat globules, and rate of active bleeding should be documented. It is not always obvious whether there is an open fracture or simply a laceration that does not communicate with the fracture; operative exploration may ultimately be required.

While continuing to distract the child, the physician should then carefully palpate the soft tissues and bones above and below the area of injury. The point of maximal bony tenderness should next be gently defined. Evidence of increased compartment pressures should be sought both by palpation and by careful assessment of the pulses and capillary blood flow distal to the injury. However, the compartment syndrome can occur in the presence of palpable pulses (see the "Compartment Syndrome" section). If no significant deformity is discovered, joint motion both proximal and distal to the fracture should be assessed. As detailed, a sensory and motor examination as the age and overall condition of the child will permit should be performed.

Radiographic Examination

All unstable and significantly deformed fractures *must* be immobilized before the initiation of radiographic studies. By so doing, further deformity and soft-tissue injury is avoided, and patient discomfort during positioning for the radiographs is decreased. A plaster or fiberglass splint can be applied quickly and does not prevent adequate radiographic assessment of the fracture (Fig. 114.5). Unless a specific contraindication exists, pain medication, often parenteral, should also be

FIGURE 114.5 Lateral radiograph through a fiberglass splint showing angulated distal tibial and fibular fractures in a 13-year-old boy. Splinting before radiologic studies provides fracture stability and comfort but does not prevent adequate visualization of bony injury.

FIGURE 114.6 Radiographs of the feet of a 3-year-old child who sustained a crush injury of the left foot. The soft-tissue swelling of the left foot *(L)* is readily apparent. That the irregularities of the proximal third, fourth, and fifth left metatarsals *(arrows)* are indisputably fractures is immediately apparent when the injured foot is compared with the uninjured right foot *(R)*. A proximal second metatarsal fracture was also suspected and was better visualized on other views.

administered. Multiple studies continue to demonstrate that many children with skeletal injuries receive no or inadequate pain medication, both in the ED and on discharge. Increased emphasis of pain as a "vital sign," combined with protocolized approaches to pain management, would seem to offer a potential solution to this ongoing wave of "oligoanalgesia." No patient should be allowed to take any food or drink by mouth until all examinations and referrals are completed.

After a complete history and physical examination, the physician should be able to order specific radiologic views to identify the injury. In some instances (e.g., a toddler who is refusing to bear weight but who has no localizing signs), the history and a knowledge of the most common injuries for a given age have to guide the choice of radiographic studies. A complete examination should include the joints above and below the fracture and at least two views taken at 90 degrees to one another (generally anteroposterior and lateral views). Oblique and other additional views are necessary at times for certain body parts (e.g., hand, ankle, foot, phalanges) and when routine views are normal but suspicions of a fracture are high. Given the degree of normal variability in bony anatomy, particularly in growing bones, comparison views are indicated on occasion (Fig. 114.6).

Although plain film radiography will no doubt remain the primary imaging technique used in fracture evaluation, other modalities, notably bone scintigraphy, computed tomography (CT), magnetic resonance imaging (MRI), and most recently, ultrasound (US) have come to play an important adjunctive role. Scintigraphy is more sensitive than plain films in certain settings, for example, when a stress fracture is suspected (Fig. 114.7). CT plays an important role in the definition of complex fractures, particularly intraarticular ones, as well as in the evaluation of spine injuries. Although seldom indicated in the acute setting, MRI has proven to be a most valuable modality in the definition of physeal and growth plate injuries, as well as in the diagnosis of avulsion and stress fractures. Its value derives from its ability to visualize cartilaginous and soft-tissue structures, as well as osseous ones, an ability of obvious value when it comes to the maturing pediatric skeleton. In the last few years, reports have begun to appear that highlight the use of US both as a diagnostic tool and as a guide during closed fracture reduction. Given the expanding role of US in the emergency setting, it seems likely that US will assume a yet to be well-defined place in acute fracture management in the years ahead.

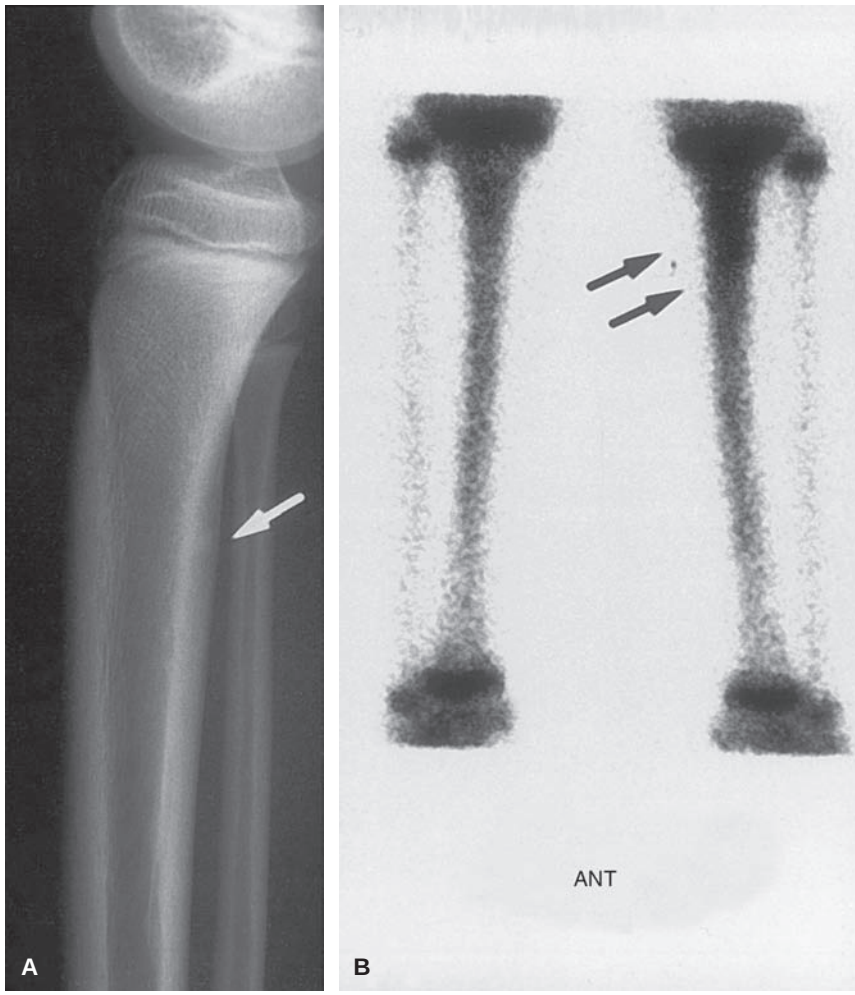

FIGURE 114.7 **A:** Routine radiographs of this 10-year-old girl revealed only a minor cortical irregularity of the posterior aspect of the proximal left tibia *(arrow)*. **B:** Bone scintigraphy was performed. The increased isotope uptake seen along the proximal left tibia *(arrows)* confirmed the clinical suspicion of a stress fracture.

Fracture Description

When obtaining an orthopedic consultation, the emergency physician must relay accurate and descriptive information to allow the orthopedist to make appropriate treatment recommendations. A clinical description should include the patient's age and gender, the mechanism of injury, the anatomic location, the status of the neurovascular structures, and the extent of associated soft-tissue injury. A careful and precise radiographic description should include the anatomic location of the fracture; the type of fracture (e.g., transverse, spiral, oblique); the amount of displacement; the degree of angulation, shortening, or malrotation; the degree of comminution; and the extent of involvement of the joint and growth plate. Accurate descriptions using appropriate terminology are helpful in assisting the orthopedist in his or her recommendations (Fig. 114.8).

Orthopedic Referral and General Principles of Acute Fracture Care

Indications for Orthopedic Referral

The indications for an orthopedic consultation vary somewhat with the ability and experience of the emergency physician and

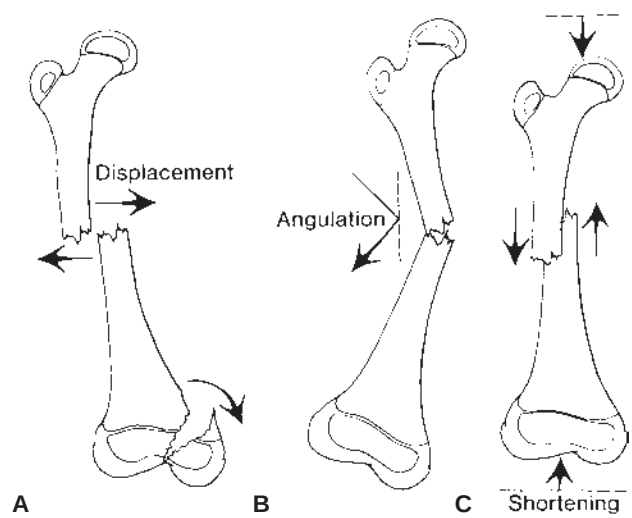

FIGURE 114.8 Diagrammatic representation of fracture deformities: displacement (**A**), angulation (**B**), and overriding with shortening (**C**).

TABLE 114.1

INDICATIONS FOR ORTHOPEDIC REFERRAL

Injuries that require immediate orthopedic referral
Open fractures
Unacceptably displaced fractures
Fractures with associated neurovascular compromise
Significant growth plate or joint injuries
Complete or displaced fractures of the long bones of the lower extremities
Pelvic fractures (other than minor avulsions)
Spinal fractures
Dislocations of major joints other than the shoulder
Injuries that can be managed initially by emergency physician
Nondisplaced Salter-Harris type I fractures (exceptions are femur, proximal tibia)
Clavicular fractures
Nondisplaced upper-extremity fractures
Incomplete, nondisplaced fractures of the long bones of the lower extremities
Nondisplaced fractures of the hand and foot
Routine dislocations of the shoulder and minor joints (no fracture)

the availability and preferences of the orthopedist. Certainly, if any question exists regarding the diagnosis, treatment, complications, or follow-up of an orthopedic injury, a consultation should be obtained. An orthopedic surgeon should be called to evaluate all fractures that are open, unacceptably displaced, or causing neurovascular compromise. Other indications for immediate orthopedic referral include significant growth plate or joint involvement, many fractures of the long bones of the lower extremity, pelvic fractures (other than avulsions), spinal injuries, and dislocations of major joints other than the shoulder. In contrast, the emergency physician should be expected to provide the initial, if not the definitive, care for many pediatric fractures. Most nondisplaced Salter-Harris type I fractures; clavicular injuries; nondisplaced upper extremity, foot, and phalangeal fractures; incomplete, nondisplaced fractures of the long bones of the lower extremity; and routine dislocations of minor joints and the shoulder can all be managed initially by physicians other than orthopedists (Table 114.1).

Acute Fracture Care

Immobilization is the mainstay of the initial treatment of any fracture. Plaster and fiberglass materials are both satisfactory, although the greater strength of fiberglass has advantages in splinting of lower extremities. Immobilization of the joints above and below the fracture provides both the greatest degree of comfort and the best guarantee against additional injury or deformity. (An exception is a minor torus fracture of the distal forearm, for which a short arm splint or cast is often adequate.) Several layers of padding material should always be applied before the actual splint or cast because the padding provides greater comfort, and the risk of neurovascular compromise, if swelling occurs, is diminished. (See Section VII "Procedures," for detailed descriptions of splinting techniques.) The degree of actual or anticipated swelling, the propensity of the fracture to lead to a compartment syndrome, and the training of the emergency physician dictate whether a splint or a cast is applied at the time of initial evaluation.

Most fractures that are initially casted should be reevaluated within 24 hours for signs of neurovascular compromise, either in the ED or by the orthopedist. Otherwise, when orthopedic follow-up is necessary, an appointment within the week following injury is generally reasonable (assuming the immobilization is adequate). Certain injuries (e.g., any fracture that could possibly displace) should be seen more promptly. Other fractures need no orthopedic referral. Discharge instructions should include a review of the need for elevation and ice application and a discussion of the signs of neurovascular compromise. The need for pain medication in children should not be ignored. Ibuprofen or oxycodone alone are adequate in most cases. All radiographs should be reviewed by a radiologist, and parents should be routinely informed that further evaluation and radiographs will be necessary despite initially negative studies if symptoms persist. The importance of immobilization of all but the most minor injuries and of careful documentation of follow-up instructions cannot be overemphasized.

Postfracture Care

Two factors influence the function regained following fractures in children: the establishment of a bony union, and the restoration of normal alignment and growth. Unlike postfracture care for the adult, physical therapy is usually not necessary to regain normal range of motion. Stiffness rarely becomes a long-standing problem for children. The child acts as his or her own physical therapist through normal activities. On occasion, it may become necessary for the parents or physical therapist to "supervise" active range-of-motion exercises until normal range of motion is obtained. If the orthopedic injury is associated with tissue loss, head injury, nerve damage, or vascular compromise, physical and occupational therapy may play a major role in reestablishing normal or near-normal function in the child.

SPECIAL CONSIDERATIONS

Open Fractures

Several considerations dictate that the emergency physician approach open fractures with special concern. Such fractures generally result from high-energy accidents, namely falls, motor vehicle collisions, and automobile–pedestrian accidents. Multiple injuries are common in such settings. The physician should not allow an open fracture to distract from the detection and orderly management of other less apparent but potentially life-threatening injuries. A complete examination is imperative.

The incidence of complications is higher with open fractures, and a complete evaluation for neurovascular compromise and for signs of compartment syndrome should be performed. In addition, the incidence of infection is increased with open fractures. Management should include cleansing the wound, applying a sterile Betadine® dressing, administering prophylactic intravenous antibiotics (e.g., broad-spectrum cephalosporins), and immobilizing the fracture. Tetanus prophylaxis should be administered according to the usual guidelines. Clearly, open

fractures must be regarded as true orthopedic emergencies. Surgical debridement, irrigation, and definitive care of the wound and fracture are uniformly necessary. The patient should be given nothing by mouth, and an urgent orthopedic consultation should be obtained. The laceration over a fracture should never be closed, even if the fracture is in good alignment.

Compartment Syndrome

The compartment syndrome is a devastating fracture complication that, if left untreated, may progress to muscle necrosis and nerve palsies. It occurs when a buildup of intracompartmental pressure results in ischemia of the muscle and neurovascular tissue. The pressure initially blocks venous outflow, resulting in increased pressure in the nonelastic compartment. Eventually, the small arterioles and capillaries are occluded, and irreversible muscle and nerve damage results.

The compartment syndrome can occur in the forearm, hand, thigh, leg, or foot; the most common site is the anterior compartment of the leg. The fracture does not need to be severe; indeed, the compartments are often torn with significantly displaced fractures and thus are less subject to pressure buildup. Pain, particularly pain with passive extension, is the earliest sign of the compartment syndrome. With any fracture or blunt tissue injury presenting with pain out of proportion to the injury, the compartment syndrome must be suspected. An increasing analgesic requirement in the setting of an acute fracture should by itself prompt consideration of this diagnosis. On palpation, the muscular compartment may feel hard, swollen, and tense. Other physical signs, including pulselessness, paresthesia, pallor, and paralysis, may or may not be present. Direct measurement of compartmental pressures confirms the diagnosis. When clinical and objective signs of compartment syndrome are present, a fasciotomy should be performed as soon as possible.

In the patient with multiple injuries, it is imperative to palpate every muscular compartment to rule out impending compartment syndrome. An orthopedic consultation should be obtained in every case of suspected compartment syndrome.

Multiple Trauma

Although fractures are common in the child with multiple injuries, only rarely are they life-threatening. There is no question that orthopedic injuries are often the most obvious or that more children require operative orthopedic surgical procedures than general surgical procedures after major trauma. In contrast, it is definitely a mistake to disregard the usual tenets of trauma management and forsake an orderly and thorough evaluation of a child's respiratory, cardiovascular, and neurologic status in a rush to provide fracture care. The B of the ABCs is not for bone.

Only in a few instances is the blood loss associated with a fracture significant enough to cause signs of shock. Exceptions include extensive pelvic fractures and multiple long bone fractures (even an isolated femur fracture rarely causes hemodynamic compromise). Clearly, then, signs of significant volume loss in a child believed only to have sustained fractures should prompt an immediate search for other injuries.

In most instances, initial fracture management in the ED should consist simply of immobilization. Traction splints are extremely useful for lower-extremity fractures. The role of pneumatic antishock garments continues to be debated; their use should be considered for unstable pelvic injuries. On occasion, application of an external fixator device may help tamponade bleeding from such fractures.

Many fractures, primarily nondisplaced ones, go undetected during initial ED management. Little harm occurs as a result. In contrast, the consequences of missing a thoracic or lumbar spine fracture can obviously be much greater. Physical signs of such fractures are generally lacking, and the status of the child often precludes an assessment of pain and neurologic function. When the mechanism of injury is unknown or suggests the possibility of a spinal injury, radiographs should be ordered and careful immobilization maintained.

Child Abuse

Although the diagnostic significance of skeletal injuries in child abuse has long been recognized, only 5% to 18% of abused children sustain fractures. In contrast, a large percentage of fractures in infants younger than 1 year do not result from accidents. Careful consideration of the details of the injury, particularly from the viewpoint of the child's developmental stage, provides the first clue regarding the likelihood of abuse. Only a limited number of fracture types and patterns can be considered almost uniformly specific for child abuse (Table 114.2). The incidental discovery of rib fractures, generally posterior, on a chest radiograph should prompt consideration of abuse and raise the possibility of injuries involving the bones of the extremities. In most cases of abuse, the radiographic findings will not by themselves confirm suspicions of an intentional injury. Although spiral fractures in nonambulating children and metaphyseal-epiphyseal injuries are essentially diagnostic, transverse fractures are common and diaphyseal fractures predominate in both abused and nonabused children (Figs. 114.9 to 114.11).

As for diagnostic studies, any clinically suspected fracture should be evaluated using the radiographic views customary for the site in question. In addition, a skeletal survey must be performed routinely as part of the evaluation of all cases of

TABLE 114.2

FRACTURES STRONGLY SUGGESTIVE OF CHILD ABUSE

1. Fractures inconsistent with history
2. Fractures inconsistent with developmental stage of child
3. Fractures with associated injuries suggestive of abuse
4. Multiple fractures, particularly in various stages of healing
5. Multiple, complex, or depressed skull fractures
6. Epiphyseal–metaphyseal rib fractures
7. Spiral fractures of the femur or tibia in preambulating children
8. Spiral fractures of the humerus
9. Metaphyseal chip (corner) fractures
10. Avulsion fractures of clavicle and acromion process

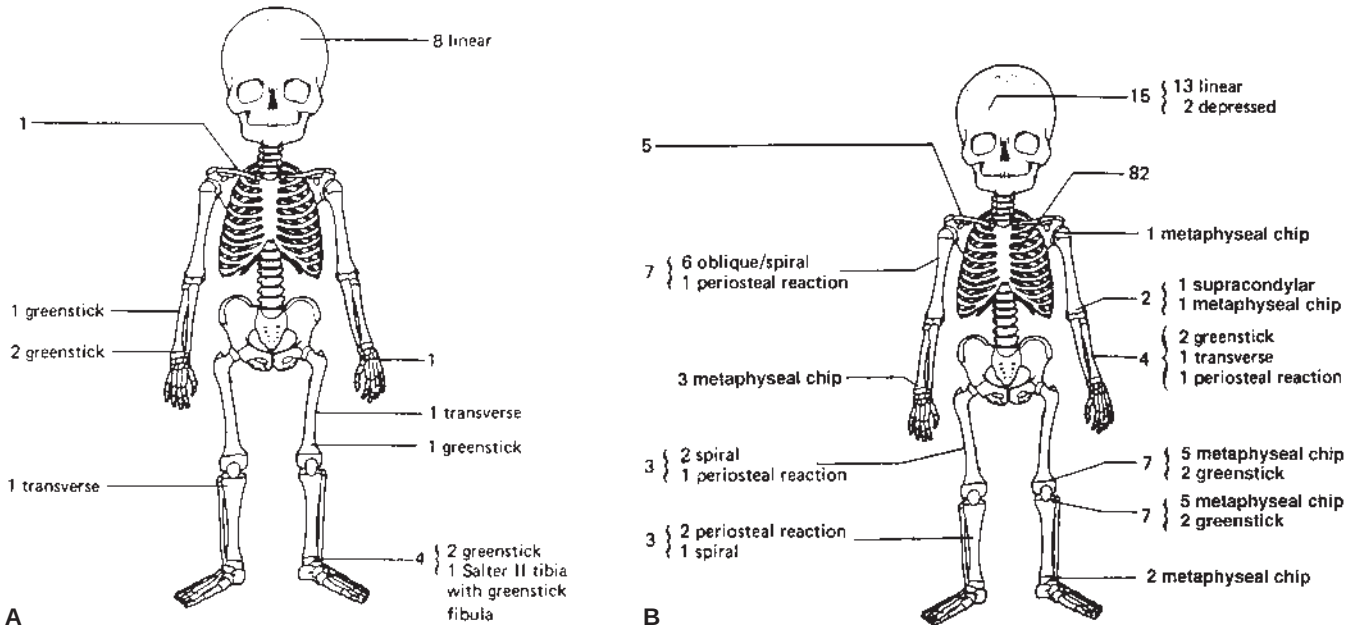

FIGURE 114.9 Comparison of the locations and types of accidental (**A**) and nonaccidental (**B**) fractures in infants younger than 18 months. (From Worlock P, Stower M, Barbor P. Patterns of fractures in accidental and nonaccidental injury in children. *BMJ* 1986;293:100–102, reprinted with permission.)

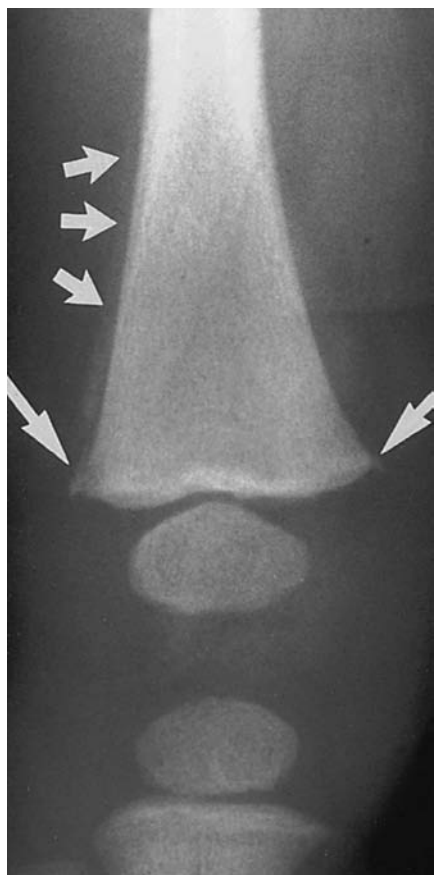

FIGURE 114.10 Radiograph of the right knee of a 3.5-month-old victim of child abuse. The metaphyseal corner fractures *(large arrows)* are considered diagnostic of abuse. Also evident is periosteal new bone formation *(small arrows)*, proof of a significant delay between injury and medical evaluation.

strongly suspected abuse in children younger than 2 years. For children 2 to 5 years of age, individual considerations determine whether a skeletal survey is needed. Skeletal surveys have little role in the evaluation of children older than 5 years. Routine radionuclide bone scans are not indicated, although this technique may be an adjunct to the detection of subtle rib and long bone shaft fractures, as well as of some spine injuries.

Pathologic Fractures

A pathologic fracture is one that occurs through abnormal bone. Many conditions, including tumors, hereditary diseases, metabolic disorders, neuromuscular diseases, and infections, can cause either generalized or localized bone weakness (Table 114.3 and Figs. 114.12 and 114.13). On occasion, the predisposing condition does not become obvious until a fracture occurs. All pathologic fractures require orthopedic consultation. The nature of the underlying disease that is identified or suspected determines the need for consultation of other specialists. In most instances, the initial treatment parallels that of a nonpathologic fracture in the same site.

INJURIES OF THE UPPER EXTREMITIES

Injuries of the Shoulder Region

For the purpose of this discussion, injuries of the shoulder region are grouped as follows: (i) clavicular fractures, (ii) scapular fractures, and (iii) shoulder dislocations.

FIGURE 114.11 Radiograph of the left forearm of a 3-month-old victim of child abuse. Although the ulnar fracture is transverse and thus by itself is not diagnostic of intentional injury, both the child's age and the extent of periosteal bone formation (again establishing a significant delay between diagnosis and medical evaluation) should strongly suggest the possibility of child abuse to the examining physician.

TABLE 114.3

DIFFERENTIAL DIAGNOSIS OF PATHOLOGIC FRACTURES

Tumors and cysts—Benign
Aneurysmal bone cyst
Endochondroma
Eosinophilic granuloma
Fibrous dysplasia
Giant cell tumor
Nonossifying fibroma
Osteochondroma
Unicameral bone cyst

Tumors—Malignant
Chondrosarcoma
Ewing's sarcoma
Neuroblastoma
Osteogenic sarcoma

Hereditary diseases
Gaucher's disease
Neurofibromatosis
Osteogenesis imperfecta
Osteopetrosis
Sickle cell disease

Metabolic disorders
Copper deficiency
Cushing's syndrome
Hyperparathyroidism
Renal osteodystrophy
Rickets
Scurvy

Neuromuscular diseases (osteoporosis from disuse)
Cerebral palsy
Muscular dystrophy
Poliomyelitis
Severe head injury
Spina bifida with paraplegia
Traumatic paraplegia or quadriplegia

Infections
Osteomyelitis

Clavicular Fractures

The clavicle ranks as the most commonly fractured bone in children. More than one-half of all clavicular fractures occur in children younger than 10 years. In children younger than 2 years (excluding the newborn period), such fractures are uncommon and should provoke consideration of intentional trauma. For the sake of discussion, clavicular injuries can be divided into fractures of the shaft, the medial end, and the lateral end.

Fractures of the clavicular shaft result from direct trauma and from indirect forces transmitted by falls onto an outstretched hand. Most are greenstick injuries of the midshaft; the thick periosteum enveloping the clavicle prevents significant displacement or angulation. The diagnosis is usually self-evident. Typically, a child complains of shoulder pain and is cradling the arm on the injured side with the opposite one. Occasionally, the initial injury is unnoticed and comes to attention only when a lump appears as callus forms. Radiographs are confirmatory, although visualization of nondisplaced fractures may require several views. Despite the proximity of the brachial plexus and subclavian vessels, neurovascular injury is rare other than when a violent direct blow results in significant displacement of the fracture fragments. Medially, strong ligaments anchor the clavicle to the sternum. Eighty percent of the growth of the clavicle occurs at the medial physis. The last epiphysis in the body to close, the medial clavicular epiphysis, is rarely visible radiographically before 18 years of age. Apparent dislocations of the sternoclavicular joint are invariably epiphyseal separations in children and young adults. With such fractures, either anterior or posterior displacement can occur. The direction of displacement can often be determined by direct palpation. Radiographic visualization may be difficult; special views and/or CT scans are often required to define the degree and direction of displacement. Posterior displacement is of particular concern because compression of the mediastinal vessels and the trachea can result. If there is evidence of neurovascular or respiratory compromise, prompt orthopedic consultation and closed reduction are indicated.

FIGURE 114.12 Radiograph of the pelvis and femur of an 18-month-old girl with osteogenesis imperfecta. There is a healing fracture of the right femur *(large arrow)*, as well as an acute fracture of the left femur *(small arrow)*.

Laterally, the coracoclavicular and acromioclavicular ligaments anchor the clavicle. Once again, fracture through the physis rather than dislocation is the rule. The usual mechanism of injury is a direct blow to the point of the shoulder. Typically, the proximal fracture fragment is displaced superiorly; the radiographic appearance suggests acromioclavicular separation. However, the periosteum remains whole inferiorly, its ligamentous connections intact. As a result, most distal clavicular fractures heal uneventfully with no loss of joint stability (Fig. 114.14).

Only infrequently is immediate orthopedic consultation necessary for a clavicular injury. Exceptions include significantly displaced (greater than 2 cm) midshaft fractures, for which closed or on occasion open reduction with fixation is desirable; posteriorly and significantly anteriorly displaced medial fractures; grossly unstable distal injuries; and all open fractures. Orthopedic referral is also indicated when there is more than 1.5 cm of clavicle shortening. Immobilization in a sling for 3 weeks followed by 3 weeks of restriction from sporting activities is adequate treatment for most shaft fractures. It

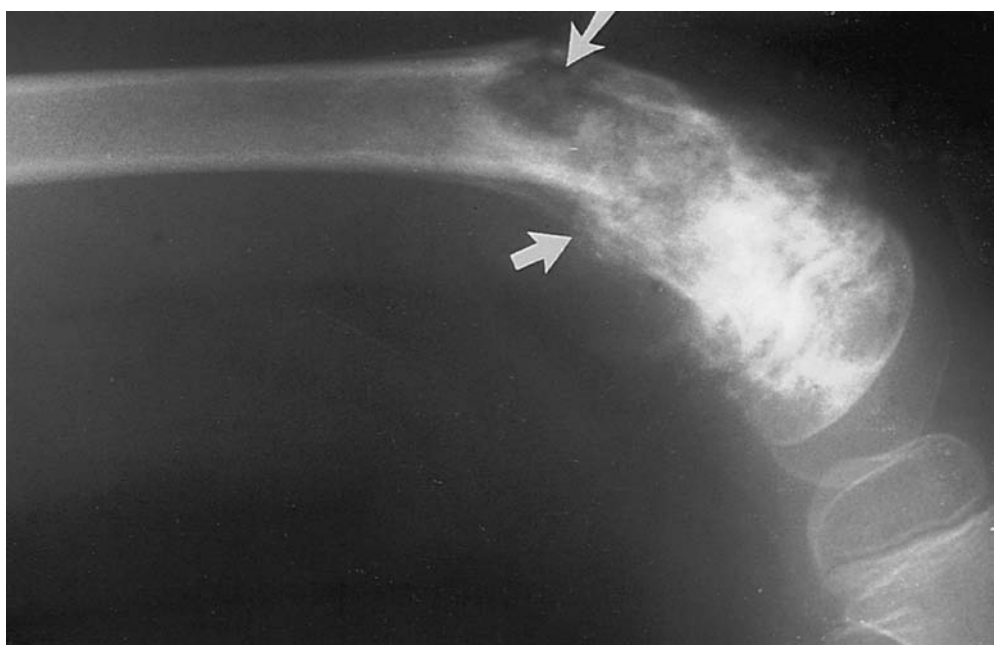

FIGURE 114.13 Radiograph of a 5-year-old girl with an osteosarcoma of the left femur showing an acute pathologic fracture *(arrows)*. Amputation was ultimately necessary.

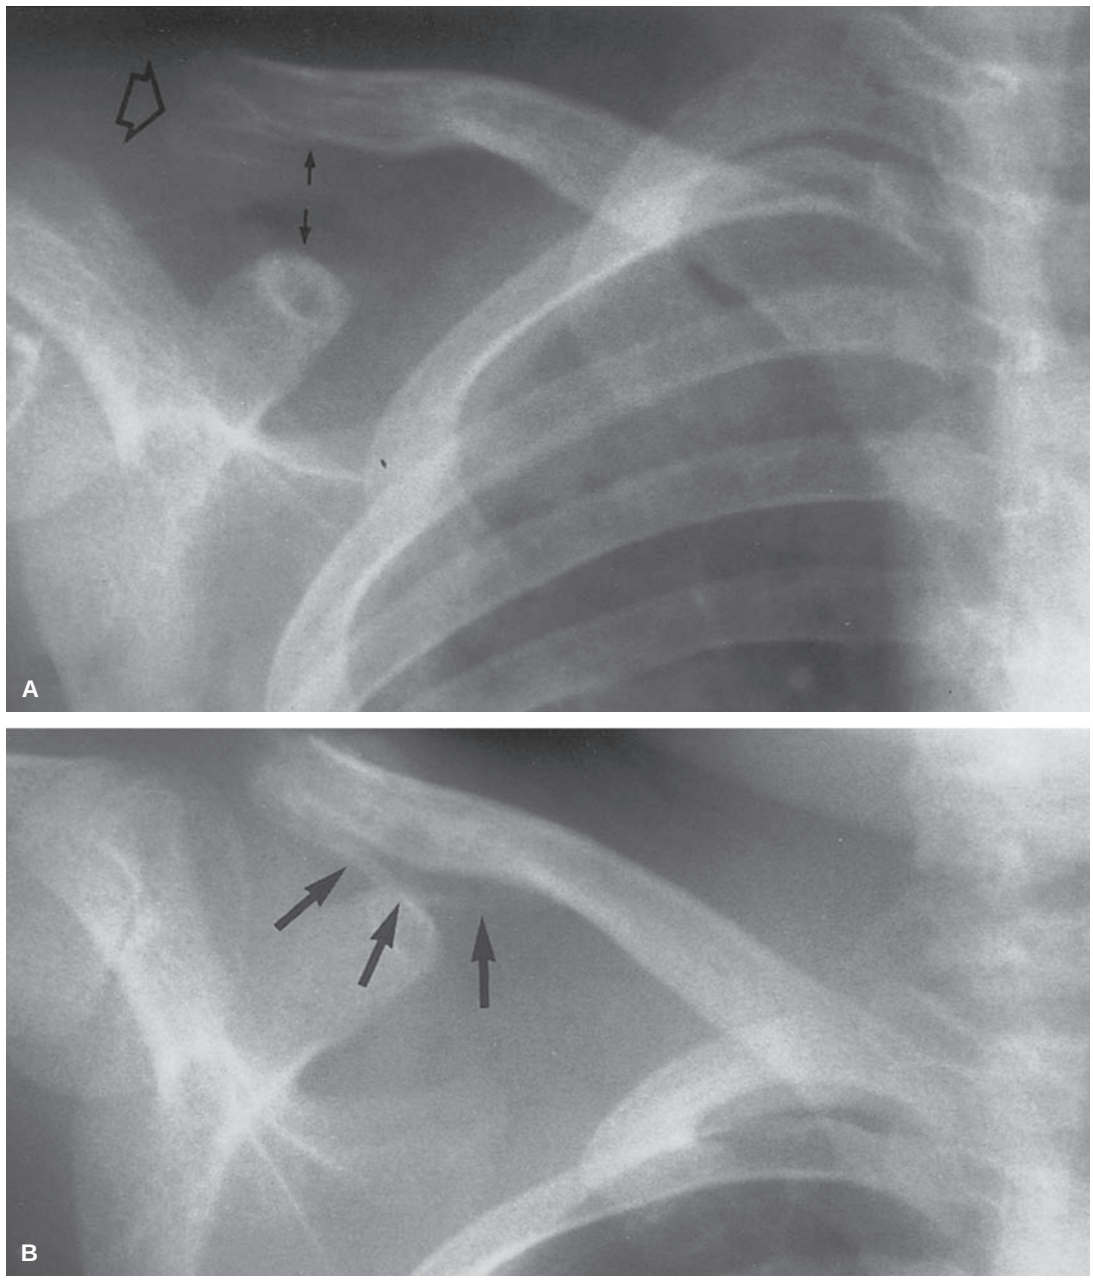

FIGURE 114.14 Radiograph of the right clavicle of a 5-year-old child. **A:** A lateral clavicular fracture *(open arrow)* and widening of the space between the clavicle and the coracoid process *(small arrows)* are evident on the initial film. **B:** The pattern of new bone formation *(arrows)* seen on the follow-up radiograph demonstrates that the periosteum and the ligaments have remained intact inferiorly.

is best to inform parents that a lump will appear as callus forms and may persist for as long as a year. With medial and distal fractures, a sling is recommended along with progressive motion as the pain subsides.

Scapular Fractures

Fractures of the scapula are unusual in adolescents and rare in children. In the isolated instances in which they do occur, the usual mechanism is a severe direct blow, such as one sustained in a fall from a height or a motor vehicle accident (Fig. 114.15). The same force that produces the scapular fracture may result in more concerning and potentially life-threatening injuries to the chest, neck, or head. Fractures of the body and neck of the scapula are usually well visualized on plain radiographs; adequate definition of glenoid injuries may require a CT scan. Although a sling and swathe is usually the only treatment necessary, orthopedic consultation is suggested given the rarity of these injuries.

Shoulder Dislocations

Dislocations of the shoulder are unusual before physeal closure. Other than medially, the proximal humeral physis runs

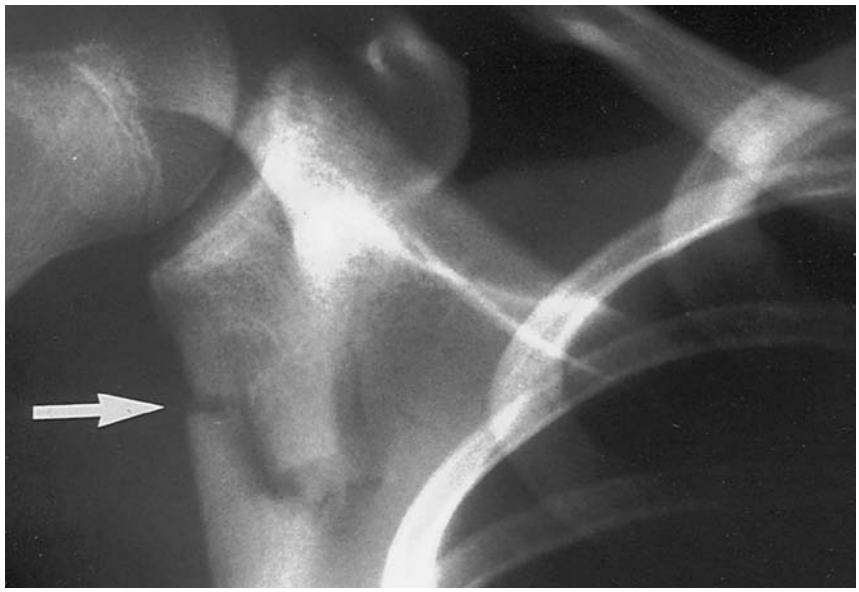

FIGURE 114.15 Radiograph of a 13-year-old boy who sustained an isolated right scapular fracture as the result of a skateboarding accident *(arrow)*.

external to the shoulder capsule, and injuries that in an adult would cause dislocation result in fractures in children and skeletally immature adolescents. Most dislocations that do occur are anterior, as is the case with adults. Findings on physical examination include swelling and deformity with loss of the usual rounded contour of the shoulder. Palpation generally reveals the displacement of the humeral head anterior to the glenoid fossa. Signs of axillary nerve injury may be present. Radiographic studies should include an axillary (Y) view in addition to the customary views of the shoulder to best define the direction of displacement. As for treatment, closed reduction of anterior dislocations can be accomplished by numerous techniques, one of which is reviewed in detail in Section VII "Procedures." Postreduction radiographs should be performed routinely in part to ensure no fracture has occurred in conjunction with the dislocation. Given their rarity, posterior dislocations merit orthopedic consultation before reduction. The rate of chronic shoulder instability and recurrent dislocation is high; even seemingly routine anterior dislocations should be immobilized in a sling and swathe for several weeks and referred to an orthopedist for subsequent care.

Fractures of the Humerus

In this section, humeral fractures are grouped as follows: (i) proximal humeral fractures and (ii) humeral shaft fractures. Supracondylar fractures are discussed in the "Injuries of the Elbow" section.

Proximal Humeral Fractures

About 80% of the growth of the humerus occurs at the proximal humeral physis. As a result, the potential for fracture healing and remodeling with fractures that involve the proximal humeral shaft and physis is remarkable. Nonunion is unheard of and malunion is rare, other than with significantly displaced or angulated injuries in older adolescents. Before adolescence, most proximal humeral fractures are metaphyseal (Fig. 114.16),

FIGURE 114.16 Impacted proximal right humeral fracture with approximately 25 degrees of angulation in a 3-year-old child. Full remodeling can be anticipated.

although Salter-Harris type I injuries are seen occasionally. With the onset of adolescence, rapid growth makes the physeal region relatively weak and thus vulnerable to injury. The incidence of proximal humeral fractures is highest in this age group; most are Salter-Harris type II injuries, and type III, IV, and V injuries are most unusual. Common mechanisms of injury include falls on an extended, adducted arm and direct blows to the shoulder.

Physical findings with proximal humeral fractures range from mild swelling to obvious deformity and shortening of the arm. Routine radiographs are generally sufficient. Care must be taken not to confuse the normal variations in the epiphyseal line with a fracture; comparison views can be useful. Conservative management is the rule. Before adolescence, as much as 50 degrees or even 70 degrees of angulation is satisfactory. In younger children, even totally displaced fractures can remodel completely. Recommendations regarding the degree of deformity acceptable in adolescents vary somewhat; 20 to 50 degrees of angulation and 50% apposition are generally tolerable. The indications for open reduction are limited. A sling and swathe for several weeks is usually the only treatment necessary. Orthopedic follow-up is recommended.

Humeral Shaft Fractures

Fractures of the humeral shaft are much less common than those involving either the proximal or distal segments. The pattern of fracture reflects the mechanism of injury; transverse fractures result from direct blows, whereas spiral fractures are caused by indirect twisting, as with a fall. When a child younger than 3 years sustains a spiral fracture of the humerus, the possibility of child abuse must be considered seriously (Fig. 114.17).

Many humeral fractures are obvious on physical examination, although only minimal swelling and tenderness may be present with buckle and greenstick injuries. Vascular injury is relatively uncommon. In contrast, evidence of radial nerve injury must always be sought, particularly with a fracture that involves the distal two thirds of the humeral shaft. Physical findings suggestive of damage to the radial nerve include loss of motor strength in the extensors of the wrist and fingers, as well as loss of sensation on the dorsum of the hand in the web space between the thumb and index finger. Of note is that, with proper fracture management, almost all cases of radial nerve palsy resolve. As for radiographs, anteroposterior and lateral views usually suffice. A prominent vascular groove in the distal humerus is a normal finding that should not be confused with a fracture.

The thick periosteal sleeve of the humeral shaft limits fracture displacement and promotes rapid healing. A sling and swathe is all that is needed for incomplete fractures. For complete or minimally displaced fractures, application of a sugar-tong splint of the upper arm, followed by a sling to support the forearm is recommended. In older children and adolescents, a hanging long arm cast is an alternative. Given the potential for overgrowth with healing, overriding of the fracture fragments by up to 2 cm is acceptable. Remodeling of as much as 40 degrees of angulation can be expected in younger children. Immediate orthopedic consultation is suggested for any completely displaced fracture, any fracture angulated more than 20 degrees in children and 10 degrees in adolescents, and any fracture with evidence of radial nerve injury. All humeral fractures should be referred for orthopedic follow-up within 5 days.

FIGURE 114.17 Spiral fracture of the right humerus in an 18-month-old girl. Although in this case the injury was accidental, spiral humeral fractures in children younger than 3 years must always evoke concerns about child abuse.

Injuries of the Elbow

Normal Anatomy and Radiographic Diagnosis

Of all the fractures encountered in the pediatric age group, those of the elbow rank as the most problematic in terms of diagnosis, treatment, and complications. In addition, they are quite common, accounting for approximately 15% of all pediatric fractures. For the emergency physician, an understanding of normal anatomy and normal radiographic findings ensures misdiagnosis and untoward outcomes are uncommon. The elbow is a complex hinge joint composed of three separate articulations, namely those between the trochlea of the humerus and the ulnar notch, the capitellum and the radial head, and the proximal radius and ulna (Fig. 114.18). To further complicate matters, there are four growth centers within the distal humerus alone, and ossification of these growth centers begins at different but predictable times (Table 114.4). The ages shown in Table 114.4 are averages; ossification begins at an earlier age in girls than in boys, and much variation exists overall. When there is confusion about what is a normal growth center and what is a fracture fragment, comparison views of the uninjured elbow can be extremely helpful.

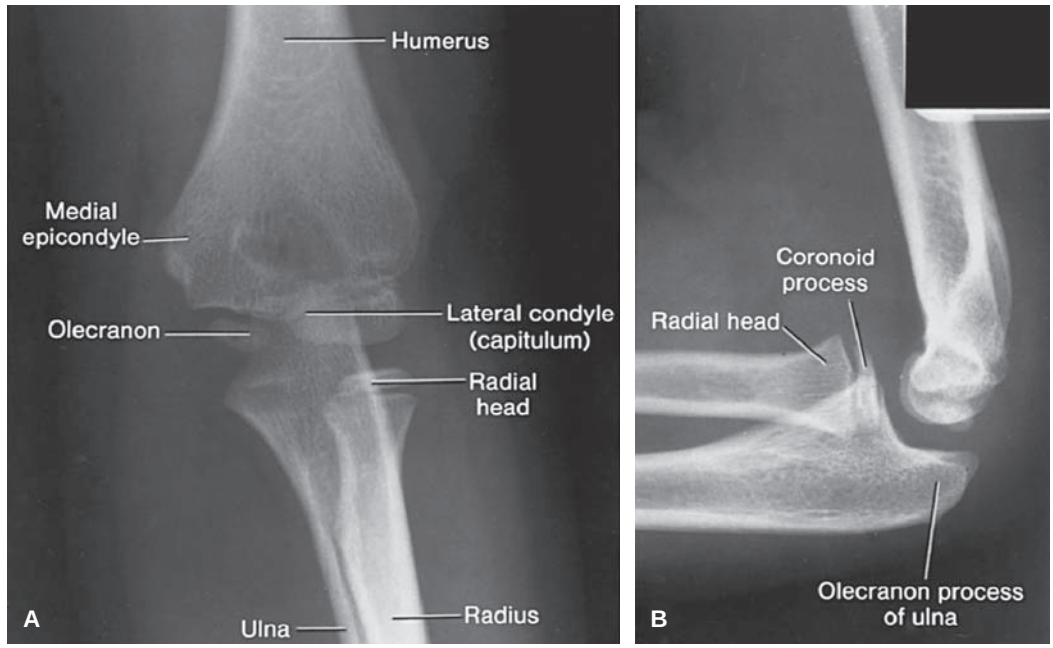

FIGURE 114.18 **A:** Anteroposterior radiograph of a normal elbow of a child. **B:** Normal lateral radiograph.

When a fracture is grossly displaced, the radiographic diagnosis is straightforward. Radiographic detection of subtle torus and nondisplaced fractures of the elbow joint is difficult. Close inspection of the radiographs for the presence of abnormalities of the fat pads and the anterior humeral line will prevent missed diagnosis in most cases. These radiographic signs are reliable only if the elbow has been properly positioned for the radiographs; the importance of a true lateral view in particular cannot be overemphasized. Of the two fat pads overlying the joint capsule along the distal humerus, only the anterior fat pad is normally visible on a lateral radiograph (Fig. 114.19). When fluid is in the joint space, as with a hemarthrosis from a fracture, these fat pads are displaced upward and outward (Fig. 114.20). If soft-tissue edema is extensive, one or both of the fat pads, although elevated, may be obscured. In the setting of known or suspected trauma, the presence of an abnormal fat pad sign should be considered a marker of an occult fracture and an indication for careful immobilization and close follow-up. Of note is that fractures of the distal humerus and of the proximal radius and ulna can produce a hemarthrosis and thus positive fat pad signs. On occasion, oblique views will reveal the fracture line. MRI studies in this setting can reveal bony and soft-tissue injuries not evident on plain radiographs, but should not be routinely ordered given the lack of any well-defined impact on actual patient management.

Close inspection of a true lateral view of the elbow for abnormalities of the anterior humeral line is also essential. In the normal elbow, a line drawn through the anterior cortex of the humerus intersects the capitellum in its middle third

TABLE 114.4

GROWTH CENTERS OF ELBOW: AVERAGE AGE FOR ONSET OF OSSIFICATION

Capitellum	11 mo
Medial epicondyle	4–6 yr
Trochlea	9–10 yr
Lateral epicondyle	10–12 yr
Radial head	5–6 yr
Olecranon	6–8 yr

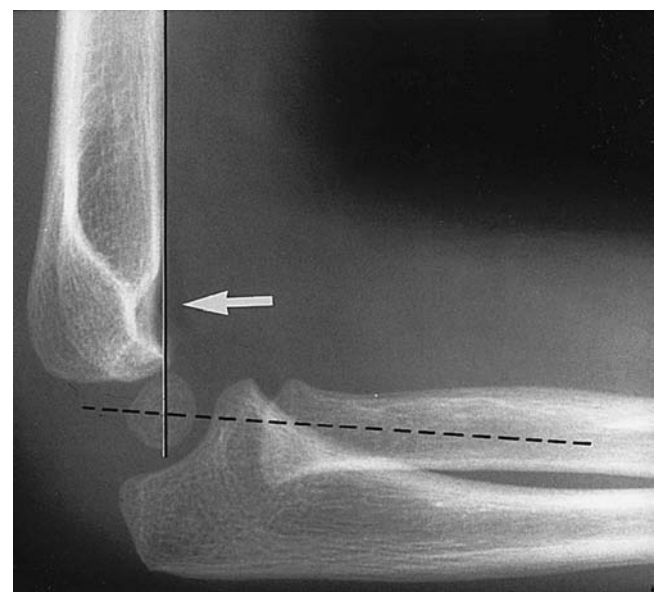

FIGURE 114.19 Normal lateral radiograph of the elbow of a 2-year-old child. The anterior fat pad is readily seen *(arrow)*; the posterior fat pad is not visible. A line drawn along the anterior cortex of the humerus intersects the capitellum in its middle third *(solid line)*. A line drawn along the axis of the radius also passes through the center of the capitellum *(dashed line)*.

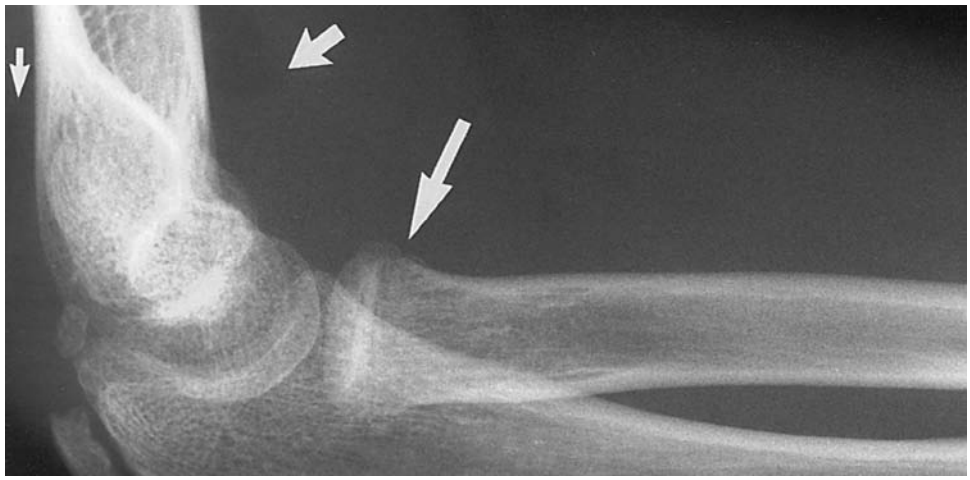

FIGURE 114.20 Lateral radiograph of the elbow of a 12-year-old girl, demonstrating marked elevations of both the anterior and posterior fat pads *(small arrows)*. A subtle radial neck fracture is also visible *(large arrow)*.

(Fig. 114.19). Because the most common mechanism of injury to the elbow is hyperextension, posterior displacement of the distal humerus is to be expected when a fracture occurs. As a result, the anterior humeral line, rather than intersecting the middle third of the capitellum, passes through its anterior third or even fails to intersect it all together (Fig. 114.21). Detection of abnormalities of the anterior humeral line in children younger than 2.5 years is complicated by the variable rates of ossification of the capitellum; once again, comparison views can be helpful in uncertain cases. In summary, errors in the management of pediatric elbow injuries can be minimized by an understanding of normal anatomy and development, careful interpretation of properly obtained radiographs, and immobilization with careful follow-up when there is even the mildest suspicion of a fracture. For the sake of discussion, elbow injuries are divided as follows: (i) supracondylar fractures, (ii) lateral condylar fractures, (iii) medial epicondylar fractures, (iv) distal humeral physeal fractures, (v) olecranon fractures, (vi) radial head and neck fractures, (vii) elbow dislocations, and (viii) radial head subluxation.

Some of these injuries are presented diagrammatically in Figure 114.22. Fractures of the medial humeral condyle and the lateral humeral epicondyle are rare and therefore not discussed.

FIGURE 114.21 Lateral radiograph of the elbow of a 2-year-old girl. Once again, both the anterior and posterior fat pads are elevated *(small arrows)*. In addition, the anterior humeral line passes along the anterior edge of the capitellum rather than through its center. Mild buckling of the posterior cortex of the distal humerus can be seen *(large arrow)*.

Supracondylar Fractures

Supracondylar fractures account for a large proportion of the fractures of the elbow in the pediatric age group. Most are sustained by children 3 to 10 years of age. A fall on the outstretched arm with hyperextension of the elbow is the most common mechanism. Accordingly, posterior angulation or displacement of the distal fracture fragment nearly always occurs (Fig. 114.23). A direct blow to the posterior aspect of the elbow can lead to anterior angulation or displacement of the

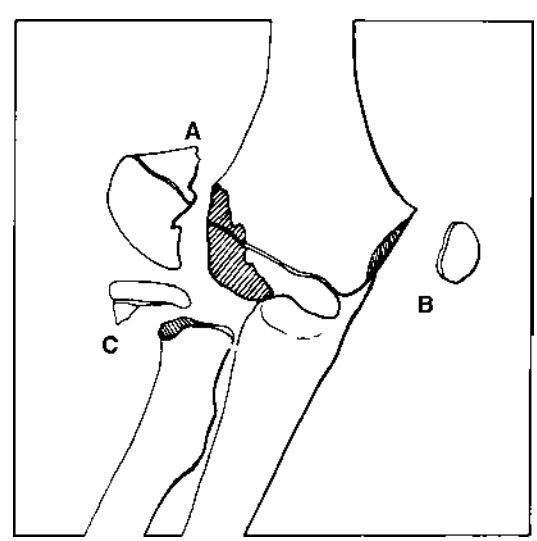

FIGURE 114.22 Common elbow fractures in children: lateral condylar fracture (**A**), medial epicondylar fracture (**B**), and radial neck fracture (**C**).

FIGURE 114.23 Displaced and rotated supracondylar fracture in an 8-year-old girl. The distal pulses were absent in this case but returned with reduction of the injury.

distal fragment, but such injuries are rare by comparison. With minimally displaced or nondisplaced fractures, recognition can be difficult. There may be only mild soft-tissue swelling. A suggestive history coupled with localized tenderness should prompt a radiologic examination. The radiographic findings may also be subtle. Close attention to the fat pads and the anterior humeral line, as detailed previously, facilitate diagnosis. At times, the actual fracture may be visualized only with an oblique view.

With more severe supracondylar injuries, the problem is not that of diagnosis (although a dislocated elbow may have a similar clinical presentation) but that of the recognition and prevention of complications. The complications associated with supracondylar fractures are multiple, ranging from immediate neurovascular compromise to long-term deformities and range-of-motion abnormalities. For the emergency physician, the first priorities are those of neurovascular assessment and fracture stabilization. The vascular examination should begin with palpation of the distal pulses and assessment of capillary refill. Use of a Doppler may allow detection of distal arterial flow when no pulse can be palpated. Absence of a pulse by itself is not extremely worrisome. Direct vascular injury is uncommon. In most instances, vasospasm or arterial compression has occurred instead, and arterial flow will resume with fracture reduction. In contrast, significant muscle ischemia can be present even when pulses and capillary refill are judged to be normal. Forearm pain, pain with passive extension of the fingers, paralysis of finger extension, and paresthesias are each worrisome and should be considered evidence of an impending compartment syndrome. Supracondylar fractures associated with ipsilateral forearm fractures are injuries at particularly high-risk for development of ischemic injury.

Neurologic deficits, usually transient, are also common with supracondylar fractures. Radial, medial, and ulnar nerve palsies all occur, as do isolated injuries of the anterior interosseous nerve (a motor branch of the median nerve). Table 114.5 outlines the innervation of these nerves and should be used as a guide to the neurologic examination. Once the neurovascular examination is completed and *before* radiographic studies, all displaced supracondylar fractures must be immobilized. It is usually best to simply splint the limb in the deformed position in which it lies. More than 20 to 30 degrees of elbow flexion will place undue tension on the neurovascular structures and should be avoided. All patients must have nothing by mouth because reduction, whether open or closed, requires general anesthesia. Frequent repeat neurovascular examinations should be performed and documented.

Minimally displaced or nondisplaced supracondylar fractures may be immobilized in a well-padded long arm posterior splint with the elbow at 90 degrees and the forearm in pronation or neutral rotation. Orthopedic referral for casting is suggested when the swelling subsides. Immobilization for a total of 3 weeks is adequate in most cases. All nonminimally displaced supracondylar fractures require immediate orthopedic referral.

Lateral Condylar Fractures

Fractures of the lateral condyle, like those of the supracondylar region, are prone to poor functional outcome if misdiagnosed or mismanaged. Unlike supracondylar fractures, lateral condyle injuries involve the articular surface; they are true Salter-Harris type IV injuries. The most commonly proposed mechanism of injury is a varus stress on the elbow, as can occur with a fall on an extended and abducted arm. The lateral ligament and the common extensor tendon remain attached to the fracture fragment, which can be partially or totally avulsed from the distal humerus (Fig. 114.24). Clinically, swelling, ecchymosis, and tenderness localized over the lateral aspect of the elbow should suggest a lateral condylar fracture. With severely displaced fractures, routine anteroposterior and lateral views usually provide adequate fracture definition. With less severe injuries, the fracture line and the degree of displacement may be evident only on oblique views. On occasion, stress views, a CT scan, or an MRI study may be needed to adequately visualize the extent of injury.

For minimally displaced and nondisplaced injuries, immobilization in a posterior splint with the elbow flexed to 90 degrees and the forearm in pronation (some authorities suggest supination instead) is satisfactory emergency management. Lateral condylar fractures as a group are inherently unstable and prone to displace despite immobilization; orthopedic follow-up within 3 to 4 days is essential. All fractures displaced more than 2 mm require reduction and often pinning.

TABLE 114.5

GUIDE TO NEUROLOGIC EXAMINATION OF DISTAL UPPER EXTREMITY

A. Motor function		
Nerve	**Muscles innervated**	**Motor examination**
Radial	Extensor carpi radialis longus	Wrist extension
Ulnar	Flexor carpi ulnaris Interosseous	Wrist flexion and adduction Finger spread
Median	Flexor carpi radialis Flexor digitorum superficialis Opponens pollicis	Wrist flexion and abduction Flexion fingers at proximal interphalangeal joint Opposition thumb to base of little finger
Anterior interosseous	Flexor digitorum profundus I and II Flexor pollicis longus	Flexion distal phalanx of index finger Flexion distal phalanx of thumb
B. Sensory function		
Nerve	**Sensory innervation**	
Radial	Dorsal web space between thumb and index finger	
Ulnar	Ulnar aspect palm and dorsum of hand Little finger and ulnar aspect of ring finger	
Median	Radial aspect palm of hand Thumb, index, middle, radial aspect ring finger	
Anterior interosseous	None	

FIGURE 114.24 Lateral condylar fracture in a 2-year-old girl *(arrow)*.

Medial Epicondylar Fractures

Fractures of the medial epicondyle occur as the result of falls directly onto the elbow and falls onto the outstretched arm in which the elbow is subjected to a valgus stress. With the latter mechanism, the flexor muscles of the forearm avulse the medial epicondyle from the humerus (Fig. 114.25). Medial epicondyle injuries are particularly common with elbow dislocations. The physical findings are those that would be expected, namely swelling and tenderness localized to the medial aspect of the elbow. Valgus instability may be evident. Given its proximity, paresis of the ulnar nerve can occur. Oblique views and comparison views may be needed on occasion. The diagnosis is particularly problematic before the onset of ossification of the medial epicondyle at 4 to 6 years of age; fortunately, it is an uncommon injury in younger children. In this setting, too, MRI examination may prove useful in defining the extent of the injury. Open reduction is almost invariably necessary for displaced fractures. Nondisplaced fractures can be placed in a posterior splint with the forearm in pronation. Orthopedic follow-up is encouraged strongly, as it is with most elbow injuries.

Distal Humerus Physeal Fractures

Fractures of the entire distal humerus physis are relatively uncommon. Most such injuries take place in children younger than 2.5 years, and almost all the remainder are sustained by children younger than 7 years. Recognition is both difficult and important, especially in infants, in whom this particular injury is often the result of child abuse. The proposed mechanism in abused children is forceful twisting of the arm that shears off the distal epiphysis. In children 5 to 7 years of age,

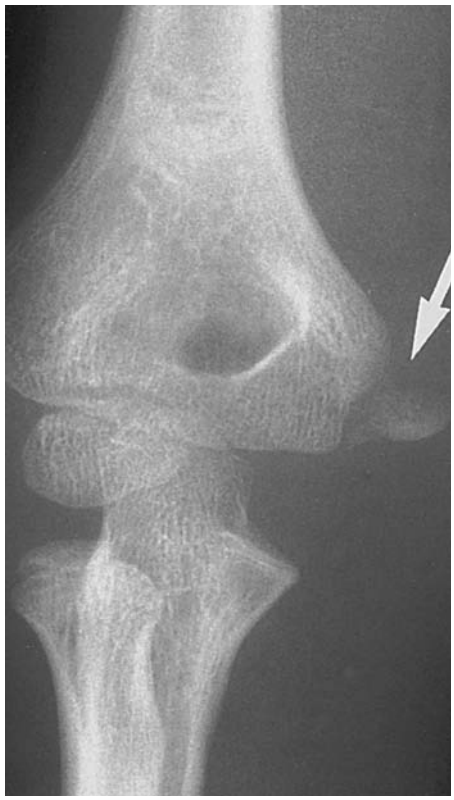

FIGURE 114.25 Displaced fracture of the medial epicondyle in an 8-year-old girl *(arrow)*. Note the extensive soft-tissue swelling.

a fall on an extended arm with hyperextension of the elbow usually results in a supracondylar injury but occasionally can lead to a fracture of the distal humerus physis instead.

Elbow swelling without significant deformity is the usual clinical finding. When displacement is significant, the appearance may mimic that of an elbow dislocation. The latter, however, is an injury of early adolescence. Radiographic diagnosis can be difficult, particularly in infants in whom the capitellum has not yet begun to ossify. Posteromedial displacement of the ulna and radius in relation to the humerus is the most important finding. Recognition of this displacement may necessitate comparison views. Given the difficulty in recognition and the frequent need for reduction and pinning, all suspected epiphyseal separations of the distal humerus merit immediate orthopedic referral. MRI studies may be necessary to define the extent of damage to the cartilaginous structures. In addition, the strong possibility of abuse needs to be considered seriously with this injury in children younger than 3 years.

Olecranon Fractures

Isolated fractures of the olecranon are seen only rarely. More often than not, they occur in conjunction with another injury of the elbow, in particular a fracture or dislocation of the radial head. Various mechanisms have been described, including sudden flexion of the elbow when the triceps is strongly contracted (essentially an avulsion injury) and direct trauma. Physical findings range from swelling localized to the olecranon to a marked hemarthrosis. Elbow extension may be weak or lacking altogether. Nondisplaced fractures may be somewhat difficult to discern radiographically; fat pad abnormalities are commonplace, however, and should be viewed as presumptive evidence of a bony injury (Fig. 114.26). A nondisplaced olecranon fracture can be splinted in partial extension and referred for orthopedic follow-up. Displaced fractures often require open reduction and internal fixation. Isolated olecranon fractures almost invariably heal quickly and without significant complications.

FIGURE 114.26 Nondisplaced fracture of the olecranon in an 8-year-old boy *(bottom arrow)*. Note the elevated fat pads *(top arrows)*.

Radial Head and Neck Fractures

Falls on an outstretched, supinated arm account for most fractures of the radial head and neck. Salter-Harris type I and II and pure metaphyseal (i.e., radial neck alone) injuries are the most common. Involvement of the epiphysis (i.e., radial head), which is largely cartilage in childhood, is rare. The physical examination typically reveals localized swelling and ecchymosis. Tenderness overlying the proximal radius strongly suggests the diagnosis. Of note is that pain may be referred to the wrist and thus distract from the true injury (Fig. 114.27). As for radiographic diagnosis, oblique and comparison views can

FIGURE 114.27 Buckle fracture of the radial neck in a 9-year-old girl. Wrist pain was the chief complaint. The treating physician failed to identify the proximal radial fracture, which was, however, noticed by the radiologist.

clarify the diagnosis in uncertain cases. When the metaphysis alone is injured, a hemarthrosis may be absent and the fat pads normal. Associated fractures are common. The incidence of complications, especially loss of motion and overgrowth of the radial head, is significant. For this reason, orthopedic referral is recommended for all radial head and neck fractures. Immobilization with the elbow in 90 degrees of flexion and the forearm in neutral rotation is acceptable emergency management for minimally displaced or nondisplaced fractures. Angulation of greater than 15 degrees is an indication for immediate orthopedic consultation.

Elbow Dislocations

The elbow is dislocated more often than any other major joint in children and adolescents. Nonetheless, it is an unusual injury. As discussed previously, the ligaments and tendons are relatively stronger than the neighboring bones (particularly the physeal plates) in children; injuries that would lead to dislocations in adults almost invariably result in fractures in the younger age group. It is not surprising, then, that dislocations of the elbow are accompanied by significant soft-tissue and bony damage. A fall on an extended or partially flexed arm with the forearm in supination is the usual mechanism of injury. Accordingly, the radius and ulna are displaced posteriorly and, in most cases, laterally (Fig. 114.28). The anterior capsule is torn and the medial collateral ligament typically ruptured. Fractures of the medial epicondyle, coronoid process, olecranon, and proximal radius are the most commonly associated bony injuries.

Major neurovascular compromise may accompany elbow dislocations. After reduction, patients should be evaluated carefully, placed in a posterior splint, and discharged, if neurovascularly intact, with careful instructions as to the signs of compartment syndrome. True arterial rupture is seen almost exclusively with open dislocations but has been described on occasion with closed injuries. When reduction of the dislocation fails to relieve arterial compromise, further investigation regarding the extent of vascular injury is warranted. Nerve injury, particularly of the ulnar nerve, is even more common than vascular injury. Ulnar nerve lesions typically occur when the medial epicondyle is avulsed and then entrapped in the joint. Early recognition and appropriate treatment of such entrapment nearly always lead to complete recovery of ulnar nerve function. Median nerve entrapment is much rarer, but when it occurs, the degree of nerve damage is such that full recovery cannot be guaranteed. Moreover, recognition of median nerve injury is made difficult by the relative lack of pain and the subtlety of the initial motor and sensory deficits.

FIGURE 114.28 Elbow dislocation in an 8-year-old girl. A displaced fracture of the medial epicondyle was evident on the postreduction radiographs.

Clinical findings with dislocation of the elbow include obvious deformity and significant swelling. The forearm appears shortened. Often, the ulnar notch can be palpated posteriorly, and the humeral head can be detected as fullness in the antecubital fossa. The importance of a thorough and well-documented neurovascular examination should be obvious from the preceding discussion. Immobilization before radiographic studies is recommended to minimize the risk of further neurovascular injury. Standard radiographic views are satisfactory. They should be closely inspected for the direction of the dislocation and for the presence of associated fractures. Although most elbow dislocations can be reduced uneventfully, the risks of entrapping a fracture fragment or a nerve in the joint space during the procedure are such that immediate orthopedic consultation is recommended. Open reduction may be needed in over 50% of cases. Numerous techniques for closed reduction have been described. Whatever technique is used, hyperextension should be avoided at all times. Postreduction films are mandatory because only then will many of the associated fractures be evident. Finally, the arm should be immobilized in a posterior splint with the elbow at 90 degrees and the forearm in midpronation.

Radial Head Subluxation

Of all the injuries discussed in this section, by far the most common is radial head subluxation, otherwise known as "nursemaid's elbow" or "pulled elbow" (see Section VII, Procedures). Pathologically, radial head subluxation occurs when the annular ligament becomes partially detached from the head of the radius and slips into the radiohumeral joint where it is entrapped. The usual mechanism is that of axial traction on an extended and pronated arm. Radial head subluxation is an injury of children a few months to 5 years of age. After 5 years of age, the strength of the annular ligament is such that the injury is uncommon.

The classic history is that of a child who cries with pain and refuses to use an arm after being pulled or lifted by that same arm. With some regularity, however, the history is one of a fall. In infants, radial head subluxation can occur when an extended arm is trapped beneath the trunk as the child is rolled over. The chief complaint is typically that the child is not using the arm; concerns about a wrist or a shoulder injury are common. Children with radial head subluxation uniformly hold the arm in pronation with the elbow slightly flexed. Much more often, the degree of distress is minimal, although supination, pronation, and elbow flexion usually elicit pain. Mild tenderness may be noted with palpation of the radial head. Significant point tenderness or swelling should suggest an alternative diagnosis (e.g., a supracondylar fracture). The radiographic findings with radial head subluxation are minimal at best. Radiographs are not routinely recommended when the

history and clinical presentation are classic. Indeed, the subluxation is often reduced when the radiology technician places the forearm in supination for the anteroposterior view.

As for treatment, various reduction techniques have been described. The most widely used is that described in Section VII "Procedures," namely, supination and flexion. If that approach is unsuccessful, either supination or pronation with elbow extension should be attempted. When reduction succeeds, the child typically uses the arm normally within 5 to 10 minutes. The delay until normal use is longer in younger children and when there has been greater than a 4- to 6-hour period between injury and treatment. When there is no evidence of recovery, the diagnosis must be reconsidered; fractures of the elbow and clavicle in particular should be excluded because the clinical presentations can be similar. With recurrent subluxations, immobilization for a few weeks in a posterior splint with the elbow at 90 degrees and the forearm supinated is suggested. Note that even when efforts at closed reduction fail, spontaneous reduction almost invariably occurs. The need for open reduction is exceedingly rare.

Fractures of the Forearm and Wrist

Children fracture the radius and ulna more often than all bones other than the clavicle. Fortunately, the incidence of neurovascular complications is low and the potential for healing with proper management high. In many instances, the emergency physician can provide the satisfactory initial, if not definitive, management for forearm injuries. However, certain types of fractures require immediate orthopedic referral, and as such they receive particular emphasis. In this section, forearm fractures are divided as follows: (i) fractures of the radial and ulnar shafts, (ii) Monteggia and Galeazzi fracture dislocations, (iii) fractures of the distal radius and ulna, and (iv) fractures of the bones of the wrist.

Fractures of the Radial and Ulnar Shafts

The usual mechanism of injury with forearm fractures, including those of the radial and ulnar shafts, is a fall on an outstretched hand. Direct blows account for some injuries, displaced and open shaft fractures in particular. Approximately three fourths of all shaft fractures involve the distal third of the shaft; most of the remainder involve the midshaft. The clinical findings generally make the diagnosis self-evident. A number of fracture patterns are seen; greenstick injuries are especially common. Standard radiographic views are sufficient other than with suspected bowing fractures when comparison views may be necessary. The emergency physician should insist that radiographs of the forearm always include both a true lateral and a true anteroposterior view and both the elbow and the wrist. In general, isolated ulnar fractures do not occur, as is discussed further in the next section.

The periosteum and remaining intact cortex limit the degree of angulation with greenstick injuries. Keep in mind that many greenstick fractures have a significant rotational deformity and that the degree of angulation alone should not determine the need for closed reduction. It must also be remembered that the potential for remodeling decreases with the distance from the epiphysis and with the age of the child. Less angulation is therefore accepted in midshaft fractures than in more distal injuries and in adolescents than in younger children. Although it is hard to make any absolute rules, any shaft fracture angulated more than 10 degrees merits immediate orthopedic consultation, at least by telephone. This is not to say that all such fractures will require reduction. (Another simple rule is that any forearm that looks crooked should be straightened.) Dorsal angulation is usual; immobilization with the arm in supination minimizes the tendency of the forearm muscles to cause further deformity.

Complete fractures can be particularly problematic, again because significant angulation can occur. If the ends of the bones are well opposed and angulation and rotation are minimal, a well-applied sugar-tong splint is adequate initial treatment. Otherwise, immediate orthopedic referral is necessary. Closed reduction, although not always as simple as it may appear, is preferable (Fig. 114.29). In children older than 10 to 12 years, adequate alignment is often obtained only with open reduction and internal fixation.

Recognition of when a bowing fracture has occurred is crucial simply because the potential for remodeling with such injuries is minimal (Fig. 114.4). Failure to correct bowing can result in permanent loss of supination and pronation. As already mentioned, in the absence of obvious deformity, comparison views may be necessary before the true extent of bowing can be appreciated. Again, no hard and fast rules regarding indications for closed reduction are offered; however, any bowing fracture that causes obvious forearm deformity or restrictions of pronation or supination certainly merits immediate orthopedic referral.

Monteggia and Galeazzi Fracture Dislocations

In general, isolated fractures of the ulna do not occur. Instead, the same force that causes the ulnar fracture leads to a radial injury, in some instances, a dislocation of the radial head. It is this combination of an ulnar fracture and a radial head

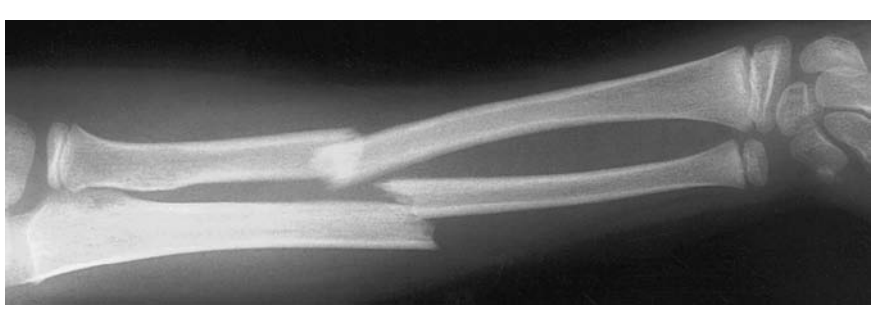

FIGURE 114.29 Complete fractures of the midshafts of the radius and ulna in a 9-year-old boy. Efforts at closed reduction failed; internal fixation was necessary.

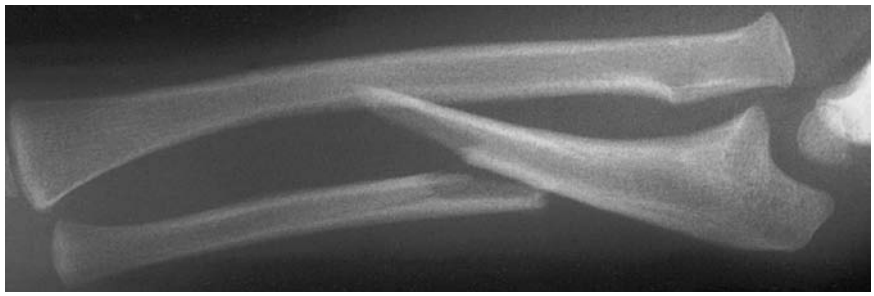

FIGURE 114.30 A Monteggia fracture in a 3-year-old boy. Note that a line drawn along the axis of the radius would fail to intersect the capitellum (compare with Fig. 114.29.)

dislocation that is known as a Monteggia fracture. Recognition is most important because failure to reduce the radial head dislocation results in permanent disability. Clues to the diagnosis on physical examination include elbow pain and swelling, which accompany signs of any ulnar fracture. Palpation may confirm the dislocation of the radial head, which may be displaced anteriorly, posteriorly, or laterally, depending on the mechanism of injury. A palsy of the posterior interosseous nerve, a motor branch of the radial nerve, may also be present.

If the radial head dislocation is to be recognized radiographically, the rule that a line drawn through the axis of the radius should pass through the center of the capitellum on all projections must be remembered (Fig. 114.30). Once again, the need for a true lateral view that includes the elbow with all forearm studies must be emphasized. Even bowing fractures of the ulna, which may require comparison views for recognition, are associated with radial head dislocation. Any suspected Monteggia injury requires immediate orthopedic referral.

The Galeazzi fracture is a radial shaft fracture, generally at the junction of the middle and distal thirds that is accompanied by disruption of the distal radioulnar joint. It is relatively rare. Physical examination reveals prominence of the distal ulna and joint instability. Radiographs are confirmatory. Once again, orthopedic consultation is necessary. The complications are few with proper management.

Fractures of the Distal Radius and Ulna

Distal radial and ulnar fractures bear special mention, not because of any undue rate of complications, but rather because of their overall frequency. Of all the fractures that occur in childhood and adolescence, those of distal forearm are by far the most common. Except for the occasional instance of nerve entrapment at the time of reduction of a complete fracture, significant neurovascular complications are rare. Overall, the capacity for remodeling is significant. The difficulties facing the emergency physician are those of diagnosis with subtle fractures and of recognition regarding when reduction is necessary with displaced fractures.

More often than not, localized swelling and tenderness accompany distal radial fractures and can guide interpretation of the radiographic studies. However, wrist pain can be the chief complaint with more proximal injuries, for example, radial head fractures. Once again, the need for studies that include the whole forearm must be reinforced. Torus fractures are most often overlooked. Often, the location of the soft-tissue swelling on the radiographs helps highlight the position of the fracture, which may be evident on only one projection and then only as a minor irregularity in the contour of the cortex. A fracture of the ulnar styloid should also prompt a diligent search for a radial injury. Ulnar styloid fractures only rarely occur in isolation; as a rule, they are accompanied by either a torus or physeal fracture of the radius. When a torus fracture is identified, a volar splint or, if the swelling is minimal, a short arm cast for 3 to 4 weeks is recommended. A removable splint for 3 weeks was shown in one study to be as effective as casting with the additional advantage of interfering less with physical functioning and activities. Orthopedic referral is optional, and serial radiographs to document fracture healing or guide management are of limited value.

Greenstick and complete fractures are readily recognized. What must be remembered is that such fractures have a tendency to displace if not properly immobilized. The distal fragment is angulated posteriorly in most greenstick and complete fractures of the distal forearm. Angulation of greater than 10 to 15 degrees is an indication for immediate orthopedic referral (Fig. 114.31). Otherwise, immobilization with orthopedic follow-up within 3 to 5 days is adequate emergency management.

FIGURE 114.31 Complete fracture of the distal radius of a 9-year-old child demonstrating 35 degrees of posterior displacement of the distal fragment. Closed reduction was uneventful.

Although there is some disagreement, immobilization with the forearm in supination is believed to decrease the likelihood of further displacement. Accordingly, either a long arm posterior splint or a well-applied sugar-tong splint are recommended with all greenstick and complete radial and ulnar fractures. Short arm volar splints should be reserved for torus injuries.

Salter-Harris type I and II injuries of the distal radial physis rarely lead to growth disturbance, which is fortunate because they are common injuries, particularly from 6 to 12 years of age. The issue again is one of recognition with these fractures. When point tenderness on the physical examination is accompanied by swelling localized to the distal radius on the radiograph, the presumptive diagnosis should be a Salter-Harris type I injury even when there is no obvious displacement of the epiphysis. Immobilization and orthopedic referral are recommended. Closed reduction is needed for all displaced physeal fractures. Of note is that the risk of growth disturbance increases with repeated and delayed manipulations.

Fractures of the Bones of the Wrist

The carpal bones are rarely fractured during childhood and adolescence. Adolescents in the later stages of skeletal maturity sustain scaphoid (navicular) fractures. Most injuries of the scaphoid in adolescence are nondisplaced fractures through the distal third of the bone (Fig. 114.32). The rate of nonunion is much lower than in adults, in whom scaphoid fractures generally involve the middle third of the bone and are more often displaced. The usual mechanism is a fall on an outstretched arm with extreme hyperextension of the wrist. Physical findings that should suggest the possibility of a scaphoid fracture include snuffbox tenderness, pain with supination against resistance, and pain with longitudinal compression of the thumb. As with adults, radiographic visualization of a nondisplaced scaphoid fracture may be difficult even with special views. If the physical signs suggest a scaphoid fracture, then immobilization in a thumb spica splint or cast for 2 weeks is recommended, regardless of the radiographic findings. At that time, radiographs should be repeated; fractures not detectable on the initial films should now be evident. If radiographs remain normal but clinical suspicions high, a bone scan or an MRI study should be considered. Although the likelihood of complication is low, orthopedic referral is recommended once a scaphoid fracture is identified.

FIGURE 114.32 A scaphoid fracture in a 16-year-old boy *(arrow)*. In this case, the fracture is through the middle third of the scaphoid; fractures through the distal third are actually more common during adolescence.

Injuries of the Hand and Fingers

By comparison with adults, younger children sustain relatively few bony injuries of the hand. The most commonly encountered hand injuries in the pediatric ED are crush injuries of the distal phalanx, in which lacerations and fractures often coexist. It has been stated that such injuries are often undertreated; definitive management often entails removal of the nail, repair of any nail-bed injury identified, careful immobilization, and close follow-up. (See Chapters 106 and 113 for additional discussion on the management of such crush injuries.)

A wide variety of other injuries, including an array of avulsion and physeal fractures, also occur. The types of injuries seen at a given joint reflect the underlying complex anatomy of the tendons and ligaments of the hand, a full discussion of which is beyond the scope of this chapter. However, by adhering to a few basic principles of physical and radiographic diagnosis, the emergency physician should have little difficulty in recognizing which injuries merit referral to a hand specialist.

Given the risks of permanent deformity and stiffness, all displaced fractures, particularly those extending intraarticularly, should be referred. Such fractures are generally self-evident. Before concluding that a fracture is a simple nondisplaced one and thus amenable to routine splinting, the practitioner must first assure himself or herself that there is no accompanying malrotation or joint instability. Malrotation is not always that apparent when the fingers are extended; it becomes much more obvious with finger flexion (Fig. 114.33). Joint stability must also be assessed in flexion and extension, as well as in both the lateral and anteroposterior planes. Adequate examination may be possible only after performance of a digital block. If either malrotation or joint instability is detected, consultation is again in order.

When the hand is radiographed, oblique views should be included in addition to the usual anteroposterior and lateral projections. Interpretation of the radiographs is complicated by the presence of multiple epiphyses and secondary ossification centers. It is essential to remember that the epiphyses of

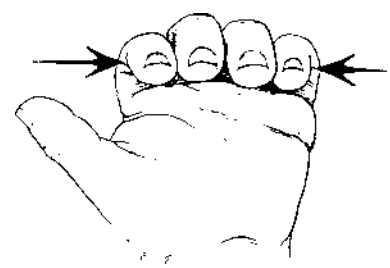

FIGURE 114.33 It is important to check for malrotation with all fractures of the metacarpals and phalanges. When flexed as shown, the fingers should all point in the same direction. If malrotation is present, overlapping will occur.

the phalanges and of the thumb metacarpal are located at the proximal ends of the bones. The growth centers of the remaining metacarpals are distal. Once again, the number of fractures missed will be minimized if close attention is paid to the physical findings and the presence of soft-tissue swelling on the radiographs. For the purposes of further discussion, hand injuries are divided into (i) metacarpal fractures and (ii) phalangeal fractures and dislocations.

Metacarpal Fractures

Perhaps the most commonly encountered metacarpal fracture in pediatrics is one of the distal fifth metacarpal in a male adolescent who has struck someone or something with a closed fist. The equivalent of a boxer's fracture in an adult, these fractures are metaphyseal rather than physeal injuries and are typically angulated. Closed reduction is usually performed if the angulation is more than 30 to 40 degrees. Salter-Harris type I and II injuries occur on occasion, primarily in the second, third, and fourth metacarpals. Nondisplaced injuries may be immobilized in a gutter splint with the wrist neutral and the metacarpal phalangeal joints at 70 degrees and then referred (Figs. 114.34 and 114.35). If they are not displaced or rotated, metacarpal shaft fractures can be managed similarly. Proximal metacarpal fractures of the second through fifth metacarpals are rarely displaced; recognition is more of an issue than management (Fig. 114.36). However, angulation is common with proximal fractures of the thumb metacarpal. Metaphyseal and Salter-Harris type II and III injuries occur and when displaced require closed reduction.

Phalangeal Fractures and Dislocations

As already mentioned, distal phalanx fractures typically accompany crush injuries of the fingertip. If only the distal tuft is fractured, anatomic closure of the laceration usually results in adequate realignment of the fracture. Displaced physeal fractures merit immediate referral (Fig. 114.37). Hyperflexion injuries of the distal phalanx, leading to so-called mallet finger deformities, are also common. In the child, Salter-Harris type I or II injuries result, whereas type III injuries are the rule in adolescents. The latter often require open reduction and internal fixation. In either case, examination reveals an extension lag at the distal interphalangeal joint. Recognition of the tendinous disruption is important, given that proper treatment entails 6 to 8 weeks of continuous splinting in hyperextension.

A whole range of proximal and middle phalangeal fractures occur, many of which the emergency physician can manage successfully (Fig. 114.38). Gutter splints that incorporate both the

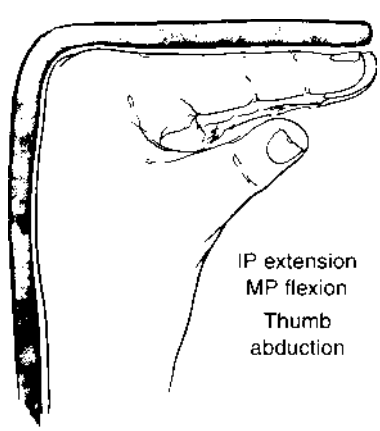

FIGURE 114.34 The hand should be splinted in this position to prevent extension contractures of the metacarpophalangeal (MP) joints and flexion contractures of the interphalangeal (IP) joints.

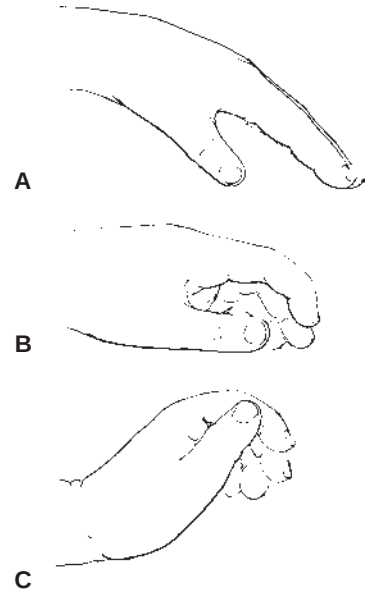

FIGURE 114.35 Splinting the hand in any of the positions shown here tends to promote joint contractures and recurrence of deformity.

FIGURE 114.36 Radiograph of the left hand of an 8-year-old girl showing fractures of the proximal second and third metacarpals *(arrows)*. Significant displacement is unusual with proximal metacarpal fractures.

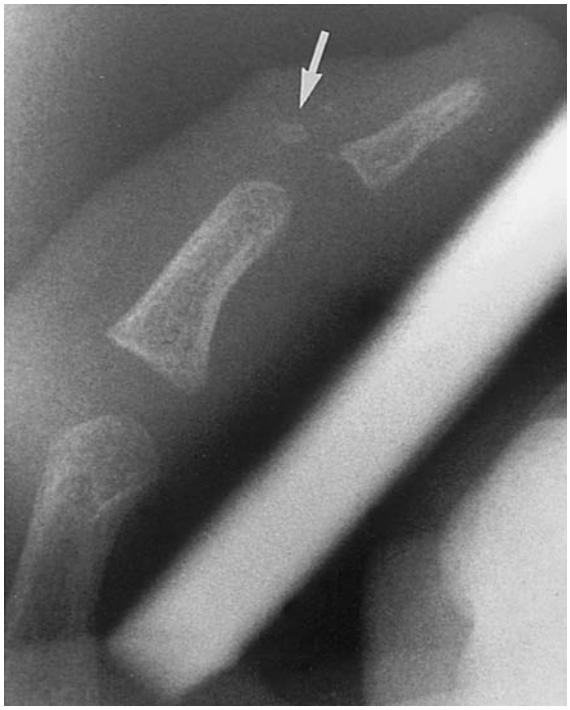

FIGURE 114.37 Displaced Salter-Harris type I fracture of the distal phalanx in an 11-month-old girl that resulted from a crush injury. The *arrow* points to the epiphysis, which is only beginning to calcify. Careful reduction is necessary if the risk of growth disturbance is to be minimized.

FIGURE 114.38 Oblique fracture of the proximal phalanx of the right third finger in a 12-year-old boy *(arrow)*. Before splinting such an injury, the emergency physician must first make certain that no malrotation is present.

injured and an adjacent uninjured finger are used commonly with the positioning discussed previously. Complete fractures almost invariably angulate as the result of the actions of the intrinsic muscles, the direction of angulation determined by the position of the fracture relative to the flexor and extensor tendons. Phalangeal neck fractures are of particular concern in that complete fractures can rotate by as much as 90 degrees and unicondylar fractures are prone to displacement. The radiographic findings may be subtle; the consequences of improperly evaluating such injuries are certainly substantial. In the proximal phalanx, particularly that of the fifth finger, laterally angulated Salter-Harris type II fractures are common. If the displacement is minimal, splinting with follow-up in 3 to 5 days is acceptable.

Special mention should be made of the so-called gamekeeper's or skier's thumb, an avulsion of the ulnar collateral ligament of the proximal phalanx of the thumb. Localized tenderness should raise concerns about this injury and prompt an assessment of the joint for adduction stability with the metacarpal joint extended and in 30 degrees of flexion. In the pediatric age range, this is a Salter-Harris type III injury. When there is evidence of only minor instability (firm endpoint, increased laxity of less than 30 degrees), thumb spica splinting for 3 to 6 weeks is generally sufficient. More severe injuries require operative intervention. Consultation is suggested when such injuries are suspected.

Despite the strength of the ligaments and tendons, hyperextension can lead to dislocations of the metacarpophalangeal and proximal interphalangeal joints in children. Dislocations of the proximal interphalangeal joints can usually be readily reduced (Fig. 114.39). After a digital block, the joint should be gently hyperextended and the distal bone then pushed back into place. Radiographs, both prereduction and postreduction, should be scrutinized for fractures, and the stability of the collateral ligaments should be carefully assessed. Buddy taping for 3 weeks is adequate for routine dislocations (Fig. 114.40).

Metacarpophalangeal dislocations are particularly problematic. Although closed reduction may be successful, often the volar plate is entrapped in the joint and open reduction is therefore necessary. Such volar entrapment can be suspected when physical examination reveals puckering of the palmar skin adjacent to the affected joint. Visualization of a sesamoid bone within the joint space is pathognomonic of volar plate entrapment. (See Section VII "Procedures" for a more in-depth review of techniques for reduction of finger dislocations.) If an initial attempt at reduction of a metacarpophalangeal dislocation fails, the finger should be immobilized and a hand specialist consulted.

FRACTURES OF THE PELVIS

When evaluating a child with a suspected pelvic fracture, attention to surrounding viscera and to signs of blood loss are the most important immediate considerations. Pelvic fractures are caused by high-energy accidents and are often associated with head, abdominal, and vascular injuries. Life-threatening hemorrhage from pelvic fractures is quite unusual in the pediatric age group; only a minority of cases require transfusion. Multiple authors have questioned the role of routine screening pelvic films in pediatric trauma. In the awake, alert patient, physical examination alone has both high specificity and

FIGURE 114.39 Dislocation of the right fourth proximal interphalangeal joint in a 15-year-old boy. Most such injuries can be readily reduced, which is not the case with metacarpophalangeal joint dislocations.

negative predictive value. When the extent of injuries is such that abdominopelvic CT scan is indicated, screening films can also be deferred as the sensitivity of CT scan for pelvic fractures is certainly higher than of a single routine radiograph. Overall, pelvic fractures in children have a favorable outcome and rarely require any more treatment than bed rest for 4 to 6 weeks. Exceptions to this rule include severely displaced sacral or sacroiliac joint dislocations and displaced acetabular fractures. An immediate orthopedic consultation is required for all pelvic fractures other than minor avulsions.

Pelvic fractures in children can be divided into three groups: (i) avulsion fractures, (ii) pelvic ring fractures, and (iii) acetabular fractures.

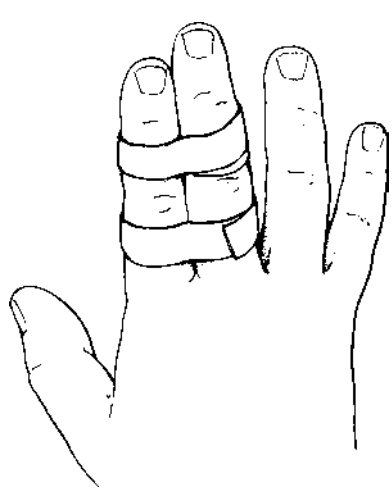

FIGURE 114.40 Buddy taping is a convenient way of splinting uncomplicated dislocations postreduction, as well as minor finger fractures.

Avulsion Fractures

Avulsion fractures occur most commonly from sporting activities. The muscular attachments to the secondary centers of ossification (i.e., the anterior superior iliac spine, anterior inferior iliac spine, and ischial tuberosity) can be pulled off during strong, active contractions against resistance (Fig. 114.41). Localized tenderness is usually present. The diagnosis is usually readily apparent on plain film radiographs, although bone scintigraphy may be necessary to confirm the diagnosis on occasion (Fig. 114.42). Treatment is based on symptoms. Often, crutches with partial or no weight bearing for 4 to 6 weeks with slow resumption of activities are all that is required even with significantly displaced fractures. With widely separated (more than 2 cm) avulsion fractures of the ischial tuberosity, some authors recommend open reduction and fixation; others continue to advocate conservative treatment.

Pelvic Ring Fractures

Single Breaks in the Pelvic Ring

Symphysis pubis diastasis, superior and inferior pubic rami fractures, and straddle fractures are classified as single breaks in the

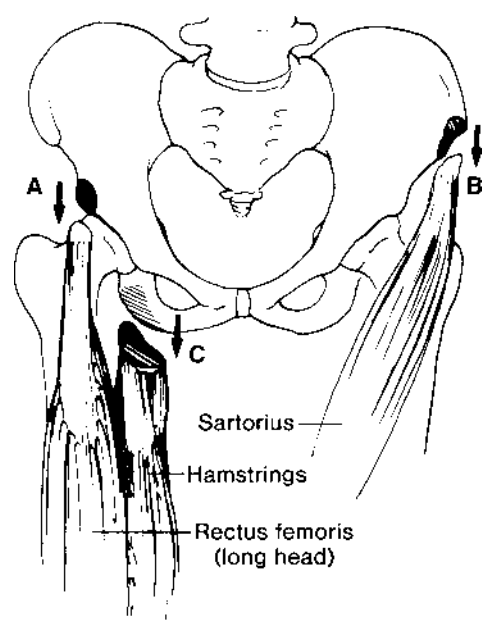

FIGURE 114.41 Common avulsion injuries of the pelvis: anterior inferior iliac spine (A), anterior superior iliac spine (B), and ischial tuberosity (C).

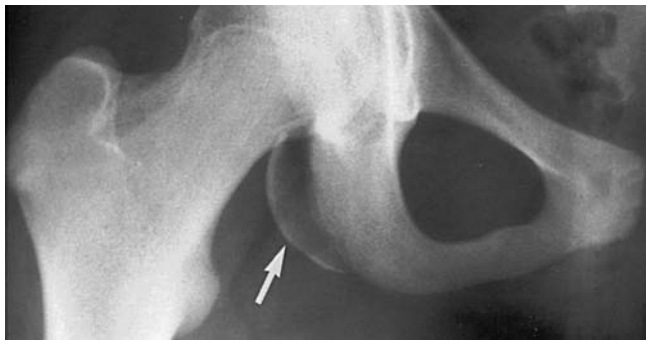

FIGURE 114.42 Avulsion fracture of the right ischial tuberosity in a 13-year-old girl *(arrow)*.

pelvic ring. These common childhood fractures often seem worse than they are. Although they are caused by high-energy accidents, they are generally stable fractures. A careful search for accompanying genitourinary and neurovascular injuries must be made. Fractures of the superior and inferior pubic rami rarely require any treatment in the child or adolescent as long as the sacroiliac joints and sacrum remain intact. One exception to this rule is a diastasis of the pubic symphysis, which is often associated with anterior disruption of the sacroiliac joint. This fracture configuration with pubic diastasis and anterior sacroiliac joint disruption is called the open book deformity. If significant displacement occurs through the symphysis pubis, closed reduction with an external fixator or a pubic plate must be considered.

Double Breaks in the Pelvic Ring

Fractures of the pubic rami or symphysis pubis associated with displaced sacroiliac joint dislocations or sacral fractures are classified as Malgaigne's fractures (Fig. 114.43). The hemipelvis is unstable and displaced cephalad. This group of fractures is associated with a high incidence of complications, including genitourinary, abdominal, and vascular injuries. Life-threatening hemorrhage can occur from pelvic vein disruption. In severe cases of bleeding, emergent application of an external fixator or a pneumatic antishock garment in the ED with compression of the pelvis may slow bleeding by a tamponade effect. Angiographic embolization should also be considered in the face of persistent bleeding.

Initial treatment of the unstable pelvic fracture is bed rest. Special radiographic views consisting of an inlet and outlet view or CT scan assist the orthopedist in deciding whether to place the child or adolescent in traction or to undertake an open reduction and internal fixation of the posterior fracture–dislocation.

Acetabular Fractures

Fractures involving the acetabulum are rare in children. They are often associated with a dislocation of the hip joint. Attention should be directed toward obtaining an early congruent reduction and evaluating the stability of the hip. Acetabular fractures associated with major pelvic disruption should be treated like those involving double breaks in the pelvic ring. An orthopedic consultation should be obtained early and treatment of life-threatening complications initiated.

INJURIES OF THE LOWER EXTREMITIES

Injuries of the Hip and Proximal Femur

Hip dislocations and femoral neck fractures in children and adolescents are the result of high-energy accidents. The care and resuscitation of the child is paramount before addressing

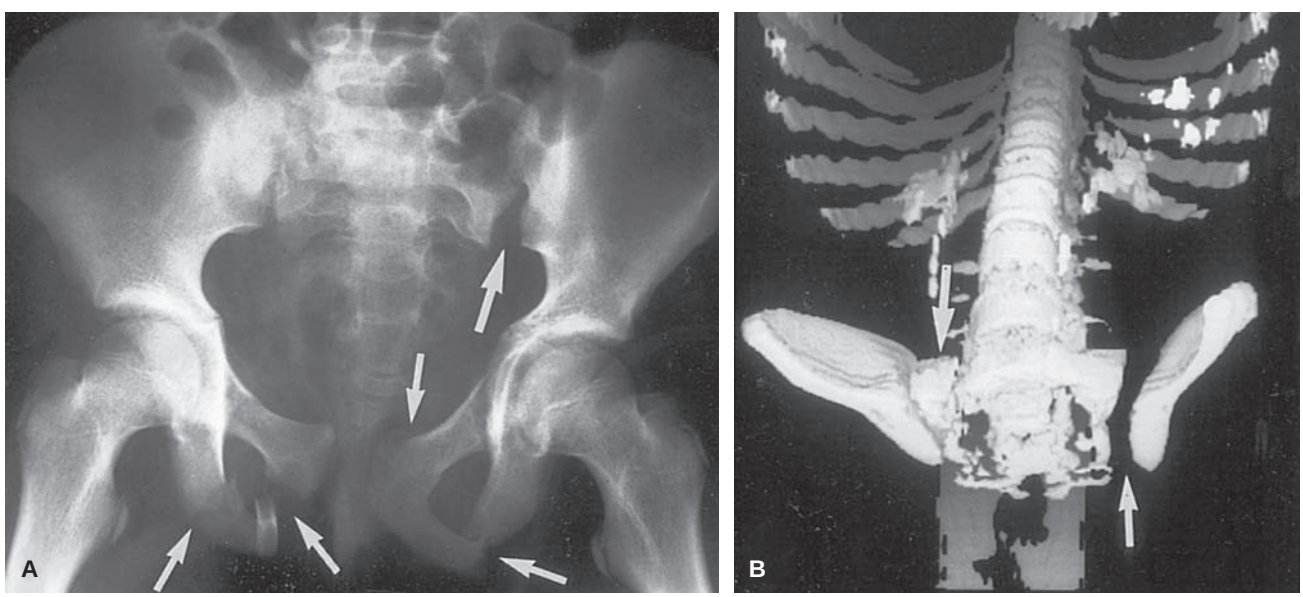

FIGURE 114.43 An unstable pelvic injury. **A:** On the plain film, multiple fractures of the pubic rami *(small arrows)* and widening of the right sacroiliac joint *(large arrow)* are apparent. **B:** On the three-dimensional reconstruction of the CT scan, the left sacroiliac fracture is even more obvious *(small arrow)*, and a right-sided sacral fracture is also seen *(large arrow)*.

the orthopedic injury. In many instances, the child can be managed in a traction splint until definitive care is given.

Injuries of the hip and proximal femur in children can be divided into five groups: (i) hip dislocation, (ii) proximal femoral physeal fractures, (iii) slipped capital femoral epiphysis (SCFE), (iv) femoral neck fractures, and (v) intertrochanteric fractures.

Hip Dislocation

Dislocation of the hip in children and adolescents is uncommon. However, it probably occurs more often than it is diagnosed because of spontaneous reduction at the time of injury. A dislocation or fracture–dislocation is rather obvious if the injured limb is shortened, externally rotated, and painful. Radiographic examinations make the diagnosis (Fig. 114.44). In evaluating suspected dislocations of the hips with spontaneous reduction, attention must be directed to the radiographic medial clear space of the hip. If a suspected dislocation with spontaneous reduction has occurred, the medial clear space is often wider than the normal contralateral side. The posterior labrum and capsule of the joint may be detached when a dislocation occurs. At the time of reduction (either spontaneous or after closed reduction), tissue may get trapped in the joint space, resulting in asymmetry of the joint space and an incongruent reduction. Further evaluation should consist of a CT scan or MRI (Fig. 114.45).

A patient presenting with a dislocated hip should undergo a closed reduction in the ED or under general anesthesia. Reduction within 6 hours of the accident is essential to decrease the incidence of osseous necrosis. The technique of closed reduction consists of hip and knee flexion to 90 degrees and axial distraction of the thigh. When closed reduction is unsuccessful or when it is suspected that tissue is trapped in the joint space, open reduction is necessary. Congruency of both hips is imperative to a good result. A CT scan or MRI may be needed to define the adequacy of reduction. Complications of traumatic hip dislocation in children include osseous necrosis of the femoral head, posttraumatic arthritis, and persistent instability of the hip joint.

FIGURE 114.44 Dislocation of the left hip in a 9-year-old boy. If dislocation is delayed beyond 6 hours, the risk of osseous necrosis rises.

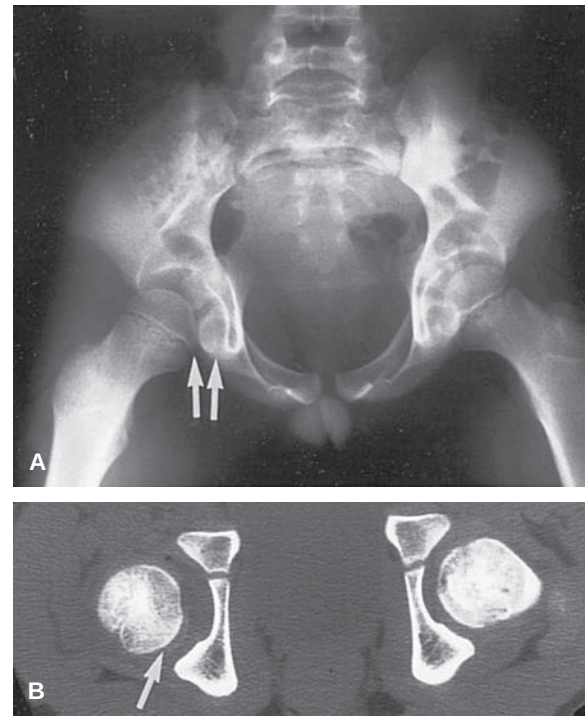

FIGURE 114.45 Radiographs taken following closed reduction of a right hip dislocation. **A:** The plain film demonstrates residual widening of the joint space *(arrows)*. **B:** Widening is also apparent with magnetic resonance imaging, as is entrapment of a portion of the posterior joint capsule. Under general anesthesia, further efforts at closed reduction were successful.

Proximal Femoral Physeal Fractures

Proximal femoral physeal fractures occur through the zone of provisional calcification of the proximal femoral growth plate. The degree of displacement can be mild to complete (Fig. 114.46). Anatomic reduction, either by open or closed means, is essential. Unfortunately, the incidence of osseous necrosis approaches 100% in totally displaced fractures and can lead to long-term disability. In minimally displaced fractures, it may be far better to accept mild displacement than to further compromise the vascularity of the femoral head by performing a reduction.

Slipped Capital Femoral Epiphysis

Although most cases of SCFE present with chronic pain, a significant percentage present acutely. Several studies have suggested that structural weakness is present in the capital femoral physis during the onset of puberty. Others have identified a genetic or hormonal influence predisposing to SCFE. This malady occurs predominantly in children 8 to 15 years of age, with a male:female predominance of 2:1 to 4:1. Obese children and African-Americans are particularly susceptible.

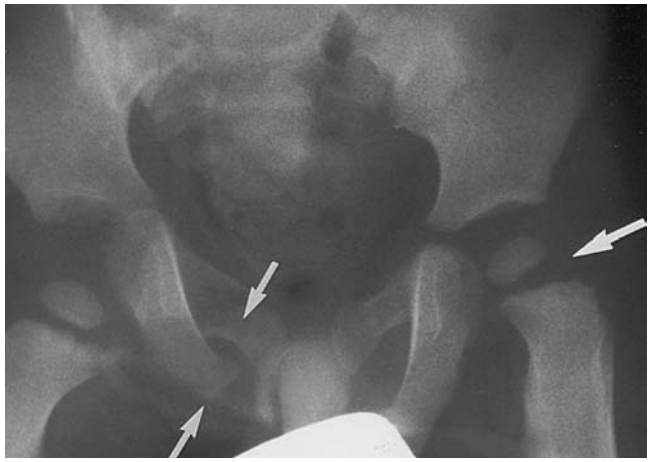

FIGURE 114.46 Displaced Salter-Harris type I fracture of the left proximal femur in a 2-year-old boy *(large arrow)*. Also seen are fractures of the right pubic rami *(small arrows)*. The pelvis is also disrupted posteriorly.

The diagnosis of SCFE should be considered in any preadolescent or adolescent complaining of hip or knee pain. The history is often one of minimal trauma, causing pain in the hip, thigh, or knee region. Vague hip or knee pain and a limp in the preceding weeks are common. The diagnosis is made by the physical and radiographic examination. Range-of-motion abnormalities of the hip, in particular limitation of internal rotation, abduction, and flexion, are almost universal. When flexing the hip from the extended position, the examiner will often note external rotation. Range of motion in all directions may be painful. The radiographic examination should include anteroposterior and frog-leg views of the pelvis. Changes on the anteroposterior film may be obscure. The slip is often seen more easily on the frog-leg view. Comparison with the normal side may assist in the diagnosis. However, 10% to 25% of slips may be bilateral (Fig. 114.47). When the diagnosis is equivocal, use of US, CT, MRI, or bone scintigraphy may be necessary.

Once diagnosis has been made, treatment should consist of strict non-weight bearing and an urgent orthopedic consultation. Prompt pinning is required to prevent further slippage. This may be performed the night of assessment or shortly thereafter, depending on the availability of anesthesia. There are those who advocate one-stage bilateral pinning as prophylaxis against contralateral disease once the diagnosis has been established.

Femoral Neck Fractures

Fractures of the femoral neck are relatively common. Initial treatment is traction and splinting followed by either closed or open reduction, depending on the position of the fracture. If the blood supply to the femoral head is damaged at the time of injury, osseous necrosis can occur. As would be expected, this complication is more likely with displaced than nondisplaced fractures. Overall, the incidence of osseous necrosis in this setting is 40% (Fig. 114.48). Stress fractures of the femoral neck are also being increasingly reported, generally in adolescents involved in repetitive activities such as long-distance running. Exercise-induced hip pain should prompt consideration of the diagnosis, which may require bone scanning or MRI study for confirmation. Early recognition is important because restriction of activity may allow healing and thus prevent progression to more complete fractures with displacement.

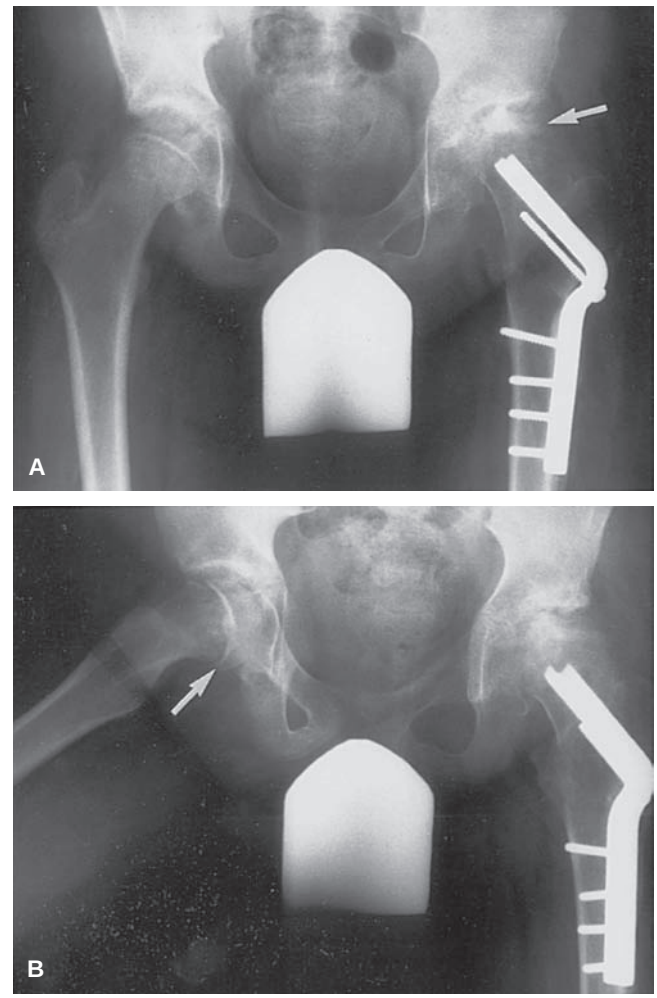

FIGURE 114.47 Radiographs of the hips of a teenager with bilateral slipped capital femoral epiphysis. **A:** Despite surgical intervention, significant avascular necrosis of the femoral head has occurred *(arrow)*. The right hip appears normal. **B:** On a simultaneous frog-leg view, however, it can be seen that the right capital femoral epiphysis has also slipped *(arrow)*.

Intertrochanteric Fractures

Although common in adults, intertrochanteric fractures are uncommon in children and adolescents. Nondisplaced or minimally displaced fractures can be treated easily in a spica cast for 6 to 8 weeks. If significant displacement occurs, internal fixation to restore the normal anatomy may be the best approach to treatment. The incidence of complications is low in this group of patients. The rate of osseous necrosis is approximately 5%.

Fractures of the Shaft of the Femur

Femoral shaft fractures occur in all age groups, from newborn to adolescents. Each group has its specific mechanisms of injury, complications, and treatments. The following age

FIGURE 114.48 Fracture of the right femoral neck in a 3-year-old girl.

FIGURE 114.49 Spiral fracture of the right femur in a 20-month-old boy *(arrow)*. In this instance, the injury occurred as the result of a motor vehicle accident. In general, spiral femur fractures in young children should prompt consideration of child abuse.

groups are considered: (i) birth to 2 years of age, (ii) 2 to 10 years of age, and (iii) adolescents.

Birth to 2 Years of Age

Most femoral fractures in the first 2 years of life result from either a slow twisting motion or a direct blow (Fig. 114.49). A large percentage of femoral fractures in this age group are the result of intentional trauma. Overhead skin traction, once the cornerstone of the treatment, has fallen out of favor because of reports of neurovascular compromise and skin problems. Treatment options include immediate spica casting or a short period of Buck's traction followed by spica casting. Shortening and angulation are rarely problems in this age group, although rotational deformity can occur if careful alignment is not maintained during casting.

2 to 10 Years of Age

Femoral fractures in children 2 to 10 years of age are most often the result of high-energy motor vehicle or automobile–pedestrian accidents. Concomitant injuries are common. Only rarely does an isolated femur fracture cause hemodynamically significant blood loss. Neurovascular evaluation should be performed and documented at regular intervals. Initial treatment consists of traction or splinting and care of other injuries (Fig. 114.50).

Distal femoral skeletal traction for several weeks followed by spica cast application has been the cornerstone of treatment in the past. More recently, early or immediate spica casting under general anesthesia has replaced traditional methods. This has reduced the hospital stay and costs, as well as alleviated the need for the invasive intervention of the traction pin placement. Contraindications to immediate or early spica casting are shortening greater than 2.5 cm, open fractures, and major concomitant injuries. The long-term complications of femur fractures in this age group include excessive shortening or overgrowth, malrotation, and malunions of the healing femur. It is usually desirable to leave the bone fragments overlapping by 1 cm to allow for some "overgrowth" of the healing femur. Stiffness of the knee and hip has been reported following prolonged spica casting treatment but is usually not a long-term complication.

Adolescents

Femur fractures in adolescents are also caused by high-energy accidents. Once again, attention to other injuries should

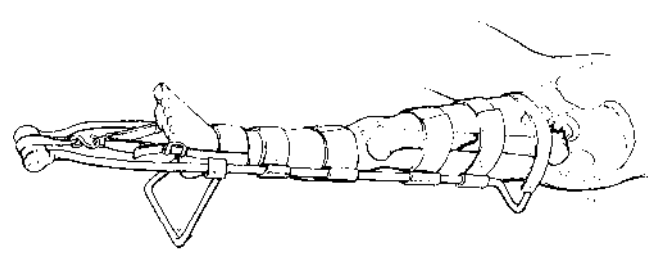

FIGURE 114.50 Use of a traction splint to stabilize femoral fractures is strongly recommended. Both adult and pediatric sizes are available.

precede treatment of the femoral fracture. Strong consideration would be given to a femoral nerve block that has been demonstrated as superior to intravenous narcotics for initial pain management. Stabilization with traction splints is adequate until an orthopedic consultation can be obtained. The management of these fractures has changed over the last several years. Closed reduction and intramedullary rodding are currently recommended to improve alignment and promote an early return to activity.

Injuries of the Knee

Although relatively uncommon, fractures about the knee arguably rank as the most serious long bone injuries in children and adolescents (Fig. 114.51). The growth centers of the distal femur and proximal tibia together account for two thirds of the length of the lower extremity. Growth arrest and deformity can occur after physeal injuries about the knee; the resultant limb-length discrepancies are hardly trivial problems. In contrast, ligamentous injuries are uncommon. For the purposes of discussion, pediatric knee injuries can be divided into the following groups: (i) ligamentous injuries and avulsion fractures, (ii) distal femoral physeal fractures, (iii) proximal tibial physeal fractures, (iv) knee dislocations, and (v) patellar fractures and dislocations.

Ligamentous Injuries and Avulsion Fractures

Compared with fractures of the epiphyses and physes about the knee, ligamentous injuries are relatively uncommon before growth plate closure. Such injuries do occur, however, both in isolation and in conjunction with fractures. Most ligamentous injuries result from direct trauma to the knee, typically when a child is struck by a motor vehicle while walking or riding a bicycle. Others occur during vigorous sporting activities when the knee is subjected to significant valgus or varus stress. The medial collateral and anterior cruciate ligaments are the ones injured most often, and injury to the latter almost invariably occurs in conjunction with an avulsion of the tibial spine. As

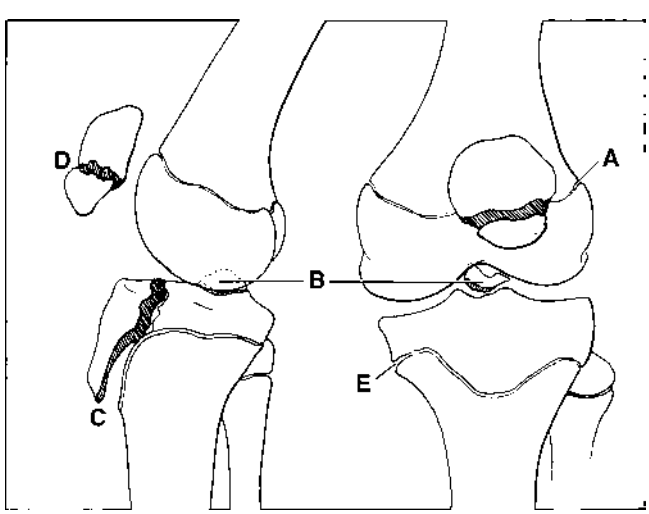

FIGURE 114.51 Common fractures of the knee in children: distal femoral physis (**A**), tibial spine (**B**), tibial tubercle (**C**), patella (**D**), and proximal tibial physis (**E**).

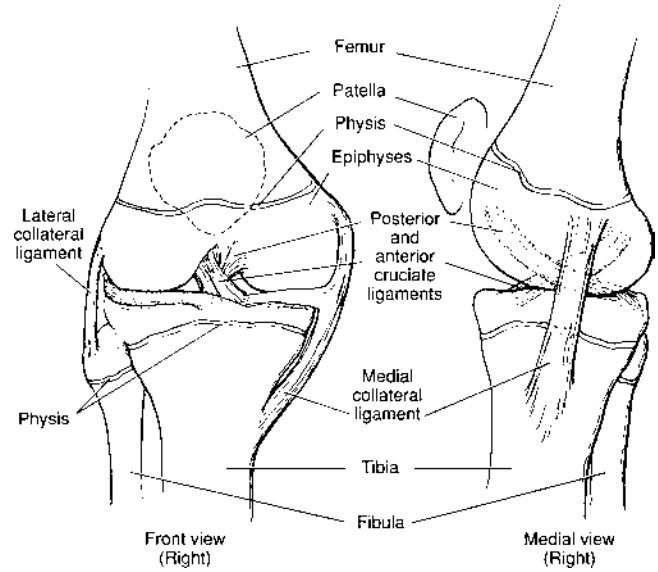

FIGURE 114.52 The ligaments of the knee. Proximally, both collateral ligaments attach to the epiphysis, whereas distally they attach to the tibia and fibula below the tibial epiphysis.

with adults, MRI studies may be necessary to define the true extent of the bony- and soft-tissue injuries.

Given the propensity for knee injuries in children younger than 14 years to result in fractures rather than ligamentous injuries, practitioners should have a low threshold for ordering radiographs. More recent studies validating the Ottawa knee rules in children provide clinicians with an evidence-based approach to imaging studies. Of the growth plates about the knee, the distal femoral physis is particularly vulnerable to injury. Both the medial and lateral collateral ligaments attach proximally to the distal femoral epiphysis. Their attachment to the tibia and fibula is distal to the epiphysis (Fig. 114.52). Given the relative strengths of the ligaments and the physeal plate, forceful valgus or varus stress results in distal femoral epiphysis separation rather than proximal tibial epiphysis injury or ligament rupture. Such injuries are discussed later in this chapter.

Avulsion of the tibial spine is the pediatric equivalent of an anterior cruciate ligament injury in an adult. The most commonly described mode of injury is hyperflexion of the knee during a fall from a bicycle. Significant pain and a refusal to bear weight are typical; a hemarthrosis is invariably present. Radiographic findings vary from minimal elevation of the anterior portion of the tibial spine (best seen on lateral views) to complete separation (Fig. 114.53). Incomplete separations can generally be managed by closed reduction with the knee held in extension. Open repair is necessary for complete avulsions and when closed manipulation does not lead to a satisfactory reduction. Arthroscopic evaluation of all tibial spine avulsions with instability on Lachman testing (see Chapter 38) has been advocated. Such an approach allows anatomic reduction of the injury with internal fixation and is believed to lead to a better long-term outcome. Immediate management in the ED should include splinting in extensions and arthrocentesis under sterile conditions when the hemarthrosis is causing severe pain.

FIGURE 114.53 Avulsion fracture of the tibial spine in a 9-year-old girl. A significant hemarthrosis was present and was aspirated. In an adult, the same mechanism of injury would have resulted in a tear of the anterior cruciate ligament.

FIGURE 114.54 A Salter-Harris type II fracture of the right distal femoral physis in a 9-year-old boy. Widening of the growth plate is seen medially *(large arrow)*, and a small metaphyseal fragment has been displaced laterally *(small arrow)*. Closed reduction was successful. In an adult, the same mechanism of injury would have resulted in a medial collateral ligament sprain or tear.

Another uncommon but severe knee injury observed in adolescents is an avulsion fracture of the tibial tuberosity. This fracture occurs essentially exclusively in boys 12 to 17 years of age who are involved in vigorous sporting activities. Most such injuries occur during jumping when the quadriceps is strongly contracted. If extension is impeded, as when a basketball player jumps to shoot but is blocked, or if the contraction of the quadriceps is particularly violent, as in high-jumping, the tibial tubercle can be torn either in part or in its entirety from the proximal tibial epiphysis. The result is a Salter-Harris type III fracture. Of note is that the patient often has an antecedent history of Osgood-Schlatter's disease. Once again, the severity of the injury dictates whether closed or open management is chosen.

Distal Femoral Physeal Fractures

Historically, fractures of the distal femoral epiphysis occurred when the leg of a child was caught between the wagon and the spokes of the wheel; thus, they were known as "wagon wheel injuries" during the nineteenth century. Today these injuries are caused by high-energy sports injuries, motor vehicle accidents, and falls from a height. Overall, this injury is rare because of the undulating course of the physis and the strong perichondrial ring that surrounds it. Of all the fractures involving the growth plate, however, injuries of the distal femoral physis have the highest incidence of posttraumatic growth arrest.

These injuries are described according to the direction of displacement of the epiphysis and the corresponding Salter-Harris classification. Most common is medial or lateral displacement with a fracture of the adjacent metaphysis (a Salter-Harris type II injury) (Fig. 114.54). As already mentioned, such injuries reflect a marked valgus or varus stress. The risk of neurovascular compromise is low, but peroneal nerve damage can accompany severe medial displacement. Even with adequate reduction, the incidence of premature growth arrest is significant. Somewhat less common is an anterior displacement of the distal epiphysis caused by hyperextension (Fig. 114.55). The risk of neurovascular compromise is high with this injury, which is the counterpart of a knee dislocation in an adult. Both compartment syndrome and direct compression of the neurovascular structures are well-recognized complications. Posterior displacement of the femoral epiphysis is uncommon but can occur as the result of a direct blow to the flexed knee. The preferred treatment of these injuries in the ED includes a thorough evaluation with splinting in place followed by prompt orthopedic consultation. Gentle closed reduction, often using general anesthesia, is usually successful. Postreduction remodeling cannot be assured because of the high rate of posttraumatic growth arrest associated with these injuries.

Proximal Tibial Physeal Fractures

Fractures of the proximal tibial physis are also rare. Hyperextension is the usual mechanism of injury. The sheer force tears the posterior periosteum and capsule of the knee, allowing a Salter-Harris fracture to occur through the growth plate. The emergency physician must recognize that the popliteal structures are tethered at this point and are therefore vulnerable to stretch or direct contusion at the time of injury. Careful, sequential neurovascular examinations are mandatory. Compartment syndrome should be considered. Closed or open

FIGURE 114.55 A Salter-Harris type I fracture of the right distal femoral physis with anterior displacement of the epiphysis in a 14-year-old boy. The injury resulted from a snowboarding accident.

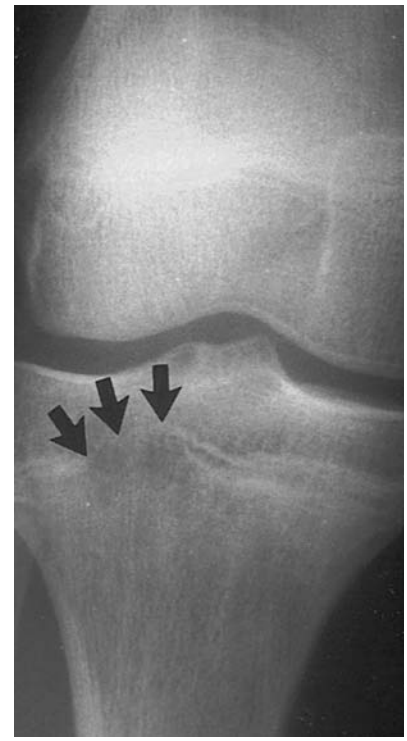

FIGURE 114.56 Although the original injury was only a Salter-Harris type I fracture of the proximal tibial physis, premature closure of the physis occurred *(arrows)*. All fractures involving the proximal tibial growth plate require orthopedic referral.

reduction will be necessary after stabilization. Complications after the injury include recurrent deformity, growth arrest, and limb length inequality (Fig. 114.56).

Knee Dislocations

Complete dislocation of the femorotibial joint, another hyperextension injury, is extremely uncommon in children. As a rule, hyperextension is much more likely to cause a distal femoral epiphyseal separation than a dislocation. Given the high likelihood of neurovascular compromise or compartment syndrome in this setting, femorotibial dislocation is considered a true emergency. A reduction maneuver may be attempted in the ED under intravenous sedation. Axial traction of the tibia with slow flexion of the knee from an extended position may lead to a reduction. Following a closed reduction, an arteriogram must be obtained to rule out an intimal tear of the popliteal artery. Definitive care of the torn ligaments resulting from this injury will ultimately be necessary.

Patellar Fractures and Dislocations

Unlike in the adult, the patella in the child is rarely fractured because of the thick covering of cartilage overlying the patella during growth and development. Fractures of the patella in adolescents are more common and present as avulsion fractures from dislocations, osteochondritis desiccans caused by overuse, symptomatic bipartite conditions, avulsion or "sleeve" fractures, and the occasional transverse displaced fracture (Fig. 114.57).

Diagnosis of a patellar fracture may be difficult. A congenitally bipartite patella can be easily confused with a fracture. In this case, an accessory ossification center is located along the superior lateral margin of the patella. The margins are smooth and rounded. A comparison view of the opposite knee may assist in the diagnosis. Sleeve fractures of the patella, in particular, can easily be misdiagnosed on radiograph. The sleeve fracture occurs when the lower half of the cartilage cap is pulled free by the patellar ligament. The visible bony portion

FIGURE 114.57 Transverse fracture of the patella in an 11-year-old victim of a motor vehicle accident *(arrow)*.

FIGURE 114.58 Radiograph demonstrating a sleeve fracture of the patella in a 10-year-old male. The inferior pole of the patella is displaced anteriorly *(curved arrow)*. The bone fragment seen *(large arrow)* was avulsed by, and remains attached to, the patellar tendon.

of the patella is displaced cephalad by the quadriceps mechanism. Often, a small fleck of bone is identified at the superior margin of the patellar ligament (Fig. 114.58). Pain usually prevents active extension of the knee.

The preferred treatment of patellar fractures parallels that of adults. Conservative care is the cornerstone of treatment in nondisplaced fractures. Cylindrical cast treatment from 4 to 6 weeks will result in union. Fractures that are displaced more than 3 to 4 mm are best treated with open reduction and internal fixation. Complications after patellar fractures include knee stiffness, quadriceps atrophy, extensor lag, and persistent pain.

Dislocation of the patella can be classified as an acute or chronic recurrent subluxation or as a dislocation. An acute traumatic dislocation of the patella results from a force displacing the patella laterally while the foot is planted. The patella may reduce spontaneously or may remain dislocated. Examination of the patient reveals an acutely swollen knee with pain to palpation noted along the medial patellar retinaculum. When reduction has already occurred, displacement of the patella laterally will usually elicit an apprehension sign. The patient may state that he or she feels like the kneecap is going to "pop out." When the patella remains dislocated, the diagnosis is readily apparent by clinical and radiographic examination. Reduction of a dislocated patella is usually accomplished easily with extension of the knee and a medial upward force on the lateral patella (see Section VII "Procedures"). Following reduction of an acutely dislocated patella, the physician must exclude the presence of an osteochondral fracture of the lateral femoral condyle or the medial patellar facet. Such fractures may be difficult to identify from a radiographic examination. Physical findings consistent with intraarticular loose bodies should suggest the diagnosis.

Chronic recurrent patella subluxation or dislocation is much less likely to result in osteochondral fractures. Predisposing factors include lateral femoral condyle hypoplasia, a loose medial patellar retinaculum, genu valgum, external tibial torsion, and quadriceps weakness. The initial treatment of a dislocated patella should consist of a thorough examination, followed by closed reduction. Immobilization in an above-the-knee posterior splint or a commercially available knee immobilizer for 4 weeks is the appropriate ED management. Orthopedic referral is recommended.

Fractures of the Tibia and Fibula

Fractures of the tibia and fibula in children can be divided into the following groups: (i) proximal tibial metaphyseal fractures, (ii) tibial and fibular shaft fractures, and (iii) toddler's fractures.

Fractures involving the distal growth plates of the tibia and fibula are discussed with ankle injuries.

Proximal Tibial Metaphyseal Fractures

Although usually easy to manage, proximal tibial fractures can lead to two major complications, namely, compartment syndrome and progressive posttraumatic valgus deformity (Fig. 114.59). As in other settings, a careful clinical evaluation followed by direct measurement of compartment pressure is the key to the diagnosis of compartment syndrome. Progressive valgus deformity can develop after any proximal tibial injury, including greenstick and nondisplaced fractures. Deformity has been known to develop even after anatomic reduction of fracture fragments. It is speculated that stimulation of the

FIGURE 114.59 Nondisplaced proximal tibial metaphyseal fracture in an 11-year-old girl *(large arrow)* through a nonossifying fibroma *(small arrows)*. Orthopedic consultation is mandatory both because the fracture is pathologic and because it is located in the proximal tibia.

physis from hyperemia causes asymmetric growth of the proximal tibial physis. Given the propensity for growth deformity, all fractures of the proximal tibial metaphysis should be managed by an orthopedic surgeon.

Tibial and Fibular Shaft Fractures

Fractures of the tibial and fibular shafts are the most common fractures of the lower extremity in children. The diagnosis is usually apparent by physical and radiographic examination. Most tibial and fibular fractures are stable and in acceptable alignment (Fig. 114.60). Discussion with an orthopedic consultant helps decide whether any reduction is necessary. In children, these fractures rarely persist because of delayed union or nonunion. Healing time is quick, averaging 6 to 8 weeks. If the neurovascular status is normal, no signs of compartment syndrome are present, and the fracture configuration is deemed acceptable, a long leg posterior splint may be applied and orthopedic referral within the next few days arranged.

FIGURE 114.60 Nondisplaced transverse fracture of the distal tibia in a 3-year-old girl. Immobilization in a long leg posterior splint with orthopedic follow-up within 3 to 5 days would be adequate emergency treatment. The potential for growth deformity is low.

Otherwise, more immediate consultation should be sought. (Most cases of compartment syndrome result from minor closed tibial fractures; with more severe injuries, the interosseous membrane typically is torn, allowing decompression of the anterior compartment.)

The indications for open treatment of tibial and fibular shaft fractures in children include open fractures, compartment syndrome, ipsilateral femur fractures, and concomitant severe head injuries. Complications of treatment after tibial and fibular fractures include malunion, limb-length inequality, malrotation, and neurovascular deficiency.

Special consideration must be given when evaluating tibial injuries in children with paraplegia. They present with warmth and swelling over the leg or joint, which may suggest infection or inflammatory conditions rather than fractures. When identified, the fracture may be treated in a conservative manner with splints or a short 3- to 4-week period of casting.

Particular note should be made as well of the fact that the tibia and the fibula are the most common sites of stress fractures in children. Overall, the proximal third of the tibia is most often affected. The history is usually that of pain and a limp of gradual onset in a child 8 to 15 years of age. Localized swelling and tenderness are present to varying degrees. Radiographs may appear normal, show limited cortical changes, or demonstrate subperiosteal new bone formation. Bone scintigraphy confirms the diagnosis in uncertain cases (Fig. 114.7). Rest is the only treatment needed.

Toddler's Fractures

Occasionally, the emergency physician is asked to evaluate a young child with an acute gait disturbance, namely, a limp or a refusal to walk. The differential diagnosis is a broad one (see Chapter 42). One possibility that should always be considered is that of a toddler's fracture. Originally, the term *toddler's fracture* referred to an oblique nondisplaced fracture of the distal tibia in children 9 to 36 months of age. The term is now used more loosely.

In most cases, the history is that of a minor accident, such as a fall from a seemingly insignificant height or while walking or running. No history of injury may be recalled in some instances. The physical findings are often subtle and at best difficult to elicit unless a gentle, unhurried examination is performed while the child is calm. The degree of swelling is minimal; warmth and tenderness are more commonly detected but are not uniformly present. Gentle twisting of the lower leg will elicit pain on occasion.

Like the physical findings, the radiographic abnormalities are often subtle. The anteroposterior or lateral views may reveal a spiral or oblique fracture extending downward and medially through the distal third of the tibia. If a toddler's fracture is suspected clinically but the routine radiographic views are normal, an internal oblique projection should be ordered. Consideration should also be given to the possibility of a fracture elsewhere in the limb; fractures of the femur, the foot, and

FIGURE 114.61 Toddler's fracture of the distal tibia *(arrows)*. The fracture line could not be demonstrated radiographically until 2 weeks after the onset of symptoms.

rarely, the pelvis can also present with an acute limp. If no fracture is visualized on routine radiographs, a US or a bone scan may be considered. Digital radiographs may also provide increased sensitivity compared with traditional plain films. Alternatively, if symptoms persist, it is certainly reasonable to repeat the plain films after 10 days, at which point subperiosteal new bone formation may be evident or enough sclerosis may have occurred at the fracture edges to render it visible (Fig. 114.61). Immobilization provides symptomatic relief and promotes healing, although no treatment may be necessary if the history suggests that the fracture occurred several weeks before actual diagnosis.

If a toddler's fracture is a spiral one and the caregivers can recall no specific time of injury, suspicions of child abuse may understandably arise. Notably, midshaft fractures are more common in abused children, and most toddler's fractures are distal injuries. When other circumstances or injuries suggestive of abuse are found or when spiral fractures occur in children who are not yet ambulating, the strong possibility of nonaccidental injury should obviously be seriously considered.

Injuries of the Ankle and Foot

Injuries of the ankle and foot in the pediatric age range can be divided into the following groups: (i) ankle sprains, (ii) distal tibial and fibular fractures, (iii) hindfoot and midfoot fractures, and (iv) metatarsal and phalangeal fractures.

Ankle Sprains

Adolescents often present to the ED complaining of ankle injuries (see Chapter 36). The differential diagnosis includes ligamentous injuries; nondisplaced Salter-Harris type I fractures; osteochondral fractures of the tibia, fibula, or talus; and avulsion injuries. Once again, before growth plate fusion, physeal injuries are much more likely than ligamentous injuries. Ligamentous injuries are certainly observed in older adolescents. The most common mechanism is adduction and inversion of the foot while it is held in plantar flexion. Of the three lateral ankle ligaments, the anterior talofibular ligament is the one most commonly injured. Injury to this ligament should be suspected when palpation just anterior to the distal fibula elicits maximal tenderness. Ankle sprains are graded from I to III. In grade I injuries, ligaments are stretched but not torn. Grade II injuries include partial ligament tears without loss of stability. Complete tears of the ligamentous complex with loss of stability are present in grade III injuries. Other than with minor injuries, a three-view radiographic examination should be performed. As with adults, use of the Ottawa ankle rules, including by nursing personnel, can guide the need for radiographic studies. If the stability of a ligament is in question, stress views are recommended.

Controversy exists regarding the appropriate care of ligamentous injuries. One schema is based on the severity of the ligamentous damage. Grade I mild sprains can be treated with an elastic wrap or air splint followed by ice, elevation, and compression for 72 hours. Crutches may be used until the patient is able to walk without a limp. Grade II and grade III injuries should be immobilized either in a cast or a posterior splint. (Because posterior splints break relatively easily, use of fiberglass and/or reinforcement with a stirrup is recommended.) Crutches are used initially. Ambulation in a cast for 3 weeks aids in initial scar formation and healing. This conservative approach with more severe sprains may help prevent recurrent ankle sprains in active athletic adolescents, as may physical therapy once the injury has healed.

Distal Tibial and Fibular Fractures

Although any Salter-Harris type I through V fracture may occur in distal physes of the tibia and fibula, several specific injury patterns are described and discussed here. Fractures involving both the growth plate and the ankle joint often need open reduction and internal fixation to ensure adequate reduction of both the physis and the joint. Only minimal amounts of displacement can be accepted at the articular surface, or altered joint mechanics will develop with possible posttraumatic pain, stiffness, and arthritis.

Of the fractures of the distal fibula, a Salter-Harris type I injury is the most common. Tenderness and swelling are present over the growth plate on physical examination. Often the only radiographic finding is soft-tissue swelling overlying the distal fibula (Fig. 114.62). When suspicions of a Salter-Harris type I injury are high, a short leg cast may be applied at the time of initial evaluation. When the diagnosis is less certain, immobilization with a repeat examination in 1 week to 10 days is recommended. If tenderness persists, a presumptive diagnosis of a nondisplaced type I fracture should be made and a short leg cast, a fiberglass boot, or a posterior splint should

FIGURE 114.62 Radiograph of the left ankle of a 10-year-old boy notable only for soft-tissue swelling localized to the distal fibula *(arrows)*. The presumptive diagnosis must be a Salter-Harris type I injury of the fibula.

FIGURE 114.63 Classic Tillaux fracture of the distal tibia in a 14-year-old boy. The fracture line runs vertically through the epiphysis *(small arrow)* and then laterally along the physis *(large arrow)*. The lateral portion of the physis is widened.

be applied. After 10 days, repeat radiographs may reveal periosteal changes confirming the presence of a fracture. In most cases, a total of 3 weeks of immobilization is adequate.

Although type I injuries of the tibia are uncommon, type II injuries are often observed, usually in combination with a greenstick fracture of the fibula. The mechanism of injury is plantar flexion with eversion. Closed reduction and a long leg cast application usually lead to a satisfactory recovery. Growth disturbance is unusual.

The Tillaux fracture is a Salter-Harris type III injury of the ankle joint that occurs as the medial distal tibial physis begins to close in adolescents who are nearing skeletal maturity (Fig. 114.63). During external rotation of the foot, the anterior tibiofibular ligament avulses the lateral epiphysis from the medial malleolus. When displacement occurs, open reduction with internal fixation is required to ensure restoration of joint anatomy.

The triplane fracture is a complex but uncommon ankle injury that is a combination of a Salter-Harris type II fracture and a Tillaux fracture. The resultant type IV injury may appear innocuous on the anteroposterior and lateral radiographs, but the degree of growth plate damage is generally significant. Suspected triplane fractures should be evaluated by CT scan to delineate the amount of displacement at the physis and the articular surface, and to determine the number of fracture fragments (Fig. 114.64).

The treatment of physeal and ankle fractures depends on the type of fracture, the amount of displacement, and the patient's age. Nondisplaced fractures may be treated with a bulky posterior splint, crutches, and a referral to the orthopedist. Immediate orthopedic referral is otherwise necessary.

Hindfoot and Midfoot Fractures

Fractures of the foot in children are uncommon and lead to few complications. Fractures of the hindfoot, which consists of the talus and the calcaneus, are particularly uncommon. In more recent years, however, fractures of the lateral process of the talus have become more common in the pediatric age group, primarily as the result of the increasing popularity of snowboarding. Not surprisingly, clinicians familiar with this entity commonly refer to it as the "snowboarder's fracture." When fractures of the hindfoot do occur, they are usually obvious because of swelling, pain, and occasionally, deformity. "Occult" fractures of the calcaneus have been increasingly recognized in children younger than 3 years. Pain with dorsiflexion may indicate a talar neck fracture. If suspicions of a fracture are high but routine radiographs are normal, additional views and/or bone scintigraphy may be necessary. Because calcaneal fractures generally occur as the result of a fall from a height, associated compression fractures of the spine can occur and must be considered. Treatment of hindfoot fractures are dictated by the amount of displacement. Often, a bulky posterior splint, crutches, and no weight-bearing will suffice until an orthopedic consult can be obtained. Complications include osseous necrosis of the talus and chronic pain from calcaneal fractures.

Fractures of the midfoot include the navicular; the cuboid; and the first, second, and third cuneiforms. Fractures of these bones are extremely unusual and usually form part of a more severe injury to the foot (Fig. 114.65). They can be produced by blunt trauma, in which case soft-tissue damage is usually significant and a potential for neurovascular compromise results. Occasionally, an accessory ossification center on the medial side of the navicular may be confused with a fracture.

Although well documented in the adult literature, tarsal/metatarsal fracture–dislocations have received little attention in children. These injuries present with swelling and tenderness over the dorsum of the foot. Radiographs, including anteroposterior, lateral, and oblique views, may be necessary to identify subtle abnormalities. Once again, treatment is based on the severity of the injury with reduction and stabilization necessary, if more than 2 mm of displacement is identified.

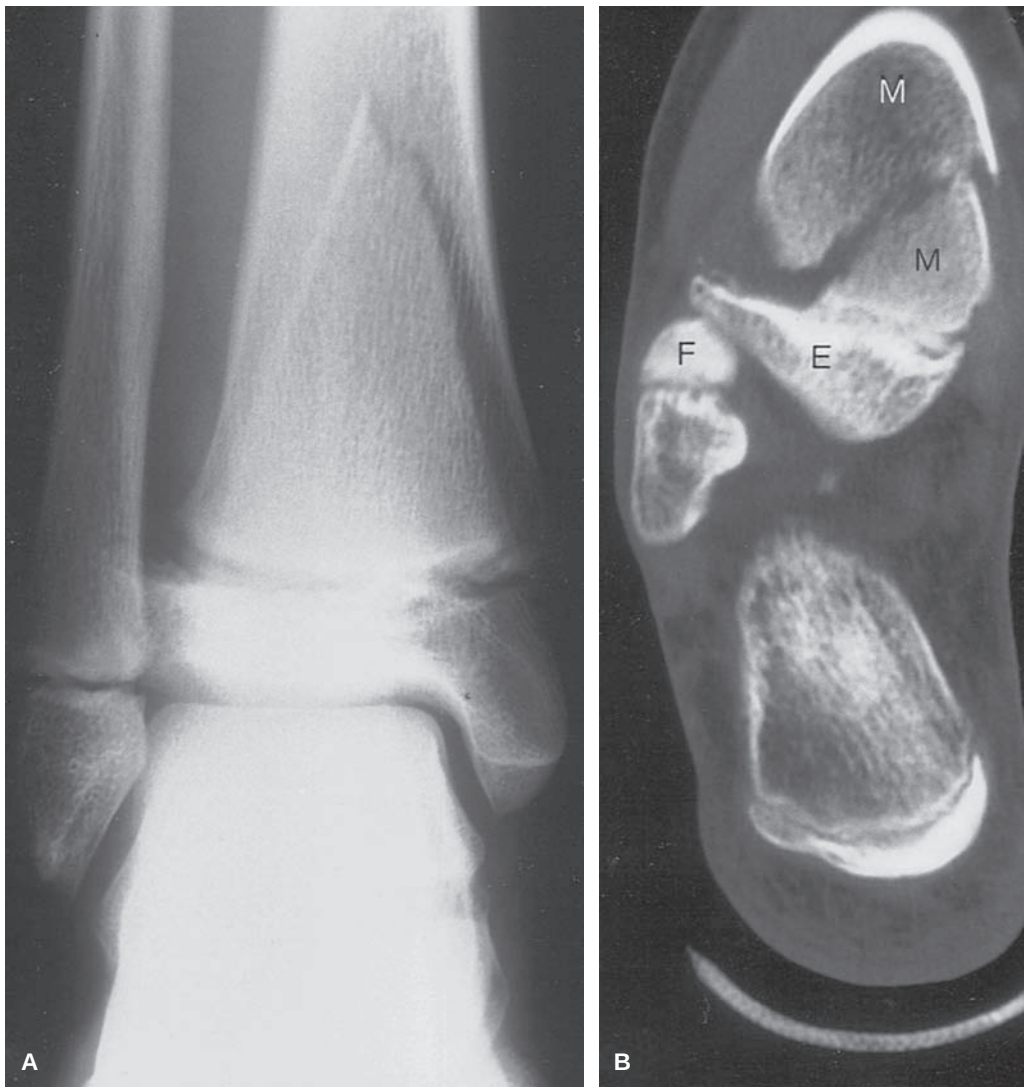

FIGURE 114.64 **A:** A triplane fracture was suspected from the plain film of the right ankle of this 11-year-old girl, although no clear epiphyseal fracture line could be seen. **B:** The coronal computed tomography scan made it possible to establish that the injury was indeed a Salter-Harris type II injury rather than the triplane fracture suspected. The fracture line runs laterally along the growth plate. E, epiphysis; F, fibula; M, tibial metaphysis.

FIGURE 114.66 Displaced fractures of the right second, third, and fifth proximal phalanges in a 7-year-old girl *(arrows)*. Stability and proper healing of the fractures of the second and third toes could be guaranteed only with pinning.

Metatarsal and Phalangeal Fractures

Metatarsal and phalangeal fractures are common in children. The diagnosis is not difficult because pain, swelling, and occasionally a deformity accompany the fracture. Radiographic evaluations should include anteroposterior, lateral, and oblique views. The possibility of compartment syndrome must be kept in mind with crush injuries or multiple fractures in the midfoot or forefoot.

Two fractures that occur commonly at the base of the fifth metatarsal bear mentioning. The Jones fracture is a fracture at the diaphyseal–metaphyseal junction at the base of the fifth metatarsal. Although more common in adults, reports in adolescents can be found. This fracture has a high incidence of delayed or nonunion and should be splinted and referred to an orthopedist. An avulsion fracture of the base of the fifth metatarsal at the site of attachment of the peroneus brevis is relatively common in children. This fracture occurs more proximally than the Jones fracture and has a better prognosis. The usual treatment is 3 to 6 weeks of immobilization in a weight-bearing cast. When considering the possibility of a proximal fifth metatarsal fracture, care should be taken to distinguish a fracture fragment from the accessory ossification center found in the same location.

The care of most metatarsal and phalangeal injuries is relatively straightforward. If the fracture is nondisplaced or minimally displaced with little angulation, as is the usual case, a bulky splint can be applied and crutches prescribed. Intra-articular fractures of the big toe and significantly displaced fractures of the other toes often require pinning (Fig. 114.66). Buddy taping and hard-soled shoes provide adequate stabilization for most other phalangeal fractures.

INJURIES OF THE THORACOLUMBAR SPINE

Fortunately, injuries to the spine are rare in children and adolescents. When a child does have a spine injury, distinguishing what is normal from what is abnormal on plain radiographs can be extremely challenging. The advent of CT scans and MRI has made evaluation of spinal injuries much less problematic.

The child's spine differs from the adult's in that growth plates are present, the proportion of cartilage is higher, and the overall flexibility is greater. Because of the overall high elasticity of the pediatric spine, significant spinal cord injury can occur in the absence of radiographic signs of bony injury. By adolescence, the spine has mechanical qualities more like those of the adult, and the fracture patterns are similar. Unlike in adults, the risk of posttraumatic scoliosis after a complete spinal cord injury in children is extremely high.

In general, any child with significant head or multisystem injury should be assumed to have a spinal injury until proven otherwise. Diagnosis of a spinal injury in the child with a severe brain injury can be particularly problematic. However, certain physical findings can suggest the possibility of a coexisting spinal cord injury and should be sought routinely whenever a child with a severe head injury is examined. These findings include asymmetry of movement and reflexes between the arms and legs, absence of sacral reflexes, lax anal tone, priapism, spinal shock, autonomic hyperreflexia, diaphragmatic breathing, and urinary retention, as well as any evidence of a motor or sensory deficit level. When a child is sedated and/or paralyzed, as is often the case when a child has a severe brain injury, many of these findings will be particularly difficult to elicit. Therefore, spinal immobilization must always be maintained until a more detailed neurologic examination becomes possible. Another setting in which spinal cord injuries are overlooked on occasion is that of the lap belt complex, which is discussed in the following section.

It is important to classify spine injuries according to the neurologic deficits to make possible a determination of prognosis. A complete lesion involves the entire cord at a given level with no motor or sensory function below that level. An incomplete lesion is associated with sparing of function or sensation below the level of injury; the degree of motor deficit is generally greater than the degree of sensory loss. After a thorough neurologic examination, a complete radiographic evaluation is necessary to determine the stability of the fracture. When faced with equivocal radiographs, flexion–extension views, CT scans, and MRI should be considered. Patients with a neurologic injury should be considered to have an unstable fracture until proven otherwise.

Initial treatment in the ED must focus on maintaining the stability of the spine with a backboard and a cervical collar. Patients should not be moved unless absolutely necessary. Patients can be logrolled to inspect the spine as long as flexion, extension, or twisting movements do not occur. After stabilization of the patient and the spinal column, orthopedic and neurosurgical consultations should be obtained. Early intervention can decrease the risk of further injury to the spine in unstable, incomplete spinal injuries. Although a large multicenter trial suggested that administration of high-dose corticosteroids within 8 hours to teenagers and adults with acute spinal cord injury improves neurologic recovery, subsequent analysis of the data from this study and further investigations have not supported the initial recommendations from this group. Thus, most experts do not routinely administer corticosteroids. If a decision is made in favor of corticosteroids, according to the protocol, methylprednisolone 30 mg per kg should be administered intravenously over 15 minutes. An infusion of 5.4 mg per kg per hour should then be begun 45 minutes after the completion of the bolus.

Fractures of the spine in children and adolescents can be divided into the following groups based on the mechanism of injury and the radiographic appearance: (i) compression fractures, (ii) flexion and distraction fractures, (iii) shear fractures, and (iv) neurologic injuries without fractures.

Compression Fractures

Compression fractures result from hyperflexion producing an axial load and causing failure of the anterior vertebral body. Multiple fractures are the rule rather than the exception; the first lumbar vertebra is the most commonly injured segment (Fig. 114.67). A CT scan should be considered if there is evidence of multiple level fractures or when plain radiographs suggest the possibility of a retropulsed fragment. Compression fractures heal quickly in children and have little tendency to progress. Many children do not require hospitalization for compression fractures and can be treated with bed rest and symptomatic mobilization. Occasionally, a well-molded thoracolumbar sacral orthosis may be necessary for persistent pain or multiple areas of compression.

Flexion and Distraction Fractures

Flexion–distraction injuries are rare in the immature spine. When they do occur, the most common mechanism of injury is hyperflexion over a seat belt during sudden deceleration in a motor vehicle accident. Associated intraabdominal injuries, particularly tears and transections of the duodenum, jejunum, and mesentery, are common. This combination of spinal and abdominal injuries is often referred to as either the seat belt syndrome or the lap belt complex. The tendency for lap belts to ride higher on children than the recommended position across the iliac crest combined with their relatively higher center of gravity predisposes them to both the abdominal and spinal injuries. A so-called seat belt sign, an abdominal contusion in a band corresponding to the seat belt, is often observed. Instances in which diagnosis of the spinal injury has been delayed because of the presence of the abdominal injury, as well as the reverse, have been described; the discovery of one component of the lap belt complex should obviously prompt a search for the other.

The lumbar spine is most commonly injured as the result of hyperflexion over a seat belt. Among the spinal injuries that can occur are distractions, subluxations, facet dislocations, and ligamentous ruptures, as well as fractures, including compression fractures as previously discussed. One particular fracture, the Chance fracture, merits special mention. A horizontal splitting through both the body and posterior elements of a vertebra, the Chance fracture was formerly thought to occur exclusively in adults. It is now recognized that the same fracture pattern occurs in children, almost always as a seat belt injury (and, once again, often in combination with an abdominal injury). Most Chance fractures are stable; associated neurologic injury is uncommon. Immobilization with a well-molded orthosis for several months is generally adequate treatment.

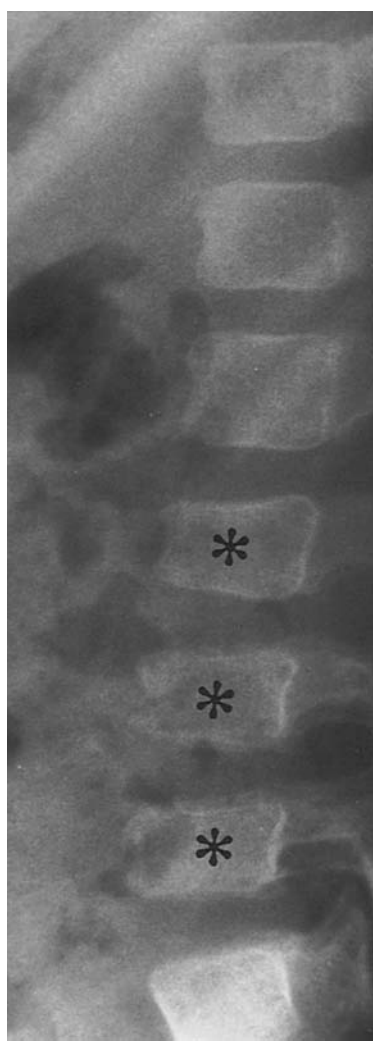

FIGURE 114.67 Compression fractures of the lumbar vertebrae in a 3-year-old boy *(asterisks)*. Multiple fractures are the rule in children.

Shear Fractures

Although the cervical spine is most vulnerable to shear injuries, violent trauma can also cause such injuries in the thoracic and the lumbar spine (Fig. 114.68). Unfortunately, neurologic deficits are common in this setting. All shear fractures should be considered unstable injuries that will need stabilization procedures to avoid progressive deformity and enhance any possibility of neurologic recovery.

Neurologic Injuries Without Fractures

It is well known that the immature spine is more flexible than the spinal cord. Injuries causing hyperflexion or extension may produce damage to the cord and neurologic injury while leaving the bony, cartilaginous, and ligamentous structures intact. Termed SCIWORAs (spinal cord injury without radiographic abnormality), two thirds of such injuries occur in children younger than 8 years. Cervical and thoracic spine injuries are the most common. Both incomplete and complete neurologic deficits can occur. Any history of neurologic deficit following spinal trauma should prompt consideration of a SCIWORA. As for radiographic evaluation, MRI can best identify cord damage in the absence of a fracture. To reemphasize, in all cases of severe trauma, spinal immobilization must be maintained until the patient's condition permits a satisfactory neurologic examination.

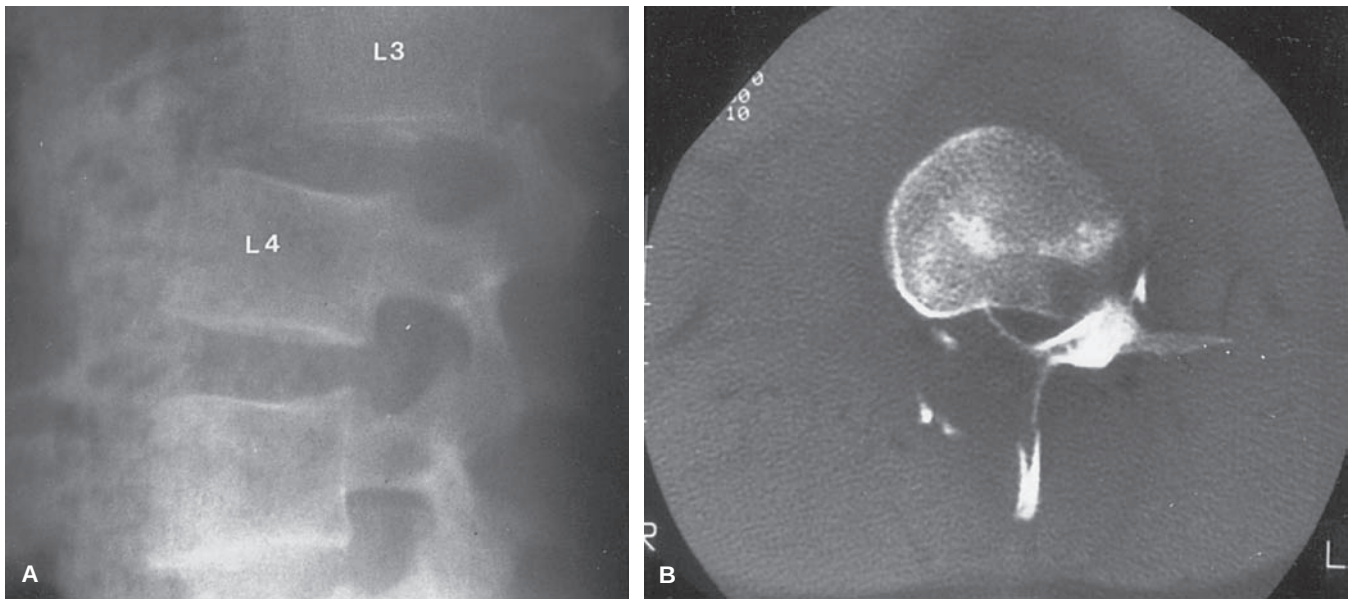

FIGURE 114.68 **A:** Fracture dislocation of the third (L3) and fourth (L4) vertebrae in a 12-year-old girl, the result of a shear injury in a motor vehicle accident. **B:** Permanent paralysis of the lower extremities resulted, as suggested by the degree of spinal canal collapse seen on the computed tomography scan.

CHAPTER 115 ■ NECK TRAUMA

GEORGE A. WOODWARD, MD, MBA

Pediatric neck injuries, fortunately, are uncommon. Many children are evaluated for cervical spine injuries secondary to trauma but few have their injuries identified. Even fewer children are evaluated for penetrating or direct blunt trauma to the neck. However, because neck injuries can be life threatening, they need to be assessed in a timely and orderly manner. It is imperative to appreciate how apparently minor or innocuous neck injuries can progress rapidly to more serious and life-threatening events. Subtle neck injuries can be easily overlooked in a patient with obvious head or chest trauma. This chapter initially discusses evaluation and management of penetrating and direct blunt injuries and then concentrates on the evaluation of the cervical spine.

When considering injuries to the neck in a child, initial management must include immediate assessment of airway, breathing, and circulation (ABCs) and treatment of abnormalities, careful not to allow an injury to progress to a more significant event. Airway abnormality may be subtle but progressive, with the precipitating injury not obvious on initial examination. Treatment should be safe and supportive and may include options within treatment categories, such as fiberoptic intubation and surgical airway placement depending on the nature and severity of the injury. Patients should be monitored closely and physically observed during their emergency department (ED) stay. A listing of common mechanisms of neck injury is given in Table 115.1.

There are several differences in neck anatomy between children and adults. The child's relatively large head and mandible and short neck make the anterior neck less accessible to direct trauma but may increase the possibility of acceleration/deceleration injuries to the cervical spine. The increased potential for acceleration/deceleration injuries is partially offset by the elasticity of the pediatric cervical spine and the child's light weight. Internal neck anatomy also differs from that of an adult and may influence the types of injuries seen. The cricoid ring is the narrowest portion of the airway and is located at the C4 level, as opposed to the adult location at C7. The arytenoids are proportionately larger, and the child's cartilage is more pliable and easily damaged.

The soft tissues and visceral components of the neck are protected by the spine posteriorly, the mandible anteriorly and superiorly, the shoulders and clavicles anteriorly and inferiorly, and the neck muscles. The head and chest of the child protrude more anteriorly than the neck and often absorb most blunt traumatic force, lessening the chance of a direct neck injury. Most injuries to the neck involve forces with relatively large masses and slow velocity, which partially account for the low incidence of serious direct trauma in this population. If the neck is hyperextended, however, the structures of the anterior neck, including the larynx, trachea, and esophagus, are more susceptible to direct trauma. The large number of vital organs and structures in the relatively small neck area enhances the potential severity of direct penetrating or blunt injuries (Table 115.2).

The neck can be divided into three anatomic zones (Figs. 115.1 to 115.3). Zone I encompasses the area between the thoracic inlet and the cricoid (the lower boundary of zone I is the thoracic inlet, the upper boundary is most often classified as the cricoid); zone II is the area between the cricoid and the angle of the mandible, the most common site of significant penetrating injuries; and zone III is the area above the angle of the mandible. Knowledge of the divisions and structures they contain is useful in the evaluation and management of neck trauma (Fig. 115.1 to 115.3). Lesions in zones I and III are often occult and difficult to diagnose by physical examination alone. Operative exploration is more difficult in zones I and III than in zone II, where injury presentation and surgical exploration are often more straightforward. The neck can also be divided into anterior and posterior elements, with the dividing line being the palpable transverse processes of the cervical spine. The posterior neck contains muscles with their individual nerve supplies and the posterior elements of the cervical spine, and the anterior neck houses most vital organs and structures. No major vascular components are contained in the posterior area of the neck. Morbidity and mortality with neck injuries result from central nervous system trauma, airway compromise, exsanguination, vascular disruption or thrombosis, venous embolism, sepsis, or mediastinitis.

PENETRATING TRAUMA

Penetrating neck trauma is uncommon in children. Penetrating trauma may be associated with extracervical injuries and may involve multiple organ systems within the neck. Most pediatric penetrating trauma is the result of a wound from a gunshot (usually low velocity), knife, broken windshield, other sharp object, or explosion (Table 115.1). The history is important in the evaluation of penetrating neck trauma. Inquiries about the mechanism of injury, time of incident, events before arrival in the ED, amount of blood loss, history of pulsatile lesions, neurologic dysfunction (including transient ischemic attack, limb paresthesias, hemiplegia, blindness, Horner's syndrome, and aphasia), and airway compromise should all be noted. In particular, knowledge of the mechanism of injury can help direct the management of both the stable and unstable patients. The mortality rate with

TABLE 115.1

COMMON MECHANISMS OF BLUNT AND PENETRATING NECK INJURIES

Penetrating trauma	Blunt trauma
High-velocity missiles	Motor vehicle accidents, including motorcycles and all-terrain vehicles
Low-velocity missiles	Sports
Knives	Fights
Windshields	Falls
Sharp objects	Clothesline injuries
Explosions	Bicycle handlebars
Dog bites	Dog bites
Iatrogenic (intubation, endoscopy, gastric tubes)	Barotrauma (bottle cap under pressure or compressed air source)
	Nonaccidental (abuse)
	Exposures (fires, caustics)

penetrating neck trauma is between 3% and 6% with or without surgical exploration. Common causes of death include vascular, neurologic, and airway injuries.

Most gunshot wounds seen in pediatric patients involve low-velocity weapons, including handguns (90 m per second) or shotguns (300 m per second), at ranges of more than 5 m, as opposed to shotguns at close range or military-style weapons (760 m per second) (Fig. 115.4).

Unlike higher-velocity missiles, low-velocity missiles tend to be redirected when they encounter vascular or other structures. Visceral injuries may be anticipated but not completely predicted by the path of the missile. Internal injuries may be more predictable with an isolated knife wound. Low-velocity neck wounds are associated with major pathology in approximately 50% of cases compared with more than 90% with high-velocity missiles.

Vascular injury is the most common complication of penetrating trauma and is the second most common cause of death. Injuries include aneurysms, dissections, occlusions, and fistulas. History of large blood loss, pulsatile lesion, rapidly expanding hematoma, hypovolemic shock, or neurologic deficits (paresis, visual loss or aphasia, altered level of consciousness) indicates the possibility of cervical arterial injury. Major vessels that can be injured in the neck include the common, internal, and external carotid arteries; vertebral arteries; internal and external jugular veins; and nearby innominate and subclavian vessels (Table 115.2). Injury to the vessels can be dramatic, with exsanguination, rapidly expanding hematoma causing airway compromise, acute neurologic deficits from ischemia or hypoperfusion, or venous air embolism, or it may be subtle with an initially normal examination. Approximately one-third of arterial injuries present with neurologic deficits, whereas the remaining two-thirds are often more challenging to diagnose. The symptoms and signs suggestive of vascular and other neck injuries are presented in Table 115.3. Completely transected arteries often retract and contract with minimal bleeding. Vessels that are partially severed may continue to bleed significantly with normal pulses because blood flow may not be totally interrupted. Vascular abnormalities can be assessed partially by evaluating the carotid (external), superficial temporal, and brachial pulses, although no pulses are easily accessible to evaluate for the internal carotid or vertebral arteries. Abnormal pulses suggest vascular injury, whereas normal pulses do not guarantee vascular integrity.

Auscultation of the neck is useful to identify bruits. Although a carotid bruit may be normal in children, a continuous bruit suggests a traumatic arteriovenous fistula whereas a systolic bruit suggests a partial arterial tear. Bleeding from a posterior neck wound, neurologic deficits in areas supplied by the vertebral arteries (brainstem, cerebellum), bleeding not controlled by carotid compression, a posterior bruit, or bleeding that accompanies a cervical spine transverse process fracture suggests a vertebral artery injury. Carotid artery trauma should be suspected if presentation involves an anterior triangle hematoma, Horner's syndrome (ptosis, miosis, enophthalmos, loss of sweating on the ipsilateral side of the face), transient ischemic attacks, loss of consciousness after a lucid interval, or hemiplegia. Evaluation of the chest for signs of major vessel injury, including hemothorax, widened mediastinum, and cardiac tamponade, should accompany the neck examination.

TABLE 115.2

NECK CONTENTS AND CLOSELY APPROXIMATED STRUCTURES

Musculoskeletal	Vascular	Venous	Gastrointestinal	Glandular
Cervical spine	Arterial	Jugulars: internal, external	Esophagus	Thyroid
Cervical muscles	Carotids: common, internal, external	Lymphatics	**Neurologic**	Parathyroid

Neck vessels may be injured indirectly as a result of shock waves from a missile. These patients may have clinically unapparent vascular intimal damage that can progress to vascular thrombus or occlusion. Venous or lymphatic (thoracic duct) injuries also occur with penetrating trauma. These injuries are rarely severe and usually present as an expanding hematoma or less often with a venous air embolism. Pulmonary embolus secondary to a venous thrombus is a rare event.

Injuries to the aerodigestive tract (pharynx, larynx, trachea, and esophagus) are also seen in cases of penetrating trauma, although these relatively mobile structures are often spared. Injury may occur with rapid acceleration/deceleration events and with a direct neck blow resulting in compression of the esophagus against the cervical spinal column. The esophagus is somewhat protected in that it is usually collapsed as it courses through the neck but it may be injured by direct penetrating objects, usually a stab or gunshot wound. Penetrating injury of the larynx and trachea occur, although blunt trauma to these areas is more common and can be associated with significant morbidity and mortality (see Chapter 123). These injuries can present initially in a subtle fashion, but delays in diagnosis can lead to significant increase in observed morbidity and mortality.

Direct nervous system injury (brachial plexus, spinal cord, cervical nerves, and cervical sympathetics) is possible with penetrating neck trauma and the evaluation of the patient should assess these structures. Symptoms correspond

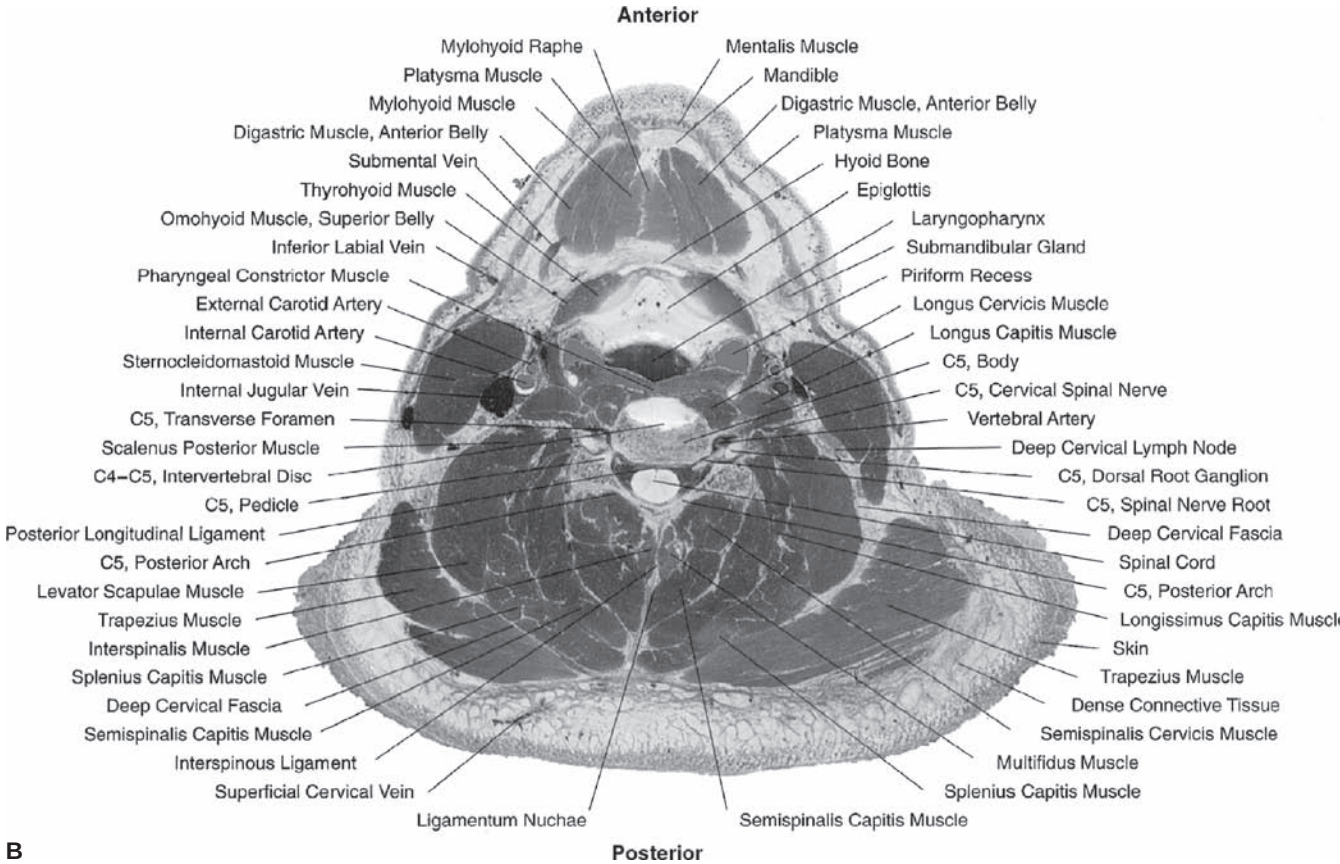

FIGURE 115.1 (*Continued*) **B:** Anatomic specimen demonstrating zone I relationships. (**B:** From Spitzer VM, Whitlock DG. *Atlas of the visible human male: reverse engineering of the human body*. Sodburg, MA: Jones & Bartlett, 1998. Reprinted with permission.)

to the injured structure, which may or may not require primary surgical repair (Fig. 115.5). Primary injury to the cervical cord often results from bony or foreign-body penetration or impingement or cord distraction. Secondary cord injury can occur from vascular compromise, edema, lipid peroxidation, ischemia, and ligamentous damage. When assessing neurologic findings or predicting location of the injury, it is important to remember that spinal cord and vertebral levels are not the same. In the cervical area, the cord level lies one segment higher than the corresponding vertebral level (C4 cord level lies opposite the C3 vertebral body). In the lower cervical area, a disparity of up to two levels may be present.

BLUNT TRAUMA

Blunt trauma is often the result of a motor vehicle accident, although it can also result from sports-related injuries; clothesline and handlebar injuries from bicycles, motorcycles, all-terrain vehicles, and snowmobiles; strangulation; hanging; blows from fists or feet; and the battered child syndrome (Table 115.1). Pediatric differences in exposures as well as the fact that children have a relatively short neck, mobile laryngotracheal structures, and a superior positioned larynx protected by the mandibular arch make it less likely for children to sustain airway fractures and may impact overall severity of injury. On the other hand, the small and narrow airway increases the risk of airway-related morbidity secondary to airway edema, bleeding, swelling, and obstruction. Blunt trauma is often associated with extracervical injuries, especially maxillofacial, head, and chest injuries, but is less likely than penetrating trauma to involve multiple structures within the neck. Blunt trauma is less likely than penetrating trauma to cause vascular damage, but the incidence of aerodigestive tract injuries is increased. The airway is often injured with direct blunt trauma in part as a result of the anterior and relatively fixed position of the larynx and trachea. High-impact blunt trauma to the trachea has been associated with a mortality rate of approximately 15%, although this is likely higher when one includes patients who die at the scene. As mentioned, the anterior neck is relatively well protected by bony structures, unless the neck is extended. With neck extension, the larynx, trachea, and esophagus are exposed to direct trauma and a blunt force may crush these structures against the posterior spinal column. A tracheal tear or rupture may occur from a sudden increase in intratracheal pressure against a closed glottis, direct blunt trauma, crush, or acceleration/deceleration injury. Shearing forces can cause edema, submucosal

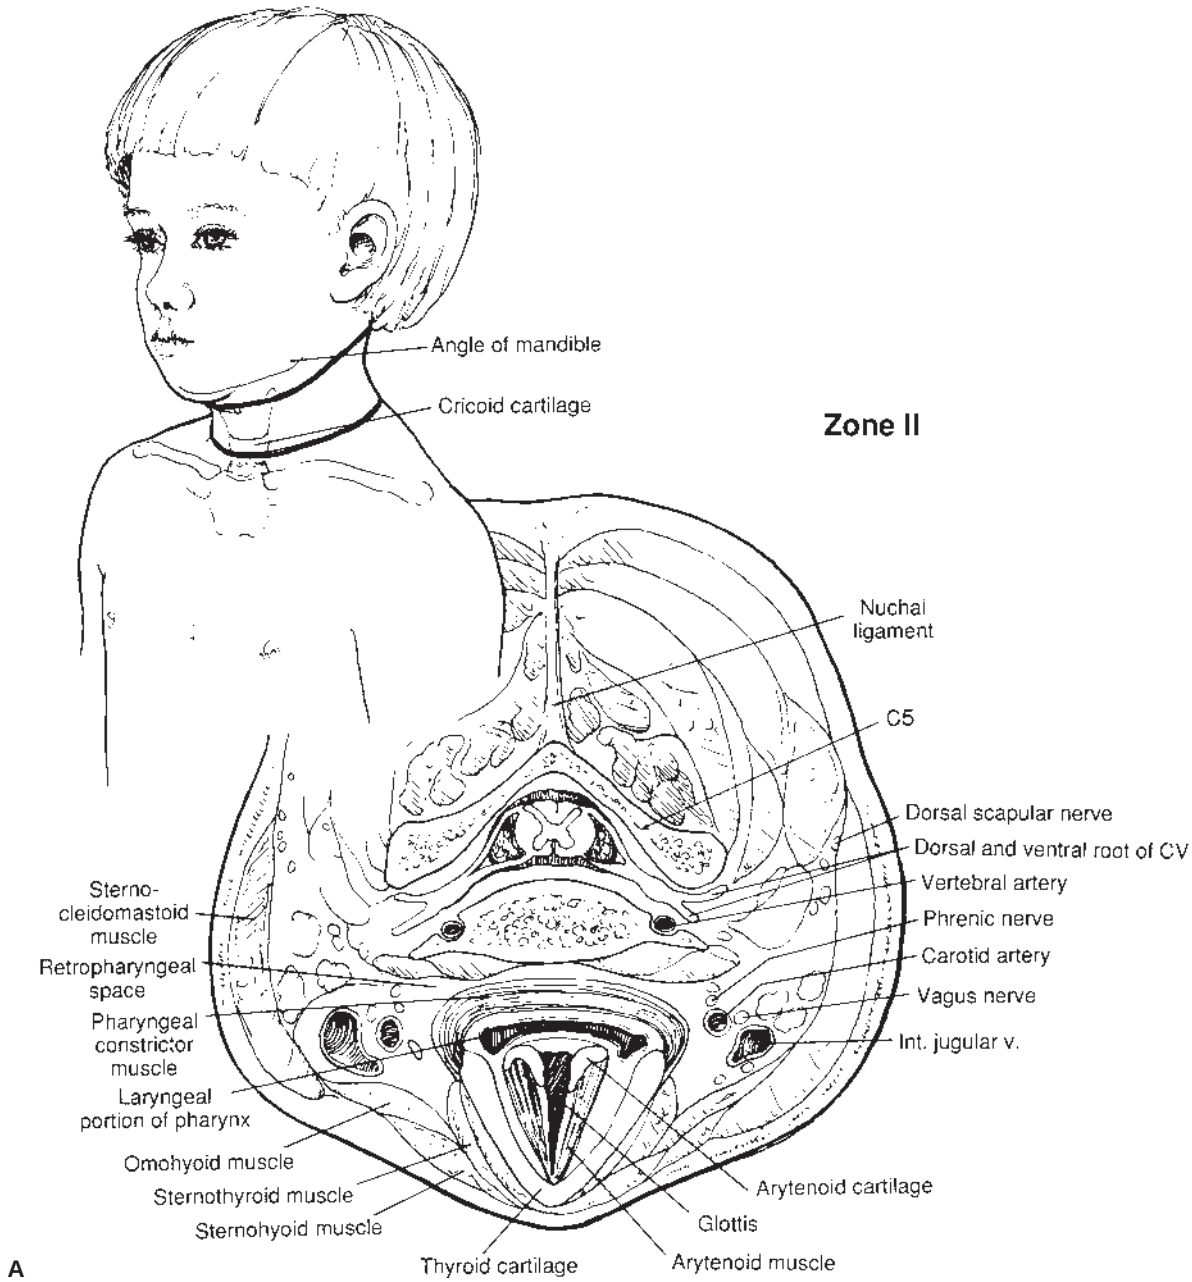

FIGURE 115.2 **A:** Anatomic neck divisions and contents of zone II located between the upper boundary of zone I and the angle of the mandible. (*continued*)

hematoma, laceration, perforation, vocal cord injury, and, less commonly, partial or complete airway transection. A prime target for airway fracture is the cricoid ring, which is the only complete tracheal ring. The general triad of dyspnea, stridor, and hemoptysis suggests laryngeal injury, with injuries above the glottis often demonstrating cervical emphysema, dysphagia, hoarseness, and progressive airway obstruction whereas those below the glottis present with hemoptysis and persistent air leak, although any or all symptoms and signs listed in Table 115.3 may be present.

Approximately 85% of patients with blunt tracheal injury reportedly have subcutaneous emphysema, although the onset may be delayed (Fig. 115.6). However, airway injuries may be subtle and not apparent with initial history or physical examination. Unfortunately, these subtle injuries may progress to severe abnormalities. The same percentage of airway narrowing from edema or hematoma may lead to significantly more distress in a child than in an adult. Airway obstruction from tracheal edema has been reported as late as 48 hours after the injury. If a laryngeal injury is noted, the

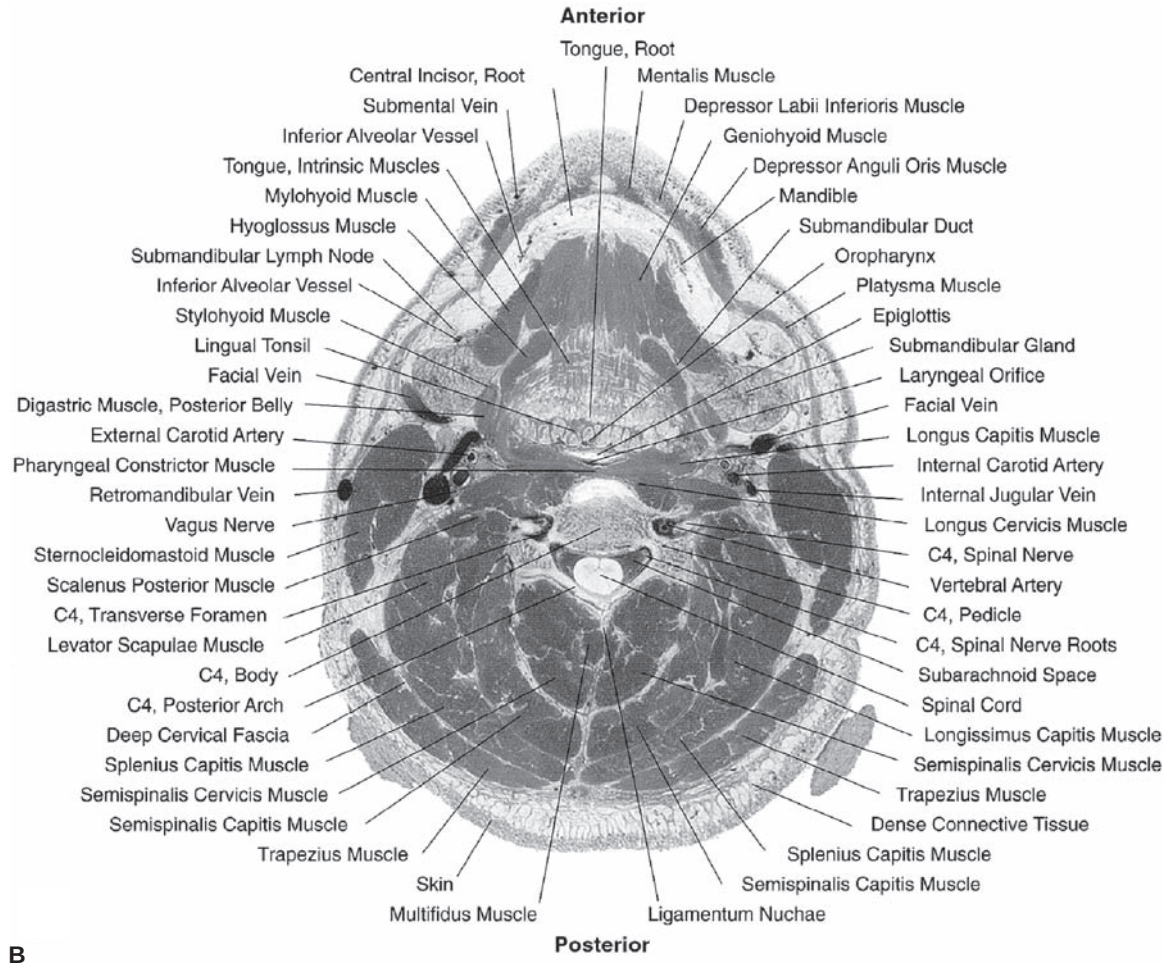

FIGURE 115.2 (*Continued*) **B:** Anatomic specimen demonstrating zone II relationships. (**B:** From Spitzer VM, Whitlock DG. *Atlas of the visible human male: reverse engineering of the human body*. Sodburg, MA: Jones & Bartlett, 1998. Reprinted with permission.)

patient should be evaluated carefully for commonly associated injuries, which include cervical spine, chest, facial, pharyngoesophageal, and recurrent laryngeal nerve palsy. Airway injuries can also result from endoscopy, thermal trauma, or caustic ingestions. There are numerous reports in the literature of laryngeal and tracheal trauma secondary to intubation attempts.

As mentioned, the esophagus is mobile and is usually collapsed as it courses through the neck but may be dilated while eating. This mobility helps protect the esophagus, but its delicate mucosal walls can be damaged easily by blunt traumatic events. Iatrogenic esophageal injuries can result from endoscopy, passage of a nasogastric or orogastric tube, vigorous suctioning, and difficult intubations. Esophageal injuries can also be seen with ingested foreign bodies and caustic chemicals. The symptoms and signs associated with esophageal injury are listed in Table 115.3 and include neck tenderness and pain, dysphagia, odynophagia, drooling, crepitus, subcutaneous emphysema, hematemesis, fever, and mediastinitis (see Chapters 29, 52 and 89). The injuries, which can be subtle, occult, and difficult to diagnose, can lead to increased morbidity and mortality if not suspected and discovered.

Isolated or concurrent hyoid bone injuries are also possible. The hyoid is mobile and fairly well protected, which explains the paucity of isolated injury. In a 1991 review by Szeremeta and Morovati, only four children 16 years or younger had been reported with an isolated hyoid fracture, three of whom sustained the injury in motor vehicle accidents. Symptoms and signs of hyoid injury include pain in the throat that worsens with swallowing or coughing, tenderness to palpation, neck crepitus, pain on head rotation, dysphagia, dyspnea, or dysphonia. As with other injuries, these symptoms and signs can be subtle initially, with progressive edema and airway obstruction.

Although vascular injuries are rare with blunt trauma, they do occur. These injuries are often unsuspected and undiagnosed on routine examination. Risk factors for injury have been reported to include Glasgow Coma Scale score of less than 8; head injury; basilar skull fracture; and facial, neck, thorax, or abdominal injury. The clinician must consider

TABLE 115.3

SYMPTOMS AND SIGNS OF NECK INJURIES

Laryngotracheal	Digestive	Vascular	Neurologic
Airway obstruction	Crepitus	Vigorous bleeding, internal or external	Altered consciousness
Dyspnea	Retropharyngeal air	Expansile or pulsatile hematoma	Generalized weakness
Stridor	Subcutaneous emphysema	Bruit	Hemiparesis
Retractions	Pneumomediastinum	Absent pulsations (carotid, superficial temporal, or ophthalmic artery)	Hemiplegia
Cough	Hematemesis	Unexplained hypotension	Quadriplegia
Aspiration	Chest or neck pain	Hemothorax	Seizures
Pneumomediastinum	Neck tenderness	Cardiac tamponade	Bruit
Pneumothorax	Dysphagia	Hemiplegia	Cervicosensory deficits
Crepitus	Odynophagia	Hemiparesis	Aphasia
Subcutaneous emphysema	Saliva in wound	Aphasia	Horner's syndrome (ipsilateral cervical sympathetics)
Tracheal deviation	Drooling	Monocular blindness	Cranial nerve IX–XII dysfunction
Endobronchial bleeding	Fever	Loss of consciousness	Tongue deviation (hypoglossal)
Hemoptysis	Mediastinitis	Neck asymmetry, swelling, or discoloration	Drooping of corner of the mouth (mandibular branch of the facial nerve)
Epistaxis		Wide mediastinum	Hoarseness (vagus/recurrent laryngeal)
Hematemesis		Cranial nerve abnormality	Immobile vocal cords (vagus/recurrent laryngeal)
Hemothorax		Clavicle/first rib fracture	Trapezius weakness (spinal accessory)
Dysphagia			Brachial palsy (arm paresthesias)
Odynophagia			Monocular blindness (vertebral artery)
Bubbling, sucking, or hissing wound			Diaphragm paralysis (phrenic)
Neck deformity			
Asymmetry			
Loss of landmarks			
Flat thyroid prominence			
Laryngotracheal tenderness

Hoarseness			
Drooling			
Neck pain, tenderness (with coughing or swallowing)			

subclavian or innominate vessel injuries if a fracture of the clavicle or first rib is identified. The most common vascular structure injured with blunt trauma is the common carotid artery. The vertebral arteries are rarely injured by blunt forces unless a concurrent transverse process or other fracture of the cervical spine or atlantooccipital dislocation occurs. The signs and symptoms of the vascular injury may be masked by the spinal injury. Many patients with atlantooccipital dislocation and arterial injury die in the field, but some survive and may recover with appropriate therapy. Vascular contusions with intimal damage may also be seen with blunt neck trauma.

The glandular structures in the neck, including the thyroid, parathyroid, parotid, and submandibular glands, may also be injured. Although these organs may be traumatized, they are rarely completely destroyed.

Burn management is covered in Chapter 108, but the physician should be aware of special considerations involving the neck. The airway must be evaluated and protected as indicated by the severity of the burn, realizing that initial symptoms may be subtle. Circumferential burns may become edematous and require an escharotomy for respiratory or vascular sufficiency. Escharotomy in the neck involves a vertical incision from the chin to the superior aspect of the sternal notch.

FIGURE 115.5 (*Continued*) **B:** Motor dermatomes. Knowledge of sensory and motor dermatomes can be invaluable in description of neurologic findings during initial and subsequent evaluations.

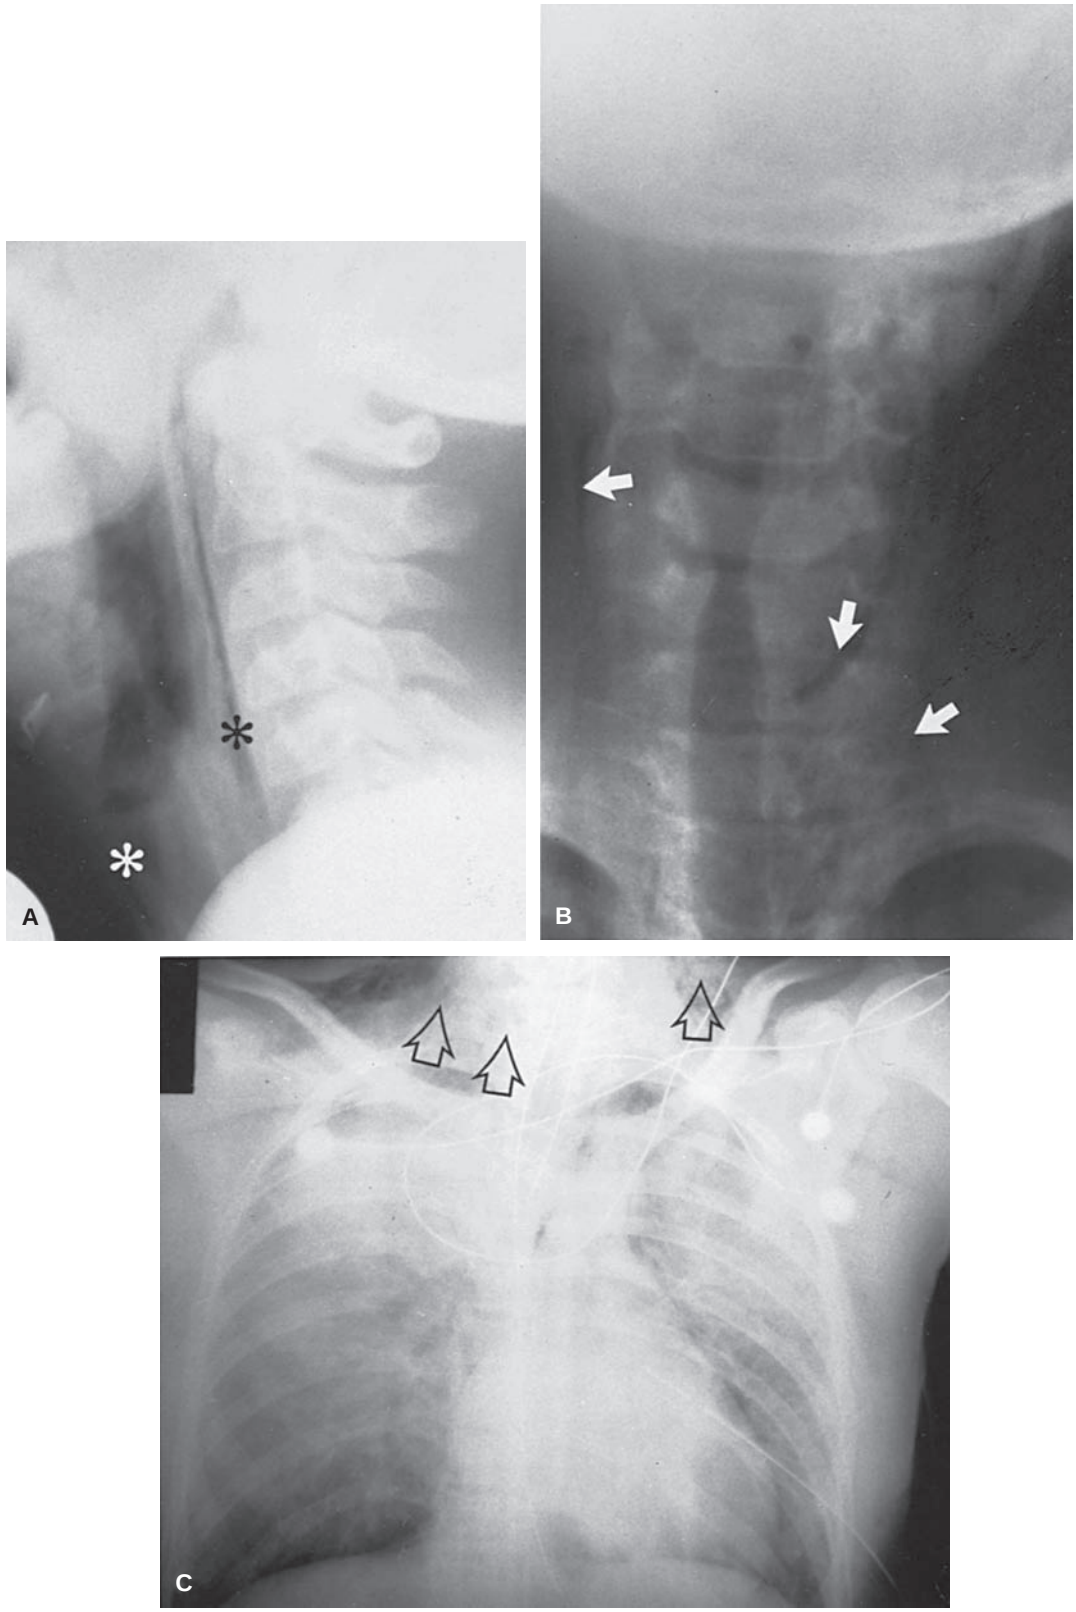

FIGURE 115.6 **A–C:** Subcutaneous emphysema of neck and chest in 11-year-old patient from barotrauma sustained when opening carbonated beverage container with teeth.

EVALUATION AND MANAGEMENT

The goals of management are to ensure airway patency and respiratory sufficiency, control hemorrhage, maintain osseous stability, and identify and prevent progression of all injuries. Methodical and timely acquisition of historical and physical findings is mandatory. The patient must be managed with strict adherence to the ABCs, with consideration of possible rapid or gradual deterioration. Penetrating objects that are lodged in the neck on evaluation should remain in place until removed under surgical care, preferably in an operating room. All patients, other than those with minor injuries such as contusions, abrasions, or superficial lacerations (not through the platysma muscle), should receive supplemental humidified oxygen, correct airway positioning, suctioning, vigilant observation, and monitoring. The patient should be maintained in a supine or Trendelenburg position to avoid the possibility of venous air embolism. If venous air embolism is suspected because of an unexplained decrease in cardiac output and blood pressure, increase in central venous pressure, cyanosis, arrhythmias, or air in the heart on chest radiograph, the patient should be placed in the left lateral decubitus and Trendelenburg positions. A decision tree for the evaluation of direct blunt and penetrating neck trauma is presented in Fig. 115.7.

Airway assessment is the initial step in the evaluation of all patients with trauma. Any airway manipulation should be accomplished with consideration and prevention of possible cervical spine injury. Potential indications for an artificial airway with neck trauma include stridor, dyspnea, hypoxia, rapidly expanding hematoma, expanding crepitus, pneumothorax, hemothorax, tracheal deviation, altered mental status, quadriplegia, hemiparesis, and other signs of vascular or airway insufficiency. If the airway is unstable or appears to be difficult, intubation of the nonparalyzed, awake, or sedated patient should be considered. Orotracheal intubation is the preferred method in children. Intubation should be attempted only after preparation for the placement of a surgical airway, if time allows. Fiber-optic intubation via the nasal route, performed by a skilled provider, may be useful if time and patient condition permit. The physician must be especially careful with the use of blind nasotracheal intubation in the patient with blunt or penetrating neck trauma because the airway anatomy may be distorted. Passage of the nasotracheal or orotracheal tube into a false or blind passage may make subsequent airway control attempts difficult, if not impossible. Therefore, along with the difficulty of emergent surgical airway placement in children, elective intubation is not recommended outside a setting where a surgical airway can be efficiently and skillfully placed.

If there is evidence of crepitus over the larynx, laryngeal or tracheal tenderness, a flattened thyroid prominence, anterior neck deformity, severe respiratory distress, an abnormal neck radiograph, or other evidence suggestive of a laryngotracheal fracture or disruption, a tracheostomy may be preferable. Intubation should be attempted only if the airway is completely obstructed. Attempts at intubation from above may separate a tenuously attached trachea and larynx, resulting in a total loss of the airway, with the trachea commonly retracting substernally into the chest (Fig. 115.8). Attempts at cricothyrotomy in patients with direct laryngeal trauma may result in retrotracheal placement of the airway. Cricothyrotomy is helpful in patients who have severe facial or other neck injuries that preclude intubation from above. Intubation may be attempted through an open laryngeal wound if present, although, if possible, a tracheostomy should not be performed through injured tissue. The flexible fiber-optic bronchoscope may be helpful in evaluating the patency of the airway and establishing the artificial airway. If patient condition allows, rigid bronchoscopy can also be useful in securing an airway in these patients. Care should be taken to ensure correct tube positioning and securing, as usual landmarks and adjacent tissues may be altered, requiring nonroutine techniques to be considered.

Breathing abnormalities may suggest associated injuries. Missiles to the neck may also pass through or lodge in the chest. Zone I injuries of the neck can easily involve the lung apices and result in hemothorax, pneumothorax, or pneumomediastinum. Further penetration may lead to cardiac tamponade. A chest radiograph is helpful in the assessment. A report from the Eddy and the Zone I Penetrating Neck Injury Subgroup suggests that normal physical examination and chest radiographs are sufficient to obviate the need for arteriography in this population.

In addition to the usual assessment for hypovolemia, the patient should be examined for expanding hematomas or other obvious external bleeding. External bleeding should be treated with gentle compression. Navsaria et al described the use of Foley catheter tamponade for actively bleeding neck wounds. Attempts to clamp bleeding vessels in the neck can injure the vessels and surrounding structures, as well as jeopardize subsequent repair attempts. Two large-bore intravenous (IV) catheters should be inserted, ideally on the side opposite to the injury if an obvious vascular abnormality is identified. If a subclavian vein injury is suspected, one of the IV catheters should be placed in the lower extremity. Type-specific and cross-matched blood should be made available and used with volume expanders as necessary.

The subtle presentation of vascular injuries has led many authors to suggest mandatory exploration of all neck injuries when the outermost muscle layer (platysma) is penetrated. Controversy exists in the literature regarding surgical exploration with low-velocity penetrating neck trauma (Table 115.4). Proponents of mandatory exploration of penetrating neck wounds report that overall morbidity and mortality have decreased with routine neck exploration and surgical repair of vascular and other abnormalities. However, more recent literature suggests that careful evaluation with ancillary studies, including arteriography, helical multislice computed tomographic (CT) scan, and color-flow Doppler (CFD) coupled with the use of selective exploration, will identify most significant injuries and that the potential short delay in operative evaluation and repair will not increase morbidity and mortality. Others suggest that delays in operative exploration due to preoperative studies may increase morbidity and mortality. Variable results have been reported regarding the use of dynamic CT in the identification of surgically significant zone II injuries. In one study, dynamic CT was no better than esophagography in diagnosing esophageal

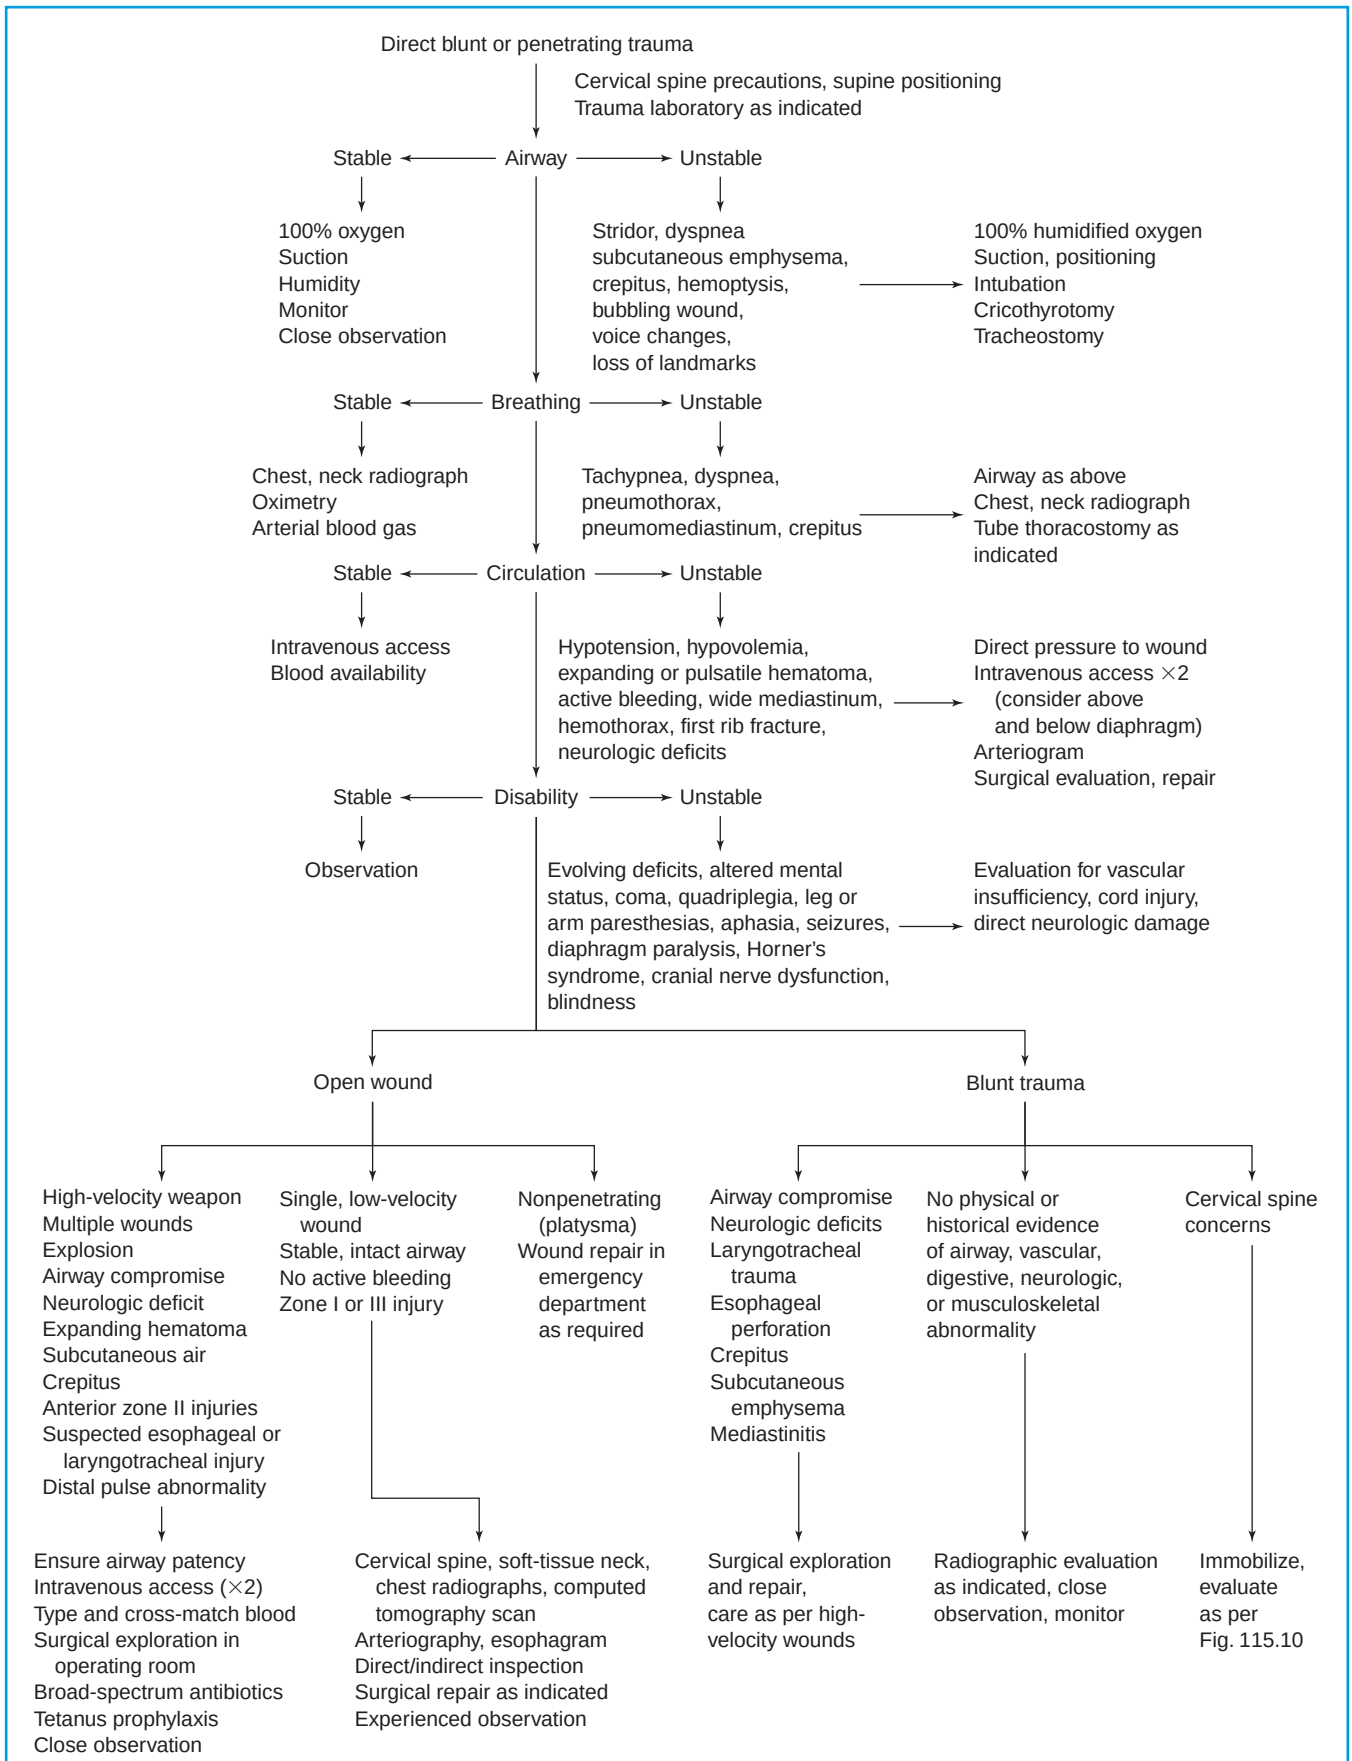

FIGURE 115.7 Evaluation of blunt and penetrating neck trauma.

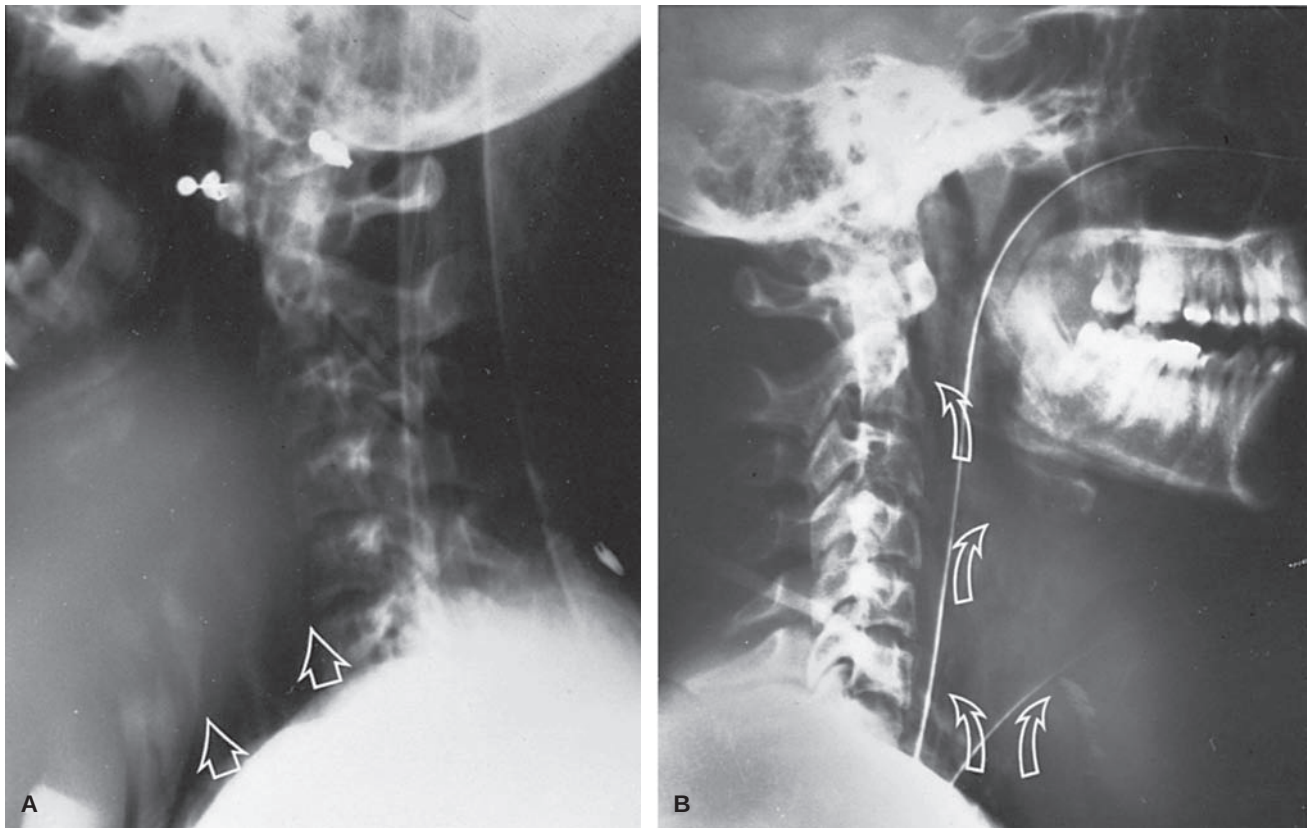

FIGURE 115.8 Tracheal injury. **A:** Initial lateral neck radiograph showing subcutaneous emphysema in 14-year-old girl kicked in the neck by a horse. Patient's airway clinically stable at the time of this radiograph (more than 1 hour after the injury). **B:** Postcricothyrotomy radiograph in same patient demonstrating significant subcutaneous emphysema and an artificial airway in place. Initial attempt at orotracheal intubation separated tenuously attached trachea, completing traumatic disruption of the trachea and requiring immediate placement of surgical airway.

injuries. In another small study, Mazolewski et al reported accurate diagnoses of penetrating zone II injuries by CT scanning. The multislice helical CT scan has been noted to be a sensitive and specific diagnostic tool. Inaba et al in their prospective study of 106 patients with penetrating neck injuries showed 100% sensitivity and 93% specificity of multislice helical CT angiography (CTA) in detecting vascular and aerodigestive injury. In stable patients, Osborn and Bell, in separate publications, report that CTA has replaced conventional angiography in their institution for the vascular assessment of neck injuries, has been noted to result in fewer neck explorations, and has essentially eliminated negative exploratory surgery findings. They also comment that the use of CTA has transcribed the zone of injury into a descriptor rather than a triage tool or guide for exploratory surgery. The use of a CT scan to determine trajectory of penetrating wound has been reported to be helpful in patient and procedure triage. CT scan images can be negatively influenced, however, by retained foreign bodies (bullets) and other injury-related artifacts. In determining assessment steps, importance of the physical examination should not be minimized. Insull et al in their 10-year case series of penetrating zone II injuries in adults note that the physical examination alone had 93% sensitivity and 87% positive predictive values in predicting vascular injuries. Surgical exploration is practiced uniformly for high-velocity or multiple low-velocity wounds. With pediatric penetrating injuries, routine neck exploration, even in the relatively straightforward zone II, is not always a benign procedure.

Repair of vascular injuries depends on the vessel injured, type of injury, and the patient's clinical status. Arterial injuries with neurologic deficits are often not repaired but are ligated to avoid the chance of reperfusion injuries to the brain. Other authors suggest that primary arterial repair may be indicated despite the possibility of reperfusion injury. Vascular repair in zones I and III is especially difficult and not without operative morbidity. Venous injuries may not need repair unless persistent bleeding or associated morbidity is demonstrated. The need for surgical repair of vascular intimal injuries is controversial.

A neurologic examination for signs of cerebral injury secondary to vascular insufficiency, direct spinal cord, cranial or cervical nerve, or brachial plexus injury should be completed. An abnormal neurologic examination result may indicate progressive vascular insufficiency and the need for rapid surgical evaluation. In blunt trauma, progressive onset pain, irritability, and signs of cord compression may suggest a spinal (usually venous) epidural hematoma. Rapid assessment by CT or magnetic resonance imaging (MRI), followed by surgical intervention, will help ensure optimal outcome. Direct neurologic injuries may not necessitate surgical repair.

TABLE 115.4

SURGICAL EXPLORATION WITH PENETRATING TRAUMA

Arguments favoring mandatory surgical exploration with penetrating trauma
Most patients have injuries to important structures
Morbidity and mortality increase with delay in surgery
Morbidity of exploration is relatively low
Negative physical examination does not preclude injury
Morbidity of missed injuries is high
Specific radiologic tests and expertise are needed for selective management
More skill is needed to observe appropriately
Length of hospitalization is similar with or without exploration
Arguments favoring selective surgical exploration with penetrating trauma
Most injuries are not secondary to high-velocity weapons
There are high negative rates of injuries with exploration in asymptomatic patients
It is unclear whether morbidity and mortality increase with delay in surgery
Zone II is involved most commonly and injuries are rarely occult
Skill is needed to explore neck
Morbidity of the more difficult zone I and III explorations is seen
Ancillary tests are helpful in zone I and III evaluation
Exploration may miss occult injuries

TABLE 115.5

INDICATIONS SUGGESTING SURGICAL EVALUATION IN PATIENTS WITH NECK TRAUMA

Unstable vital signs
Expanding or massive hematoma
Pulsatile or active bleeding
Hemorrhagic shock
Vascular deficits in the upper extremities
Abnormal distal pulses (brachial, superficial temporal, ophthalmologic, fundi)
Hematemesis, hemoptysis, epistaxis
Hemothorax
Progressive respiratory distress
Airway obstruction
Expanding subcutaneous emphysema
Bubbling or sucking wound
Pneumothorax
Progressive neurologic deficits
Hemiparesis
Horner's syndrome
Cranial or cervical nerve dysfunction
Diaphragm paralysis
Decreased sensorium
Neurologic deficits in upper extremity
Increasing dysphagia
Odynophagia or dysphonia
Hoarseness
Severe neck pain or tenderness
High-velocity wounds (rifles, explosions)
Multiple low-velocity wounds
Ancillary radiographic studies not available
Experienced observation personnel not available

Tetanus status should be assessed in all patients with penetrating trauma. The clinician should consider a broad-spectrum antibiotic for a patient with evidence of neck trauma, especially if esophageal or pharyngeal injury seems likely. Placement of a nasogastric or an orogastric tube is controversial for the patient with cervical injury because it may worsen a preexisting esophageal injury or dislodge clots in zone I of the neck. When placed, these tubes should be well lubricated, inserted gently and slowly, and withdrawn if difficulty in passage or evidence of obstruction occurs.

Superficial abrasions, lacerations, and puncture wounds are common in children. Wounds superficial to the platysma can be cleaned and sutured in the normal fashion under local anesthesia in the ED. Clean wounds can be sutured as late as 12 to 18 hours after the injury because of the excellent blood flow in the neck. In wounds beyond 12 to 18 hours postinjury, closure after 72 hours is recommended. Penetration of the external muscle layer in the neck, the platysma, is an indication for surgical referral and, in some cases, surgical exploration. When neck wounds that penetrate the platysma are evaluated, exploration in the ED is discouraged because of the risk of clot dislodgment and venous air embolism. Rapid surgical exploration and repair are indicated in patients struck by a high-velocity missile and in those with unstable vital signs, uncontrollable bleeding, rapidly expanding hematomas, progressive airway compromise, worsening neurologic symptoms, increasing subcutaneous emphysema, or bubbling wounds (Table 115.5).

Surgical evaluation may give false-negative results with esophageal tears, small vessel lacerations, pharyngeal tears, or tracheal injuries. The patient who has apparently stable vital signs, no symptoms of impaired neurologic or cardiovascular status, an intact airway, and mechanisms of injury with a low-velocity bullet or single knife wound may be managed expectantly with the use of ancillary diagnostic tests and close, experienced observation, preferably for at least 48 hours. These decisions should be made in conjunction with experienced surgical staff.

Adjuncts to the history and physical examination are given in Table 115.6. Initial evaluation should include cervical spine radiographs to detect bony or structural abnormalities, as

TABLE 115.6

ADJUNCTS TO HISTORY AND PHYSICAL EXAMINATION

Cervical spine radiographs	Xeroradiography
Soft-tissue neck radiograph	Tomography
Chest radiograph	Indirect (mirror) laryngoscopy
Computed tomographic scan	Direct laryngoscopy
Arteriography	Flexible bronchoscopy
Doppler	Direct bronchoesophagoscopy
Esophagram	Surgical exploration
Contrast laryngotracheography	
Oculoplethysmography	

well as a soft-tissue lateral neck radiograph to assess for blood, edema, subcutaneous air, foreign bodies, and airway impingement or disruption. A chest radiograph should be evaluated for evidence of hemothorax or pneumothorax, mediastinal emphysema or widening, and heart size. If a serious injury is likely, these radiographs should be obtained in the ED or the patient should be accompanied to the radiology department by someone skilled in airway management. Fluoroscopy may be helpful in airway evaluation. If the patient is stable and a vascular injury is suspected, an arteriogram should be performed (Fig. 115.9). Arteriography has excellent sensitivity, specificity, and accuracy, as well as low morbidity. Some authors suggest that an arteriogram is not needed in penetrating zone II injuries if an exploration is to be performed because this can be done fairly easily without significant complications. Others suggest that, even with zone II injuries, the stable patient should receive an arteriogram before the operative procedure.

Noninvasive Doppler studies and oculoplethysmography may be useful in evaluating vascular injuries. CFD is an inexpensive, non invasive, relatively sensitive screening tool but can be limited by adjacent or overlying hematomas and pneumothoraces, as well as by the skill of the individual operator. Williams et al noted that in 4 prospective trials to evaluate penetrating neck injuries, CFD could exclude vascular injury in 77% of these cases. The collective data showed 95% sensitivity for identifying vascular injury after penetrating trauma, with specificity of 98.6%, positive predictive value of 97%, and negative predictive value of 98.6%. Contrast laryngography, tomography, and xeroradiography have been used for further evaluation; however, these methods have generally been replaced by the CT scan. The noninvasive, rapid, and safe CT scan provides excellent bone and soft-tissue detail and can be obtained easily with a stable, immobilized patient. The addition of IV contrast material allows identification and initial evaluation of the cervical vasculature. The advent of spiral CT technology allows rapid scans and illustrative coronal, sagittal, and three-dimensional reconstruction of the neck anatomy. CT may not be accurate for detection of mucosal degloving injuries, mucosal perforation in the presence of subcutaneous emphysema, endolaryngeal edema or hematoma, and partial laryngotracheal separation.

Barium or Gastrografin esophagram is helpful in evaluating the esophagus for tears or perforations, but false-negative rates of up to 50% have been reported. Evaluation can also include indirect mirror laryngoscopy to assess the larynx, vocal cord mobility, presence of mucosal edema, ecchymosis, and mucosal tears, as well as direct endoscopy to examine for tracheal, bronchial, and esophageal damage. Flexible endoscopy may be less invasive and easier to accomplish, but rigid endoscopy offers the most complete examination. Even rigid endoscopy, however, is not 100% sensitive in detecting tracheal and esophageal injuries. As mentioned, operative evaluation is mandatory for some patients and optional for others. Determinants of specific management direction include mechanism of injury, wound size and type, patient signs and symptoms, and relative stability. The clinician must maintain a high index of suspicion for potential injury to the structures contained in the neck. Consequences of missed injuries include airway obstruction, delayed hemorrhage, neurologic compromise, and deep neck infection, with potentially significant morbidity and mortality.

CERVICAL SPINE EVALUATION

Cervical spine injuries are also uncommon in children, occurring in an estimated 1% to 2% of patients with multiple trauma. Traumatic brain injury has been reported to be the most common associated injury, accounting for 37% of the patients in Cirak's 2004 retrospective review of 406 patients over an 11-year period. It is estimated that 5% of all spinal injuries occur in children younger than 16 years. However, approximately 72% of spinal injuries in children younger than 8 years occur in the cervical region. Certain preexisting conditions (Down, Maroteaux-Lamy, Morquio's, Grisel, and Klippel-Feil syndromes; achondroplasia; congenital cervical stenosis; Chiari malformation; rheumatoid disease; and acute soft-tissue or bony infection or infiltration) may result in a cervical spine more predisposed to injury with minor or more significant trauma. Suspected child abuse with altered level of consciousness or neurologic deficits should alert one to the potential of cervical spine or cord injury as well. Vohra et al reported neurologic sequela in pediatric patients who underwent spinal manipulation for therapeutic purposes. Neonatal spinal injury is reported in approximately 1 in 60,000 births. These patients often have a history of cephalic forceps use during delivery and may have presenting signs that include weakness, flaccid quadriplegia, spinal shock, and apnea. These birth related injuries carry high morbidity and mortality. The clinician must assume that all children who sustain multiple trauma, have significant head or neck injuries, or have symptoms of neurologic impairment, including altered level of consciousness, have a cervical spine injury until proven otherwise. Goals in the care of these children include effectively stabilizing the primary injury that has occurred and preventing progression to a more severe or significant injury. The devastating nature of a cervical cord injury makes it imperative to not inadvertently miss a potentially unstable cervical spine injury. While attending to the basic ABCs of trauma resuscitation, the clinician should stabilize the cervical spine. Caution must be exercised when applying airway maneuvers to a child with a possible cervical spine injury. Airway interventions, however, often cannot wait until the cervical spine is "cleared." The clinician must prioritize and proceed with lifesaving airway maneuvers while minimizing motion of the potentially unstable cervical spine.

Hyperextension of the neck to facilitate intubation should be avoided. A vigorous chin lift or jaw thrust may also inadvertently hyperextend the unstable cervical spine. Gentle cricoid pressure should not cause excessive movement to the cervical spine; however, if applied vigorously, it may cause flexion of the spine. When inline neck immobilization is used to assist with airway maneuvers, the clinician should be careful to avoid applying significant traction to the spine because this pressure can also stress the unstable cervical column. Tracheal intubation in a patient with a potential cervical spine injury ideally requires at least two providers to perform the procedure safely and efficiently. Simulation models with the ability to gauge amount of cervical motion may be useful in developing, maintaining, and assessing airway skills for this subset of patients. One provider should maintain inline immobilization of the neck while

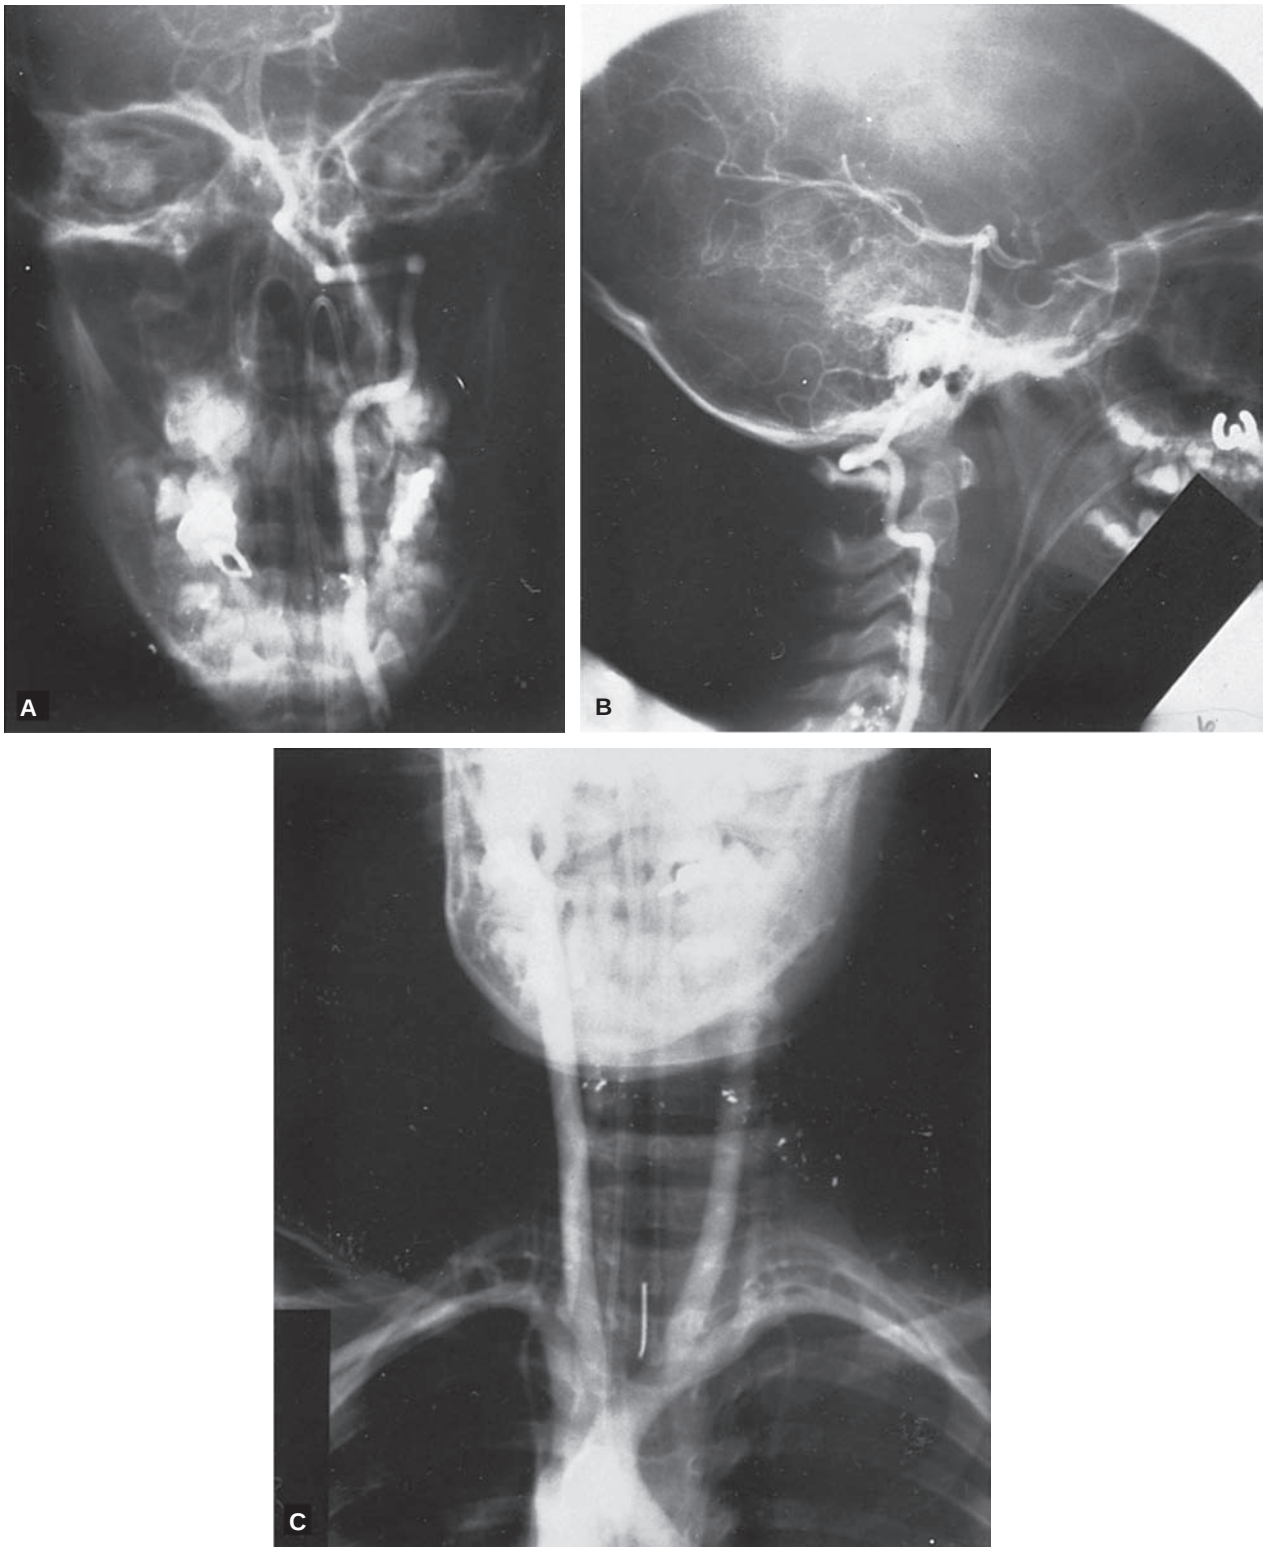

FIGURE 115.9 Angiograms in 5-year-old child shot in the neck, demonstrating normal vascular integrity. **A:** Vertebral artery angiogram (anteroposterior view). **B:** Vertebral artery angiogram (lateral view). **C:** Carotid angiogram.

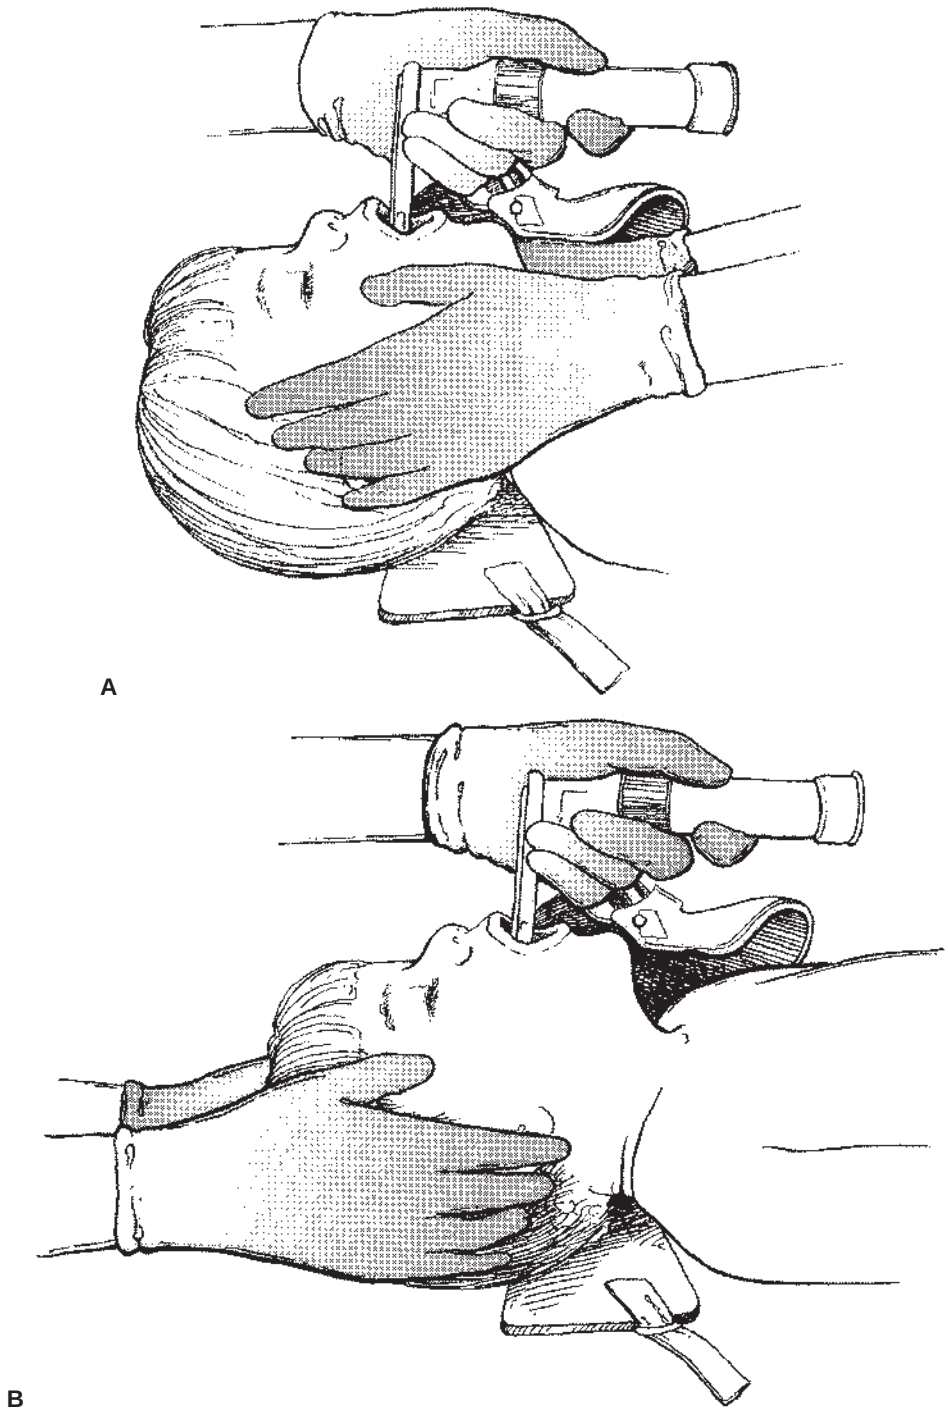

FIGURE 115.10 **A:** Manual immobilization from below. **B:** Manual immobilization from above. Adequate and expert manual cervical spine immobilization is required during airway maneuvers. The head and neck can be adequately secured from above or below. Immobilization by the second provider from below allows the airway maneuver to be accomplished without requiring a change in preferred positioning of the professional performing the maneuver.

another performs the intubation. The immobilization is often best accomplished from below, allowing the intubator as much room as possible to maneuver (Fig. 115.10). The hard cervical collar should be opened anteriorly, or removed, while this process is being performed. It is difficult to intubate a child unless the reduction in mouth opening and jaw immobilization afforded by the collar is temporarily removed, as the trachea is more anterior than in an adult. As usual, oral intubation is often the preferred method because of the child's airway position and the usual experience of providers. Adjunctive airway techniques that do not require vigorous laryngoscopy, such as video fluoroscopy and optical stylets, may be useful in managing the airway of these patients. The collar should be resecured after the airway intervention is complete.

Several concepts should be kept in mind concerning cervical immobilization in children. It is been estimated that 3% to

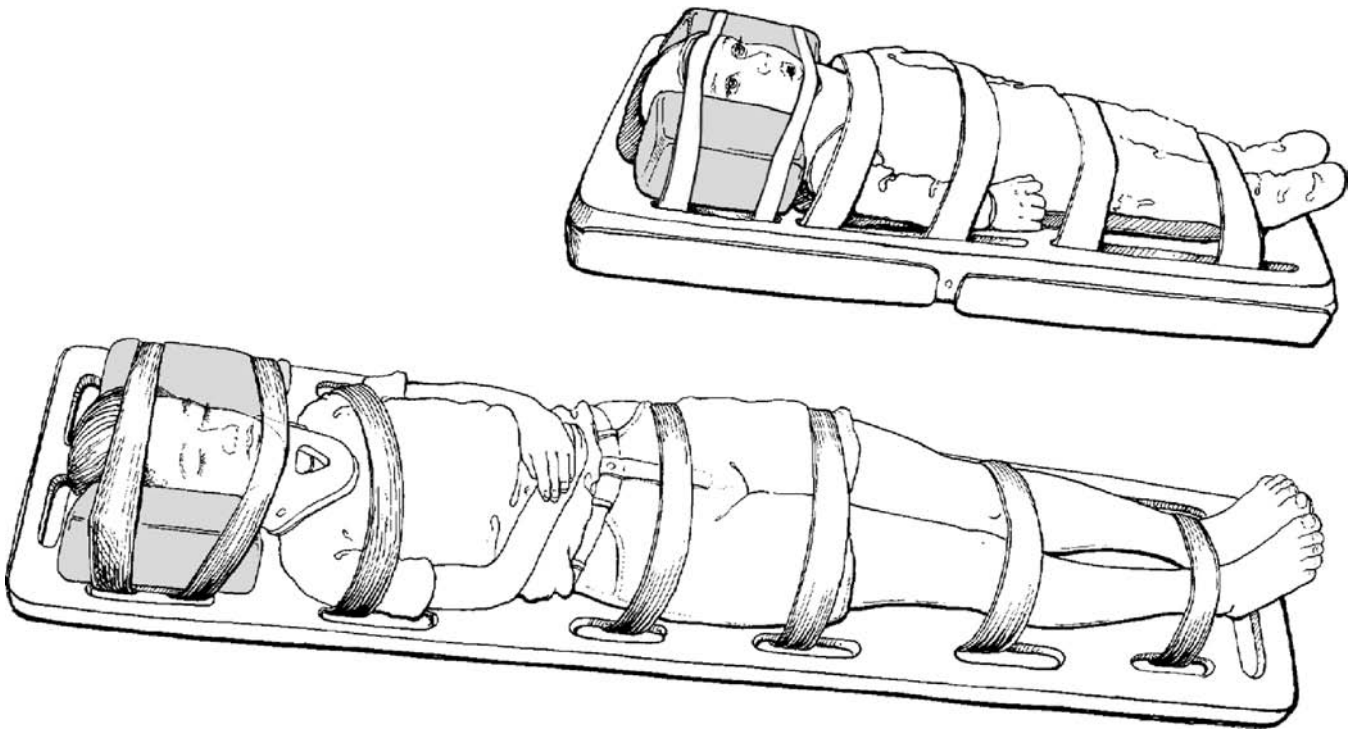

FIGURE 115.11 Cervical spine immobilization should not place the patient at an increased risk for morbidity. Securing straps should be placed around bony prominences and strap location reassessed after any movement of the patient. A neutral position of the neck should be ensured, and if necessary (younger child), a spacer can be placed underneath the child's torso and lower extremities to achieve the desired position.

25% of spinal cord injuries occur during transit or early in the course of management, although a 2001 Cochrane report noted that there are no randomized controlled studies on the effect of immobilization on mortality, neurologic injury, spinal stability, and other adverse effects. It is also important to realize that as many as 20% of spinal injuries involve noncontiguous vertebral elements, so entire spinal column immobilization is imperative. Soft cervical collars offer no protection to an unstable spine, and hard collars (Philadelphia, Stifneck) alone still allow a fair amount of flexion, extension, and lateral movement of the cervical spine. Ideal immobilization involves a hard cervical collar in conjunction with a full spine board, soft spacing devices, and securing straps (Fig. 115.11). Zhang et al noted that additional hard collars, including the C-Breeze and XTW (Deroyal Industries, Inc. Powell, TN), Miami J (Jerome Medical, Moorestown, NJ), and Aspen (International Healthcare Devices, Long Beach, CA), are effective in restricting range of motion in the cervical spine. Tescher et al report lower levels of mandibular and ocular pressures with Miami J collars, reducing the risk of occipital pressure ulcers while maintaining appropriate immobilization.

There is research suggesting that emergency medical services (EMS) protocols for selectively clearing adult cervical spines in the field are somewhat effective, but there is limited information regarding this practice in the pediatric population. For example, in the 2007 study of Armstrong et al, their prehospital cervical spine assessment protocol specifically excluded children younger than 16 years. Domeier et al in a study of more than 13,000 patients reported that prehospital protocols had a sensitivity of 92%, resulting in nonimmobilization of 8% of patients who were later evaluated for the diagnosis of spinal injury (although none developed neurologic sequela). This study included 1,200 patients who were younger than 15 years with one missed fracture. Although these are interesting data, the nuances of pediatric cervical spine evaluation, the fact that up to 75% of children with cervical spine injuries present with incomplete injuries along with the evaluation challenges encountered with variable ages and developmental status of young children, lead us to not recommend routine clinical clearance of the cervical spine by EMS in children who may have experienced potentially significant mechanisms of injury. More research may help us better understand this potential option for the prehospital care provider. An appropriately sized hard cervical collar should be chosen. The longest collar that does not hyperextend the neck is the correct choice. The choice between a one-piece collar (e.g., Stifneck) and a two-piece collar (e.g., Philadelphia) is important only in that correct fit must be ensured and the provider must understand how to apply the specific brand of collar. It is helpful to fold over the Velcro connectors on the collar before sliding it under the patient's neck to avoid Velcro attachment to the child's hair

or clothing. If a patient is seated and needs to have a collar placed, this maneuver should be accomplished by positioning the collar's chin portion first, followed by the placement of the posterior portion. If the patient is wearing a helmet, it should be carefully removed. Helmet removal, if possible, should involve at least two people to avoid potential neck motion. Inline stabilization is ensured by one provider while the other provider spreads and gently removes the helmet. Occasionally, mechanical bivalving of the helmet may be required for safe removal.

The clinician must be prepared to log-roll the patient if vomiting occurs. This reaction may happen at any stage of the evaluation process and should be anticipated. Adequate personnel to safely log-roll the vomiting patient are required to avoid potential gagging, aspiration, or secondary cervical spine or cord injury. The patient should be secured to a long spine board by tape or straps that cross the forehead and chin area of the cervical collar. Appropriate straps should be used to secure the patient to the board at the bony prominences of the shoulders, pelvis, and lower extremities. There may be a role in the future for the use of vacuum stabilization mattresses rather than hard spine boards for spinal immobilization. This could be used either as a primary immobilization tool or in combination with a hard spine board in those patients who may require hard board support for extrication or transfer. Incorrect immobilization may impede respiration by obstructing chest rise or contributing to secondary spinal injury by hyperextending the neck. The securing straps should be assessed periodically to ensure adequate and safe attachment of the patient to the spine board. When a child is immobilized on a spine board, the clinician must consider that the child's head is disproportionately large compared with that of the adult. A child's head reaches 50% of postnatal growth by approximately 2 years of age, whereas chest circumference reaches 50% of postnatal growth by about 8 years of age. This disparate growth of the head and trunk causes the neck to be forced into relative kyphotic position when a child is placed on a hard spine board (Fig. 115.12). This is distinctly different from the adult patient whose neck is in 30 degrees of lordosis, the neutral position, when immobilized on a hard spine board. Suggestions have been made to allow a recess in the head area of the spine board to accommodate the child's large occiput or to place a spacing device such as a blanket underneath the torso to allow the neck to rest in a neutral position (Fig. 115.12). Figure 115.13 demonstrates how cervical spine alignment can be greatly affected and improved by this technique. As the evaluation continues, one should be aware of the consequences of prolonged hard board immobilization. These include inadequate long-term immobilization and support, pain, discomfort, pressure sores, and potential respiratory insufficiency. The spine board should be removed as soon as practical, potentially during the log-roll portion of the clinical ED assessment.

Patients often arrive in the ED with full or partial cervical spine immobilization already in place. An immediate assessment of this immobilization is imperative. Several important issues should be considered: (i) Is the patient appropriately and fully immobilized? (ii) Is the cervical collar of the correct size and type for the patient? (iii) Is the patient's neck in a neutral position? (iv) Is the patient securely strapped to a long spine board? (v) Has there been a shift in the patient or the immobilization during the prehospital or interfacility transport that might diminish effective immobilization, cause hyperflexion or hyperextension of the cervical spine, or compromise excursion of the chest with respiration? and (vi) Does the immobilization interfere with the assessment or management of the ABCs? If these or other immobilization difficulties are identified, they should be immediately addressed.

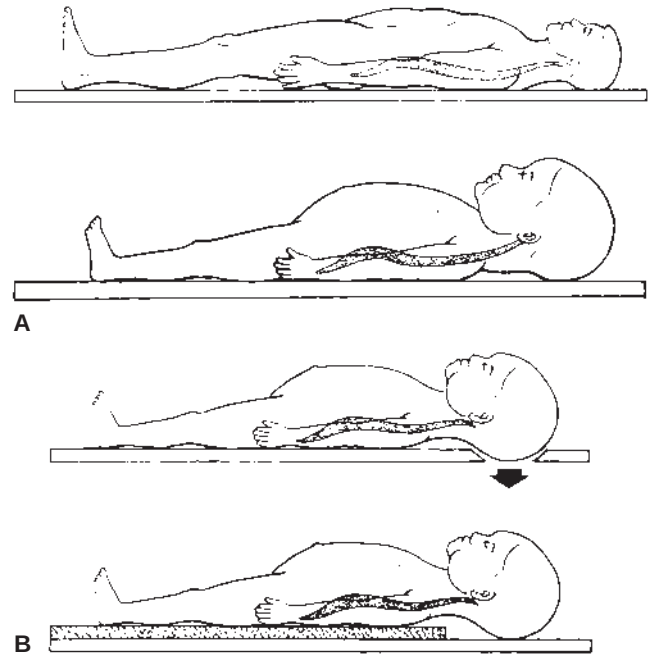

FIGURE 115.12 Effects of backboard on cervical spine position. **A:** Adult and child immobilized on standard backboard. **B:** Backboards modified with occipital recess and mattress pad to allow neutral positioning of the cervical spine in a young child. (From Herzenberg J, Hensinger R, Dedrick D, et al. Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. *J Bone Joint Surg Am* 1989;71-A:16, 21. Copyright The Journal of Bone and Joint Surgery, Inc. Reprinted with permission.)

Occasionally, the use of a semipermanent immobilization device (tongs, halo) may be indicated (Fig. 115.14). This should be accomplished after neurosurgical consultation. Attempts to rapidly reduce a cervical fracture are usually discouraged to avoid the potential for further cord injury. Frequent reassessment is necessary for the patient in cervical traction. Transport of the patient in cervical traction has the potential to further damage the injured cervical spine.

The pediatric cervical spine and its evaluation differ in many ways from the adult spine. The fulcrum of the cervical spine of an infant is at approximately C2–C3 and reaches C3–C4 by 5 to 6 years of age. At about 8 years of age, the fulcrum (C5–C6) and other characteristics of the cervical spine approximate that of an adult. The higher fulcrum of a child's spine in combination with relatively weak neck muscles and poor protective reflexes account for young children often having fractures that involve the upper cervical spine, whereas older children and adults have fractures that more often

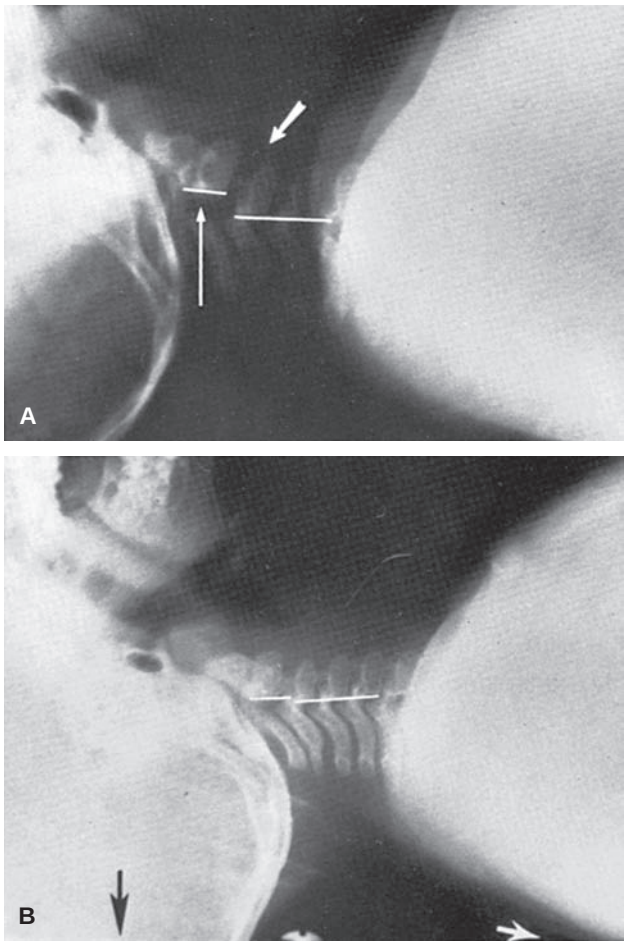

FIGURE 115.13 Effects of backboard on cervical spine position in 6-month-old child with a hangman's fracture (traumatic spondylolisthesis of posterior elements of C2) indicated by *thin arrow*. **A:** Large occiput contributes to anterior subluxation (*thick arrow*) of unstable cervical spine. **B:** Same child on backboard with occipital recess. Anterior subluxation is decreased. (From Herzenberg J, Hensiger R, Dedrick D, et al. Emergency transport and positioning of young children who have an injury of the cervical spine: the standard backboard may be hazardous. *J Bone Joint Surg Am* 1989;71-A:18. Copyright The Journal of Bone and Joint Surgery, Inc. Reprinted with permission.)

involve the lower cervical spine. Neurologic disability can occur from cervical lesions at all levels, but high cervical cord injuries are more likely to be fatal than are lower cervical cord injuries.

The large amount of cartilage present in a pediatric cervical spine not only cushions forces that are transmitted to the spine but can also make radiographic evaluation somewhat challenging. The radiolucent nature of cartilage makes the ability to appreciate soft-tissue changes on the radiograph extremely important. The pediatric cervical spine seems to have more anterior and posterior movement than its adult counterpart as a result not only of radiolucent cartilage but also of ligamentous laxity and relatively horizontal facet joints. The pediatric cervical spine also has the ability to revert to a relatively normal appearance after a significant distortion, which can hinder the radiographic search for abnormalities. It is important to realize that any persistent distortion demonstrated on the radiographs was probably more exaggerated during the actual precipitating event. There is more room around the spinal cord within the spinal column in a young child than in an adult, which means that compressive problems such as tumors or bleeds may be slower to manifest neurologic symptoms.

Evaluation of a child with trauma begins with a focused history and complete physical examination. The history (if reliable) can be invaluable in identifying the potential for cervical spine or cord injury. The following questions should be answered: (i) Was the child involved in a high-speed motor vehicle accident? If so, was he or she restrained, and at what angle did the car(s) collide? (ii) Was there a sports injury? If so, did it involve a spearing motion? (iii) Did the child fall? If so, how high was the fall and how did the child land? A neurologic history is imperative to assess whether there was any evidence of abnormal findings such as paresthesias, paralysis, or paresis at any time after the injury. These symptoms may have been transient and may (or may not) be present at the time of the examination or volunteered by the patient during gathering of the history, yet they are important because they may suggest a cervical contusion, a concussion, or a spinal cord injury without radiographic abnormality (SCIWORA). The answers to these and other historical questions can often be obtained from the patient, parents, bystanders, and EMS personnel and can help determine the potential for cervical injury. A plethora of clues can aid in the diagnosis of a cervical cord injury (Table 115.7). The symptoms and signs may be obvious or masked by other abnormalities such as altered level of consciousness, hypovolemic shock, or concurrent head injury. Head and neck injuries may present with overlapping abnormal neurologic signs, and differentiation of causation may be difficult.

Consideration of cervical spine radiographic evaluation is the next step in assessment. Radiographic options include radiographs, CT, and MRI. MRI scans are more appropriate when evaluating the subacute or chronic stages of injury or when looking for an acute problem with cord impingement

TABLE 115.7

SYMPTOMS AND SIGNS OF CERVICAL SPINE INJURY

Abnormal motor examination (paresis, paralysis, flaccidity, ataxia, spasticity, rectal tone)	Diaphragmatic breathing without retractions
Abnormal sensory examination (pain, sensation, temperature, paresthesias, anal wink)	Spinal (neurogenic) shock (hypotension with bradycardia)
Altered mental status	Priapism
Neck pain	Decreased bladder function
Torticollis	Fecal retention
Limitation of motion	Unexplained ileus
Neck muscle spasm	Autonomic hyperreflexia
Abnormal or absent reflexes	Blood pressure variability with flushing and sweating
Clonus without rigidity	Poikilothermia
	Hypothermia or hyperthermia

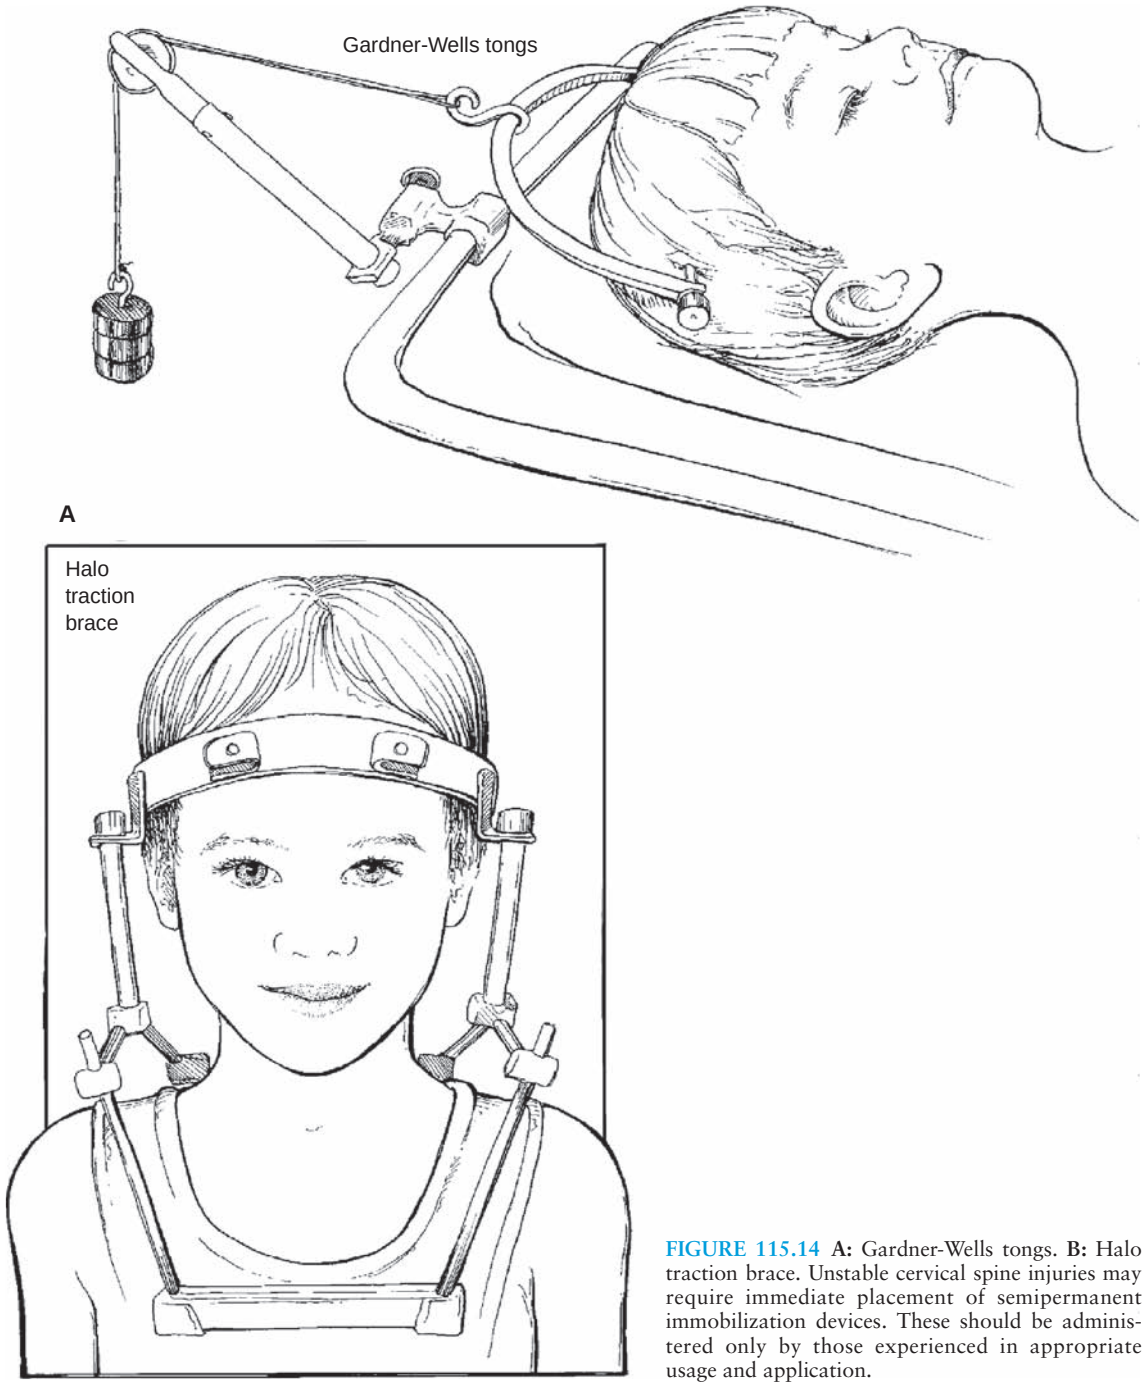

FIGURE 115.14 **A:** Gardner-Wells tongs. **B:** Halo traction brace. Unstable cervical spine injuries may require immediate placement of semipermanent immobilization devices. These should be administered only by those experienced in appropriate usage and application.

by blood or soft tissues such as tumors or intervertebral discs, instability, and ligamentous disruptions. Acute MRI evaluation is increasing in popularity in the cervical spine evaluation of patients with altered mental status. MRI does not provide images of the cortical bone well and should not be used to evaluate the cervical spine for fractures, whereas the CT scan demonstrates fractures clearly but does not offer direct evidence of ligamentous injury. A CT scan is often used as a secondary screen when adequate plain radiographs cannot be obtained or to substantiate suspected fractures. The use of the spine CT scan as an initial rapid screening tool has been suggested by several authors. The detail and reconstruction provided by the CT scan promise to present greater detail to the reviewer. The issue of increased radiation exposure needs to be considered when developing institution-specific protocols. A common scenario is the use of CT to supplement viewing the C1–C2 region in young children with trauma. Several studies have demonstrated the superiority of upper cervical spine CT scan versus plain radiographs in diagnosing injuries in the region. The CT scan images soft tissue well; however, it does not demonstrate the intrathecal, ligamentous, disc, or vascular detail that can be obtained with an MRI scan.

The plain radiograph remains the preferred initial test for patients with acute trauma. Several authors have attempted to devise criteria to limit the use of cervical spine radiographs because the number of positive studies constitutes a small proportion of the total number of radiographic studies completed. The perception of unnecessary tests should be balanced against the severity of consequences that may occur with a missed cervical spine injury. The literature suggests that if the patient does not have a high-risk mechanism of injury (motor vehicle accident, fall, dive, or sports injury), is awake and alert, can have an interactive conversation (not inebriated, no altered level of consciousness, older than 4 to 5 years), does not complain of cervical spine pain, has no tenderness on palpation (especially in the midline), has normal neck mobility, has a completely normal neurologic examination without a history of abnormal neurologic symptoms or signs at any time after the injury, and has no other painful injuries (which may distract the patient and mask neck pain), the patient probably does not need radiographic evaluation of the cervical spine. The National Emergency X-Radiography Utilization Study (NEXUS) suggests the following criteria for the assessment of risk of spinal injury: (i) midline cervical tenderness, (ii) intoxication, (iii) alertness, (iv) focal neurologic deficit, and (v) distracting (painful) injury (i.e., long bone fracture, visceral injury, large laceration, degloving or crush injury, large burns, and injuries producing impairment in appreciation of other injuries). If these are negative, then the patient is believed to be at low risk for a spinal injury and may be able to forgo radiographic evaluation. NEXUS low-risk criteria have been reported to be 99.6% sensitive in detection of clinical important cervical spine injury and have a high negative predictive value for low-risk patients. Garton and Hammer's 2008 retrospective 20-year review applying NEXUS criteria to 187 eligible patients with radiographically proven cervical spine injury noted that the NEXUS criteria appeared to be more sensitive in children older than 8 years. This information, as well as the low incidence of spinal cord injuries and the presence of pediatric patients, in the studies makes the results less clear for this population, although the approach appears sound in adult patients. The provider should use clinical judgment and ancillary signs to determine whether a long bone fracture or other potentially painful injury is indeed distracting to a patient with a mechanism of injury (short fall etc.) that would suggest minor risk for a cervical spine injury. For example, if an adequate response and appreciation of painful stimuli (pinch or other effort to elicit appreciation of pain) during the physical evaluation is elicited, the provider may be more confident that the physical examination could suffice to clinically clear the patient's cervical spine. If one is unable to determine whether an injury (and associated pain) is indeed distracting, or if neck pain or appreciation of the pain may potentially have been diminished by medication for other injuries, cervical spine radiographic evaluation should be strongly considered. This approach is also being used in the out-of-hospital environment to determine initial need for immobilization. This out-of-hospital screening should not be used in the pediatric EMS population at this time, as noted above. Another screening algorithm called the Canadian C-Spine Rule evaluates high-risk factors (e.g., age, dangerous mechanism, paresthesias) and low-risk factors that would allow for safe assessment of range of motion (e.g., low-speed motor vehicle accident, delayed evaluation, delayed onset of pain, absence of midline tenderness) and ability to rotate neck 45 degrees to the right and left. This has been reported to be sensitive in alert and stable adult trauma patients. Regardless of clearing algorithm embraced, the clinician must also be sure to never "clear" the cervical spine, regardless of studies performed, in an unconscious patient in the ED.

When radiographs are obtained, a normal lateral radiograph does not "clear" the cervical spine. The sensitivity of a lateral cervical spine radiograph traditionally varies between 70% and 85%–98% in the literature. Brohi et al, in a study of 437 unconscious, intubated blunt trauma patients, reported a 53% sensitivity of adequate cross-table lateral films in identifying cervical spine fracture. When evaluating a lateral cervical spine radiograph, the clinician must ensure that C1–C7 are included as well as the C7–T1 junction. Additional films, which include an anteroposterior (AP) view of C3–C7 and an AP open-mouth (odontoid) view of C1–C2, increase the sensitivity of initial radiographic evaluation to more than 95%. Avellino and colleagues reported their experiences with radiologic misdiagnosis of pediatric cervical spine injuries found at a level 1 combined adult/pediatric regional trauma center. The most common reasons for a missed injury on initial radiologic evaluation included unfamiliarity with pediatric cervical spine anatomy, failure to recognize normal developmental variants, and suboptimal conventional film techniques. An adequate open-mouth view is often technically difficult to obtain in young children and those who are intubated. If further information is required, a CT scan of C1–C2 can be useful to augment or replace the open-mouth view. A CT scan is more expensive than a plain radiograph of C1–C2 but is easier to obtain, offers enhanced and more consistent information, and avoids the risk of missing a subtle injury in that critical area. The advent of the spiral CT scan allows this study to be completed in 1 to 2 minutes and to be reconstructed by the computer to demonstrate vivid detail of the region (Fig. 115.15). CT scan or MRI should be considered in cases where plain radiograph has identified an injury. These studies can increase the understanding regarding the severity and significance of the identified injury and potentially identify other injuries not noted on the initial screening films. Barrett et al, in 2006, reported that 36% of their patients with cervical spine injury identified from plain radiograph had a second injury identified by CT scan, and in 27% of those patients, these injuries were noncontiguous. An algorithm for considering radiographic evaluation is presented in Fig. 115.16. An approach to ordering cervical spine imaging studies is shown in Fig. 115.17.

The cervical spine has anterior (vertebral bodies, intervertebral discs, ligaments) and posterior (lamina, pedicles, neural foramen, spinous processes, ligaments) components (Fig. 115.18). The initial three-view series evaluates the anterior cervical spine well; however, it is not ideal for evaluating the posterior cervical spine. Oblique (pillar) views are helpful in imaging these posterior elements. In practice, however, oblique radiographs rarely add significant information to the initial radiographic assessment. Flexion and extension radiographs are accomplished in an awake patient by having the patient flex and extend the neck as far as possible without discomfort. As the end point involves the sensation of pain,

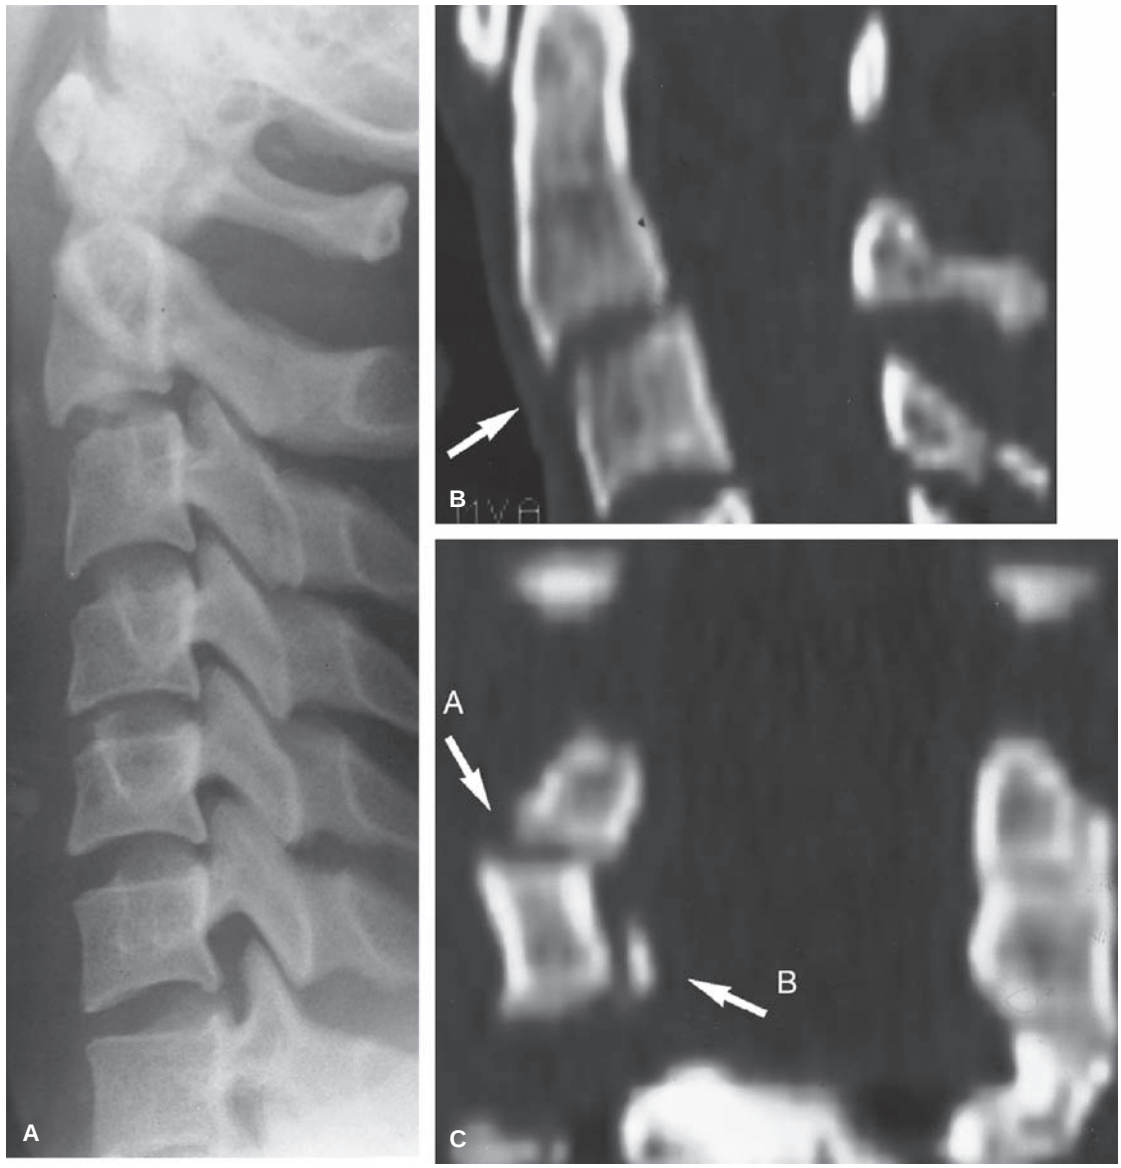

FIGURE 115.15 **A:** Apparently "normal" lateral cervical spine radiograph (16-year-old patient after motor vehicle accident). **B:** Spiral computed tomography (CT) scan demonstrating dens fracture (*arrow*). **C:** Sagittal view of spiral CT scan demonstrating dens fracture (*arrow A*) and vertebral body avulsion fracture (*arrow B*). The detail demonstrated by the spiral CT scan could help clinicians quickly identify lesions not easily visible or appreciated on conventional radiographs.

flexion/extension radiographs should not be obtained in a patient who has preexisting neck pain. Flexion and extension radiographs are believed to be of limited diagnostic use and probably should not be routinely used. Dynamic fluoroscopy could be substituted in specific instances for flexion/extension radiographs. These studies can help evaluate underlying soft-tissue or ligamentous injury that was not evident on the initial radiographs, although ligamentous injury without fracture (via radiographs and CT scan) is not a common finding. Traumatic quadriplegia has been reported during the use of this study. These radiographs are often inadequate because the neck muscles have splinted the cervical column into a position of comfort and stability, and alignment does not change with flexion and extension. If a question remains concerning the integrity of the cervical spine following this radiographic scheme, a CT scan should be considered. Without reconstruction, a CT scan may miss a horizontal fracture or injuries obscured by artifacts from retained foreign bodies or dental work. The use of CT as a primary screening tool, as well as an adjunct to initial radiographic evaluation, is noted in the literature. Garton and Hammer noted increased sensitivity of combined plain radiograph and occiput-C3 CT (94%) compared with plain radiographs (75%) and plain radiographs coupled with flexion/extension radiographs

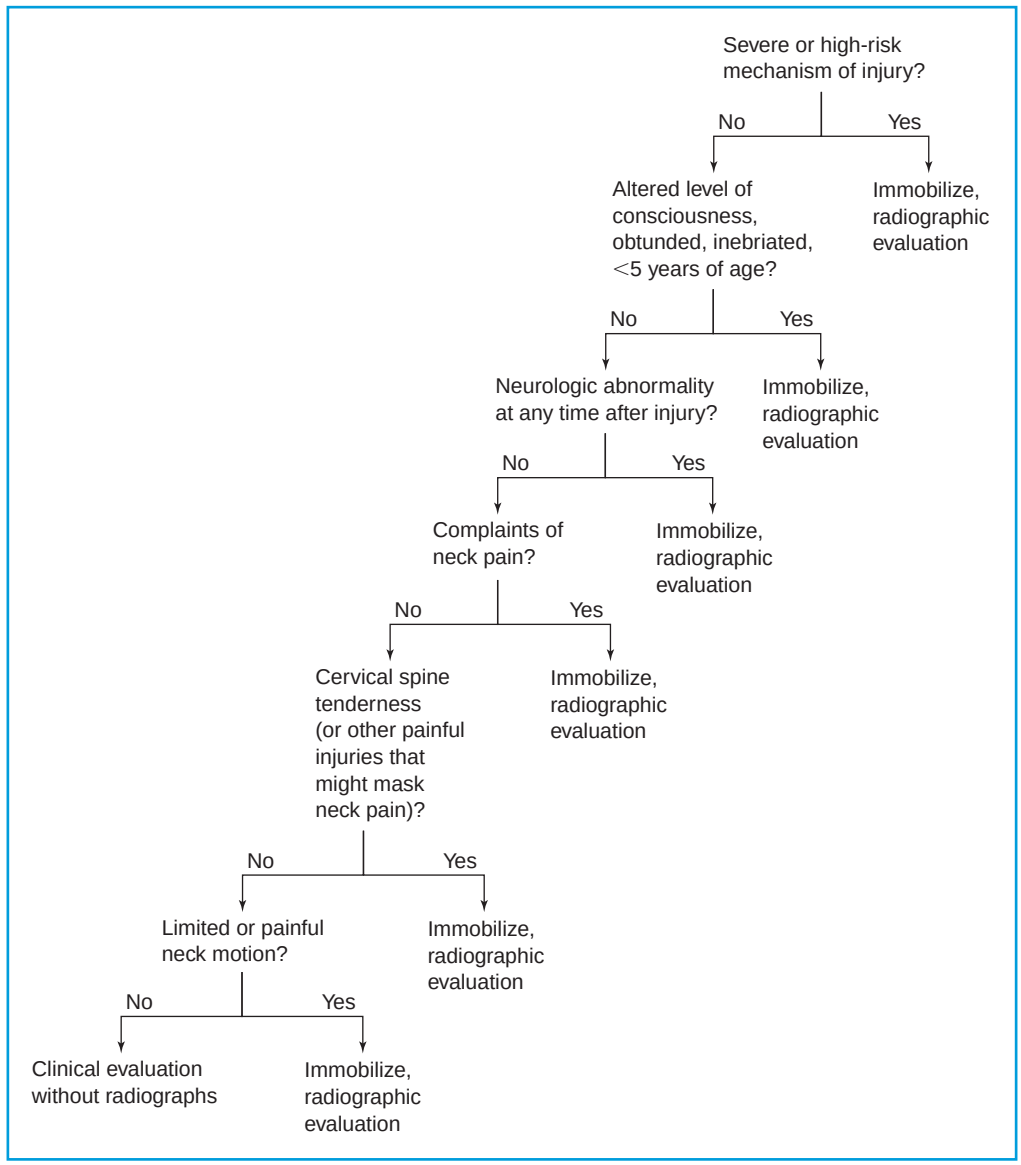

FIGURE 115.16 Decision tree for radiographic and clinical evaluation of patients with possible neck injury.

(81%) in children younger than 8 years. In children older than 8 years, the sensitivities are similar (93% to 97%), suggesting that limited use of CT may be helpful. Blackmore et al in their 1999 study reported that in adults, a CT protocol was more effective and less costly in high-risk patients (11% injury incidence), reasonably cost-effective with moderate risk of injury (4% injury incidence), but extremely costly if there is a low risk of injury (2% injury incidence). Others note that CT alone is sufficient in high-risk patients, as the combination of CT plus plain films does not markedly enhance sensitivity of injury identification. Adelgais et al noted increased radiation and radiology resource usage and no decrease in sedation usage or ED length of stay in pediatric patients using a CT screening protocol. Debate exists in the literature regarding the clearing of the cervical spine in an obtunded patient. While this should not be an ED debate, as obtunded patients should not have their cervical spine cleared in the ED, variations in practice exist. Como et al in 2007 reported that CT was sufficient to clear the cervical spine in this population, whereas Menaker et al in 2008 reported that in unreliable or obtunded adults who were admitted following a CT scan that did not demonstrate injury, the addition of MRI evaluation changed the management in 7.9% of those patients. Tomograms can also be obtained but require patient movement, are time-consuming, and are not performed easily in the acutely ill patient. An MRI should be considered to detect ligamentous, soft-tissue, or subtle cord injuries.

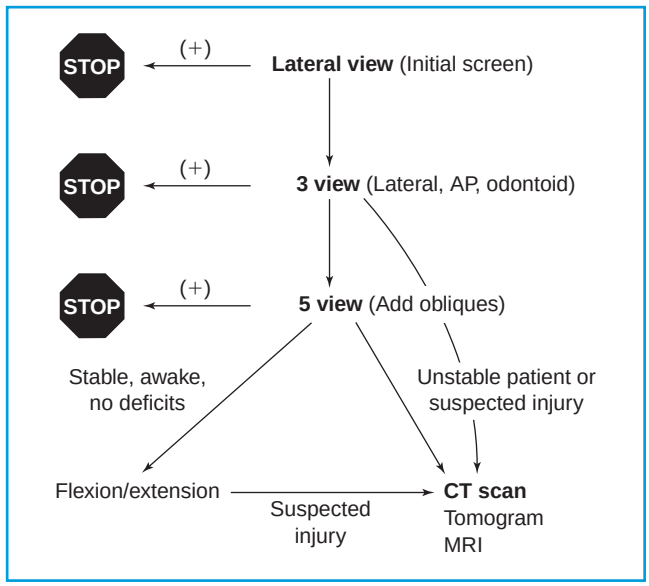

FIGURE 115.17 Approach to ordering cervical spine radiographs. Additional films or studies may not be needed in the acute CT scan images can be negatively influenced, however, by retained foreign bodies (bullets) and other injury-related artifacts. Emergency department evaluation if a fracture or other abnormality is identified, but CT or MRI may be indicated when the patient is stabilized to further elucidate the identified injury. If adequate radiographs cannot be obtained, an abnormality is identified or suspected but not demonstrated or the patient is unconscious or unreliable, consider further evaluation as suggested. AP, anteroposterior; CT, computed tomography; MRI, magnetic resonance imaging. Oblique and/or flexion/extension radiographs may also be options in the evaluation, prior to or in place of a CT or an MRI evaluation, depending on the specific patient and question to be answered, but are often not part of the routine cervical spine radiographic evaluation in pediatrics.

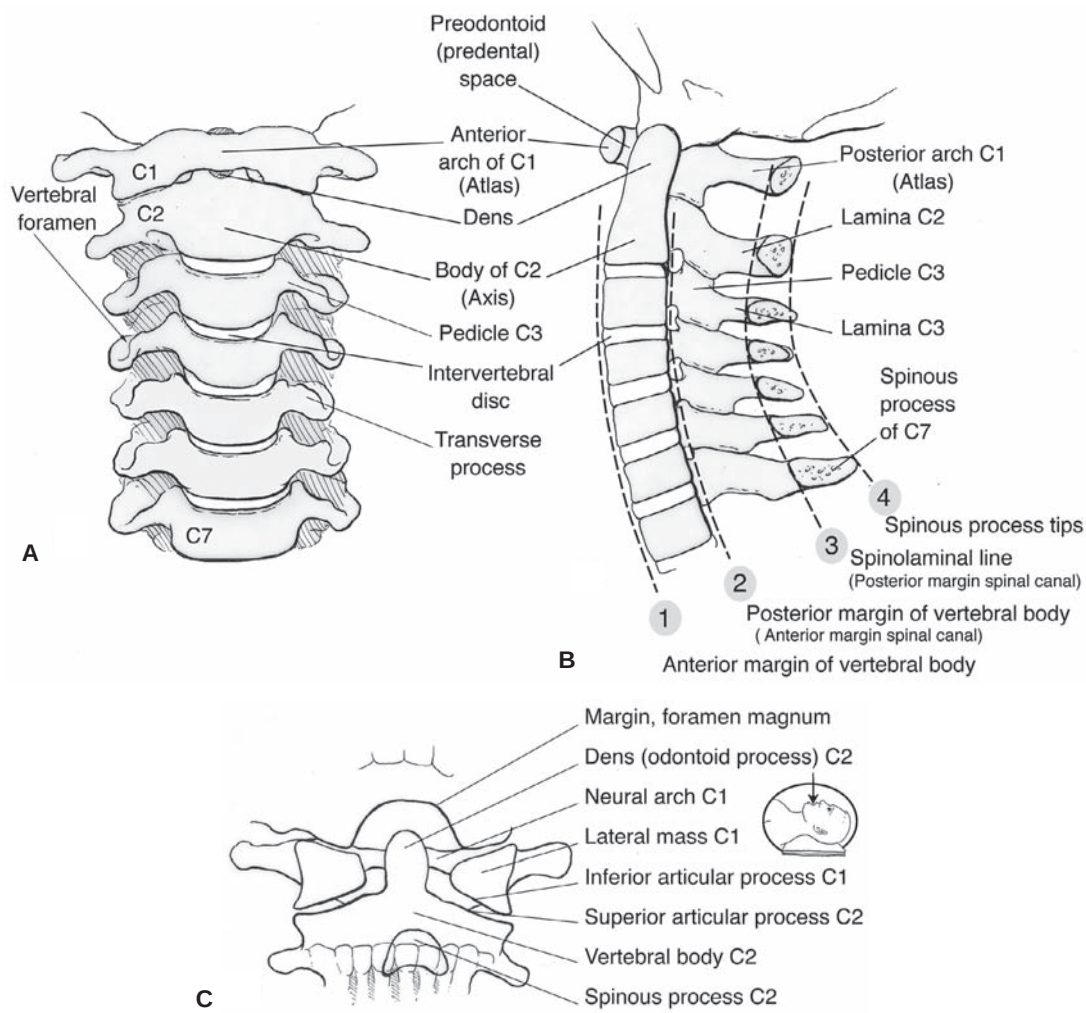

FIGURE 115.18 A–C: Knowledge of normal cervical spine anatomy is useful when evaluating cervical spine radiographs.

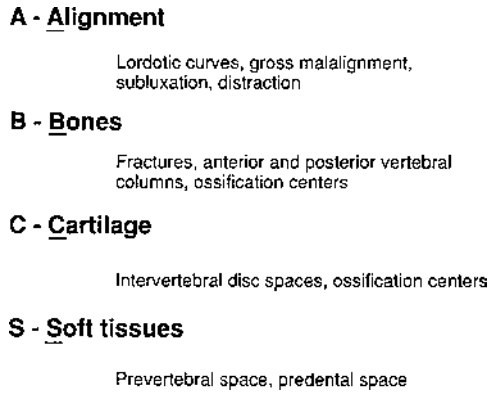

FIGURE 115.19 The ABCS of radiographic cervical spine interpretation.

A systematic approach should be used when evaluating radiographs of the cervical spine. The ABCS method is a useful approach (Fig. 115.19). Alignment is assessed as demonstrated in Fig. 115.20, keeping in mind that the spinal cord lies between the posterior spinal line and the spinolaminal line. These lordotic curves may not be present in children younger than 6 years, those on hard spine boards or in cervical collars, or those with cervical neck muscle spasm. Gross malalignment should be detectable with this assessment.

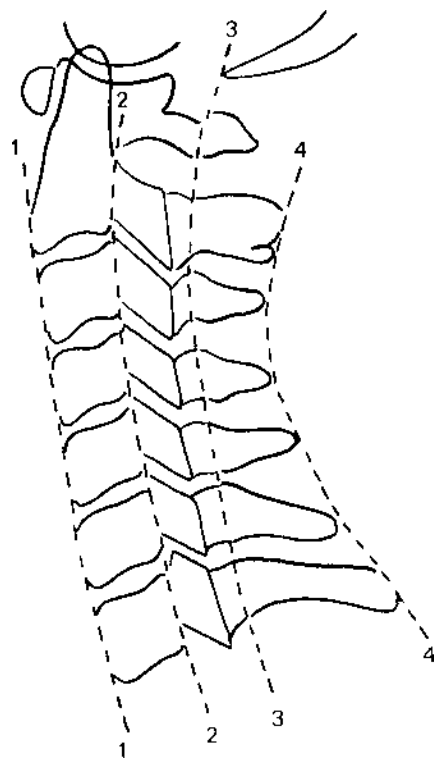

FIGURE 115.20 Four contour lines of alignment with normal cervical spine lordosis: *1*, anterior vertebral bodies; *2*, posterior vertebral bodies (anterior spinal canal); *3*, spinolaminal line (posterior spinal canal); and *4*, spinous process tips. (From Gerlock A, Kirchner S, Heller R, et al. *Advanced exercises in diagnostic radiology: the cervical spine in trauma*. Philadelphia, PA: WB Saunders, 1978:6. Reprinted with permission.)

TABLE 115.8

RADIOGRAPHIC CHARACTERISTICS OF PEDIATRIC CERVICAL SPINE

Cartilage artifact
Tapered anterior vertebrae
Apparently absent ring of C1
Atlas (C1) body not ossified at birth and may fail to close
Axis (C2) has four ossification centers
Apex of odontoid ossifies between 12 and 15 yr of age
Spinous process ossification centers
Increased mobility
Pseudosubluxation
C1 override on dens
Increased predental space (5 mm maximum)
Ligament laxity
Facet joints shallow
Growth plates (synchondrosis)
Dens ossifies between 3 and 8 yr of age (may persist into young adults)
Posterior arch of C1 ossifies at 3 yr of age
Anterior arch of C1 ossifies at 6–9 yr of age
C1 reaches adult size at 3–4 yr of age
C2 through C7 reach adult size at 5–6 yr of age
Lack of cervical lordosis
Fulcrum varies with age
Soft-tissue variability with respiration
Congenital clefts or other bony abnormalities (os odontoideum, spondylolisthesis, spina bifida, ossiculum terminale)

The bones should be evaluated for typical abnormalities, realizing that these may be subtle. Acute fractures are often irregular in location and appearance without sclerosis as compared with the more routine locations and appearance of cartilaginous growth areas. The clinician should be aware that structures that overlay the spine, including the skull and the teeth, might simulate fractures.

The next area of evaluation involves assessing the cartilage. Cartilage is radiolucent on plain radiographs. Children's spinal columns contain significant cartilage that may not only buffer a traumatic force and help prevent some injuries but can also make radiographic evaluation challenging. The cartilaginous areas include the synchondroses or growth plates and intervertebral disc spaces (Table 115.8). The growth plates may mimic fractures and may be confusing to those who are unaware of their presence. Growth centers in the anterior–superior vertebral bodies cause a sloped appearance that may appear as a compression fracture to the untrained eye. Anterior wedging can approach 3 mm and still be considered normal. Vertebral disc abnormalities may indicate specific types of injuries. A vertebral disc space that is narrowed anteriorly may indicate disc extrusion, whereas a widened space suggests a hyperextension injury with posterior ligamentous disruption.

Soft-tissue evaluation is extremely important. Abnormal soft-tissue spaces may be the only clue to the underlying ligament, cartilage, or subtle bone injury, which may not be obvious on the radiograph. The soft-tissue widening may represent blood or edema, which suggests an underlying injury. The prevertebral space at C3 should be less than one-half to two-thirds

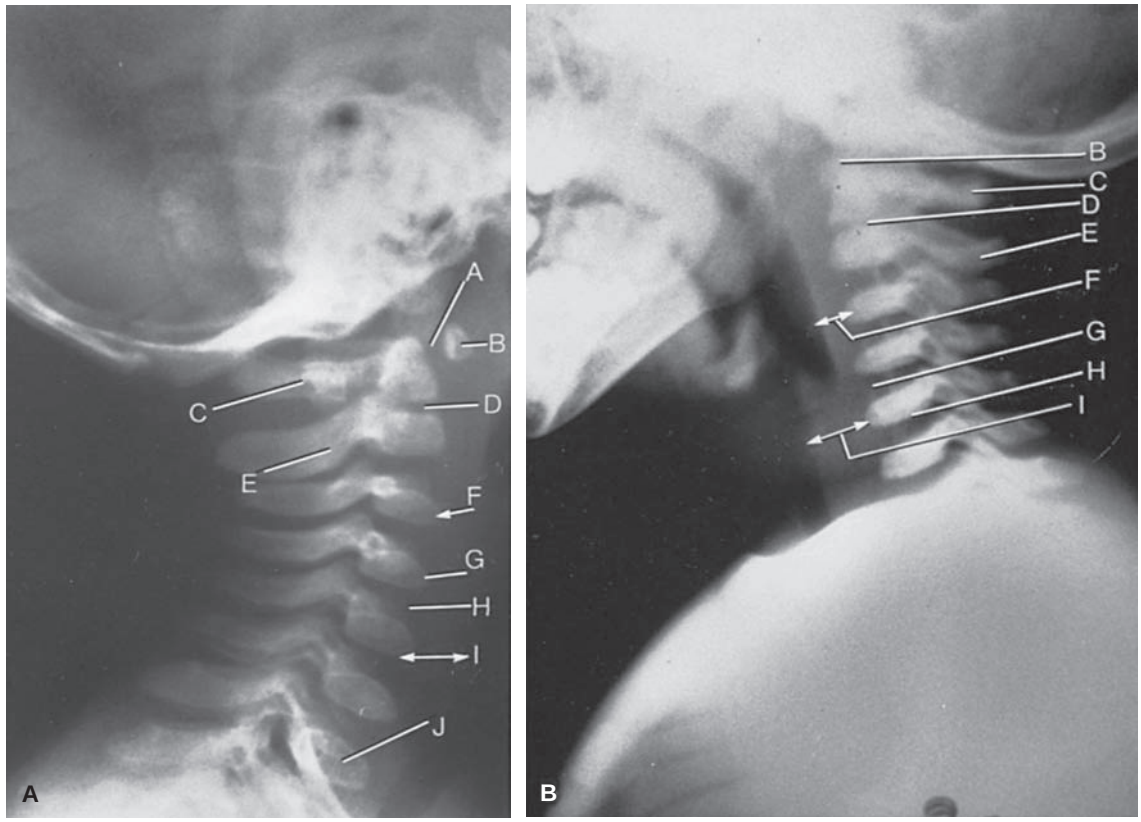

FIGURE 115.21 Normal pediatric lateral cervical spine radiographs. **A:** Three-month-old child. **B:** Twenty-month-old child. *A*, predental (predontoid) space; *B*, anterior ring of C1 (note apparent override of C1 over dens); *C*, posterior ring of C1; *D*, dens synchondrosis (growth plate); *E*, posterior elements C2; *F*, normal prevertebral space (C3 level); *G*, wedged vertebral appearance caused by cartilage artifact; *H*, intervertebral disc space; *I*, normal prevertebral space below the glottitis (thickened because of radiopaque collapsed esophagus); and *J*, vertebral body C7.

of the AP width of the adjacent vertebral body (Fig. 115.21). This space will double to approximately the width of the adjacent vertebral body below C4 (the level of the glottis) because the usually non–air-filled esophagus is present at this area. Care must be taken when evaluating the prevertebral soft-tissue space because crying, neck flexion, or the expiratory phase of respiration may produce a pseudothickening in the prevertebral space (Fig. 115.22). Soft-tissue abnormality should be reproducible on repeated radiographs if an actual underlying injury exists.

SPECIFIC INJURIES

The Jefferson fracture is a bursting fracture of the ring of C1 as a result of an axial load. The axial force compresses the ring of C1 between the occipital condyles of the skull and the lateral masses of C2. This reaction can cause an outward burst of C1, but it rarely causes immediate neurologic impairment because the fracture does not physically impinge on the spinal cord. The radiographic criterion for the diagnosis of a Jefferson fracture is lateral offset of the lateral mass of C1 of more than 1 mm from the vertebral body of C2 (Fig. 115.23). Neck rotation may give a false-positive radiographic finding. These fractures may be unstable, however, and require adequate immobilization. If the transverse ligament is intact, these may be relatively stable, whereas if the transverse ligament is injured and there is an increased distance between the lateral masses and odontoid process, these should be considered unstable. A reduced AP diameter of the cervical spinal canal is also associated with spinal cord injury. Approximately one-third of Jefferson fractures are associated with other cervical spine fractures, most often involving C2. The clinician must be aware of the pseudo-Jefferson fracture of childhood, which is present in 90% of children at 2 years of age and usually normalizes by 4 to 6 years of age. The pseudo-Jefferson fracture has the radiographic appearance of a Jefferson fracture because of increased growth of the atlas (C1) compared with the axis (C2) and radiolucent cartilage artifact. This disorder can present with unilateral or bilateral lateral mass offset. If a Jefferson fracture is suspected by radiographic findings and mechanism of injury in children younger than 4 years, a CT scan may be necessary to further elucidate the suspected injury (Fig. 115.15).

Hangman's fracture is a traumatic spondylolisthesis of C2. This injury occurs as a result of hyperextension, which

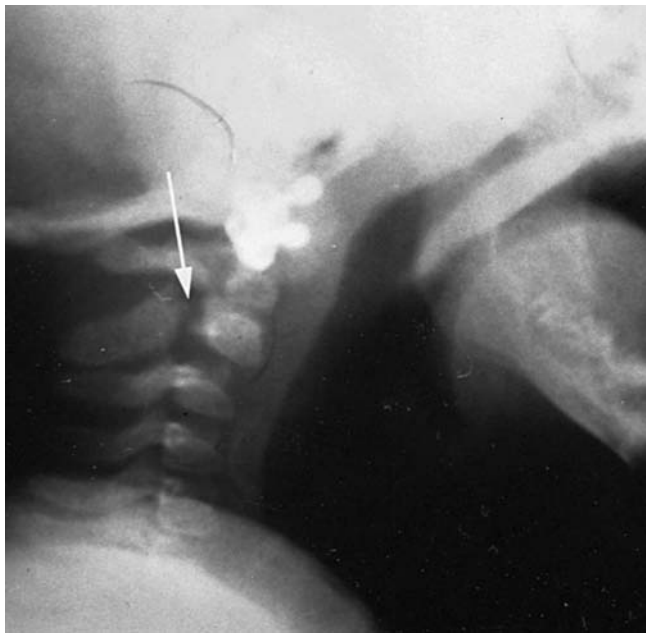

FIGURE 115.24 Hangman's fracture. A 7-week-old infant with fracture through the posterior elements of C2 as indicated by the *arrow*. (From Sumchai A, Sternback G. Hangman's fracture in a 7-week-old infant. *Ann Emerg Med* 1991;20:87. Copyright Elsevier Inc. Reprinted with permission.)

fractures the posterior elements of C2. Hyperflexion, with resultant ligamentous damage, may follow the hyperextension or may lead to anterior subluxation of C2 on C3 and subsequent damage of the cervical cord (Fig. 115.24). The subluxation associated with a hangman's fracture can sometimes be mistaken for the normal or physiologic subluxation that exists in the C2–C3 or C3–C4 region in approximately 25% of children younger than 8 years; it may also be seen in up to 16 years of age. This pseudosubluxation is caused by ligamentous laxity, relatively horizontal facet joints, weak neck muscles, and cartilage artifact. Distinguishing between a subtle hangman's fracture and pseudosubluxation can be accomplished using Swischuk's "posterior cervical line," as described in Fig. 115.25. A value of more than 1.5 to 2 mm suggests an occult hangman's fracture as the source of the anterior subluxation of C2 on C3. The increase in magnitude of the distance between the cortex of the spinous process of C2 and the posterior cervical line in a hangman's fracture is the result of anterior displacement of the skull, C1, and the anterior portion of C2 on the remainder of the lower cervical spine. Nontraumatic subluxation has also been reported at the C5/C6 and C6/C7 spinal levels, although subluxation at these lower levels should always be fully investigated for potential ligamentous injury.

Atlantoaxial (AA) subluxation is a result of movement between C1 and C2 secondary to transverse ligament rupture or a fractured dens (Fig. 115.26). Ligament instability may be precipitated by tonsillitis, cervical adenitis, pharyngitis, arthritis, or connective tissue disorders. It is also well described in patients with Down syndrome. Approximately 15% of patients with Down syndrome have radiographically demonstrated AA subluxation and therefore should be discouraged from contact sports. The presence or absence of AA subluxation in patients with Down syndrome, once believed to be a static phenomenon, may actually be transient and/or progressive. This ligament instability may progress to ligament rupture with minor trauma. Subluxation caused by a transverse ligament disruption is evidenced by a widened predental (preodontoid, atlantodental interval) space on a lateral radiograph (Fig. 115.26). Rotary subluxation can be classified as follows: type I (no displacement of C1), type II (3 to 5 mm C1 on C2 anterior displacement), type III (more than 5 mm C1 on C2 anterior displacement), and type IV (posterior displacement of C1 on C2). Normal predental measurement in children is less than 5 mm compared with less than 3 mm in adults. This space is wider in children than in adults for the same reasons as described for pseudosubluxation. *Steele's rule of three* states that the area within the ring of C1 consists of one-third odontoid, one-third spinal cord, and one-third connective tissue (Fig. 115.27). Therefore, limited space is available for dens movement or predental space widening without neurologic compromise. Neurologic symptoms are often not seen until the predental space exceeds 7 to 10 mm. A dens fracture is the cause of AA subluxation more often than ligamentous disruption in a young child because the weakest part of the musculoskeletal system in a child is the osseous component (Fig. 115.26). Several case reports describe odontoid fractures in children facing forward in car seats as a result of rapid stops. These fractures may traverse the growth plate in young children, although the clinician must be careful not to overcall fractures because of the presence of a growth plate. Neurologic damage can occur from direct spinal cord injury or secondarily from vertebral artery damage.

Cervical distraction injuries may result from rapid acceleration- or deceleration-type incidents, such as high-speed motor vehicle or pedestrian accidents (Fig. 115.28). This type of injury, although uncommon, is reported to be approximately 2.5 times more common in children than in adults. An injury that was incompatible with long-term survival, but for which initial cardiopulmonary resuscitation was successful, is shown in Fig. 115.28A. Cervical distraction injuries may be obvious or subtle on the lateral radiograph. Measurements for potential distraction injuries include the atlantooccipital and C1–C2 interspinous distances. The atlantooccipital distance should not exceed 5 mm. The C1–C2 interspinous distance should not exceed 10 mm. Sun et al noted the relationship between the C1–C2 and C2–C3 interspinous distance with regard to tectorial membrane (the stabilizing upper section of the posterior longitudinal ligament in the upper cervical spine) integrity and injury. A C1–C2:C2–C3 ratio of more than 2.5 suggests injury to the tectorial membrane and potential ligamentous instability. Sun's ratio, as well as a ratio of measurements of the basion to the posterior arch of C1 (BC) and the opisthion to the anterior arch of C1 (OA), is demonstrated in Fig. 115.29. If the BC:OA ratio is more than 1, it signifies atlantooccipital dislocation. Atlantooccipital dislocation is often fatal, but there are reports of survivors. Neurologic deficits may develop from direct spinal damage or associated carotid or vertebral artery injury. Distraction injuries may also be seen with difficult newborn deliveries. These injuries may not be visible on a plain radiograph because the pediatric cervical spine can transiently distract 2 inches before residual radiographic evidence of spinal column separation is present. However, the spinal cord can distract only 0.25 inches before permanent neurologic

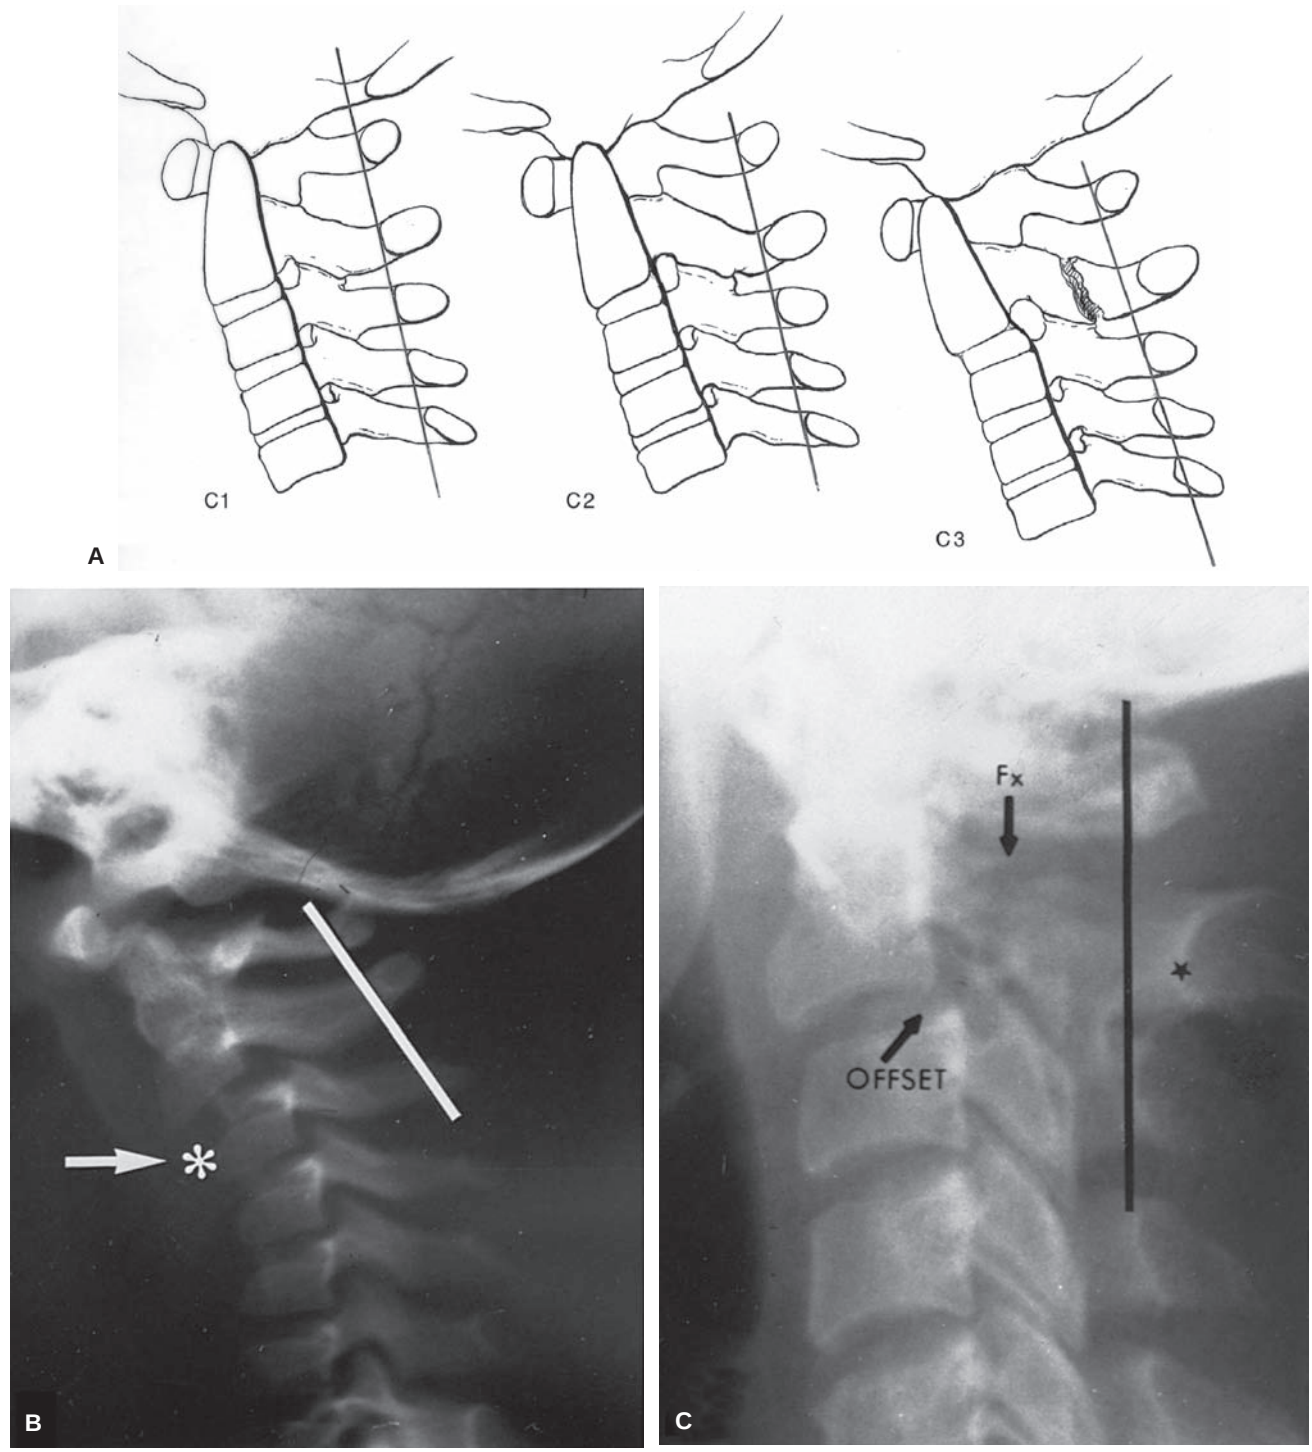

FIGURE 115.25 **A:** Posterior cervical line of Swischuk. Line is drawn from the cortex of the spinous process of C1 to the cortex of the spinous process of C3. Relationship of the line to cortex of the spinous process of C2 is noted. If the line is situated more than 2.0 mm anterior to the cortex of the spinous process of C2, underlying cervical pathology should be present. This line should be used only with anterior displacement of C2 on C3. **B:** Pseudosubluxation of C2 on C3 with normal posterior cervical line in a 2-year-old child. Note apparent widening of prevertebral soft tissue. **C:** Abnormal posterior cervical line with an underlying hangman's fracture. Actual offset is 4 mm. (**C:** From Swischuk L. *Emergency radiology of the acutely ill or injured child,* 2nd ed. Baltimore, MD: Williams & Wilkins, 1986:562–563. Reprinted with permission.)

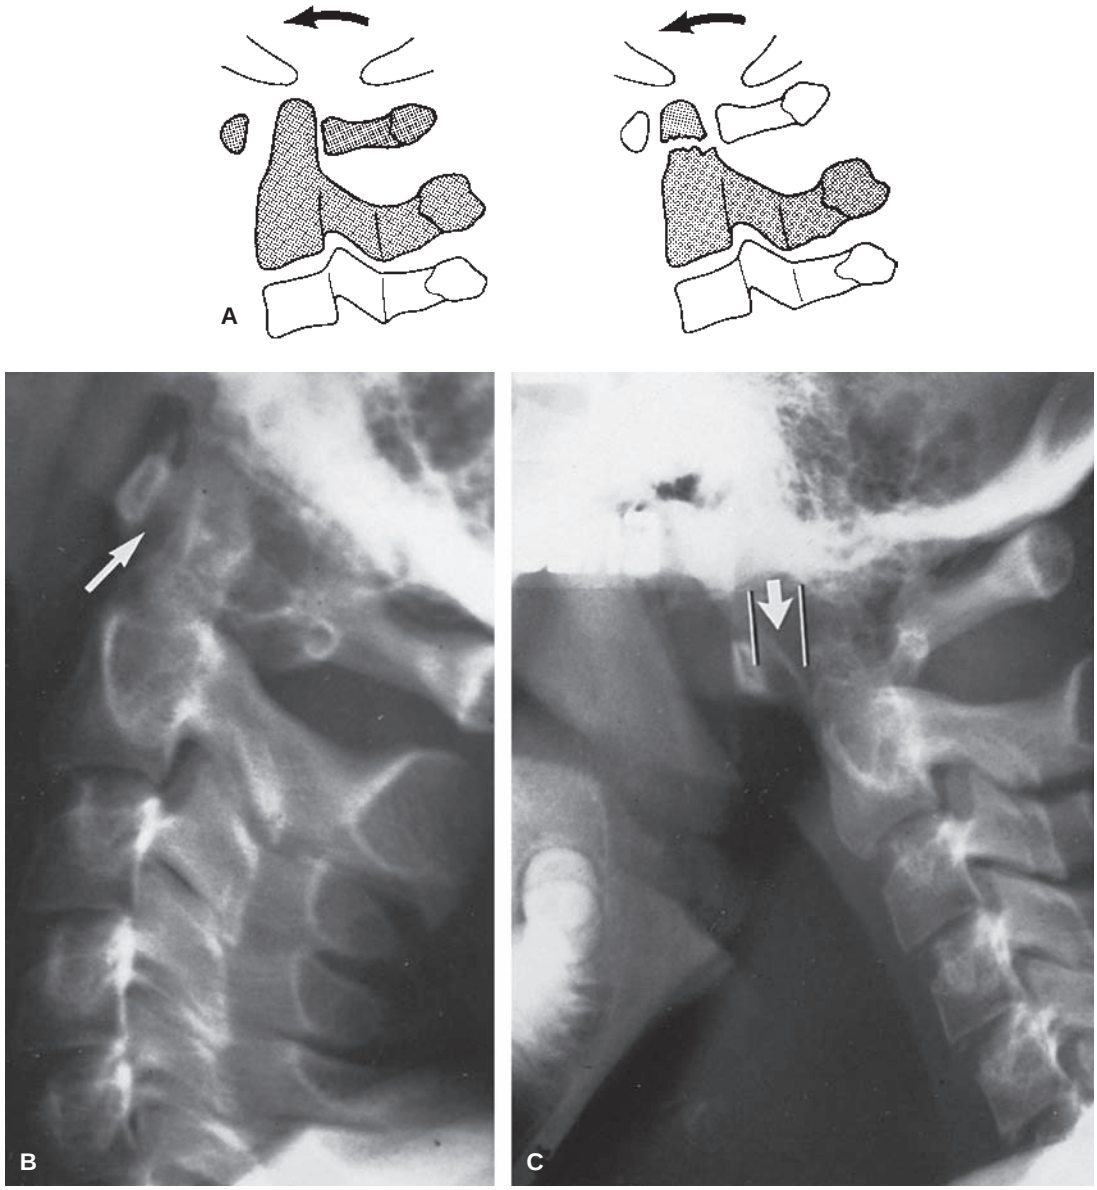

FIGURE 115.26 **A:** Diagrammatic representation of transverse ligament disruption (*left*) and dens fracture (*right*). **B:** Widened predental space on initial lateral radiograph in 15-year-old girl (actual measurement was 4 mm). **C:** Flexion radiograph in same patient demonstrating increased predental space with evidence of transverse ligament disruption. (*continued*)

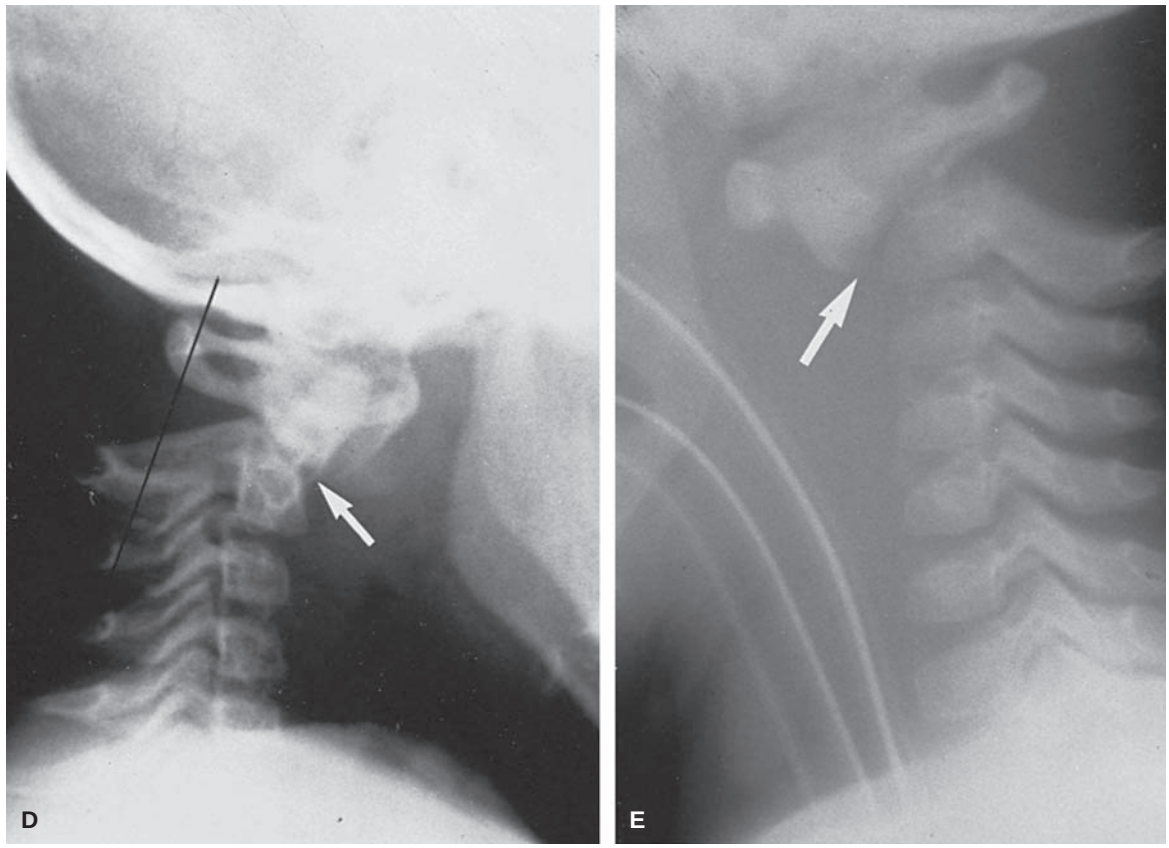

FIGURE 115.26 (*Continued*) **D:** Dens fracture with anterior subluxation of C1 and the dens on the remainder of the spinal column. *Arrow* indicates fracture. Abnormal posterior cervical *line* is also shown. **E:** Dens fracture (*arrow*) with anterior subluxation of the dens on the body of C2. (**A:** From Swischuk L. *Emergency radiology of the acutely ill or injured child*, 2nd ed. Baltimore, MD: Williams & Wilkins, 1986:572. Reprinted with permission.)

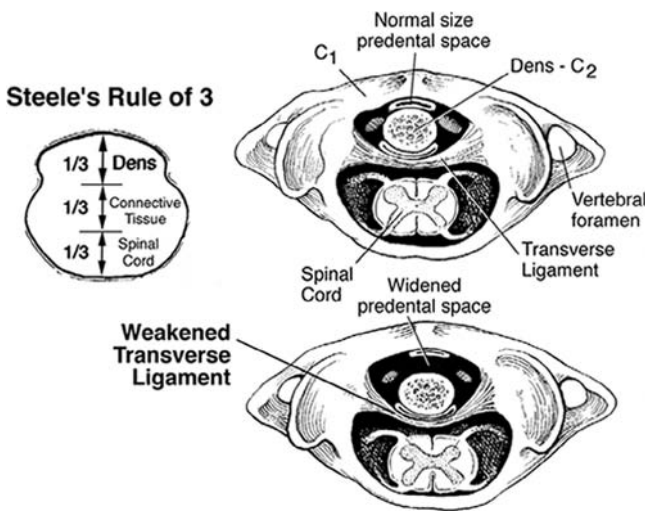

FIGURE 115.27 A cross section through the ring of C1 demonstrates Steele's rule of three. The space between the cervical cord and dens allows limited movement between C1 and C2 without immediate neurologic compromise.

damage occurs. An MRI scan is useful in evaluating an infant with diminished motor activity and who is suspected of having a distraction injury.

Vertebral compression injuries are suggested by isolated anterior wedging, teardrop fractures, or burst vertebral bodies (Fig. 115.30). The vertebral bodies should be regular, cuboid, and consistent between adjacent cervical levels (Fig. 115.30). A flexion/rotation stress can lead to anterior subluxation of one vertebral body on another with facet dislocation ("locked" or "jumped" facet) (Fig. 115.31). If the anterior displacement is less than 50% of the vertebral body width, it is consistent with a unilateral facet dislocation (Fig. 115.31). More than a 50% anterior subluxation suggests a bilateral facet dislocation (Fig. 115.31). These injuries are often accompanied by widened interspinous and interlaminar spaces, anterior soft-tissue swelling, and a narrowed disc space.

SCIWORA has been described in up to 67% of children with cervical cord injuries (Fig. 115.32). It has more recently been estimated to account for up to 25% of cervical cord injuries in children younger than 8 years. Interestingly, the 2002 NEXUS SCIWORA report, which included more than

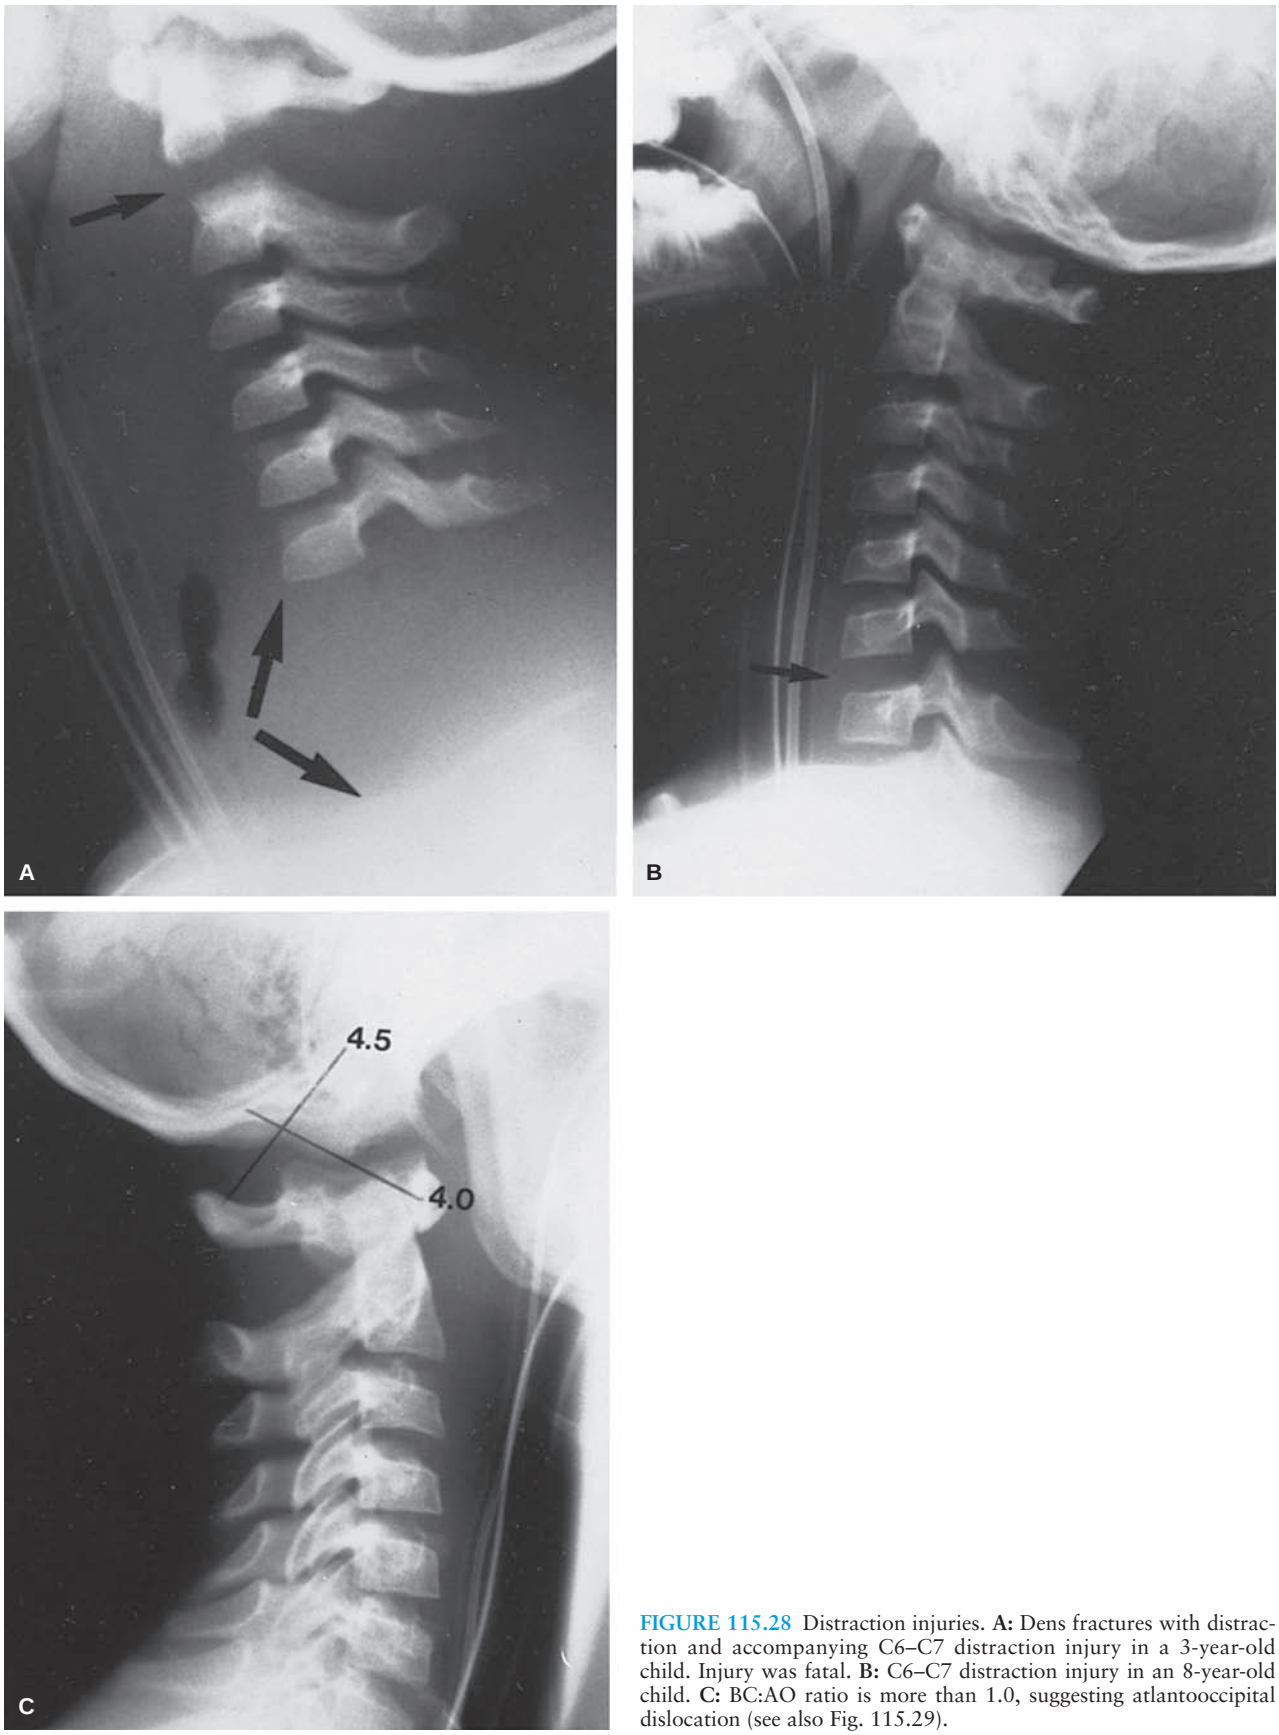

FIGURE 115.28 Distraction injuries. **A:** Dens fractures with distraction and accompanying C6–C7 distraction injury in a 3-year-old child. Injury was fatal. **B:** C6–C7 distraction injury in an 8-year-old child. **C:** BC:AO ratio is more than 1.0, suggesting atlantooccipital dislocation (see also Fig. 115.29).

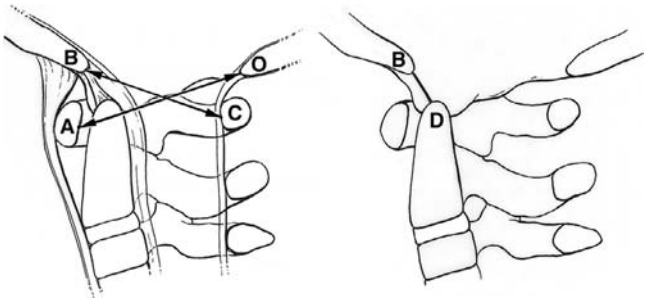

FIGURE 115.29 Examples of methods to assess occipital/C1 relationships. *A*, C1 anterior arch; *B*, basion (anterior margin of foramen magnum); *C*, anterior portion of the posterior ring of C1; *O*, opisthion (posterior margin of foramen magnum); and *D*, tip of the dens (odontoid process). These landmarks may not be easily visible on all radiographs. A BC:AO ratio of more than 0.9 to 1.0 suggests anterior dislocation or subluxation of the atlantooccipital joint. A BD distance of more than 10 to 12.5 mm should be suggestive of atlantooccipital dislocation. A C1–C2:C2–C3 ratio of more than 2.5 suggests injury to the tectorial membrane and ligamentous instability.

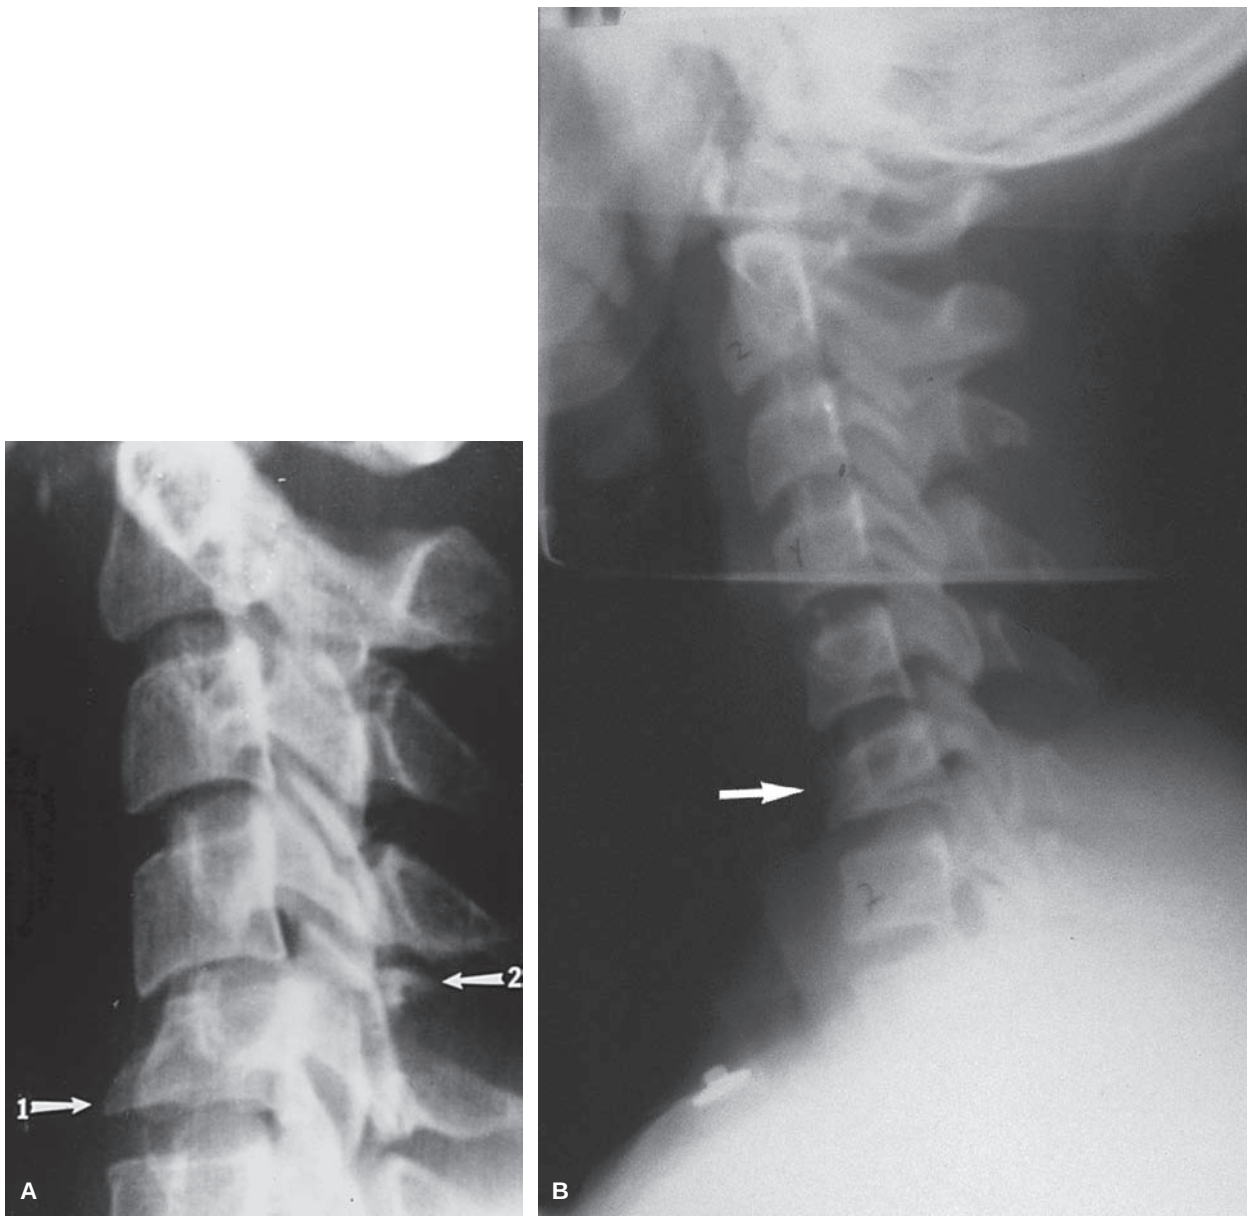

FIGURE 115.30 Examples of cervical compression injuries. **A:** Teardrop fracture. This patient sustained a whiplash injury with resultant flexion injury. A typical flexion teardrop fracture is demonstrated at (*1*). An increased interspinous distance and an associated avulsion fracture of the posterior elements of C5 are demonstrated at (*2*). **B:** Anterior C6 vertebral wedge fracture. (*continued*)

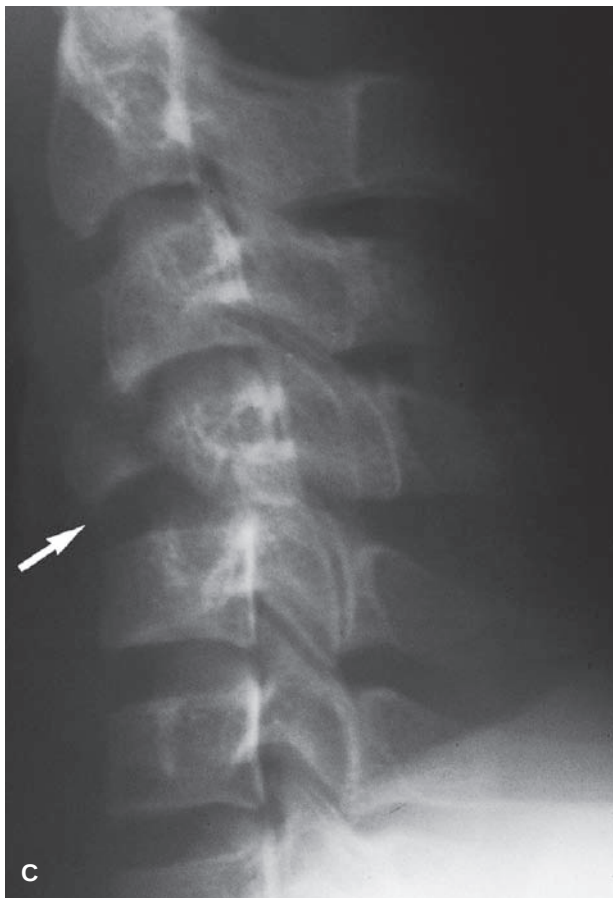

FIGURE 115.30 (*Continued*) **C:** Burst fracture of C4 vertebral body. (**A:** From Swischuk L. *Emergency radiology of the acutely ill or injured child,* 2nd ed. Baltimore, MD: Williams & Wilkins, 1986:674. Reprinted with permission.)

3,000 children (although only 30 with cervical spine injury), did not have any pediatric patients falling into the SCIWORA category (although 22 adults did have injuries consistent with the SCIWORA syndrome). SCIWORA has been described as mainly occurring in children younger than 8 years who present with, or develop symptoms consistent with, cervical cord injuries without any radiographic or tomographic evidence of bony abnormality. SCIWORA is not often seen in children older than 8 years because the forces necessary to injure the spinal cord also cause persistent spinal column abnormalities. The young child's elastic spinal column allows the spine to deform beyond physiologic extremes, injuring the cord and then reducing spontaneously without any persistent (radiographic) evidence of bony injury. The causes of the neurologic compromise can include segmental spinal instability, vascular injury (occlusion, spasm, and infarction), ligamentous injury, disc impingement, or incomplete neuronal destruction. A subset of patients has initial transient neurologic symptoms as previously described, apparently recover, and then return an average of 1 day later with significant neurologic abnormalities. Therefore, many authors recommend hospitalization, immobilization, and further radiographic evaluation (MRI) for young patients who had a history of transient

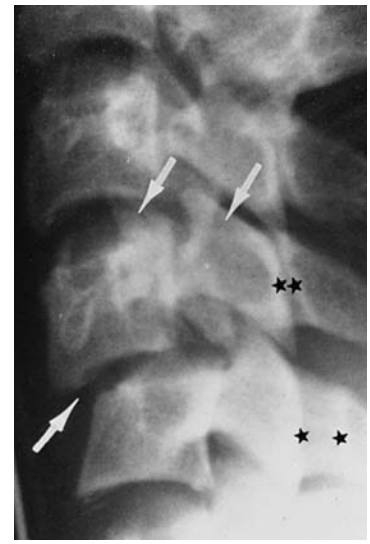

FIGURE 115.31 Unilateral facet dislocation. C4 is offset anteriorly on C5 less than 50% of the width of the vertebral body. *Arrows* denote the offset of vertebral body and apophyseal joints. The disc space between C4 and C5 is narrowed. Note that the distance between the posterior cortex of the apophyseal joint facet and the anterior cortex of the spinous process tip is wider below the level of dislocation than above the level (*stars*). Anterior vertebral offset of more than 50% would denote a bilateral facet dislocation. (From Swischuk L. *Emergency radiology of the acutely ill or injured child,* 2nd ed. Baltimore, MD: Williams & Wilkins, 1986:697. Reprinted with permission.)

neurologic symptoms at the time of injury. At the least, neurosurgical consultation is recommended if the history suggests a SCIWORA-type injury in a child younger than 8 years.

Torticollis (wry neck) is a common complaint in the pediatric ED. The clinician should always inquire about

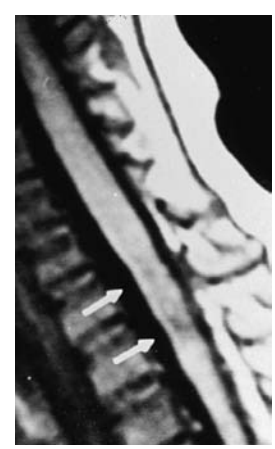

FIGURE 115.32 Magnetic resonance imaging (MRI) of SCIWORA patient. Accompanying cervical spine radiographs were normal. The MRI demonstrates an area of cord contusion in the midcervical area. This patient had physical evidence of a central cord syndrome. (From Swischuk L. *Emergency radiology of the acutely ill or injured child,* 2nd ed. Baltimore, MD: Williams & Wilkins, 1986:710. Reprinted with permission.)

traumatic causes because an underlying bone injury may be present. Often, however, torticollis is caused by spasm of the sternocleidomastoid (SCM) muscle. The patient with muscular torticollis has spasm of the SCM muscle on the opposite side as the chin points because the cause of torticollis is muscular spasm. This condition is opposite from rotary subluxation. Rotary subluxation is a cervical spine injury that is often misdiagnosed or undiagnosed because of difficulty in interpreting these patient's radiographs. Rotary subluxation or displacement may be spontaneous or may follow an upper respiratory tract infection or minor or major trauma. These patients rarely present with abnormal neurologic findings. They will assume the typical (cock robin) position with the spasm of the SCM muscle on the same side as the chin points. This reaction is logical considering that the SCM muscle is attempting to reestablish normal neck position. Radiographs may be useful to help distinguish between muscular torticollis and rotary subluxation, although the radiographs may be normal in both cases (Figs. 115.33 and 115.34). Rotary subluxation should be suspected if, on an open-mouth radiograph, one of the lateral masses of C1 appears forward and closer to the midline whereas the opposite lateral mass appears narrow and away from the midline (lateral offset), although a normal film does not rule out rotary subluxation. Cineradiography can demonstrate that C1–C2 moves as a unit; however, the CT scan appears to be the most useful diagnostic tool in rotary subluxation (Fig. 115.34). Patients with mild rotary subluxation should be treated with a cervical collar and analgesia for comfort, whereas those with moderate or resilient rotary displacement may need immobilization and traction. If anterior displacement of C2 on C1 is present, longer immobilization may be needed to allow injured ligaments to heal.

Several specific spinal cord syndromes may be encountered in the ED (Fig. 115.35). A spinal cord concussion (transient traumatic paresis or paralysis) involves neurologic symptoms that completely resolve over a short period. This condition can occur with or without associated fracture or dislocation. A complete cord transection (either mechanical or physiologic) results in immediate and permanent loss of all neurologic functions distal to that level (Fig. 115.35). The anterior spinal artery (anterior cord) syndrome results from the loss of neurologic function in those areas supplied by the anterior spinal artery (Fig. 115.35). Motor function is lost below the level of the lesion. Touch and proprioceptive functions, carried by the dorsal (posterior) columns, are preserved. The posterior cord syndrome is rare (Fig. 115.35). It involves the loss of proprioceptive functions, deep pressure, and pain and vibratory sense, with preservation of motor and temperature sensation. This can occur with direct posterior cord trauma or posterior spinal artery involvement. The Brown-Sequard syndrome (hemisection of the cord) involves contralateral loss of pain and temperature sensation with ipsilateral motor findings (weakness or paralysis) below the lesion (Fig. 115.35). The central cord syndrome signifies an injury that is most severe in the center of the cord and less so toward the periphery (Fig. 115.35). The resultant physical examination demonstrates motor strength that is more severely affected in the arms than in the legs. These designations are useful in suggesting prognosis. Approximately two-thirds of those patients with central cord syndrome and one-third of those with the Brown-Sequard syndrome recover. Complete transections and anterior spinal artery syndrome usually signify nonreversible lesions. Patients with posterior cord syndrome usually recover but may demonstrate some degree of ataxia.

The os odontoideum is an abnormality that may be the result of an occult flexion injury with a subsequent incomplete healing and bone resorption (Fig. 115.36). It may also represent an overgrowth of the ossiculum terminale, often associated with a hypoplastic dens. This leads to a risk of increased mobility and cord injury at the C1–C2 level and may require surgical stabilization. This condition can be confused with a fracture at the base of the odontoid. The ossiculum terminale is a small ossicle at the tip of the dens (Fig. 115.37). It is seen in most children, fusing with the rest of the dens by adolescence. This ossicle can be large and associated with a hypoplastic dens, as previously described.

Spinal epidural hematomas are also seen in the pediatric population. These hematomas are venous bleeds that compress the adjacent spinal cord and present hours or days after apparently minor trauma, with ascending neurologic symptoms as the bleed progresses. The MRI scan can be helpful in evaluating these patients (Fig. 115.38). Rapid evaluation and surgical decompression are mandatory.

Treatment of children with suspected cervical spine injuries may involve basic and advanced life-support measures, initiation and/or maintenance of immobilization, neurosurgical consultation, and consideration of pharmacologic treatment. Airway support for patients with traumatic quadriplegia should be considered because they will develop respiratory embarrassment as they tire. Children may present in spinal shock (hypotension, bradycardia, peripheral flush) from the loss of sympathetic input to the vascular system. The physical examination may be misleading in that these patients are bradycardic (unable to mount tachycardic response to relative hypovolemia) and demonstrate warm, flushed skin in the setting of hypotension (loss of vasomotor tone). These symptoms may also be superimposed on traumatic (hypovolemic) shock. These patients need fluid resuscitation and may require inotropic (alpha agonist) support, such as norepinephrine or phenylepherine, to maintain adequate perfusion and avoid fluid overload. Appropriate fluid management is important in preventing hypoperfusion of the already injured spinal cord. Investigations in the adult population suggested that methylprednisolone (Solu-Medrol) in a dosage of 30 mg per kg over 15 minutes, followed by 5.4 mg per kg per hour for 24 to 48 hours, may improve functional outcome in patients with spinal cord injury. These studies specifically excluded children younger than 13 years. Methylprednisolone was reported to be most effective if administered as soon as possible after the injury and maintained for 24 to 48 hours, depending on the time of initiation (Table 115.9). If started within 3 hours, it should be maintained for 24 hours. If started between 3 and 8 hours after the injury, continuation for 48 hours was recommended. The use of steroids for blunt cervical trauma has come under scrutiny in more recent years. Several authors suggest that steroid administration increases potential risk to the patient and does not lead to meaningful neurologic recovery and that its use as a standard of care is not justified. Frampton and Eynon, in 2006, reported marked variability in current practice regarding methylprednisolone

Actual measurement was 22 degrees of rotation. (*continued*)

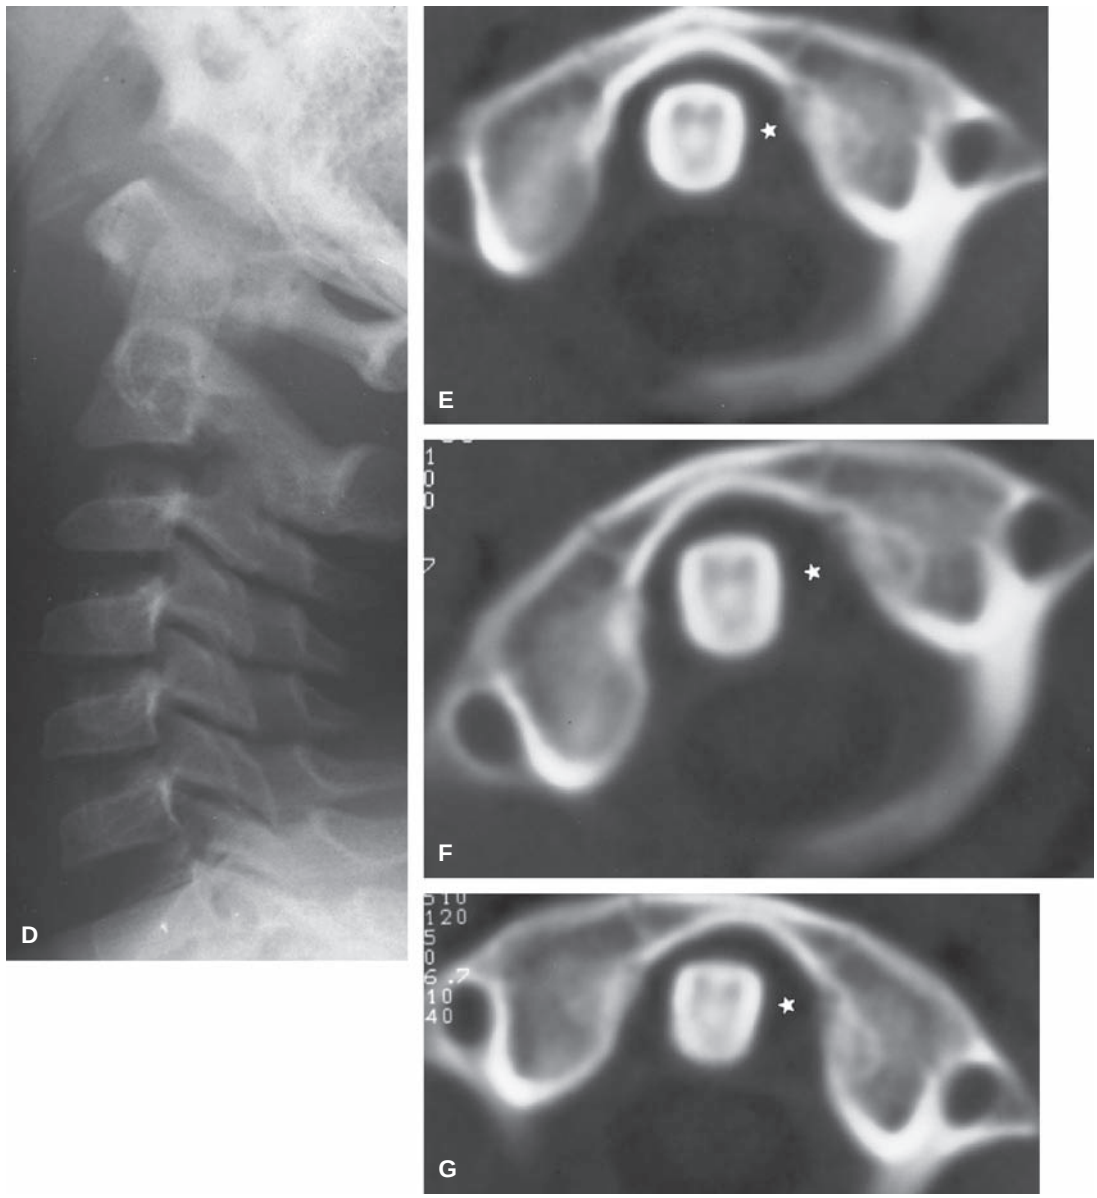

FIGURE 115.34 (*Continued*) **D–G:** CT evidence of fixed rotary subluxation in a 6-year-old child. **D:** Lateral radiograph demonstrating mild increased distance of predental space. **E:** Axial CT scan demonstrating increased distance between dens and patient's left side of C1 (asymmetry between right and left sides). **F:** Axial CT scan with patient's head turned to the right, demonstrating asymmetry between the dens and ring of C1. **G:** Axial CT scan with patient's head turned to the left, demonstrating fixed asymmetry between the dens and the ring of C1.

TABLE 115.9

METHYLPREDNISOLONE ADMINISTRATION SCHEDULE FOR BLUNT CERVICAL SPINAL CORD TRAUMA[a]

Time after injury	0–3 h	3–8 h	8 h
Initial IV dosage	30 mg/kg (over 15 min)	30 mg/kg (over 15 min)	Efficacy not demonstrated
Maintenance IV dosage	5.4 mg/kg/h	5.4 mg/kg/h	
Suggested duration	24 h	48 h	

[a]Consideration and/or potential use of methylprednisolone should be established with input from local experts. See text for discussion of methylprednisolone use in pediatrics and cervical spine trauma.

after spinal injury in the United Kingdom and noted that steroids are not recommended by the Canadian and British spinal cord associations for acute blunt spinal cord injury. Steroid use for the pediatric patient with a clear or potential blunt cervical cord injury is not routinely indicated and should be a joint decision between the treating emergency, trauma, and neurosurgical physicians. Methylprednisolone is not recommended in conjunction with penetrating neck injuries.

CHAPTER 116 ■ NEUROTRAUMA

DAVID S. GREENES, MD

HEAD TRAUMA

In the United States, approximately 1.2 million people visit emergency departments (EDs) with a complaint of head trauma each year, including approximately 475,000 children younger than 14 years. About 1 of every 1,400 children is hospitalized each year for a traumatic brain injury, with the highest rates in infants. Brain injury is the leading cause of death and disability among pediatric trauma patients. Because morbidity and mortality after head trauma can be lessened by prompt stabilization, emergency physicians need to be thoroughly familiar with the manifestations of significant head injury and the necessary diagnostic and therapeutic maneuvers.

The approach to the child with a head injury is outlined in Chapter 37. This chapter focuses on the clinical anatomy, pathophysiology, clinical manifestations, diagnosis, and management of specific traumatic lesions to the head.

Clinical Anatomy

The anatomy of the head can perhaps best be considered initially in layers, traveling from the scalp inward toward the brain parenchyma.

Injuries to the scalp, including hematomas and lacerations, are common, although not usually serious. The scalp is well vascularized. Therefore, even minor scalp lacerations may result in vigorous bleeding. Rarely, there is enough bleeding to cause some hemodynamic compromise, especially in infants. The rich vascularity of the scalp also makes it prone to the development of impressive hematomas.

Beneath the skin and subcutaneous fat of the scalp is a strong layer of tissue known as the galea aponeurotica. Deep lacerations of the scalp can also be associated with a laceration to the galea. Hematomas beneath the galea are common after blunt impact to the cranium, especially in cases associated with skull fracture. As the clotted hematomas begin to liquefy several days after the injury, large, boggy subgaleal hematomas become evident.

The bony "skullcap" or calvarium is composed of the frontal, parietal, occipital, and temporal bones, each of which is joined to one another by cranial sutures. Portions of the temporal and occipital bones, along with the sphenoid, palatine, and maxillary bones, comprise the skull base. Any portion of the cranium may fracture, although fractures are most likely where the bone is thinnest, as in the temporal and parietal regions and in the skull base. Fractures of the skull base may in some cases involve the mastoid air cells, the sphenoid sinus, or the cribriform plate, and they may also be associated with a tear in the underlying meninges. In such cases, there is a direct communication between the cerebrospinal fluid (CSF) system and the nasopharynx or middle ear, posing a risk for intracranial infection. Basilar skull fractures can also be associated with injuries to the cranial nerves or cerebral vessels that course through foramina in the skull base.

Just beneath the skull is the dura mater, which tightly adheres to the skull at the suture lines. Between the dura mater and the skull is a potential space known as the epidural space. The meningeal arteries are embedded between two layers or "leaves" of the dura. As the body matures through childhood, some vessels—most notably the middle meningeal artery—begin to groove into the overlying bone. Therefore, traumatic impacts to the skull are particularly likely to injure these vessels. In addition, layers of the dura mater split away from each other to form the venous channels known as dural sinuses. These sinuses, which drain the venous blood from the brain, may also be lacerated by trauma to the skull. The result of a laceration to the dural sinus or meningeal vessels is an epidural hematoma (EDH).

The next layer of meningeal tissue is the arachnoid mater. The arachnoid is a thin layer of tissue that is closely associated with the cerebral cortex but that does not course into the brain sulci. The arachnoid mater separates the CSF-containing cisterns and subarachnoid space below from the subdural space above. The subdural space is traversed by the cerebral veins as they course from the brain to the dural sinuses. These so-called bridging veins may be sheared by acceleration/deceleration forces that violently move the brain relative to the position of the skull. The collection of blood that results is a subdural hematoma (SDH).

The subarachnoid space, which separates the arachnoid mater from the pia mater below, contains the CSF that bathes the brain and the spinal cord. The pia mater is a layer of tissue that is essentially inseparable from the underlying brain, coursing with it over all gyri and sulci. The pia mater is highly vascularized with small vessels that may be injured when shear forces or direct blows are applied to the brain. Localized bleeding from these vessels may result in subpial or subarachnoid hemorrhage (SAH).

Just beneath the pia mater is brain parenchyma. The brain does not adhere to the skull at any point; rather, it can move freely within the skull, cushioned to some extent by the CSF in which it bathes. Direct blows to the head, associated with some deformation to the skull, may lead to bruising or hemorrhage in the cortex at the point of impact. In other cases, in which a blunt impact causes the brain to move against a relatively stationary skull, a contrecoup injury to the cortex on the side opposite the site of impact may occur.

In other cases, shear forces (as in severe acceleration/deceleration injury) can lead to diffuse injury to the axons comprising the subcortical white matter.

The brain is separated both by bony prominences and by projections of the dura into three compartments: the anterior, middle, and posterior fossae. Clinically, the most important separation is that which is made by the tentorium cerebelli, a projection of dura mater that separates the cerebellum below from the cerebral cortex above. A notch in the tentorium allows passage of the midbrain. Cranial nerve III, the oculomotor nerve, courses along the edge of this tentorial notch. The parahippocampal gyrus and uncus of the temporal lobe lie just above the tentorial notch. When there is an increase in intracranial volume (as from a mass lesion or from cerebral edema), the temporal lobe is pushed down through the tentorial notch, compressing cranial nerve III and the midbrain and brainstem in the process. Tentorial herniation syndrome results.

Another projection of the dura, the falx cerebri, separates the two cerebral hemispheres. Mass lesions in either hemisphere can rarely cause herniation beneath the falx to the opposite side. Herniation can also rarely occur when mass effect in the frontal lobe pushes the frontal brain posteriorly across the lesser wing of the sphenoid bone, which separates the anterior fossa from the middle cranial fossa.

Deep within the subcortical white matter of the brain lies the ventricular system, which is composed of two lateral ventricles, the third ventricle, and the fourth ventricle. The ventricular system is in communication with the subarachnoid space via connections from the fourth ventricle to the subarachnoid space at the levels of the pons and the medulla. A mass lesion or cerebral edema may cause compression of the third or fourth ventricle or of the outflow tracts, thereby blocking CSF egress and causing acute hydrocephalus.

Finally, it is important to consider the foramen magnum, the opening that allows passage of the neural tissue at the level of the junction between the medulla and the spinal cord. Mass lesions in the posterior fossa can lead to herniation of the cerebellar tonsils through the foramen magnum, with resultant compression of the medulla and potentially devastating consequences.

Pathophysiology

Primary versus Secondary Brain Injury

Traumatic brain injury typically can be divided into two main components: primary and secondary brain injury. *Primary brain injury* refers to neural damage that is attributed directly to the traumatic insult itself. Shearing of neuronal axons, contusion or laceration of cerebral tissue, or direct penetration of the brain by a missile, for instance, all constitute primary brain injury.

Secondary brain injury refers to subsequent injury, after a trauma has occurred, to brain cells not injured by the initial traumatic event. These injuries may result from numerous causes, including hypoxia, hypoperfusion, excitotoxic damage, free radical damage, or metabolic derangements. In some cases, the effect of secondary brain injury is far more devastating than the primary brain injury itself. Because many of the causes of secondary brain injury are at least theoretically preventable, most of the efforts in neurotrauma care are directed at monitoring for, and attempting to prevent, these complications.

Cerebral Ischemia

Probably the most important cause of secondary brain injury is brain ischemia, resulting from inadequate cerebral blood flow (CBF). Adequate CBF depends first on the presence of patent cerebral vessels to deliver blood to the brain. Occasionally, severe head injury can be associated with shear, dissection, compression, or thrombosis of the major cerebral vessels, leading to tissue infarction. Vasospasm of the cerebral vasculature can also contribute to secondary brain injury. Vasospasm is not uncommon in cases of severe head injury, especially in those cases that are associated with SAH. Recent studies using advanced imaging techniques in patients with severe head injury suggest that up to 45% have cerebral vasospasm and as many as 8% are complicated by cerebral infarction.

Adequate CBF depends not only on patent vessels but also on adequate cerebral perfusion pressure (CPP). The CPP reflects a balance between the mean arterial pressure (MAP) of blood flowing to the brain and the intracranial pressure (ICP), which acts as a counterforce, limiting blood flow to the brain. The relationship between these forces can be described mathematically: $CPP = MAP - ICP$.

In healthy children, the ICP is less than 20 mm Hg and MAP is 70 to 80 mm Hg or more (depending on the patient's age), yielding a CPP of 50 to 60 mm Hg or more. The CPP fluctuates, but the healthy body maintains constant CBF in the face of minor fluctuations in CPP through autoregulation. *Autoregulation* is a process of reflex vasoconstriction or vasodilation in response to changes in CPP, thereby modulating resistance to blood flow in the cerebral vasculature to maintain a constant CBF. However, if the CPP drops too low (i.e., less than 40 or 50 mm Hg), the body will not be able to maintain adequate CBF despite maximal vasodilation. At this point, cerebral ischemia ensues. Several studies have demonstrated impaired autoregulation in some patients with head injury, especially in younger children. Disordered autoregulation may contribute to impaired CBF.

Increased Intracranial Pressure

Severe drops in CPP can result either from systemic hypotension (as in multiple trauma patients with exsanguinating injuries) or from significant increases in ICP. Increases in ICP are common in patients with serious head injuries, and they account for much of secondary brain injury.

Increased ICP may result from any process that increases the volume of the intracranial contents. Because the cranium has a fixed size and is relatively noncompliant, it can accommodate only a certain volume of intracranial contents at low pressure. An idealized pressure-volume curve (as seen in Fig. 116.1) represents the relationship between intracranial volume and ICP. In the normal state, small increments in intracranial volume can be made without significant change in the ICP (point 1 on the curve in Fig. 116.1). At this point, the intracranial contents are not particularly "tightly" packed into the cranium and there is room for additional volume. After a certain critical point is reached, however (as indicated by point 2 on the curve in Fig. 116.1), additional volume begins to lead to increases in ICP. At some point soon thereafter, the compliance of the intracranial space is exhausted (point 3 on the curve in Fig. 116.1) and the pressure-volume curve becomes steep, with

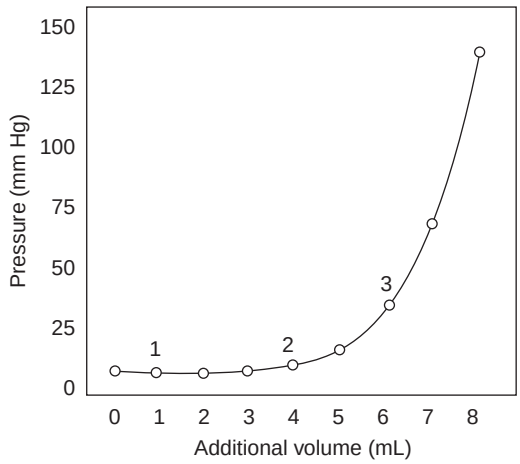

FIGURE 116.1 Effect of additional intracranial volume on intracranial pressure.

even tiny increments in intracranial volume leading to massive increases in ICP. For patients on this steep part of the curve, the addition or removal of even 1 mL of intracranial volume may cause significant changes in the clinical status.

Causes of Increased Intracranial Pressure

Increased ICP may result from any abnormal increase in intracranial volume. This increase in volume is often a result of intracranial hemorrhage. When intracranial blood vessels are sheared or lacerated, the blood that is extravasated may accumulate to such an extent that it becomes a sizable intracranial mass. The increase in ICP that results may compromise CPP and lead to global ischemia. In addition to this global effect on ICP, the hematoma may compress the local underlying brain tissue, leading to local ischemia or metabolic derangements. As the mass expands in size, it may lead to significant shift of the brain structures within the cranium, with associated stretching or kinking of the intracranial blood vessels, and resultant ischemia to areas of brain served by these vessels. If the hematoma continues to expand, it may ultimately become so large that it leads to cerebral herniation, with resultant compression of the brainstem, neurologic deterioration, and ultimately death from cessation of brainstem functions.

A similar mass effect may occasionally be seen with large cerebral contusions, even in the absence of frank hemorrhage. In the absence of focal mass lesions, increases in ICP may also be a result of diffuse brain swelling (DBS). Progressive brain swelling, if left unchecked, may ultimately lead to cerebral herniation.

Cerebral Herniation Syndromes

Cerebral herniation refers to the abnormal passage of brain tissue into an anatomic space in which it does not normally reside. Cerebral herniation occurs when the brain tissue is displaced by a large intracranial hematoma and/or massive brain swelling. Several distinct herniation syndromes exist, each correlated with distinct anatomic sites of herniation.

The best known herniation syndrome is *tentorial herniation*, which refers to the herniation of the parahippocampal gyrus and often the uncus of the temporal lobe through the tentorial notch, from the middle fossa into the posterior fossa. Tentorial herniation most typically results from a focal mass lesion in or overlying the ipsilateral cerebral hemisphere, although it may also result from massive DBS. As the mass lesion or swelling expands, it pushes the brain tissue down, until a portion of the temporal lobe begins to slide through the tentorial notch. As the temporal cortex passes through, it becomes pressed against the brainstem structures and against cranial nerve III, which runs along the edge of the tentorial notch. In addition, the feeding vessels (branches of the basilar artery system) in this region may be stretched and distorted.

Most discussions of tentorial herniation describe a stereotyped sequence of clinical events that follows from the anatomic progression described previously. In many patients, however, the constellation of clinical findings varies considerably from this "classic" presentation. Classically, the patient first complains of headache, which may reflect stretching of the dura or the basal blood vessels. Next, a depression in the level of consciousness occurs, as the reticular activating system is compressed. The ipsilateral third nerve is compressed next, with resulting pupillary dilation ("blown pupil"), and eventually loss of third nerve motor function (ptosis, and loss of medial gaze). As the process continues and the cerebral peduncle is compressed, hemiparesis or decerebrate posturing develops (usually contralateral to the herniating cortex, but sometimes ipsilateral). Brainstem control of vital signs is also affected, with the development of bradycardia, hypertension, and irregular respirations (Cushing's triad). As the progression of herniation and brainstem compression continues, the patient typically loses function of both pupils and develops decerebrate posturing or flaccid paresis bilaterally. Ultimately, respiratory arrest ensues. Even if the cause of the herniation is relieved before cardiorespiratory arrest occurs, prolonged compression of brainstem structures may be associated with hyperemia of the brainstem and fatal brainstem hemorrhages after the compression is relieved.

Some other brain herniation syndromes should also be recognized. One site of herniation is the foramen magnum through which the cerebellar tonsils may herniate. This form of herniation is usually a result of the progression of a posterior fossa mass lesion. The herniation process produces compression of the cervicomedullary junction. As the brainstem and aqueduct of Sylvius are compressed, ventricular outflow obstruction may occur, with the acute onset of hydrocephalus, which will severely worsen the increased ICP, exacerbating the herniation process. Patients with herniation at the foramen magnum may present with symptoms of neck pain, vomiting, depressed mental status, bradycardia, or hypertension. In other cases, the patient may be relatively asymptomatic until sudden cardiorespiratory arrest occurs.

Another herniation syndrome is subfalcine herniation, which occurs when one cerebral hemisphere herniates beneath the falx cerebri to the opposite side. This form of herniation typically results from the progression of a unilateral supratentorial mass lesion. It is associated with symptoms of unilateral or bilateral leg weakness and disturbances of bladder control, which result from compression and ischemia in the territory of the anterior cerebral artery.

Finally, the clinician should consider the retroalar herniation syndrome, which results from the herniation of frontal lobe tissue posteriorly across the lesser wing of the sphenoid

bone, usually as a result of frontal lobe mass lesions or swelling of the frontal lobes. The herniation may lead to distortion or compression of one or both intracranial carotid arteries, with resultant ischemia and infarction in the territories of the anterior and middle cerebral arteries.

Metabolic Derangements

Other physiologic mechanisms of secondary brain injury are also important. Hypoxia, resulting from thoracic injuries, airway obstruction, or inadequate respiratory effort, can be an important cause of brain injury. Hyperthermia increases cerebral metabolism and magnifies the severity of ischemia to an already compromised brain. Hyperglycemia also appears to contribute to cerebral injury in the compromised brain.

Excess concentrations of the neurotransmitter glutamate, released from injured neurons into the synaptic cleft, appear to contribute to brain injury through excess excitation of otherwise healthy postsynaptic neurons. Other neurotoxins such as aspartate, bradykinin, free fatty acids, and glycine may also play a role. Injured brain cells may also release various peptides that promote programmed cell death, or apoptosis, of neighboring cells. Oxidizing agents and oxygen-free radicals, released from injured neurons or elaborated as part of the brain's inflammatory response to injury, also appear to play a role in causing secondary brain injury.

Management and General Principles

Initial Resuscitation

Management of patients with head injury focuses on the prevention of secondary brain injury. Management begins with the ABCs (airway, breathing, and circulation) of resuscitation. A patient with a head injury who has altered sensorium may require assistance with the positioning of the airway or suctioning of oral and pharyngeal secretions. Cervical spine precautions must be taken during airway management. Immobilization of the cervical spine with a semirigid cervical collar or with inline manual stabilization must be maintained until the clinician is certain that no cervical spine injury has occurred.

Breathing may be impaired if neural control of respiratory function is compromised or if traumatic injuries involve the thorax. All patients with serious trauma require 100% inspired oxygen until it is certain that supplemental oxygen is not needed. Positive-pressure ventilation with a bag-valve-mask apparatus should be provided for any patient with inadequate respiratory effort. Unless there is increased ICP, the clinician should aim to achieve normocarbia (P_{CO_2} 35 to 40 mm Hg) and oxygen saturations of 100%. In cases with increased ICP, therapeutic hyperventilation may be indicated (see the following text).

Endotracheal intubation should be performed in patients making inadequate or labored respiratory effort or for patients who have a blunted gag reflex, cannot manage their oral secretions, or are comatose. Orotracheal intubation is generally safer than nasotracheal intubation, particularly if there is any concern about injuries to the midface. Care must be taken to minimize manipulation of the cervical spine.

Premedication for rapid sequence intubation begins with atropine 0.02 mg per kg (maximum dose 0.5 mg) for children younger than 8 years to lessen the vagal response to intubation. Lidocaine may also be useful at a dosage of 1 to 2 mg per kg as premedication to blunt the airway reflexes, which may increase ICP.

If possible, a sedative drug should be used, both to make the patient comfortable and to decrease the patient's responsiveness to airway manipulation. Thiopental (4 to 7 mg per kg) and etomidate (0.3 mg per kg) are both excellent choices because they decrease cerebral metabolism, thereby reducing the risk of cerebral ischemia. Thiopental must be used cautiously, however, in patients with hemodynamic instability because it may reduce vasomotor tone and cardiac contractility, thereby leading to a decrease in blood pressure. Etomidate, in contrast, tends to have little effect on systemic arterial pressure. Fentanyl (2 to 3 mcg per kg) and midazolam (0.1 mg per kg), which provide sedation and analgesia with minimal effect on cardiac contractility or vasomotor tone, could also be used. In cases in which intubation must proceed but intravenous (IV) access cannot be achieved, midazolam may be given intramuscularly (0.1 mg per kg), with onset of action in about 3 minutes. Traditional teaching has suggested that ketamine should be avoided in patients with head injuries because it can increase ICP and may in fact be beneficial. However, several recent studies have suggested that ketamine can effectively be used for the sedation of patients with head injury without leading to increased ICP and may in fact be beneficial.

For neuromuscular blockade, rocuronium (0.6 to 1.2 mg per kg IV) is commonly used because it has the fastest onset of action among the nondepolarizing agents, providing intubating conditions within 60 to 90 seconds if the high end of the dosing range is used. Succinylcholine (1 to 2 mg per kg IV) is an alternative. Succinylcholine offers the advantage of rapid action, with intubating conditions developing within 45 to 60 seconds. Because of its very short duration of action (usually about 5 minutes), succinylcholine offers the advantage of allowing ongoing clinical assessment of the neurologic status soon after intubation is complete. However, succinylcholine may cause important adverse effects, including hyperkalemia (especially in patients with prior denervating injury or neuromuscular disease) or malignant hyperthermia. For these reasons, the U.S. Food and Drug Administration has attached a "black box" warning to succinylcholine. In addition to these general risks of succinylcholine, the diffuse fasciculations caused by succinylcholine may serve to both increase resistance to venous drainage from the head and increase ICP, which could theoretically be problematic for patients with head injury.

The circulatory status of patients with isolated head trauma is generally not compromised, although the potential for other organ system trauma, with associated hemodynamic compromise, must be immediately recognized. IV access should be obtained immediately in all patients with moderate or severe head injuries.

Hypotension [systolic blood pressure less than 70 mm Hg + (age in years × 2)] should be avoided whenever possible and corrected quickly when present. The clinician should remember that the patient would only have an adequate CPP if the MAP were maintained in a normal range. Isotonic crystalloid solutions—normal saline or lactated Ringer's solution—should be given as needed to restore normal intravascular volume (see Chapter 105). Studies evaluating the role of albumin in resuscitation of hypotensive patients with

traumatic brain injury have not shown benefit over isotonic crystalloid solutions. Studies comparing hypertonic saline with isotonic saline for the resuscitation of hypotensive patients with brain injury in the intensive care unit (ICU) have suggested some benefit with the use of hypertonic saline. However, the limited data currently available from prehospital or ED settings do not show a convincing benefit for hypertonic saline over isotonic solutions and thus their use is not currently recommended.

For patients with adequate intravascular volume, excess fluid administration should be avoided. Patients with a normal hemodynamic status can be managed without IV hydration for the first several hours, or with normal saline or lactated Ringer's solution, running at one-half to two-thirds the maintenance fluid rate, while evaluation and treatment of the head injuries proceeds.

Brain-specific Therapies

Once the ABCs of resuscitation have been addressed and the patient has been stabilized, attention can be given to the neurologic status. The neurologic assessment of the patient with a head injury and the criteria for deciding which patients need neuroimaging are described in detail in Chapter 37.

In any patient with signs of increased ICP on examination (i.e., a progressively deteriorating neurologic status and/or signs of impending herniation), a computed tomographic (CT) scan of the head should be performed immediately, with the goal of identifying any mass lesions that require evacuation. If a head CT scan is not available on site, emergent transfer to a facility where CT can be performed is usually the most appropriate course.

There is a long history in emergency neurotrauma care of empiric "blind" trephination (drilling of burr holes) for patients with signs of impending herniation. The goal of such therapy is to provide immediate decompression for patients who are clinically suspected of having an intracranial hematoma. As emergency CT imaging of the head has become readily available, the role for empiric trephination is very limited. In almost all cases, the benefits of the information provided by head CT scanning outweigh the costs of waiting a few extra minutes to have the scan performed, even in cases in which herniation is impending. Especially for the pediatric age group, in which most cases of increased ICP result from DBS rather than intracranial hematoma, empiric trephination is unlikely to be beneficial. Nonetheless, empiric trephination may still have a role in select patients who are too unstable to be transported to the radiology suite or in cases in which the nearest CT scanner is too far away.

When increased ICP is suspected, medical maneuvers to decrease ICP should be undertaken immediately. These maneuvers include elevation of the head of the bed to an angle of 30 degrees and maintenance of the head and neck in a midline position, both of which promote venous drainage from the head.

Sedating medications may also be used. Some sedating medications, including etomidate, barbiturates, ketamine, and midazolam, lead to lower ICP. The opiates, on the other hand, have generally been shown to cause no change or even modest increases in ICP. Propofol infusions can effectively lower ICP but are associated with a high risk of adverse effects and are therefore not recommended.

Sedation is indicated when patients are agitated or when they are coughing and choking, which may lead to dislodgement of the endotracheal tube. When sedating drugs are used, the clinician must be vigilant for hypotension. Paralytic agents should generally be reserved for situations in which sedating medications fail to adequately control the patient's behavior.

Hyperventilation lowers ICP by decreasing the volume of the intracranial vasculature. The cerebral arteriolar circulation responds to hypocarbia with reflex vasoconstriction. The therapeutic use of hyperventilation requires a delicate balance: too little ventilation leads to vasodilation and increased ICP, but too much ventilation leads to excess vasoconstriction and decreased CBF. The optimal balance for therapeutic hyperventilation appears to be achieved at a P_{CO_2} of 30 to 35 mm Hg. Arterial blood gases or end-tidal CO_2 measurements should be followed to ensure that P_{CO_2} is in the desired range.

IV mannitol (0.5 to 1 g per kg) can be administered to increase the serum osmolarity. The increased serum osmolarity draws free water into the vasculature, thereby decreasing the blood viscosity. The lower blood viscosity leads to improved CBF, which helps prevent cerebral ischemia. The autoregulatory system responds to the improved CBF and cerebral oxygenation with reflex vasoconstriction, thereby lowering intracerebral volume (and ICP) without compromising CBF. The effect of mannitol on ICP is seen within a few minutes of administration. During the ensuing hour or so, mannitol also leads to some intravascular volume depletion because of its action as an osmotic diuretic. Clinicians should be cautious when using mannitol in patients with possible hemodynamic compromise because the diuretic effect may exacerbate hypovolemia and worsen perfusion. Some clinicians advocate the use of a Foley catheter in patients receiving mannitol to prevent bladder rupture.

Hypertonic saline (typically dosed as an infusion of 0.1 to 1 mL per kg per hour of 3% saline) is an effective alternative to mannitol. As with mannitol, the hyperosmolarity of this solution leads to decreased blood viscosity and improved CBF. In contrast to mannitol, however, hypertonic saline does not have a diuretic effect. Guidelines for the care of pediatric patients with severe head injury suggest that mannitol and hypertonic saline are both reasonable alternatives for patients who require hyperosmolar therapy. There is a disagreement in the literature about the optimal use of hyperventilation and hyperosmolar therapy in the management of patients with a head injury. The clearest indication for these maneuvers is to "buy time" for several minutes in a patient with clinical signs of impending herniation. Stabilization of the patient with impending herniation with hyperventilation and/or hyperosmolar agents may allow enough time for the patient to be safely transferred to the radiology suite, for emergency head CT imaging. If an evacuable hematoma is discovered on the CT scan, these maneuvers can be used to stabilize the patient en route to the operating suite, where the increased ICP will be more definitively relieved.

It is less clear that sustained hyperventilation or repeated doses of hyperosmolar agents are useful in patients who have increased ICP but who do not have surgical mass lesions. In particular, research studies have documented a clear relationship between even mild degrees of hyperventilation (P_{CO_2} 30 to 35 mm Hg) and decreased CBF. Because the overall goal of resuscitation in patients with a head injury is to optimize CBF,

prolonged hyperventilation may be counterproductive in that it may actually worsen cerebral ischemia. Therefore, hyperventilation is most useful as a transient therapy for acute changes in neurologic condition or as a second-line therapy after other methods of managing ICP have failed.

Some concern has also been raised that repeated doses of hypertonic agents may be counterproductive in the ongoing care of patients with brain swelling because the hypertonic agent can leak across the injured blood-brain barrier, with its osmotic pull serving to worsen cerebral edema. Although some experimental models of mannitol therapy have documented this phenomenon, most data from clinical studies indicate lasting improvements in CBF with repeated doses of mannitol or hypertonic saline. Therefore, many authors consider mannitol and hypertonic saline to be a useful adjunct in the management of increased ICP in patients with brain swelling.

No evidence exists that hyperventilation or a hyperosmolar agent prevents the development of brain swelling. Therefore, the prophylactic use of these therapies is not recommended.

Many studies over the years have evaluated the utility of corticosteroids in patients with a head injury. Theoretically, corticosteroids might blunt the inflammatory response to brain injury, thereby decreasing brain swelling. However, clinical researchers have been unable to show any improvement in outcome for patients with head injuries treated with corticosteroids. The use of corticosteroids for the treatment of head injury is therefore not recommended.

The potential role of intentionally induced brain hypothermia, instituted as a neuroprotective measure, has been evaluated in clinical trials. Although studies have found some modest benefit for adult patients treated with hypothermia, a multicenter randomized trial for children with severe head injury found no improvement in outcome but a possible increase in mortality among children treated with hypothermia. Thus, hypothermic therapy is not recommended.

Anticonvulsant medications are clearly indicated for patients who are having ongoing seizure activity. Short-acting benzodiazepines (lorazepam or diazepam) may be used in the short-term management of ongoing seizures, and phenytoin or fosphenytoin may be used for maintenance anticonvulsant effect.

A multicenter randomized trial showed no benefit for the use of phenytoin for seizure prophylaxis in pediatric patients with moderate to severe brain injury. Nonetheless, phenytoin (loading dose of 10 to 20 mg per kg) or fosphenytoin [loading dose of 10 to 20 mg per kg phenytoin equivalent (PE)] can be considered as an option for antiseizure prophylaxis for patients who have increased risk of early posttraumatic seizures. Younger age and lower Glasgow Coma Scale (GCS) score appear to be risk factors for seizures. Patients with parenchymal brain lesions, SAH, or subdural hemorrhage may also have some increased risk.

In recent years, researchers have designed clinical trials of novel therapies intended to block the actions of specific cytokines or neurotoxins such as bradykinin and glutamate. Other researchers have attempted to improve outcomes by infusing metabolic substrates or cytokines, such as creatine, magnesium sulfate, or nerve growth factor, that may limit brain injury or promote brain healing. To date, none of these therapies have been sufficiently proven to be recommended for routine clinical use.

Disposition

Generally, all patients with intracranial hematomas or brain injuries noted on head CT imaging should be hospitalized, no matter how mild or severe their symptoms. In addition, any patient with an abnormal neurologic examination should be hospitalized even if head CT findings are normal. More mildly symptomatic patients with a normal neurologic status and small cerebral contusions or intracranial hematomas may be candidates for observation in a ward setting.

Patients with neurologic compromise and sizable intracranial hematomas require emergency operative intervention, and they are monitored postoperatively in the ICU for the development of cerebral edema or recurrence of bleeding. Patients with neurologic compromise but no surgical lesions also need intensive care monitoring, often with the placement of a device for the measurement of ICP. In general, ICP monitors are indicated for any patient with a head injury who is comatose and whose head CT findings are abnormal. Although many different types of ICP monitors have been used, the intraventricular catheter has the advantage of being useful both for monitoring and for therapy because CSF can be drained through the catheter if needed to lower the ICP in the short term. The goal of ICU management for patients with ICP monitors is to maintain an adequate CPP, which generally entails maintaining ICP at 20 mm Hg or less. Maneuvers used to lower ICP may include CSF drainage, sedation, hyperosmolar therapy, hyperventilation, and, in some cases, decompressive craniectomy.

Well-appearing patients with head injuries who either require no head CT scan (see Chapter 37) or have no intracranial lesions on head CT imaging may be suitable for discharge to home with careful instructions.

Blunt Trauma: Specific Lesions

Concussion

Clinical Findings and Pathophysiology. *Concussion* is generally defined as a head injury associated with any alteration in mental status. Most clinicians use the term *concussion* to refer to mild head injuries, with no or minor depression in the level of consciousness (GCS scores of 13 to 15) and with no associated focal neurologic deficits. Concussion most commonly results from falls in infants and toddlers and from sports-related injuries in older children and adolescents.

Common symptoms of concussion include initial loss of consciousness, amnesia, confusion, headache, nausea, vomiting, and dizziness. For the most part, clinicians use the term *concussion* to describe cases of minor head trauma in which no brain imaging is performed or cases in which head CT imaging reveals no intracranial pathology.

Despite the normal CT imaging findings, patients with concussion have clearly suffered an injury to the brain. In fact, many concussed patients with normal head CT findings do in fact have subtle evidence of brain contusion or diffuse axonal injury (DAI) noted on magnetic resonance imaging (MRI) of the brain. Research studies have shown that even when there is no structural injury to the brain, there are functional disturbances, which are clearly demonstrable by imaging methodologies such as functional MRI and diffusion tensor imaging. Furthermore, researchers have found abnormalities in cerebrovascular

autoregulation in some patients with concussion. Animal models of concussion have similarly shown disruptions both in CBF and in cerebral metabolism.

Patients with concussion, even if they appear normal on gross neurologic evaluation, can be demonstrated to have abnormalities on neuropsychological testing. Neuropsychological abnormalities are typically present even in seemingly minor "ding" concussions that involve no loss of consciousness and no posttraumatic amnesia.

Prognosis and Management

Most patients with concussion can be demonstrated to have persistent neuropsychological abnormalities for 5 to 7 days after a head injury. Some studies of school athletes suggest that younger players (i.e., high school students) have a higher risk for persistent cognitive deficits than college students with similar injuries. In general, patients who have amnesia at the time of initial evaluation appear to be at the highest risk for these persistent neuropsychological symptoms. Persistent complaints of amnesia or headache 24 hours after the injury have also been shown to be accurate indicators of ongoing neuropsychological dysfunction.

Patients with minor head injury who have normal head CT scans are at low risk for subsequent clinical deterioration. In general, these patients may be safely discharged to home if no other issues require inpatient care.

Numerous guidelines have been developed to help determine when patients with concussion can return to contact sports. The various proposed "return-to-play" guidelines are based on concerns that the concussed brain is especially vulnerable to repeat injury if a second head impact occurs before the brain has fully recovered from the initial concussion. A large study of NCAA football players, for instance, has shown that approximately 90% of second concussions during a given football season occur within 10 days of the initial concussion. In some respects, the concussed brain appears never to fully recover. Multiple studies have shown that patients with one or more concussions in the past, even if these prior concussions were years earlier, are at increased risk for repeated concussions.

One devastating complication of repeat head injury after concussion is the rare and poorly understood "second impact syndrome." There are several case reports in the literature of this syndrome in which patients have experienced an initial concussion during a sporting event and then have had serious neurologic deterioration and died after a second seemingly minor head impact occurred on the same day. In these cases, the initial concussion presumably led to some impairment of cerebral metabolism and cerebrovascular autoregulation that was exacerbated by the second impact. Despite the apparent rarity of this syndrome, its catastrophic nature has been one of the factors motivating the development of return-to-play guidelines.

A substantially more common outcome of repeated concussions is the progressive accumulation of subtle neuropsychological deficits. Several studies have shown persistent cognitive deficits in patients who have suffered concussions in the past, with a higher rate of abnormalities in patients who have had multiple concussions. This concern for progressive damage with repeated concussions has been a major motivation behind the dissemination of return-to-play guidelines for sports-related concussions.

The first widely accepted return-to-play guidelines were developed by the American Academy of Neurology and published in *Morbidity and Mortality Weekly Report* in 1997. These guidelines emphasized the importance of initial loss of consciousness in determining the severity of concussion. Since that time, other authors have developed alternative guidelines that depend less on loss of consciousness, which has proven to be a rare phenomenon in sports-related concussions, and more on duration of amnesia, confusion, headache, or other symptoms. Many of these later guidelines reject the classification of concussion severity on the basis of initial symptoms, because of the finding that even minor "ding" concussions can lead to neuropsychological abnormalities that persist for several days after the injury.

One widely noted set of guidelines was released by the Second International Conference on Concussion in Sports, held in Prague in 2004. These guidelines recommend a stepwise return to sports activities after concussion. The concussed athlete progresses from no-sports activity to light aerobic activity (e.g., walking) to sport-specific aerobic activities (e.g., running or skating) to noncontact training drills to full contact training drills and then finally to full game-playing activities. Each step forward is taken only if the athlete tolerates the previous step without symptoms.

Concussion guidelines emphasize the importance not only of physical rest but also of "cognitive rest," with limitations on academic work or other cognitively stressful activities, until symptoms resolve.

Acetaminophen may be used for headache, but more potent analgesics should probably be avoided so that any progression of symptoms can be detected. The warning signs of progressing intracranial injury should be reviewed with the patient before discharge, with instructions to return immediately if any of these new symptoms or signs appear.

Symptoms after a concussion generally resolve within hours to days after the injury. However, some patients develop the postconcussion syndrome, in which symptoms of confusion, amnesia, headaches, or dizziness may persist for weeks or even months after the injury. Some research in adults has indicated that a scheduled follow-up visit with a head injury clinic, involving education, neuropsychological assessment, and anticipatory guidance, reduces the likelihood of the postconcussion syndrome. Some head injury follow-up clinics for pediatric patients with concussion have been developed in recent years. Many public and private schools have developed their own programs of neuropsychological assessment and follow-up to help identify patients with persistent symptoms and to guide athletes in their decision to return to sports.

Skull Fracture

Clinical Findings and Diagnosis. Skull fractures occur in approximately 2 per 1,000 infants per year and in approximately 0.5 to 1 per 1,000 older children and adolescents. Skull fractures result mainly from falls in infants, but they may also result from child abuse, motor vehicle crashes, or other mechanisms. In older children and adolescents, skull fractures usually result from motor vehicle crashes or sports-related injuries.

Infants have a higher risk for skull fracture than older children, probably because their skulls are thinner. Many skull fractures in infants result from short distance falls; generally, about 50% of infants with skull fracture have fallen from less

than 4 or 5 ft. As the child matures beyond the first year of life, the propensity to sustain skull fracture disappears quickly.

Fractures may occur in any bone of the skull, although fractures of the parietal bone constitute about 70% of cases. The occipital and temporal bones are the next most commonly involved bones, with the frontal bone least likely to fracture. Basilar skull fractures also commonly occur in pediatrics, although less commonly in infants and more often in older children and adolescents.

Most cases of skull fracture present with soft-tissue swelling or hematoma overlying the fracture site. Skull fracture may also occur in the absence of recognized soft-tissue findings, perhaps because subtle swelling is missed beneath the patient's hair or because the swelling may take several hours to develop. Palpable bony abnormalities are rarely detected in cases of linear or minimally depressed skull fracture but may be evident in cases with more severe depression. Other symptoms and signs of head injury, such as loss of consciousness, vomiting, lethargy, seizures, or irritability, may be seen, but they are often absent in cases of isolated skull fracture.

Signs of basilar skull fracture may include hemotympanum, Battle sign (hematoma or discoloration overlying the mastoid bone), "raccoon eyes" (blue or purple discoloration of the periorbital tissue), or CSF rhinorrhea or otorrhea. There may be no abnormalities on examination of the scalp and there may be no signs or symptoms of intracranial injury.

Skull fracture may be diagnosed by plain radiographs of the skull or by head CT imaging (Figs. 116.2 to 116.4). Head CT scanning is usually preferred because it provides information not only about the skull but also about the intracranial contents. Skull radiographs may occasionally reveal fractures not seen on head CT scanning, especially those horizontal

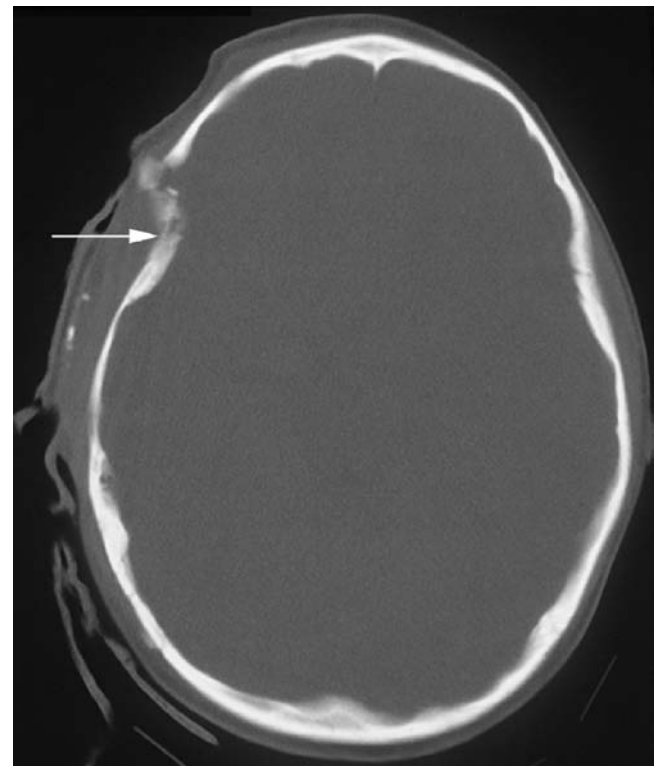

FIGURE 116.3 Depressed skull fracture. This head computed tomographic scan was performed on a 6-year-old boy who was unresponsive and apneic after being a passenger in a high-speed motor vehicle collision. The *arrow* indicates a depressed skull fracture involving the right temporal bone. He also had an associated right temporal contusion (Fig. 116.7).

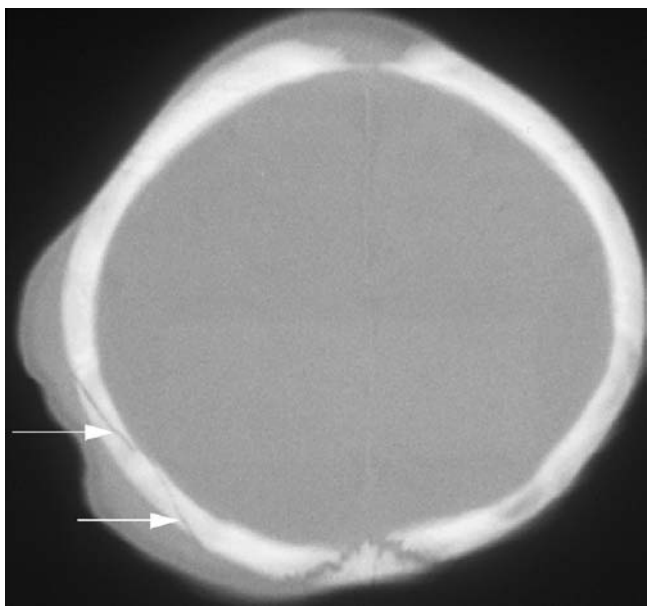

FIGURE 116.2 Linear skull fracture. This is a head computed tomography scan performed on a 6-month-old girl who fell down 20 steps. The *arrows* indicate a comminuted linear right parietal skull fracture. Note also the extensive soft-tissue swelling of the right parietal scalp. No intracranial abnormalities were identified.

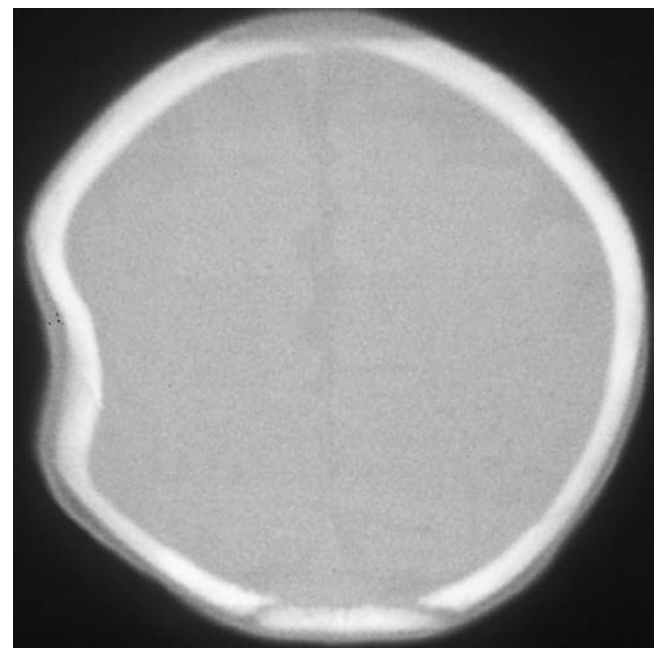

FIGURE 116.4 Depressed skull fracture. This 3-month-old boy fell out of bed and was noted to have a palpable depression of the skull. Head computed tomographic imaging shows a "ping pong ball"–type depressed skull fracture. No intracranial abnormalities were identified.

fractures that run parallel to and between adjacent "cuts" on the CT scan. However, head CT scanning is better than skull radiography for revealing subtle depression of the fracture fragments. Head CT scanning is also preferred in cases in which a diagnosis of basilar skull fracture is considered because it allows better imaging of the basilar skull and visualization of pneumocephaly or fluid in the mastoid air cells, which are common associated findings (Figs. 116.5 and 116.6). Additional imaging in cases of basilar skull fracture may include finer cuts through the temporal bone to provide better visualization of otic or cranial nerve injury. For stable patients with injuries to the bony structures of the middle or posterior cerebral fossae, MRI may offer better visualization of the associated brain parenchyma than does CT.

Management

Linear skull fracture. The presence of a linear skull fracture is associated with a risk of intracranial injury that is increased by as much as 10-fold to 20-fold. Skull fracture in older children and adolescents is even more likely to be associated with an intracranial injury than in infants. In cases in which acute linear skull fracture is diagnosed, therefore, a head CT scan is recommended to evaluate for possible intracranial injury. In addition, any diagnosis of skull fracture in a young child should lead the clinician to consider the possibility of abuse. If the history provided is not a plausible explanation for the injuries observed, further evaluation for possible child abuse should be initiated.

Most linear skull fractures require no specific intervention. Fractures of the frontal bone, if they also involve the posterior wall of the frontal sinus, are an exception. These fractures typically require surgical repair to prevent intracranial infection.

Many clinicians routinely admit children with skull fracture to the hospital for a period (e.g., 24 hours) of observation to exclude even the small possibility of late complications. For well-appearing children with a linear skull fracture and no associated intracranial injuries, however, the risk of late complications is low. Therefore, if a child with skull fracture but no intracranial lesions remains well over a short period of observation in the ED and child abuse is not suspected, the child may be considered for discharge to home. The warning signs of advancing intracranial injury should be carefully reviewed, with advice to return immediately if any of these signs are noticed. The family should also be advised that the scalp hematoma might become more evident as the clotted blood overlying the fracture site begins to liquefy. The liquefying hematoma may develop a boggy consistency, typically between 5 and 7 days after the injury. Unless the hematoma develops signs of infection, it will resolve gradually on its own and should not be aspirated.

Linear skull fractures generally heal well without intervention. Less than 1% of patients will develop a growing skull fracture; that is, a fracture that fails to heal and becomes wider over time. Patients with linear skull fracture should generally have a follow-up examination 1 month after the initial injury to ensure there are no signs indicating the development of a growing fracture.

Depressed skull fracture. Skull fractures may be associated with depression of the fracture fragments, which may range

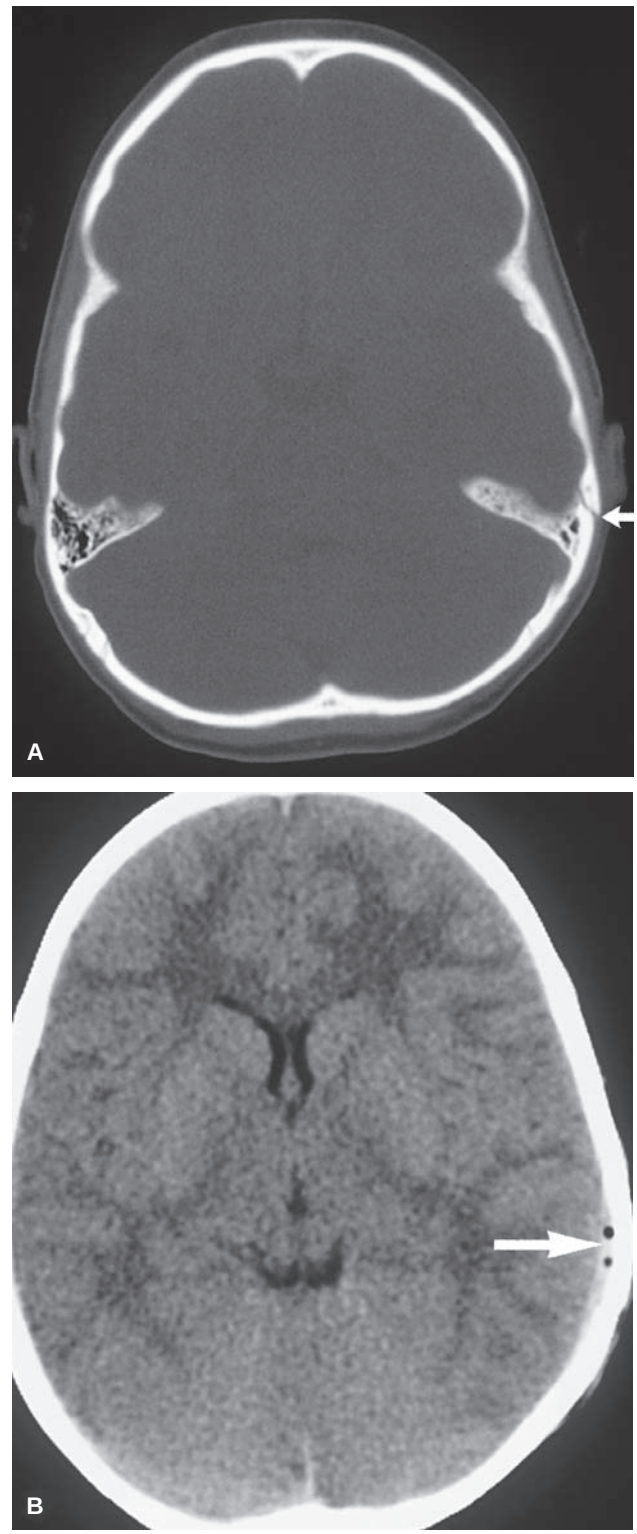

FIGURE 116.5 Basilar skull fracture. This 5-year-old girl was a pedestrian struck by a bicycle. Hemotympanum was noted on examination. **A:** The *arrow* indicates a fracture of the left temporal bone. The adjacent mastoid air cells are somewhat opacified. **B:** A small extraaxial hematoma with associated pneumocephaly is seen *(arrow)*.

FIGURE 116.6 Basilar skull fracture. This 10-year-old boy fell 10 ft to the ground. He had left hemotympanum. A head computed tomographic (CT) scan shows a fracture through the petrous portion of the temporal bone *(thin arrow)*, extending toward the internal carotid canal *(thick arrow)*. The left mastoid air cells are somewhat opacified. Other "cuts" of the CT scan confirm that the fracture involves the wall of the carotid canal. A cerebral angiogram was performed, which showed normal vascular integrity.

from barely detectable depressions to more obvious, palpable deformities in the skull (Figs. 116.3 and 116.4). If there are no other complicating features, isolated skull fractures with minimal depressions can be managed in a fashion similar to that previously described for linear skull fractures.

More significant depressions of the skull, however, may be associated with contusion or laceration to the underlying brain. In cases in which injury to the underlying brain is noted on head CT imaging, especially if there are seizures or focal neurologic findings referable to the brain injury, prompt surgical elevation of the fracture fragments may be required. Surgical intervention is also usually necessary for compound or open, depressed skull fractures, in which early debridement and closure are performed, especially for those patients who have lacerations of the dura mater. Penetrating injuries of the skull are a special case of open, depressed skull fracture and are discussed later in this chapter.

Surgical elevation is generally necessary (although not necessarily emergently) for patients with depressed skull fracture who have associated compression to the underlying brain parenchyma or intraparenchymal bone fragments. Patients with significant cosmetic deformity are also candidates for surgical repair. Most neurosurgeons would recommend operative repair either for any skull fracture with a 1-cm or more depression or for depressions with a depth greater than the thickness of the skull. Some neurosurgeons have reported success in elevating depressed skull fractures noninvasively with suction devices from obstetrical vacuum extractors or from breast pumps.

Basilar skull fracture. Fractures through the skull base are unique in that they may involve disruption of the mastoid air cells or the paranasal sinuses, raising the possibility of intracranial infection. Most recent studies suggest that the risk of meningitis after basilar skull fracture is low, with rates between 0.4% and 5%. The highest risk is in patients with evident CSF rhinorrhea or otorrhea. Although some controversy exists in the literature, it appears that prophylactic antibiotics reduce the risk of meningitis in high-risk patients. Many would recommend, therefore, that patients with basilar skull fracture and CSF leak be admitted to the hospital for IV antibiotics. Neurosurgical management of CSF leaks may also include several maneuvers such as external CSF drainage to lower pressure and allow the leak to heal, packing of the sinuses, or operative repair of dural lacerations.

Fractures of the skull base may be associated with cranial nerve injury, especially to the facial nerve, which courses through the temporal bone. Temporal bone fractures can also be associated with injuries to the ear, such as dislocation of the ossicles and/or injuries to the labyrinth. In cases of temporal bone injury, therefore, audiologic evaluation is usually performed.

Intimal tears of the carotid artery, sometimes leading to the development of intracranial aneurysms or stroke, are a rare but devastating complication of basilar skull fracture. If carotid artery injury is suspected, conventional or magnetic resonance angiography is indicated.

Although it has been traditional management for all patients with basilar skull fracture to be admitted to the hospital for observation, published data suggest that if patients with basilar skull fracture are neurologically normal, have no intracranial pathology on head CT scanning, and have no CSF leak, they may be safely discharged to home. If they are to be discharged, instructions about the management of head injury, as previously described for linear skull fractures, should be discussed in detail. Furthermore, the family should be warned to watch closely for fever, stiff neck, photophobia, or any other signs of developing intracranial infection.

Growing skull fracture. Growing skull fractures are seen not only in patients who sustain the initial injury in the first year of life but also occasionally in older children. Growing skull fractures result from a tear in the dura underlying the fracture, allowing subsequent herniation of meningeal tissue into the fracture line. There is almost always associated injury to the underlying brain parenchyma, sometimes with herniation of parenchyma into the fracture line, and often with a porencephalic enlargement of the adjacent ventricle. Although the pathogenesis of growing skull fracture is not fully understood, it is believed that the constant pressure exerted by the herniated tissue leads to the erosion of the fractured edges of bone.

Growing fractures are more likely in patients who had larger, more widely diastatic fractures on presentation, especially if damage to the underlying parenchyma was significant and if herniation of the brain tissue was evident at the time of injury.

Growing fractures present weeks or months after the initial injury, usually as persistent swelling overlying the fracture site, sometimes with the development of a boggy or pulsatile soft-tissue mass. Occasionally, the presenting sign is a palpable bony defect. Growing skull fractures involving the skull base may present as exophthalmus. Associated neurologic symptoms such as developmental delay, focal neurologic deficits, or seizures may also be evident, probably reflecting injury and abnormal development of the brain tissue adjacent to the fracture.

Surgical repair is required in cases of growing skull fracture, with repair of the rent in the dura (often involving placement of a synthetic graft) and autologous bone graft over the fracture site.

Parenchymal Injuries

Cerebral Contusion and Intraparenchymal Hematoma

Pathophysiology. Cerebral contusions are bruises of the cerebral cortex. On a microscopic level, there is focal injury to neurons, glial cells, and blood vessels, with extravasation of blood and swelling of neural cells.

Cerebral contusion occurs after blunt trauma because of the impact of the relatively mobile brain against a relatively fixed skull. Injuries may occur at the point of traumatic impact (coup injuries) or at a site opposite the point of impact (contrecoup injuries). Contusions are most likely to occur in those locations where the brain is less cushioned by CSF and is more able to come into direct contact with the bony skull. Most commonly, contusions are seen on the undersurface of the frontal lobe or at the poles of the temporal lobes.

The presence of cerebral contusion indicates primary brain injury to the tissue involved. Focal neurologic deficits associated with dysfunction of the contused tissue should be expected. Cerebral contusion is associated with alterations in local CBF and metabolism, as well as release of inflammatory cytokines that may lead to secondary injury to adjacent tissue. In addition, the contusion may exert some mass effect on the surrounding tissue, with resulting cerebral dysfunction and risk for further ischemia. Finally, contusions are associated with a risk of late intraparenchymal hematoma.

Intraparenchymal hematoma may occur as a late complication of an initially nonhemorrhagic contusion, or it may be evident from the initial time of injury. These hemorrhages usually result from severe traumatic forces. The presence of hemorrhage may cause impaired blood flow to the adjacent parenchyma. If the hemorrhage becomes large enough, it may exert mass effect and even lead to cerebral herniation.

Clinical manifestations. The severity of the clinical manifestations associated with cerebral contusion can vary widely. Often, there is a history of loss of consciousness and/or some disturbance in the mental status. Focal neurologic deficits related to the contusion may be noted. Frontal contusions, for instance, may be associated with behavioral alterations or confusion, and occipital contusions may be associated with cortical blindness. Seizures are relatively common. Occasionally, smaller contusions are discovered in patients with no or mild symptoms (headache, nausea and vomiting, lethargy).

Many patients with intraparenchymal hematomas are comatose, and they may have focal neurologic deficits. Other patients with intraparenchymal hematoma may initially be alert, but they have a high risk for deterioration over the ensuing hours. Small areas of petechial hemorrhage may be noted in patients with more minimal symptoms.

FIGURE 116.7 Cerebral contusion. This head computed tomographic scan was performed on a 6-year-old boy who was found unresponsive and apneic after being a passenger in a high-speed motor vehicle collision. The *arrow* indicates a large area of hypodense nonhemorrhagic contusion in the right temporal lobe.

Diagnosis. Cerebral contusions are generally evident on a head CT scan as hypodense areas of edema, sometimes intermingled with hyperdense areas of hemorrhage (Figs. 116.7 and 116.8). Intraparenchymal hematomas are more uniformly hyperdense, although areas of active bleeding may be isodense (Fig. 116.9). Studies in recent years have shown evidence of cerebral contusion or subtle intraparenchymal hemorrhages on MRI or diffusion tensor imaging in some patients with minor head injury and normal head CT findings.

Management. All patients with acute cerebral contusion and intraparenchymal hematoma should be admitted to the hospital for observation. Patients with a smaller contusion, a normal neurologic status, and no other lesions noted on head CT imaging may be appropriately managed on the inpatient ward. More seriously ill patients with an abnormal neurologic status generally require ICU monitoring.

Management of cerebral contusions focuses on efforts to prevent secondary brain injury, with the recognition that the contused tissue and surrounding areas are especially at high risk for ischemia. For patients in a coma, ICP monitoring is generally indicated and maneuvers for managing increased ICP may be required. The clinician must be especially alert for the possibility that an initially nonhemorrhagic contusion will

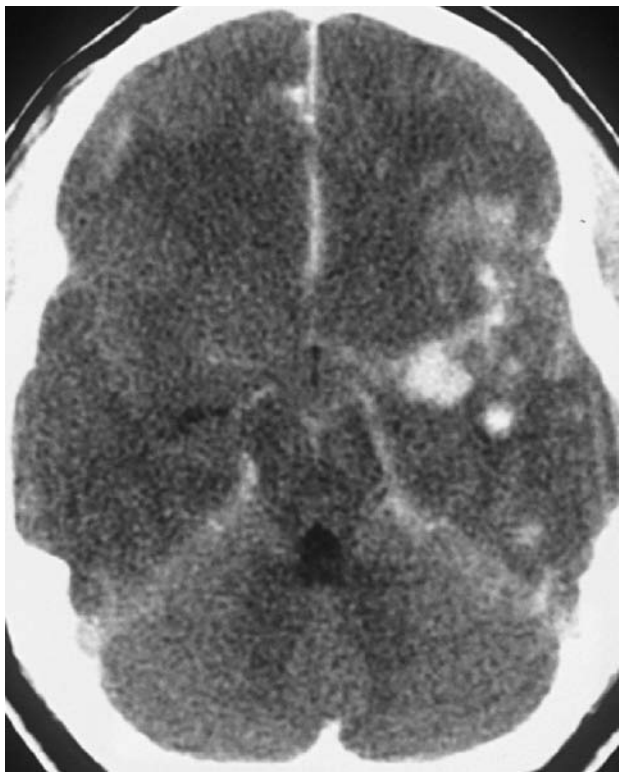

FIGURE 116.8 Cerebral contusion. This 16-year-old adolescent girl was comatose after being a passenger in a high-speed motor vehicle collision. A head computed tomographic scan shows hemorrhagic contusion of the left temporal lobe, subdural hematoma along the tentorial margins, and effacement of the sulci throughout. The patient died despite intensive medical management for increased intracranial pressure.

FIGURE 116.9 Intraparenchymal hemorrhage. This adolescent boy was an unrestrained passenger in a high-speed motor vehicle collision. He was comatose on presentation. A head computed tomographic scan shows a large area of intraparenchymal hemorrhage in the right frontal region. Note also the surrounding area of low-density cerebral contusion.

undergo late hemorrhage, which would manifest as a sudden increase in ICP and/or deterioration in clinical status.

Management of increased ICP for patients with cerebral contusion is similar to patients with other types of brain lesion. Hyperosmolar therapy, however, should be used with caution. Impairment of the blood-brain barrier may allow the hyperosmolar fluid to extravasate into the contused region, thereby leading to increased contusion volume.

Patients with large contusions exerting a significant mass effect may require surgical resection. Some research data indicate better outcomes for surgical versus nonsurgical management of large contusions. Nonetheless, surgical resection is typically avoided when possible because the contused tissue may actually be viable and regain function over the long term. Early decompressive craniectomy has also been used successfully in some patients with large contusions.

Operative drainage of intraparenchymal hematomas is technically difficult. Large hematomas exerting a significant mass effect require operative drainage. Smaller lesions may initially be managed nonoperatively, but with the clinician recognizing the high risk for sudden deterioration. ICP monitoring is necessary for most patients with intraparenchymal hematoma to detect early signs of a growing lesion.

The prognosis for patients with cerebral contusion varies widely, depending mainly on the patient's neurologic status on presentation and on the presence or absence of other lesions. Patients with more significant cerebral contusion often have some residual neurologic disability. Follow-up CT scans on such patients show areas of encephalomalacia at the site of injury. Patients with brainstem or hypothalamic lesions also often have a poor prognosis. Other patients may essentially have full recovery, with no residual neurologic deficits evident. Patients with intraparenchymal hematomas usually have incurred severe brain injury, and they often have a poor outcome. However, relatively asymptomatic patients with petechial hemorrhage may have an excellent recovery.

Diffuse Axonal Injury

Pathophysiology. DAI is characterized by diffuse primary injury to the white matter tracts of the brain, often at the junction of gray and white matter or sometimes deeper at the level of the corpus callosum, brainstem, or cerebellum. Pathologically, degeneration of the axons is noted, with the presence of axonal retraction balls, microglial proliferation, and demyelination. There is usually accompanying endothelial damage to the capillaries, with some punctate areas of hemorrhage. Focal or diffuse edema may be present.

DAI results from the application of severe acceleration/deceleration or angular rotational forces to the brain, which lead to shear injuries of the axons and associated vasculature. It usually results either from motor vehicle crashes or from child abuse.

Clinical manifestations. The clinical manifestations of DAI can range from symptoms of concussion to coma. Loss of consciousness is common. In one study of patients with DAI, 82% developed coma. In general, patients with more extensive DAI noted on radiographic imaging (especially if involving the brainstem) have more severe symptoms. As imaging technologies have improved, subtle signs of DAI have been noted even in patients with milder symptoms and signs of brain injury.

Diagnosis. DAI may be evident on CT scanning as small nonexpansive hemorrhagic lesions of the white matter, most typically seen at the gray–white junction of the cerebral hemispheres, or in the corpus callosum, brainstem, or cerebellum. Cerebral swelling sometimes accompanies DAI, but it need not be present for a diagnosis of DAI to be made. Slit ventricles may be seen. Intraventricular hemorrhage is sometimes noted (Fig. 116.10). Intraparenchymal hemorrhages and cerebral contusions are also commonly noted in patients with DAI.

Although some of these abnormalities may be evident on CT, advances in MRI technology such as diffusion tensor imaging have demonstrated superior sensitivity for detecting axonal hemorrhage or other forms of white matter damage that would be missed on CT.

FIGURE 116.10 Intraventricular hemorrhage. This head computed tomographic (CT) scan was performed on an 8-year-old girl who was involved in a sledding accident. She presented in coma. The *arrow* indicates hemorrhage in the right lateral ventricle. Note the layering of blood inferiorly in this supine patient. Other "cuts" of the CT showed areas of punctate hemorrhage consistent with diffuse axonal injury. The patient made an excellent recovery, with minimal neurologic deficits.

Management. Patients with DAI should be admitted to the hospital for observation. Patients with a normal neurologic examination and no other lesions evident on CT scan may be managed on a general inpatient unit. Those with an abnormal neurologic status require ICU-level monitoring. Management of patients with DAI is supportive, with efforts directed at preventing secondary brain injury. ICP monitoring is generally indicated for patients who present in coma. Specific therapies may be required for the management of increased ICP.

In a large series of patients with DAI, mortality rates range from 10% to 15%. Of those who survive, persistent neurologic dysfunction occurs in 30% to 40% of patients. Children with DAI tend to have a better prognosis than adults. A good functional outcome can be expected for patients with DAI who have mild symptoms of head injury (GSC score of 13 to 15).

Diffuse Brain Swelling

Pathophysiology. DBS is a common manifestation of pediatric head trauma, occurring in approximately 40% of cases of severe head injury. The origin of DBS is probably multifactorial. Cytotoxic edema, caused by inflammatory mediators released from injured cells, is the largest contributor to brain swelling. Increased expression of aquaporins, water channels embedded in the neuronal membranes, likely contribute to the development of brain swelling in areas of neuronal injury. Vasogenic edema, caused by fluid leaking from the injured vasculature, may also contribute to a lesser extent. Cerebral vasodilation, likely reflecting disordered autoregulation in the injured brain, can also play a role in DBS. Younger children may be at higher risk for disordered autoregulation. Although some studies show increased CBF in cases of DBS, other studies suggest that abnormal vasodilation does not contribute substantially to most cases of DBS. In fact, in many cases of brain injury with DBS, the cerebral blood volume appears to be decreased below the normal level.

DBS is probably a final, common manifestation of brain injury caused by a number of different mechanisms. It can be a manifestation of primary brain injury, as when it accompanies large areas of brain contusion or DAI. In other cases, it probably represents secondary brain injury, caused by hypoxia or hypoperfusion. If left unchecked, the development of DBS can lead to a vicious cycle. That is, the presence of DBS causes an increase in ICP and then the resulting ischemia leads to the development of more DBS.

Clinical Manifestations. Most patients with DBS are comatose on initial evaluation, sometimes with associated focal neurologic deficits. Rarely, patients with DBS have less impressive symptoms with more minor neurologic deficits. These patients often experience neurologic deterioration over the ensuing several hours.

Diagnosis. DBS is diagnosed by a head CT scan when there is evidence of smaller ventricles, effacement of the sulci, or obliterated basal cisterns in the absence of other intracranial pathology that may be exerting significant mass effect (Fig. 116.11). Signs of cerebral edema per se, such as loss of gray–white differentiation, may be present. Other accompanying intracranial lesions, such as DAI, subdural hemorrhage, cerebral contusion, or SAH, are also often diagnosed. In one large study of children with DBS, 60% had no other intracranial lesions identified. It is

FIGURE 116.11 Brain swelling. This 1-year-old boy fell from a second-story window. The neurologic examination was normal. A head computed tomographic scan shows a small, right-sided subdural hematoma in the temporal region. Note also the effacement of the sulci on the right *(straight arrow)*, which can be compared with the normal sulci on the left *(curved arrow)*. There is also a mild shift of the midline toward the left.

likely, however, that many of these same patients would exhibit subtle evidence of DAI if more advanced imaging technologies had been used. One study found head CT scanning to have a sensitivity of 99% for detecting cases of DBS associated with increased ICP.

Management. Patients with DBS need to be admitted to the hospital. Generally, admission to the ICU is required for careful monitoring of hemodynamics, oxygenation and ventilation, and ICP. ICP monitors are indicated for any patient with DBS in coma.

Management of the patient with DBS focuses on optimizing cerebral perfusion and minimizing any stressors that may lead to worsening of the DBS. If the ICP is elevated, measures to control the ICP are required. DBS is often worse between 1 and 3 days after the occurrence of primary injury, so patients who initially have well-controlled ICP may have more serious difficulties later.

The outcome of DBS after head trauma is better for children than it is for adults. In one large study, 78% of children with DBS had a functional outcome. Patients with more severe neurologic symptoms on presentation clearly have worse outcomes, as do those with extensive areas of DAI or accompanying intracranial lesions, especially subarachnoid or intraventricular hemorrhage. Patients who experience secondary systemic insults (e.g., hypotension, hypoxia) also have a worse prognosis.

Epidural Hematoma

Pathophysiology. Most EDHs result from blunt impact to the cranium. In most EDH cases, the skull is fractured, with an associated laceration to the epidural vessels underlying the fracture site. In other cases, there is no fracture, but the deformation of the skull and associated linear deceleration from impact lead to shearing of the epidural arteries or veins. In some cases of injury to the epidural vessels, pseudoaneurysms may form.

Many patients with EDH have experienced relatively low-energy mechanisms of injury. In pediatrics, most EDH cases result from falls, although a minority of cases result from motor vehicle collisions, child abuse, or other mechanisms. About one-half of the pediatric EDH cases result from falls of 6 ft or less.

Other mechanisms of injury, such as the shaking implicated in cases of child abuse, are less likely to be associated with EDH because they do not lead to deformation of the skull. Because the low-impact falls that lead to EDH rarely involve high energy being applied to the brain itself, about 90% of EDH cases have no associated parenchymal injuries.

A small EDH may be asymptomatic. As the EDH expands, it begins to occupy an increasingly large intracranial volume. This increasing mass effect leads to an increase in ICP and, if left unchecked, may result in diffuse secondary brain injury. If the EDH continues to expand, it may ultimately lead to cerebral herniation.

If an EDH can be recognized and surgically drained before this process occurs, secondary brain injury can be prevented. In many cases, the patient has a completely normal neurologic status after the EDH is drained. If the EDH is not drained in time, however, persistent neurologic deficits may result.

Approximately 18% to 36% of patients with EDH have an arterial source of bleeding identified. In most cases, the middle meningeal artery is involved. Another 10% to 20% have bleeding from meningeal veins, the emissary veins, the diploic veins, or the dural sinuses. Finally, about 30% to 40% have no recognized source of bleeding identified and are probably oozing from small venous sites in the dura. In general, the more severe symptoms are seen in patients with arterial bleeding, an intermediate course in patients with venous sources, and the most benign course in patients with no discrete source identified. Occasionally, patients with venous or oozing EDH are first diagnosed days or even weeks after the injury.

EDH in the occipital and frontal regions or vertex may be fairly well tolerated. In contrast, bleeding in the temporal region is more likely to cause symptoms early because a temporal EDH will more quickly lead to tentorial herniation. Posterior fossa bleeding may also lead to earlier symptoms because of the potential for early compression of vital brainstem structures, as well as the potential for obstruction to CSF outflow and the development of hydrocephalus. In recent years, several cases of pediatric epidural bleeding behind the clivus as a result of ligamentous injury at the craniocervical junction have been reported, leading to cranial nerve dysfunction.

Clinical Symptoms/Signs. The classic presentation of EDH involves an initial loss of consciousness at the moment of impact, the "lucid interval" of several hours after the trauma when the patient is awake and relatively asymptomatic, and

then neurologic deterioration as the enlarging hematoma begins to exert its mass effect.

In fact, however, pediatric patients with EDH rarely present with these classic symptoms. In one large series of pediatric patients with EDH, only 20% had an initial loss of consciousness and 38% were alert with normal neurologic examinations at the time of diagnosis. The most common symptoms of EDH in pediatrics are headache, vomiting, and lethargy. In addition, ataxia may be noted in cases of posterior fossa EDH. Seizures are relatively rare, occurring in less than 10% of cases.

A small number of patients with EDH may not have any symptoms of brain injury. Skull fracture may be a particularly important indicator of EDH, especially in patients with few other symptoms, because skull fracture is noted in 70% to 80% of cases of EDH. Temporal or parietal skull fractures are particularly associated with a risk of arterial bleeding.

Diagnosis. EDH can be readily diagnosed by noncontrast CT of the head. The classic appearance on CT is that of a high-density biconvex lesion subjacent to the skull (Fig. 116.12). The EDH is usually bounded by suture lines but may rarely cross these lines if diastasis of the suture has occurred. EDH is most commonly noted in the parietal, temporal, or temporoparietal region (approximately 78%) and rarely in the frontal (16%) or occipital (6%) region. The classic high-density appearance on CT indicates clotted blood. Occasionally, an adjacent or intermixed, swirled isodense lesion is noted, which represents ongoing acute bleeding that has yet to clot (Fig. 116.13).

On CT, midline shift, small ventricles, and loss of patency of the basal cisterns indicate a mass effect from the EDH. Signs of herniation may be seen. Other associated intradural hematomas or parenchymal injuries may also be present.

In more recent years, some researchers and clinicians have begun using MRI for the diagnosis of EDH. Because MRI requires a longer imaging duration and is more likely to require sedation, CT remains the preferred modality. However, MRI may occasionally be useful for regions of the brain not well imaged with CT, such as the region subjacent to the skull vertex. Some research suggests that gadolinium enhancement of the EDH indicates ongoing bleeding and an increased likelihood of expansion of the lesion.

Management. The mainstay of treatment of EDH is craniotomy, with drainage of the hematoma and repair of the lacerated epidural vessels. Patients with EDH who have depression in their level of consciousness, focal neurologic findings, pupillary abnormalities, and/or signs of increased ICP should proceed immediately to surgical intervention.

Some patients with EDH may be safely managed with observation. Conservative management is typically considered acceptable only for patients with a small EDH (generally less than 30 mL in volume and with a thickness of less than 2 cm), no focal neurologic deficits, and a normal level of consciousness. Patients with posterior fossa EDH are rarely candidates for conservative management because of the high risk of sudden deterioration resulting from medullary compression and hydrocephalus.

In virtually all cases, a neurosurgeon should be consulted immediately because children who are initially well may experience rapid neurologic deterioration in the first several hours after diagnosis. In one series, 32% of patients who were initially managed conservatively ultimately required surgical drainage of the EDH. Patients who have the initial head CT performed early—especially those within 2 hours of the trauma—have a high likelihood of subsequent progression in the size of the EDH. Physicians should be especially vigilant with cases of temporal EDH because of the risk of arterial bleeding and uncal herniation associated with these lesions.

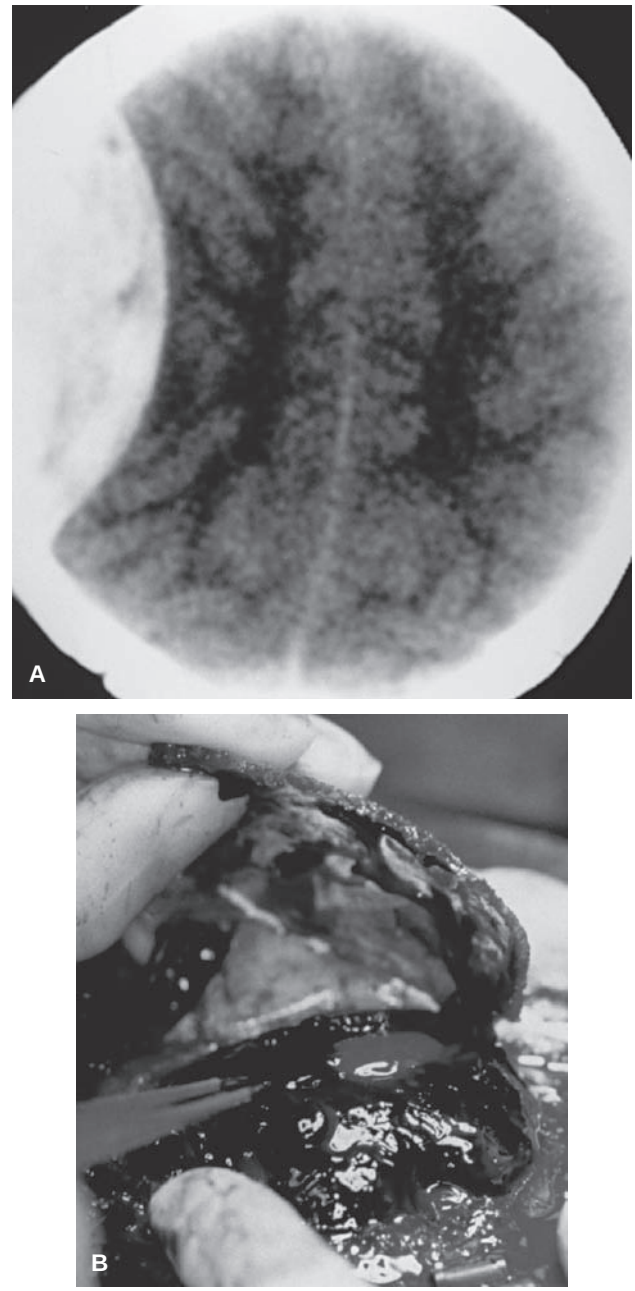

FIGURE 116.12 Epidural hematoma (EDH). This 8-year-old boy presented after a sledding accident. He had no loss of consciousness, but he complained of headache and vomiting. A head computed tomographic scan (**A**) shows the classic biconvex hyperdensity of an EDH. He proceeded to the operating room, where a large mass of clotted blood (**B**) was removed.

FIGURE 116.13 Epidural hematoma (EDH). This 11-month-old boy presented with progressive lethargy and vomiting after falling 2 ft off of a bed. Several hours after the injury, he became unresponsive with dilated, nonreactive pupils. This head computed tomographic scan shows a large EDH, with intermingled hypodense areas representing active bleeding. Note also the midline shift and the compression of the ipsilateral ventricle. After an emergency craniotomy, the patient made a full recovery.

Mortality rates in pediatric EDH range from 0% to 10%. Among survivors, approximately 85% have a good neurologic outcome. The most important predictor of outcome is the patient's neurologic status prior to operative intervention. Patients with coma and pupillary abnormalities are much more likely to have sustained secondary brain injury. However, even among patients who present in coma or with nonreactive pupils, a majority will have a moderate or good neurologic outcome. Minimally symptomatic patients with EDH who do not require surgery typically have a normal neurologic outcome, with no abnormalities on follow-up assessments either of neuropsychiatric outcome or of CBF.

Subdural Hematoma

Pathophysiology. SDHs result from tearing of the bridging veins that traverse the subdural space. Mechanisms of injury that are associated with shear forces being applied to these veins are especially likely to lead to SDHs. In particular, SDHs result from injuries associated with significant acceleration/deceleration forces.

In older children and adolescents, SDHs most commonly result from motor vehicle crashes. In infants, SDHs are commonly a result of the shaking impact syndrome of child abuse. Occasionally, cases of shaking impact syndrome involving SDH can be seen in older children as well. SDHs may also result from falls, especially if the fall is from a significant height. Because of the more significant forces applied to the brain in most injuries leading to SDHs, they are often associated with other intracranial lesions.

For some patients with SDH, the mass effect of the accumulating SDH is the primary cause of neurologic impairment. Many cases of SDH, however, are associated with cerebral contusions, brain ischemia, or DBS. For these patients, the SDH may be more of a marker of a high-force mechanism of injury than a cause of neurologic injury in itself. Therefore, even if the SDH is drained in a timely fashion, serious brain injury may persist.

Clinical Manifestations. SDHs are often associated both with an initial loss of consciousness and with a depressed mental status. Approximately 50% of patients with SDH present in coma. Pupillary abnormalities may also be noted, indicating impending herniation. In less severely ill patients, headaches, vomiting, lethargy, irritability, visual difficulties, or seizures may be noted. In patients with SDHs involving the posterior fossa, cerebellar signs such as ataxia or nystagmus may be noted. Some asymptomatic or minimally symptomatic patients may also be diagnosed with small SDHs.

Although most symptoms of SDH present within hours after the trauma, occasional symptoms of chronic SDH are diagnosed days or even weeks after a head trauma. In pediatrics, chronic traumatic SDH is most commonly seen in infants, usually as a consequence of child abuse. Presenting symptoms in these infants may include tense fontanel, macrocephaly, psychomotor retardation, depressed level of consciousness, seizures, vomiting, irritability, or focal neurologic deficits.

Diagnosis. On head CT scanning, acute SDH is seen as a hyperdense, crescentic collection of extraaxial fluid (Fig. 116.14). There may be areas of intermingled hypodense fluid, which represent active bleeding, sometimes termed a hyperacute SDH (Fig. 116.14). Because the subdural space is continuous around each hemisphere, subdural blood flows freely through this space, while respecting the midline and tentorial margins (Figs. 116.15 and 116.16). SDH is usually unilateral, although cases of child abuse may be associated with bilateral SDH. The CT scan should be evaluated for evidence of mass effect and associated intracranial lesions, such as brain swelling, cerebral contusions, or SAH. The density of the subdural fluid collection varies over time. With older hematomas, the collection may be almost isodense with CSF.

Management. In the early 1980s, researchers showed remarkable decreases in mortality from SDH if patients underwent timely surgical drainage. Not surprisingly, this effect was most evident in those patients with large SDHs associated with midline shift and coma. In this subgroup, the neurologic prognosis is optimized when surgery is performed within 4 hours of the trauma. It appears that early relief of the mass effect in these patients prevents secondary brain injury.

Many patients with SDH who are not so severely ill can be managed nonoperatively. Some authors have proposed nonoperative management for patients with SDH who are not comatose, who have small SDHs with no significant mass effect, and who have patent basal cisterns. Generally, even well-appearing patients with posterior fossa SDHs undergo

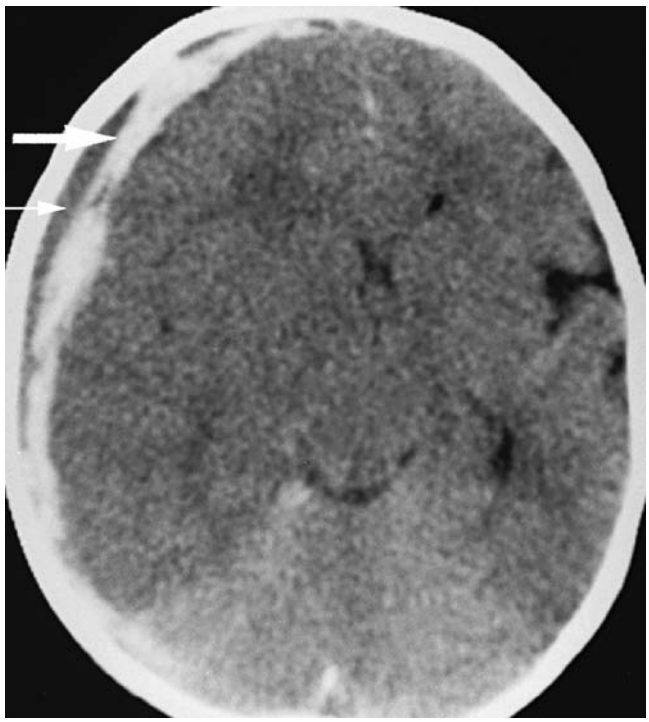

FIGURE 116.14 Subdural hematoma (SDH) and brain swelling. This 9-month-old boy reportedly became suddenly unresponsive. There was no history of trauma. On examination, he was comatose with fixed dilated pupils and extensor posturing. Massive bilateral retinal hemorrhages were seen. This head computed tomographic scan shows a right-sided SDH, with acute hyperdense *(thick arrow)* and hyperacute isodense *(thin arrow)* components. Midline shift to the left is noted. There is also evidence of brain swelling, with effacement of the sulci and poor gray–white differentiation. The diffuse hypodensity of the cerebral cortex can be contrasted with the normal density of the cerebellum, which appears whiter in this view. A diagnosis of child abuse was made.

surgery because of the high risk of brainstem compression. Even if a patient is a candidate for nonoperative management, immediate consultation with a neurosurgeon is essential because of the potential for rapid clinical deterioration over the first several hours of observation.

Patients with chronic SDH generally do not require craniotomy and decompression. Most centers manage these patients with a strategy of serial subdural taps or continuous external drainage. In some cases, the SDH is successfully drained in this manner and no further therapy is necessary. In most cases, eventual placement of a subduroperitoneal shunt for ongoing drainage of the lesion is necessary.

The clinician must recognize the strong association of SDH with child abuse, especially in infants with no clear mechanism of injury reported and in those patients with associated retinal hemorrhages. If the circumstances of the injury cannot be clearly explained, further evaluation for nonaccidental trauma should be pursued. Cases of SDH in which the CT findings indicate a mix of higher- and lower-density fluid collections (indicating a mix of older and newer blood) are also more suggestive of nonaccidental trauma.

Mortality rates for children with acute SDH range from 10% to 20%. Among survivors, persistent neurologic sequelae are common. Patients who present in coma or who have pupillary abnormalities clearly have poorer prognoses. In addition, patients with more significant brain injury on CT or increased ICP have a worse prognosis. Even the patients who appear to be at high risk, however, may have moderate or good functional outcomes. Most patients who are managed nonoperatively do well, with few, if any, neurologic sequelae and with full resolution of the SDH. A small percentage will develop chronic SDH. Chronic SDH is seldom lethal but may be associated with ongoing neurologic problems such as seizures or developmental delay.

Subarachnoid Hemorrhage

Pathophysiology. SAH is a common complication of head trauma, especially in more severely injured patients. In one large study, SAH occurred in approximately 25% of patients who were comatose on initial evaluation.

SAH results from tearing of the small vessels of the pia mater. SAH, especially if involving the basal cisterns, can rarely indicate rupture of a dissecting traumatic arterial aneurysm. SAH generally occurs either after relatively severe blunt trauma to the head or as a result of significant shear forces.

Because the cerebral subarachnoid space is large and freely communicates with the basal cisterns and the spinal subarachnoid space, the blood in an SAH can be distributed widely. As a consequence of this wide distribution and because it is generally smaller pial vessels that bleed, SAH rarely accumulates to the extent that it causes clinically important mass effect.

SAH appears to exert its main pathophysiologic effect by causing cerebral vasospasm. SAH is associated with increased cerebrovascular resistance and, consequently, with an increased risk of cerebral ischemia or infarction. In most cases, however, even when cerebral vasospasm can be documented with imaging studies such as transcranial Doppler ultrasound, the vasospasm will not be associated with specific clinical sequelae. In general, SAH is seen in association with other intracranial injuries, especially SDH, cerebral contusion, and intraparenchymal hemorrhage. The presence of SAH may be most important as a marker for severe primary brain injury rather than as a cause of secondary injury in itself.

Because of the presence of the blood in the subarachnoid space, and probably because of associated release of inflammatory mediators from adjacent cells of the pia and arachnoid mater, SAH causes meningeal irritation and clinically mimics many of the symptoms and signs of meningitis.

Clinical Manifestations. Patients with posttraumatic SAH often have other intracranial hemorrhage or parenchymal injuries as well, so they may present with a wide range of symptoms and are those who have minimal if any symptoms and those who are comatose with signs of impending cerebral herniation. As an isolated intracranial lesion, traumatic SAH most commonly causes headache and other signs of meningeal irritation, such as nausea and vomiting, nuchal rigidity, and photophobia. Patients with isolated SAH often have a history of loss of consciousness and sometimes present with depressed mental status, or even coma. Seizures are reported in 2% to 10% of cases. Subhyaloid or preretinal hemorrhages, located just adjacent to the optic nerve head, may also be seen with SAH.

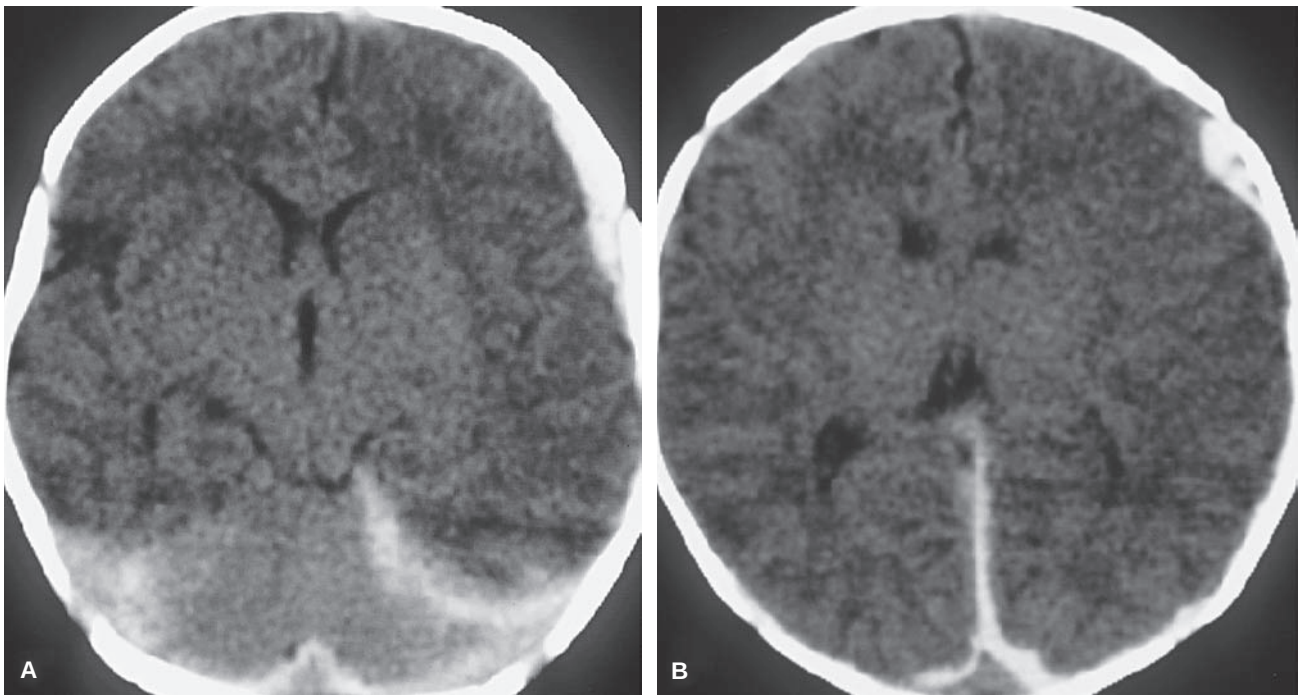

FIGURE 116.15 Subdural hematoma. This 14-day-old patient presented with a complaint of lethargy and vomiting. There was no history of trauma. This head computed tomographic scan shows subdural blood tracking along the tentorium (**A**), in the interhemispheric fissure (**B**), and in the left frontoparietal region (**A** and **B**). There is also some effacement of the sulci and loss of gray–white differentiation. Child abuse was suspected.

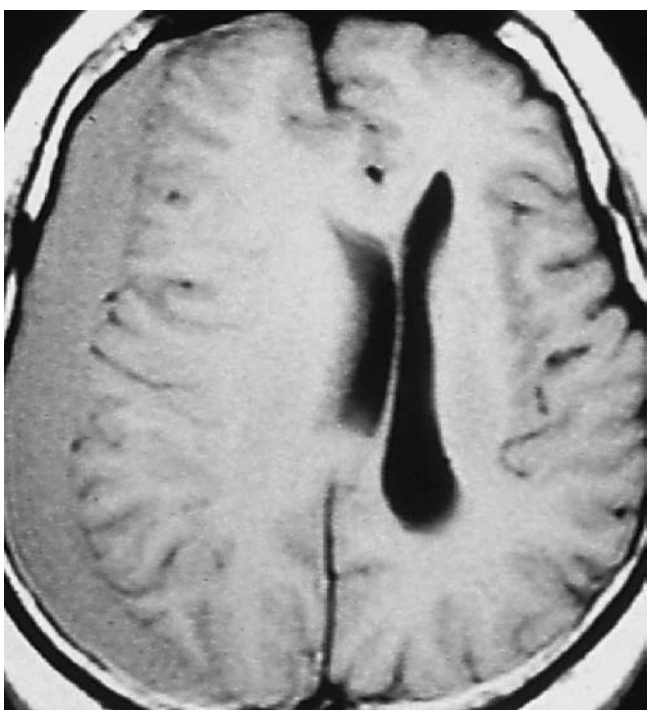

FIGURE 116.16 Subdural hematoma (SDH). This T_1-weighted magnetic resonance image shows the classic appearance of a large acute SDH, with a crescent-shaped extraaxial hematoma that covers the entire right cerebral convexity. There is significant midline shift with compression of the right lateral ventricle and enlargement of the contralateral ventricle, which probably represents obstruction to cerebrospinal fluid outflow. An emergency operative procedure was performed.

Diagnosis. SAH can usually be detected on noncontrast head CT scanning as a collection of hyperdense fluid in the CSF spaces, either in the subarachnoid space overlying the cerebral convexity or in the basal cisterns. Subarachnoid blood overlying the cerebral hemisphere can be distinguished from SDH in that the subarachnoid blood may flow into the depths of the brain sulci, fissures, and cisterns, whereas the subdural space does not penetrate into these depths. Head CT imaging has a sensitivity of only about 90% for detecting SAH, with a lower sensitivity for patients seen more than 24 hours after the SAH began. However, lumbar puncture is not recommended and may be dangerous in the setting of focal intracranial pathology or brain swelling because it may increase the risk of cerebral herniation.

Management. All patients with traumatic SAH should be admitted to the hospital for observation. In most cases, specific therapy directed at the SAH is not required. Although rare cases of traumatic SAH will result from the presence of either a preexisting cerebral aneurysm or a dissecting traumatic intracranial aneurysm, imaging studies aimed at diagnosing cerebral aneurysms are generally not indicated. Such investigations should be considered, however, when traumatic SAH is diagnosed in patients with a suggestive medical or family history, with focal neurologic findings, or with progressive or late deterioration after head injury.

Calcium channel blockers appear to be efficacious for preventing morbidity secondary to vasospasm in patients with spontaneous SAH. However, published data do not suggest a benefit from the use of calcium channel blockers in patients with traumatic SAH; thus, calcium channel blocker therapy is

not indicated. The general principles of management for patients with head injuries should be followed. Prophylactic anticonvulsants are sometimes used for patients with SAH.

In one study, 24% of patients with traumatic SAH died and another 24% had a poor neurologic outcome. Patients with associated intracranial injuries and those with a larger SAH (especially if it involves both the hemispheric convexities and the basal cisterns) have the worst outcome. Posttraumatic hydrocephalus is sometimes seen as a late complication in patients with traumatic SAH. Patients with minor or no symptoms and small SAH generally do well.

Penetrating Trauma

Penetrating trauma includes injury from sharp objects, such as knives, darts, or animal bites, and from missiles, usually bullets. High-velocity penetration (as with bullets) often occurs through the skull, but lower-velocity penetrating injuries involving such objects as air gun bullets, chopsticks, and toothbrushes have occurred through the orbit or mouth. Penetrating head trauma is far less common than blunt head trauma in pediatrics, especially in younger children. Several urban hospitals reported that the rate of hospital admissions for teenagers shot in the head increased by as much as 10-fold between the 1980s and 1990s. Fortunately, surveillance data reported by the Centers for Disease Control and Prevention have shown a steady decrease in firearm injury rates since then. Nonetheless, there were about 3,000 firearm-related deaths reported in the United States in the year 2005.

Pathophysiology

Penetrating head trauma leads to brain injury by several mechanisms. First, there is direct injury along the path of the penetrating object, with laceration or contusion of neural tissue, and hemorrhage from injured vessels. For low-velocity penetrating injuries (e.g., knife wounds), this may be the primary source of brain injury.

Higher-velocity injuries (from bullets) also cause significant damage because of the shock waves created by the impact of the penetrating object. These shock waves can cause contusions or vascular injury at the sites that had no contact with the penetrating object itself.

Vascular injury may result either from direct laceration or from percussion-related damage. Dissection of an intimal flap, thrombosis of the vessel lumen, or aneurysm formation may result. Ischemia or infarction resulting from these vascular injuries may occur immediately after impact, or they may occur days or even weeks later. Occasional patients become symptomatic with rupture of an aneurysm years after the initial trauma.

Because the skull and dura are violated by the penetrating object, there is direct communication from the CSF spaces or brain to the outside world and, consequently, a risk for intracranial infection. Penetrating objects that pass through the paranasal sinuses or mastoid air cells particularly increase the risk of intracranial infection.

Clinical Manifestations

Patients with penetrating injuries sometimes may present without a clear history, either because the injury was not witnessed or because the patient and/or witnesses fear the repercussions of full disclosure.

The local signs of penetrating injury can sometimes be subtle, especially if the penetrated area is covered either by hair or by a dressing. Without careful exploration, the entrance wound might be mistaken for a superficial scalp laceration. In more obvious cases of penetrating injury, meningeal or parenchymal tissue may be visualized in the wound, or CSF may be oozing.

Signs of neurologic injury are often severe in patients with high-velocity injuries, but they may be subtler in patients with low-velocity injuries. Patients with progressively enlarging intracranial hematomas or worsening brain swelling may deteriorate quickly during the several hours after presentation.

Of course, patients with penetrating head injury may have injury to other body parts as well. Patients with penetrating head injuries sometimes develop a serious coagulopathy, manifesting either with intracranial bleeding or with bleeding from other sites of injury.

Management

The initial management of the patient who has sustained penetrating head trauma focuses on the ABCs of resuscitation. The clinician should also perform a secondary survey to identify serious injuries to other body part that might require rapid intervention. Once the ABCs and the secondary survey have been addressed, attention can be focused on the possible need for brain-specific therapies.

The patient should be examined carefully for evidence of entrance or exit wounds. The clinician should recognize the potential for multiple penetrating wounds or exit wounds in unpredicted locations because of a complicated migratory path of the penetrating object.

Bleeding lacerations should be occluded with direct pressure. Occasionally, immediate suturing of the laceration may be necessary to achieve hemostasis. Other penetrating wounds may simply be covered with a sterile gauze dressing until more definitive debridement and repair can be achieved. Any penetrating objects still in place should not be removed because of the potential for serious hemorrhage if the object is tamponading a lacerated vessel.

Patients with ongoing bleeding may have a coagulopathy. If laboratory results indicate a coagulopathy, infusion of fresh frozen plasma, cryoprecipitate, or platelets may be indicated. Although several case reports have described successful use of recombinant factor VIIa in patients with penetrating head injury and coagulopathy, this therapy is still generally considered experimental. Published data indicate that cervical spine injury is rare in patients with isolated gunshot wounds to the head. Still, the clinician should recognize the possibility that the bullet or penetrating object may have directly penetrated the neck and injured the vertebral column. Furthermore, some cases of penetrating head injury may also include a blunt force to the head or neck that might result in cervical spine injury. Cervical spine precautions should be maintained until the clinician is confident that no neck injury has occurred. In cases in which cervical spine injury cannot be excluded on the basis of clinical findings, radiographs of the cervical spine should be obtained.

Patients with penetrating head injuries generally require prophylactic antibiotic therapy. A first-generation cephalosporin

such as cefazolin (30 mg per kg IV; maximum dose 2 g) is usually appropriate.

Most patients with penetrating head injuries are started on prophylactic anticonvulsant therapy [usually with phenytoin (loading dose 10 to 20 mg per kg) or fosphenytoin (loading dose 10 to 20 mg per kg PE)], especially if there is any concern about parenchymal injury or SAH.

Patients with penetrating injuries to the head require immediate head CT scanning to delineate the extent of brain injury and assess for associated intracranial hematomas, brain swelling, and/or mass effect. The head CT scan can also demonstrate the presence of intracranial foreign material.

Patients with intracranial hematomas exerting a mass effect will need an immediate operation to evacuate the hematoma. Patients with large areas of contusion exerting a significant mass effect may also require surgical resection. In addition, most patients with penetrating injuries to the head require prompt operation to debride the infected or contused brain tissue at the entry site. Traditionally, trauma surgeons have performed extensive debridement of deeper tissues along the path of the penetrating object. Many surgeons, however, have reported equally high success rates with more limited debridement. After debridement, the dura must be repaired to achieve a watertight seal.

In general, it is unnecessary to remove deeply embedded foreign material (e.g., bullets) because the risk of infection does not seem to increase when these objects are left in place. Bullets that are lodged in the ventricular system usually are removed, however, because of the potential for outflow obstruction and hydrocephalus if the bullet migrates.

All patients with penetrating head injury require hospitalization. Except in circumstances of superficial penetration with no underlying brain injury, ICU-level monitoring is indicated. Intracranial ICP monitoring is indicated for patients in coma.

Most patients with penetrating head injuries require angiography (conventional, CT, or MRI angiography) to exclude the possibility of traumatic injuries to the cerebral vasculature. Most authors recommend angiography as soon as it can be safely performed.

The prognosis after penetrating head injury depends most commonly on the level of neurologic function at the time of presentation. For patients with severe neurologic dysfunction (GCS scores in the range of 3 to 5), the likelihood of a good functional outcome is low, although occasional patients will do well. Many neurosurgeons will not operate on patients who present with an absence of neurologic function (GCS score of 3 and nonreactive pupils) because the prognosis is so dismal for this subgroup.

For patients with a better neurologic status, the prognosis is influenced by the degree of tissue damage seen on a head CT scan. Lateral-to-lateral injury paths tend to have a worse prognosis than anterior-to-posterior paths. Tracks of injury that crosses the midline or that involves the ventricles are associated with a worse prognosis. Patients with SAH also have a worse prognosis.

SPINAL CORD TRAUMA

Spinal cord injury is rare in pediatrics, occurring in approximately 2 of every 100,000 children per year. Nonetheless, spinal cord injuries, when they do occur, are associated with significant morbidity and mortality, and the consequences of missing early signs of spinal cord injury can be devastating. Furthermore, some clinical evidence suggests that prompt diagnosis and therapy for spinal cord injuries may improve the prognosis.

Anatomy

The spinal cord runs from the foramen magnum, where it extends from the base of the medulla to its distal tip in the upper lumbar region of the spine. The cord consists of an H-shaped central section of gray matter, surrounding white matter that is divided by this "H" into a ventral (motor) compartment and dorsal and lateral (sensory) compartments.

Upper motor neurons originate on one side of the cerebral cortex but then cross to the other side at the level of the medulla before entering the spinal cord. Axons from motor neurons in the left cerebral cortex, therefore, run in the right-sided white matter of the spinal cord and serve the right side of the body. Sensory neurons, in contrast, originate on one side at the level of the dorsal root ganglion and then cross immediately to the other side (at the level of the spinal nerve roots) before entering the cord. Sensory impulses from the right side of the body, therefore, run in the left-sided white matter of the spinal cord before reaching the left cerebral cortex.

The spinal cord is surrounded by three layers of meningeal tissue, which are continuous with the meninges surrounding the brain. As with the cerebral meninges, blood could potentially accumulate in the spaces between these layers of tissue, leading to spinal SDHs or EDHs.

The spinal cord runs in the vertebral canal, protected by the bones of the spinal column, with the vertebral bodies anteriorly and the vertebral arches laterally and posteriorly. Injuries to the spinal cord generally involve some injury to the surrounding spinal column. Because the spinal cord is significantly shorter than the spinal column, injuries at a certain level of the spinal column are associated with spinal cord injuries corresponding to a lower level. A low thoracic spinal column injury, for instance, may be associated with neurologic deficits corresponding to the lumbar cord.

Some unique features of the pediatric spine make spinal cord injury more likely in children. Specifically, the ligaments of the pediatric spine are especially lax, allowing more movement, or subluxation, of vertebrae on one another. In addition, the paraspinous musculature, which provides stabilization and support to the adult spine, is less developed in children. Decreased ossification of the spine, which persists throughout childhood, also makes the cervical spine more pliable. Furthermore, the facet joints between adjacent vertebral bodies are more flattened or horizontal in pediatric patients, which makes subluxation more likely.

Finally, there is excess strain on the upper cervical spine in young children because the head is a proportionately larger component of total body weight. The fulcrum of movement of the cervical spine is at the level of C2–C3 in young children, as opposed to C5–C7 in older children and adults. This feature makes the upper cervical spine especially prone to injury in young children. These "immature" features of the pediatric spine persist to around the age of 8 years. For older children,

the anatomy of the spine is fairly similar to that seen in adult patients.

Pathophysiology

As with the pathophysiology of brain injury, injuries to the spinal cord can be considered to occur in two phases: primary and secondary. *Primary spinal cord injury* refers to the irreversible neural damage initiated at the time of traumatic impact. *Secondary spinal cord injury* refers to the associated pathophysiologic processes that occur hours to days later, damaging neurons not necessarily injured by the primary impact itself.

Primary injuries to the spinal cord may result from several different mechanisms. Rarely, direct transection of the cord can occur as a result of penetrating injuries to the spine or, more commonly, from bone fragments displaced after fracture or subluxation. More common are bruises or contusions of the spinal cord, which result from compression of the cord by subluxated bone or herniated intervertebral disks. Spinal cord injuries may also result from the application of shear forces to the cord, as when the spine is hyperflexed, hyperextended, or distracted during blunt trauma. The flexible spinal column of the young child makes these types of shear injuries especially common. Finally, the spinal cord can be injured if its vascular supply is disrupted, leading to ischemia and infarction of the cord, sometimes in the absence of any direct traumatic force being applied to the cord itself.

Secondary pathophysiologic changes are believed to cause much of the clinical disease noted after spinal cord injury. Proinflammatory cytokines appear to be released from injured tissue, promoting the development of more inflammation and perhaps stimulating apoptosis, which in itself leads to the release of more injurious cytokines. Much of the more recent research on acute spinal cord injury has focused on efforts to interrupt this injury cascade.

Secondary pathophysiologic changes may also result either from the local mass effect caused by SDH or EDH or from the edema associated with a contused area of cord. Secondary spinal cord injury can also be initiated or exacerbated by any systemic process that leads to hypoxia or ischemia. Areas of spinal cord that are already contused, or partially compressed by local bleeding or edema, may be especially at high risk for ischemic injury.

Clinical Manifestations

Spinal cord injuries are generally associated with significant mechanisms of injury, such as motor vehicle crashes, falls from significant heights, high-impact sports injuries (especially in football, ice hockey, and diving), or child abuse. Patients with injuries to the spinal cord often have evidence of injuries to other organ systems. In particular, there is a high association between head injuries and injuries to the cervical spine and/or spinal cord. Injuries to the thoracic or lumbar spine may also be associated with head injuries, but they are seen more often in the setting of chest or abdominal trauma. Lap belt injuries are a common cause of Chance fractures of the lumbar spine and associated spinal cord injury.

Patients with high cervical cord injuries may sometimes have abnormal vital signs, reflecting an interruption of autonomic impulses to the heart and the vasculature. These patients demonstrate bradycardia and hypotension, along with peripheral vasodilation, a syndrome known as spinal shock. They may also have abnormal or absent respiratory effort. Because most trauma patients with hypotension are hypovolemic and have a reflex tachycardia, those with bradycardia should be strongly suspected of having spinal shock.

Spinal cord injuries should also be suspected in any patient with trauma who complains of decreased motor strength or in whom focal deficits in strength or tone are noted on examination. In the acute setting, severe spinal cord injuries are usually associated with decreased or absent reflexes. Partial injuries to the cord, in contrast, may be associated with initial hypertonia and hyperreflexia. Abnormalities of bladder control and rectal tone may also be noted.

Motor deficits correspond to the spinal roots whose neural impulses are compromised by the spinal cord injury. Most typically, all motor impulses that originate from spinal nerve roots at or below the level of the spinal cord injury are affected. An understanding of the motor deficits after spinal cord injury requires knowledge of the innervation of the important muscle groups of the body. A list of the important muscle groups and the spinal roots that serve them is presented in Table 116.1.

Sensory deficits may also be noted, and these may range from paresthesias to complete loss of sensation. Because sensory impulses are carried in both the dorsal columns and the lateral compartments of the spinal cord, injuries to one of these compartments may lead to partial sensory deficits (e.g., loss of pain and temperature sense from the lateral compartment or loss of joint position sense and vibration sense from the dorsal column) but with other forms of sensation intact for the same body part. A diagram of the body's sensory dermatomes is shown in Appendix D. Often, a well-demarcated sensory "level" of the spinal cord can be identified, below which sensory impulses are absent and above which sensation is intact.

Many injuries to the spinal cord involve solely or predominantly one of the two lateral sides of the cord. Because of the distribution of sensory and motor neurons in the spinal cord, a lesion to the left spinal cord affects left-sided motor strength but right-sided sensation. This classic crossed pattern of sensory and motor deficits is known as the Brown-Sequard syndrome.

Other patterns of neurologic deficits may also be noted. Partial injuries to the spinal cord may result in partial deficits. In some cases of ventral cord injury, for instance, only motor deficits may be observed. Cases of hyperextension injury may cause more severe injury to the central or deep regions of the cord (the gray matter), while sparing the more superficial white matter. This leads to a "paradoxical" pattern of symptoms known as the central cord syndrome, in which the more distal function (served by the white matter) is spared but more proximal function (served by gray matter) is compromised. Finally, occasional patients with more minor injuries to the spinal cord report transient symptoms of paresthesias, numbness, or weakness that may have resolved by the time of evaluation.

TABLE 116.1

MAJOR MUSCLE GROUPS LISTED WITH SPINAL ROOTS AND PERIPHERAL NERVES THAT SUPPLY THEM

Muscle	Segmental innervation	Peripheral nerve
Diaphragm	C3–C5	Phrenic nerve
Trapezius	C3–C4	Spinal accessory nerve
Deltoid	C5–C6	Axillary nerve
Supraspinatus	C5–C6	Suprascapular nerve
Biceps brachii	C5–C6	Musculocutaneous nerve
Triceps brachii	C6–C8	Radial nerve
Wrist extensors	C6–C7	Radial nerve
Finger extensors	C6–C8	Radial nerve
Wrist flexors	C6, C7–T1	Ulnar, median nerve
Intrinsic hand muscles	C8–T1	Ulnar nerve
Psoas	L1–L2	Psoas nerve
Quadriceps femoris	L2–L4	Femoral nerve
Gastrocnemius	L5–S1	Deep peroneal nerve
Urinary bladder	S2–S4	

Patients with associated head injury may be obtunded and therefore unable to report symptoms of spinal cord injury. However, even in comatose patients, asymmetric motor tone, strength, or reflexes may be noted. Abnormalities of posture or tone may be a clue to the presence of spinal cord injury in these patients. In patients with injuries at the level of C6, for instance, biceps function (with impulses from nerve root C5) is intact but triceps function (impulses from C6) is not, and the elbow is held in tonic flexion.

Patients with injury to the spinal column are at risk for spinal cord injury even if no such injury has occurred at the time of evaluation. Therefore, children with signs of spinal injury, such as pain, tenderness, decreased range of motion, or deformity of the back or neck, must be treated with the utmost caution.

Management

Care for the patient with spinal cord injury begins with the ABCs of resuscitation. This initial resuscitation must be accomplished with meticulous attention to the stabilization of the spine. For older children and adolescents, a semirigid cervical collar or manual inline stabilization should be used. For infants, a semirigid cervical collar might actually be too large and may lead to distraction or hyperextension, which could be deleterious. For some infants, therefore, it may be preferable to immobilize with sandbags on the sides of the head, without using a cervical collar. In addition, the patient should be maintained in a supine position on a backboard so that no undue manipulation of the spine occurs. Because infants have a relatively large occiput, supine positioning on a flat surface may result in flexion of the neck. Proper neutral positioning for these young patients may require that the occiput be allowed to rest at a level slightly lower than the shoulders. Any transfers of the patient from one bed to another or "log rolling" of the patient to examine the back should be done with careful attention to maintaining neutral positioning at all times.

Patients with spinal cord injury require adequate oxygenation, ventilation, and perfusion. Careful attention should be given to positioning of the airway (using the jaw-thrust maneuver rather than the chin-lift maneuver), suctioning if needed, and supplemental oxygenation. The head should never be turned in efforts to clear secretions from the oropharynx; if the patient needs to be turned, a log-roll maneuver should be used. Patients with inadequate respiratory effort require positive-pressure ventilation. Patients with coma, inadequate respiratory effort, or inadequate airway protective reflexes need intubation with mechanical ventilation. When possible, rapid sequence intubation (as previously described; also see Chapter 5) should be performed. If sedating or paralytic agents are to be used, a brief neurologic assessment (see the following text) should precede the administration of the drug if time allows.

The circulatory status of patients with spinal cord injury may be impaired if there are other organ system injuries leading to hemorrhage and hypovolemia. Fluid and blood product resuscitation should be initiated in the usual fashion (see Chapter 105), and the definitive treatment of the hemorrhagic injuries should be pursued. Rare patients with spinal cord injuries have signs of spinal shock, with bradycardia, hypotension, and peripheral vasodilation. These patients may require pressor agents to maintain adequate vascular tone. Primary α-agonists, such as norepinephrine or phenylephrine, are often first-line agents chosen in patients with spinal shock to maximize vasoconstriction with limited effect on cardiac performance.

As soon as possible after an injury, the patient's neurologic status should be recorded so that any early progression of neurologic symptoms can be noted and so that the injuries are not attributed to the emergency medical care provided. For conscious, cooperative patients, the clinician should test motor strength in all four extremities, tone in all extremities, deep tendon reflexes, and rectal tone. The sensory examination should include an assessment of light touch sensation, pain sensation (as from a pinprick), and joint position sense (of fingers and toes). For patients with depressed consciousness, an assessment of tone and reflexes may be all that is possible.

Plain radiographs of the spine should be obtained to evaluate for fractures or subluxations. However, the absence of fractures or subluxations does not eliminate the possibility of spinal cord injury. The syndrome of spinal cord injury without radiographic abnormalities (SCIWORA) is well reported in the literature. SCIWORA has also been documented in adult patients, in whom it appears to be a fairly rare phenomenon. Several series of children with spinal cord injury report that 15% to 20% of cases may be classified as SCIWORA. Children may have an especially high risk for SCIWORA because of the flexibility of the pediatric spinal column, which allows the spinal cord to withstand shear or compressive forces without necessarily causing a fracture. In some cases, the flexible and lax spinal column may sublux transiently, causing a compressive injury to the cord and then reduce back into normal position before radiographs are obtained.

In more recent years, MRI has become a mainstay for the diagnostic evaluation of patients with suspected spinal cord injury. MRI provides detailed images of the spinal cord, which cannot be well imaged by plain radiographs or CT. In cases with more severe clinical findings, spinal cord edema, hemorrhage, or even cord transaction may be seen on MRI. Increasingly, MRI has been used to document spinal cord abnormalities in cases that would be classified as SCIWORA by plain radiographs and CT. Many cases of spinal cord injury with mild or incomplete neurologic deficits are associated with normal MRI findings.

MRI should be performed as soon as possible for patients with progressive neurologic deficits who may have extraaxial mass lesions compressing the spinal cord, such as subdural or epidural hemorrhage, or a herniated intervertebral disk. In other cases, MRI may provide useful diagnostic and perhaps prognostic information, but it is less likely to alter the short-term management.

Specific therapy directed at the spinal cord focuses on the prevention of secondary cord injury. The mainstay of this therapy is careful immobilization. In all cases of spinal cord injury, a neurosurgeon should be consulted immediately. If compressive spinal cord lesions are noted, especially with incomplete but progressing neurologic injury, emergent laminectomy with surgical evacuation of the lesion may be necessary. Displaced fractures or subluxations of the spinal column require immobilization and generally some form of traction (e.g., a halo brace, skull tongs) to reduce them and maintain stability (see Chapter 115 for more details). Some patients with irreducible subluxations or unstable fractures require urgent surgery to achieve reduction. Patients with SCIWORA are often managed with long-term immobilization as well, because they are presumed to have some ligamentous instability of the spine.

High-dose corticosteroid therapy has been widely used since the mid-1980s for the management of patients with spinal cord injury. The use of corticosteroids is based primarily on the results of a multicenter prospective, randomized trial known as the National Acute Spinal Cord Injury Study II (NASCIS II). The NASCIS II trial found that a 24-hour regimen of high-dose corticosteroid therapy significantly improved the outcome for patients treated within 8 hours of injury but not in patients treated later. In more recent years, a number of authors have questioned the validity of the data from NASCIS II, pointing out that the benefit for patients treated within 8 hours was discovered only on post hoc analysis. Subsequent studies intended to replicate the results of NASCIS II have had somewhat mixed results, with one Japanese study showing some benefit to steroid administration whereas another French study showing no benefit. A subsequent trial, known as NASCIS III, found that a 48-hour regimen of high-dose steroids was better than a 24-hour regimen for patients treated 3 or more hours after the injury. In recent years, some retrospective studies have shown better outcomes for patients treated with steroids than those not treated with steroids. All studies found a higher rate of complications, including primarily gastrointestinal, pulmonary, and infectious manifestations, in patients treated with steroids than in patients treated with placebo.

Because of the lack of definitive data regarding the efficacy of steroids in spinal cord injury, most authors consider the use of steroids as an option but not a required standard of care. If steroids are used, they are probably most appropriately reserved for patients with documented motor deficits who can be treated within 8 hours of injury. As per NASCIS II, the dosing regimen is methylprednisolone at an initial IV bolus dose of 30 mg per kg, followed by an infusion of methylprednisolone at 5.4 mg per kg per hour for the subsequent 23 hours. According to the data from NASCIS III, continuation of the infusion for an additional 24 hours (total duration 48 hours) might be considered for patients for whom therapy was initiated between 3 and 8 hours after the injury.

All patients with spinal cord injury need to be admitted to the hospital for careful observation and immobilization. For patients with persistent deficits, a long-term plan for rehabilitation and ongoing medical care will need to be developed.

The prognosis after spinal cord injury depends most commonly on the severity of disease at presentation. Patients with complete loss of function below the injured level have the worst prognosis. In contrast, patients with partial injuries often have significant improvements. Although the initial neurologic status is the best predictor of long-term outcome, MRI findings may also be of prognostic value. Patients with documented transection of the cord clearly have little hope of recovery. Patients with cord hemorrhage, long segments of cord edema, or more proximal locations of cord lesions also tend to have worse prognosis. In patients with cord compression seen on MRI, the extent of cord compression also correlates well with the clinical prognosis. In contrast, patients with minor or no abnormalities on MRI generally do well.

Pediatric patients with spinal cord injuries tend to fare better than their adult counterparts. Most pediatric patients with some useful motor function at the time of presentation regain full function of the compromised motor groups. Children with no motor function distal to the site of injury usually have some permanent disability, although they still often have some improvement after their initial presentation.

Penetrating Spinal Cord Trauma

Penetrating spinal cord trauma is especially rare in pediatrics. It may occur as a result of violent injuries from stabbing or gunshot wounds. Accidental injuries may occur, most commonly from shards of glass that penetrate into the spinal column.

Wounds caused by stabbing or sharp foreign bodies usually involve penetration from the posterolateral aspects of the neck. These injuries generally lead to hemisection of the cord, with only one side of the cord affected. This predilection for unilateral injury probably reflects the fact that the posterior spinous processes and lateral transverse processes form an anatomic "gutter" through which the penetrating object is guided, thereby offering some protection to the opposite side of the cord. Bullets, in contrast, may penetrate the bones of the spinal column and cause less predictable patterns of injury.

Some cases of penetrating spinal cord injury may not be obvious on presentation. Gunshot wounds to the head, for instance, may involve migration of the bullet to the level of the spinal cord, even if the initial trajectory of the bullet might not have suggested cord involvement. Some patients with stab wounds or penetrating glass present with what appear to be innocent lacerations on the neck or back.

Plain radiographs demonstrate the presence of many radiopaque foreign bodies; in some cases, CT may be required to demonstrate less radiodense materials. In cases in which no foreign body is left in the wound, plain radiographic and CT findings may be normal. MRI is the best imaging modality for delineating injury to the cord itself.

When caring for patients with penetrating spinal cord injury, the clinician should recognize the potential for other associated injuries. Penetrating injuries of the neck, for instance, can be associated with injury to the esophagus, airway, or vasculature. Similarly, penetrating trauma to the thoracic spine may be associated with pulmonary, esophageal, or cardiovascular injury.

A neurosurgeon should be consulted in all cases of penetrating cord injury. In some cases, surgical removal of intraspinal foreign bodies, bone fragments, or expanding hematomas is indicated. Surgical repair of ongoing CSF leak from the site of injury may also be indicated. Most penetrating spinal cord injuries are not associated with instability of the spine, even in cases of gunshot wounds. Nonetheless, appropriate immobilization is recommended until spinous instability can be definitively excluded. Prophylactic antibiotic therapy is also recommended for penetrating spinal cord injury. Generally, a first-generation cephalosporin such as cefazolin (30 mg per kg IV; maximum dose 2 g) is preferred.

PERIPHERAL NERVE INJURIES

Pathophysiology

Peripheral nerve injuries in pediatrics usually involve the extremities, most commonly the hand and upper extremity. Most peripheral nerve injuries in pediatrics result from acute traumatic insults. Transection of the nerve may result either from deep soft-tissue lacerations or from severe crush injuries. Rarely, transection of a nerve may also result from a fracture, with laceration of the nerve by a displaced bony fragment.

More commonly, however, displaced fractures or dislocations lead to reversible compression injuries to the nerve. Nerve compression may also occur in the absence of acute trauma, usually because of tight anatomic compartments that exert constant pressure on the nerve (carpal tunnel syndrome is one common example).

Peripheral nerve injuries may be graded in terms of the severity of the clinical course. The mildest form of nerve injury is known as *neurapraxia*, which refers to nerve conduction impairment without structural injury to the axon itself. Neurapraxia commonly results from a situation of transient compression or ischemia, as when a patient complains that a limb has "fallen asleep." The numbness and paresthesias reflect a rapidly reversible physiologic conduction block. If biopsy of the nerve were performed in this situation, no histologic abnormalities would be expected.

More severe cases of neurapraxia may be associated with symptoms that persist for as long as several months. In these cases, histologic examination reveals focal demyelination in the injured area of the nerve, but with no injury to the axon itself. In general, as long as the axon itself is not injured, full recovery can be expected.

Axonotmesis is a more severe injury to peripheral nerve, involving injury to the axon itself, but with preservation of the surrounding connective tissue of the nerve sheath. Axonotmesis generally results from crush injuries to the nerve. Recovery of peripheral nerve function is likely to occur well, although it will progress slowly, with lengthening of the nerve axon from its proximal stump progressing at a rate of approximately 1 to 4 mm per day. Distal nerve lesions, near the target muscles or sensory regions, are associated with earlier and more complete recovery of function than do more proximal lesions.

The most severe form of nerve injury is known as neurotmesis, which involves injury both to the nerve axon and to the surrounding connective tissue. Neurotmesis usually results from direct laceration to the nerve or, rarely, from severe crush injuries. Because there is no intact nerve sheath to guide the development of the regenerating proximal nerve, spontaneous recovery of function is unlikely and surgical repair is required.

Clinical Manifestations

Significant peripheral nerve injuries are usually seen in association with other obvious signs of traumatic injury, such as a soft-tissue laceration, crush injuries to the extremity, or fracture. In some cases, however, such as with sudden stretches of the brachial plexus ("burners" or "stingers"), with repetitive microtrauma or with anatomic compressive lesions (as seen in carpal tunnel syndrome), the symptoms of peripheral nerve injury may be the primary complaint.

The cardinal symptoms of peripheral nerve injury are disturbances of sensory or motor function in the distribution of the nerve. Appropriate diagnosis of peripheral nerve injury requires an understanding of the anatomic distribution of sensory and motor functions of the major peripheral nerves. A full description of this clinical anatomy is beyond the scope of this discussion, but a summary of the motor functions of the major peripheral nerves is presented in Table 116.1.

Disturbances of sensation may include paresthesias, pain (which may be described as sharp, burning, or stabbing), or numbness. In some cases, the patient may not report a sensory deficit, but sensory abnormalities are noted on examination. A gross assessment of sensory function can be obtained simply by testing the patient's ability to recognize light touch stimuli in the distribution of the nerve in question.

A more sensitive test for identifying disturbances in sensory function is two-point discrimination. Although instruments for assessing two-point discrimination are commercially available, in common practice, a paper clip is often used. The paper clip should be unfolded so that the two ends are in close proximity, with a distance of approximately 1 cm in between. The patient should then be briefly trained on an uninjured part of the body to differentiate between being touched with one or two points of the paper clip simultaneously. Once it is determined that the patient can reliably perform the task, the injured area should be assessed.

The two points must touch the skin simultaneously, and they must occur in the same axial line. If the patient is able to successfully discriminate one- and two-point stimuli, the distance between the two ends of the paper clip can be decreased successively to find the patient's threshold for discrimination. A hand with normal sensation should be able to distinguish between two points that are 2 to 5 mm apart at the fingertips, 7 to 10 mm at the base of the palm, and 7 to 12 mm on the dorsum of the hand. More proximal parts of the upper extremity may have even less sensitive discriminatory abilities.

A problem occasionally arises in trying to assess sensory function in a patient who is unresponsive or who cannot communicate with the examiner. In these cases, a test of sympathetic innervation, such as the O'Riain wrinkle test, may be useful. To perform this test, the patient's hand is immersed in a warm water bath for approximately 20 minutes. Normal digital pulps will wrinkle; fingers with disrupted sympathetic innervation will not wrinkle.

Appropriate motor testing of the peripheral nerves depends on the isolation of muscle activity that reflects the peripheral nerve in question. The clinician must be careful to recognize that a patient will compensate for a motor deficit by using other motor groups to accomplish the same task. Motor function can be assessed by examining not only active motor strength but also resting tone and, for more chronic injuries, muscle bulk.

"Burners" or "stingers" are a special form of peripheral nerve injury that result from trauma to the neck and shoulder, usually in football players after contact with another player. The injury leads to immediate onset of a burning paresthesia that radiates down the arm, often associated with ipsilateral arm weakness. The symptoms usually resolve over the course of several minutes. Although the exact pathophysiology of burners and stingers is not well understood, they appear to result from stretch of the cervical nerve roots and brachial plexus and/or compression of the nerve roots as they course through narrow cervical neural foramina. The differential diagnosis for these injuries should also include spinal cord contusion, although the characteristic involvement of a single arm, the rapid resolution of symptoms, and the absence of associated cervical spine injury help distinguish burners and stingers from spinal cord injury.

Management

Clean lacerations to a primary nerve are often repaired primarily. There is some evidence to indicate that recovery of function is better if the nerve is repaired within 48 hours of injury. Crush injuries to peripheral nerves are often repaired secondarily, several days or weeks after the injury. For these cases, many surgeons believe that delayed repair allows better debridement of devitalized tissue and easier identification of injured nerve tissue that needs to be resected. In all cases in which transection of a peripheral nerve is suspected, prompt consultation with an appropriate surgical consultant is indicated so that a decision can be made about the appropriate timing of repair.

Injuries to peripheral nerve associated with fracture or dislocation generally improve after the orthopedic injury is reduced. If there is any question about the recovery after reduction, nerve function should be carefully followed.

For burners and stingers, no diagnostic tests are routinely necessary, but imaging of the cervical spine is appropriate if there are clinical signs to indicate possible cervical spine or spinal cord abnormalities. Patients with burners and stingers should be counseled to avoid sports activities until the symptoms have fully resolved, and they should be informed about the risk of recurrent injury. Follow-up with a sports medicine or orthopedics specialist for further diagnostic evaluation, strength training, and possible orthotics may also be helpful.

Nerve compression syndromes not associated with acute traumatic injuries, such as carpal tunnel syndrome, can generally be treated with rest and nonsteroidal antiinflammatory medications. Splinting may also be indicated for some syndromes. In all cases, appropriate follow-up should be arranged so that the patient can be referred for further interventions, if necessary.

The prognosis after peripheral nerve injury clearly depends on the severity of the injury. Compressive lesions without transection of the nerve have a better prognosis, with full recovery expected in all but the most severe or most chronic cases. With transections of the nerve, however, there is often some degree of permanent disability. In general, those lesions resulting from clean lacerations that can be repaired primarily have a somewhat better prognosis. Children, in general, have a better prognosis after peripheral nerve injury than do adults. In some cases, remarkable recoveries after severe crush injuries to the nerve have been reported.

CHAPTER 117 ■ EYE TRAUMA

ALEX V. LEVIN, MD, MHSC, FRCSC

When faced with a child who has sustained eye trauma, the pediatric emergency physician must keep in mind four important basic principles:

1. The management of life-threatening systemic illness or central nervous system trauma must always take precedence over the eye injury. Even the most serious eye injury may be acutely "neglected" if urgent lifesaving procedures are underway.
2. Ensure the structural integrity of the eyeball (i.e., rule out ruptured globe).
3. Check the vision in both the injured and uninjured eye.
4. When in doubt, and when indicated, seek ophthalmology consultation.

This chapter is designed to assist the pediatric emergency physician in the diagnosis and management of basic and uncomplicated ocular injuries, yet, it is important to recognize when ophthalmology consultation is necessary. Even with the increasing number of emergency departments (EDs) that have slit lamp biomicroscopy available to the nonophthalmologist, the ophthalmologist is more expert at using the slit lamp and has experience with a wide array of other diagnostic tools that allow viewing and recognition of intraocular injuries that can not otherwise be seen. For example, when trauma damages the retina, it often does so at the edges of the retina. This area is out of the field of view of the direct ophthalmoscope and requires indirect ophthalmoscopy to be viewed adequately. Most children who sustain high-risk blunt trauma to the eye, even in the absence of injury that can be seen on external examination, warrant a dilated retinal examination by an ophthalmologist, using the indirect ophthalmoscope. If in-house ophthalmology consultation is not readily available, it is important to identify an ophthalmologist in the community who is comfortable examining children for outpatient follow-up.

HISTORY

Certain questions help identify possible intraocular injury. What was the child's prior visual status? If the child was previously known to have poor vision in the eye, then less concern will be elicited if the same poor vision is noted after the trauma. Has the child ever had a prior eye examination, and if so, what were the results? Has the child ever had a patch over one eye for an extended period? This history would indicate that the child previously had poor vision secondary to amblyopia in the eye that was *not* patched. Has the child ever had eye muscle surgery? Children who have had strabismus are at a greater risk of developing amblyopia. Therefore, poor vision in one eye is more common. Does the patient wear glasses? If so, the glasses should be worn when visual acuity is tested. Does the patient wear contact lenses? If so, removal of the contact lenses may be necessary.

Additional questions include the following: What was the nature of the injury? How hard was the eye struck? Certain types of trauma have a particularly high risk for causing intraocular damage: significant blunt impact directly to the eyeball (e.g., fist, ball), projectiles, and sharp implements (e.g., pencil, stick). Different antibiotic coverage may be necessary for suspected contamination (e.g., *Bacillus* species) by soil or other outdoor implements. Hammering is a particularly high-risk behavior for causing intraocular foreign bodies. If an intraocular foreign body is suspected, the clinician must establish by history whether it is metallic. This may influence the choice of imaging and treatment (e.g., magnets are sometimes used by the ophthalmologist during surgical removal of a metallic intraocular foreign body).

EXAMINATION

An attempt should always be made to assess the visual acuity in the injured eye before proceeding with the rest of the eye examination. Some patients may be unable to perform this task because of eye pain, noncompliance, an inability to open swollen lids, or obtundation from accompanying head trauma. At the very least, even if the eyelids remain closed, the physician can test for light perception. By shining a bright penlight or direct ophthalmoscope in the direction of the eyeball through the closed eyelid, the physician can ask the patient to indicate whether he or she perceives the additional light on that side. Even without a patient response, a reflex contraction of the lids may be seen, indicating light perception.

If the patient is able to exhibit a greater degree of compliance, the examiner may ask the patient to count fingers that are held before the affected eye at varying distances. The maximum distance at which these fingers can be counted should be noted on the chart (e.g., counting fingers at 4 feet). If the patient cannot stand but can identify letters or numbers, a commercially available near card or any other reading material (the font isize on this page is approximately 20/60 vision) can be used to assess the quality of near vision. Very few injuries cause abnormal distance vision but normal near vision. Normal near vision usually indicates that the patient has not sustained a significant ocular injury that is impairing vision at that time. The subnormal distance vision may simply be due to uncorrected myopia or other refractive errors.

If the patient is able to comply, the examiner should try to obtain a standard visual acuity, using a distance chart. Letter charts should be used only if the child is known to be able to

accurately identify all letters either by parental report or by walking up to the distance chart and identifying them at close proximity. If the child has any trouble with letters, a matching chart or a picture chart can be used (see Chapter 127).

The patient's visual acuity in each eye should be tested. The presence of bilaterally poor vision in a patient with unilateral eye trauma suggests that the cause of the poor vision is unrelated to the trauma. The eye that is not being tested should be covered well to prevent any conscious or unconscious attempt on the part of the patient to peek around the obstruction. Children will naturally try to do this if their better eye is being covered. To ensure the child is actually viewing the chart with the eye that is being tested, the examiner should stand by the chart, facing the patient, indicating which letters are to be read while observing the patient's compliance (see Chapter 127).

If a patient demonstrates poor vision in the traumatized eye, the clinician can readily establish whether this deficit is related to the trauma or uncorrected refractive error (i.e., a need for glasses). When a person looks through a pinhole and experiences improvement in performance on visual acuity testing, he or she must have an uncorrected refractive error as the cause of the initially tested poor vision. For example, if a patient comes in with a traumatized eye that is able to read only 20/400 (needs to stand at 20 feet to see what a normal person can see at 400 feet) but then improves to 20/25 by using a pinhole device, the patient has not sustained visual impairment from the ocular injury. Rather, the patient simply needs glasses. The maximum vision obtainable through a pinhole may be only 20/25 to 20/30 due to optical aberrations inherent in the pinhole test. Although commercial pinhole devices for testing vision can be used, the test can also be conducted by poking holes through opaque paper or cardboard with an 18-gauge needle. A cluster of five or six holes may be easier for the patient to use.

After visual acuity has been established, an attempt may then be made to examine the eyeball. By using a step-by-step anatomic approach, the examiner should first inspect the periorbital tissues and eyelids for the presence of ecchymosis, lacerations, and ptosis. Eye muscle movements (see Chapter 24) and the anterior surface of the eye should be evaluated next. All attempts should be made to examine these structures without touching or upsetting the child, particularly if by history or examination a ruptured globe is suspected. An upset child creates a Valsalva maneuver while crying, which may lead to extrusion of intraocular contents out of a ruptured globe. If a ruptured globe or hyphema has been ruled out, the examiner may proceed with full eye examination, including pharmacologic dilation of the pupil. Regimens for pupil dilation are suggested in Table 117.1.

TABLE 117.1

EMERGENCY DEPARTMENT OCULAR DILATING REGIMEN[a]

Phenylephrine 2.5%	For brown irides replace tropicamide with cyclopentolate 1%
Tropicamide 1%	

[a]May repeat regimen in 30 minutes if needed. Instilling proparacaine or tetracaine prior to these dilating drops will enhance the dilation effect.

A red reflex should be documented unless the vision is normal and there is no concern about a possible eye injury. By standing approximately 1 m away from the patient, the examiner should shine the largest available circle of white light from the direct ophthalmoscope onto the patient's face such that both eyes are illuminated simultaneously (see Chapter 24, Fig. 24.6). The focusing dial is then spun until the patient's face and eyes come into focus. The patient should be instructed to look at the observer. The room light should be turned out to encourage maximum physiologic pupillary dilation. The red reflex is usually orange–red or yellow–orange (see Chapter 24, Fig. 24.6); only rarely is it actually red. The absence of a red reflex (black reflex) in its entirety or in part of the pupil may indicate an obstruction within the eyeball to the passage of light, such as a corneal scar, cataract, or hemorrhage within the eyeball. A darkened reflex may also be caused by small pupils or misaligned eyes (see Chapter 24, Fig. 24.6). Rechecking the reflex after pharmacologic dilation may be helpful in these situations. A white reflex indicates white intraocular pathology such as a corneal scar, cataract, coloboma, or retinoblastoma (a malignant eye tumor). An abnormal red reflex (with the exception of a dark reflex that clears with pupil dilation) always requires ophthalmology consultation.

The emergency physician often finds the direct ophthalmoscope to be useful for the identification of possible papilledema or retinal hemorrhages in the setting of acute central nervous system injury, the latter being particularly concerning for the possibility of abusive head injury. Pupillary size should be maximized by the use of dim ambient illumination and the small white circle direct ophthalmoscope beam. Pharmacologic agents (Table 117.1) can be used to dilate the pupil and improve the view. The patient should be encouraged to fixate on a distant target. The examiner must avoid inadvertently lowering his or her head in a way that obstructs the eye that is not being examined, therefore, obstructing the fixation of that eye (Fig. 117.1A). The patient would then begin looking elsewhere, making adequate examination of the optic nerve difficult. To avoid this scenario, the examiner should sit or stand such that his or her head is at level with and parallel to the patient's head rather than leaning over (Fig. 117.1B). If the examiner is standing above the patient, the patient's head can be tilted away from the examiner such that it becomes parallel to the examiner's head when he or she leans over to look into the eye (Fig. 117.1C).

The ophthalmoscope may be used with or without the examiner's glasses (or contact lenses) in place. The examiner holds the direct ophthalmoscope approximately 30 to 60 cm from the patient while standing at his or her side, holding the instrument in the same hand and in front of the same eye that corresponds to the eye to be examined (i.e., examiner's right hand and right eye used to examine patient's right eye). The focusing dial should be set at zero, and a red reflex should be obtained. Then the examiner approaches the patient slowly until a blood vessel is seen within the red reflex. As the examiner moves closer, he or she should follow the blood vessels while turning the focusing wheel with the forefinger to keep the blood vessels in focus. The apex of any branching blood vessel points in the direction of the optic nerve head (Fig. 117.2, see also color plate). The optic nerve head (disc) is best found in this manner. When the disc is located and in focus, the examiner's forehead should be no more than 3 to 6 cm away from the patient's forehead.

FIGURE 117.1 Use of the direct ophthalmoscope. **A:** Examiner is in incorrect position. His head is blocking patient's ability to fixate with the left eye during examination of right eye. By placing his head at level of patient's (**B**) or by tilting patient's head away (**C**), the left eye can continue to fixate.

Two common scenarios prove particularly difficult for those less familiar with direct ophthalmoscopy. If the pupil is too small relative to the light beam from the direct ophthalmoscope, not all the light will enter the pupil. Rather, some light will reflect off the iris, resulting in glare. In this situation, ensure that the smallest diameter white circle projected by the direct ophthalmoscope is being used and the pupil size is maximized by either turning off the ambient light or using pharmacologic pupil dilation. Examining infants is particularly difficult because they cannot follow the direction to fixate on one spot during the examination. If the baby is placed on an examining table or in the parent's arms in the supine position, the examiner can approach from the side as described above: lean over the child, obtain a red reflex, and then move to the usual working distance described previously. Do not chase the roving eyeball of the child. The physician should "hold his ground," staying motionless about 45 degrees away from the child's midline visual axis approximately 3 to 6 cm away from the face. Because the optic nerve head is a physiologic blind spot in the visual field, the child will eventually adopt a position to avoid the light by placing their blind spot (i.e., the optic disc) in the path of the light source, at which time the optic nerve will have come into view.

The optic nerve should be yellow–orange to pink (Fig. 117.2, see also color plate). Centrally, a white depression called the *optic cup* is apparent. Normally, this depression may be barely visible or may occupy up to 50% to 60% of the optic nerve surface area. Both optic nerves usually have symmetric cup sizes. The retinal blood vessels usually emerge from the center of the cup. In papilledema (Fig. 117.3, see also color plate), the edges of the optic nerve become indistinct and difficult to differentiate from the surrounding retina. The blood vessels may become engorged and tortuous. There may be associated hemorrhages on the optic nerve surface or immediately surrounding the disc. Yellow–white exudate may also be seen within the retina. The optic nerve cup may not be

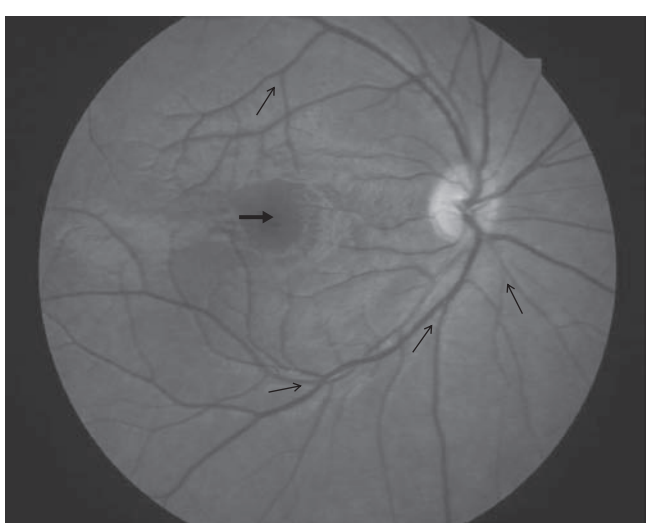

FIGURE 117.2 Normal right retina as viewed by indirect ophthalmoscope. Central dark area *(thick arrow)* represents fovea. Note that the apex of the branch point of the blood vessels *(thin arrows)* always points back toward the direction of the optic nerve head.

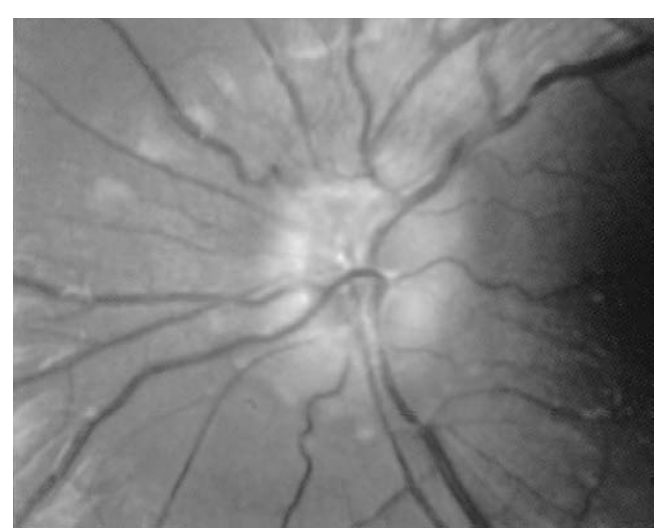

FIGURE 117.3 Papilledema. Note blurred disc margins and loss of view of blood vessels on disc.

identifiable because of swelling of the neurons. It may be difficult to focus on the optic nerve surface and the retina at the same time because of the elevation of the optic nerve. Perhaps the most important and distinguishing sign to aid in the recognition of papilledema is the disappearance of the vessels on the disc surface as they course among opaque edematous neurons. Papilledema may at times be subtle. If any question exists in the mind of the examiner that papilledema may be present, ophthalmology consultation is appropriate.

Papilledema is almost always bilateral. Presence of unilateral papilledema suggests an ipsilateral orbital trauma, such as an orbital hemorrhage, orbital tumor, or direct injury to the optic nerve. The optic nerve can be injured from blunt trauma without a penetrating orbital injury. The optic nerve can be injured even by severe blunt trauma to the frontal bone by which forces are carried to the optic foramen surrounding the optic nerve as it enters the orbit.

If the eye has been traumatized such that the patient is unable to voluntarily open the eyelids, attempts should be made to assist the patient in doing so. A warm compress may be gently applied to the eyelashes to loosen any crust or discharge that may be holding the eyelashes together. When opening the eyelids, it is essential to avoid pressure on the eyeball, which might lead to extrusion of intraocular contents via an underlying ruptured globe. By placing his or her thumbs on the supraorbital and infraorbital ridges while exerting pressure against the underlying bone, the examiner's thumbs can then be pulled away from each other such that the eyelids are separated (Fig. 117.4). Various commercially available speculums can also be used to open swollen eyelids (Fig. 117.5). A drop of topical anesthetic (e.g., tetracaine, proparacaine) should be instilled before placing a speculum or retractor. The Desmarres retractor is perhaps one of the least uncomfortable yet effective means for opening swollen lids. After instillation of a topical ophthalmic anesthetic, the cupped end of the retractor (Fig. 117.6A) is slipped under the upper lid and gently retracted with the handle parallel to the forehead (Fig. 117.6B). A second retractor can be simultaneously applied to the lower lid to further improve exposure. Paper clips can also be bent to create a retractor (see Chapter 127, Fig. 127.3).

In the trauma setting, with enough lid swelling that precludes a readily available view of the eyeball using the techniques previously described, it is probably safer to refer the patient for an ophthalmology consultation unless the emergency physician is comfortable with the recommended techniques. Risking the use of a speculum or retractor may upset the patient and cause a struggle that could also contribute to disruption of the intraocular contents in the presence of a ruptured globe. Even the ophthalmologist may choose to abandon

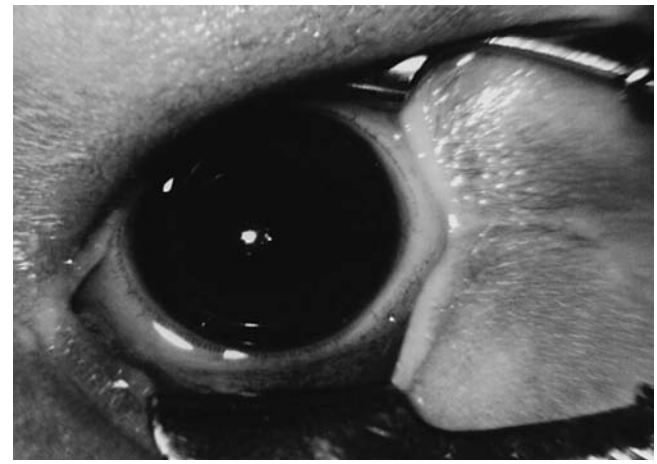

FIGURE 117.5 Commercially available eye speculum in place.

such attempts and proceed directly to an examination under anesthesia if the risk of ruptured globe is believed to be high.

RUPTURED GLOBE

Clinical Manifestations

Laceration or puncture of the cornea and/or sclera creates a ruptured globe. This condition can occur following trauma by projectile, sharp implement, or blunt trauma. Although severe intraocular disruption may occur, the eyeball has a remarkable ability to maintain its integrity. Immediately upon laceration, the iris or choroid (which is the extension of the iris posteriorly underneath the sclera) plugs the wound. This plug may appear as a blue, brown, or black material on the surface of the sclera (Fig. 117.7, see also color plate). At the corneoscleral junction, the iris will come forward and plug a corneal wound (Fig. 117.8). Because of this iris or choroid movement, the pupil often takes on a teardrop shape, with the narrowest segment pointing toward the rupture (Figs. 117.7 and 117.8). Hemorrhage within the anterior chamber (hyphema) often accompanies a corneal or anterior scleral laceration (Fig. 117.7). With small lacerations that are plugged by iris or choroid, the eyeball does not deflate but rather takes on a remarkably normal external appearance. Subconjunctival hemorrhage for 360 degrees may obscure an underlying scleral rupture but leave the eye fairly intact. Patients who present following trauma with this finding or with severe 360-degree conjunctival swelling without hemorrhage should be treated as if they had a ruptured globe and should be referred immediately to an ophthalmologist. The ophthalmologist can then make the assessment via intraocular examination.

Management

Although the outcome in some ruptured globes, particularly small peripheral corneal lacerations, may be good, eyeball rupture is certainly an ominous sign that warrants emergent referral for ophthalmology consultation. Further ocular examination should be stopped immediately. No eyedrops should be instilled. A patch should never be used in this circumstance. A plastic shield should be placed over the eye such that the edges of the shield make contact with the bony prominences above and below the eyeball (Fig. 117.9). If a commercially marketed shield is not available, the clinician should cut off the bottom of a Styrofoam or plastic cup and use it as a shield, resting it against the bony prominences (Fig. 117.10). If possible, a shield can even be placed over an obviously injured eye while resuscitative efforts are ongoing to prevent further accidental injury or contamination by the medical staff.

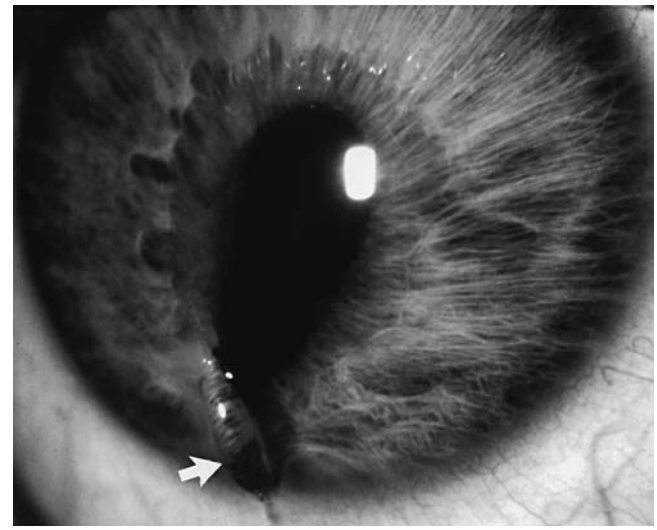

FIGURE 117.8 Corneal laceration (ruptured globe). Note iris protruding through wound *(arrow)* and teardrop-shaped pupil pointing in direction of laceration.

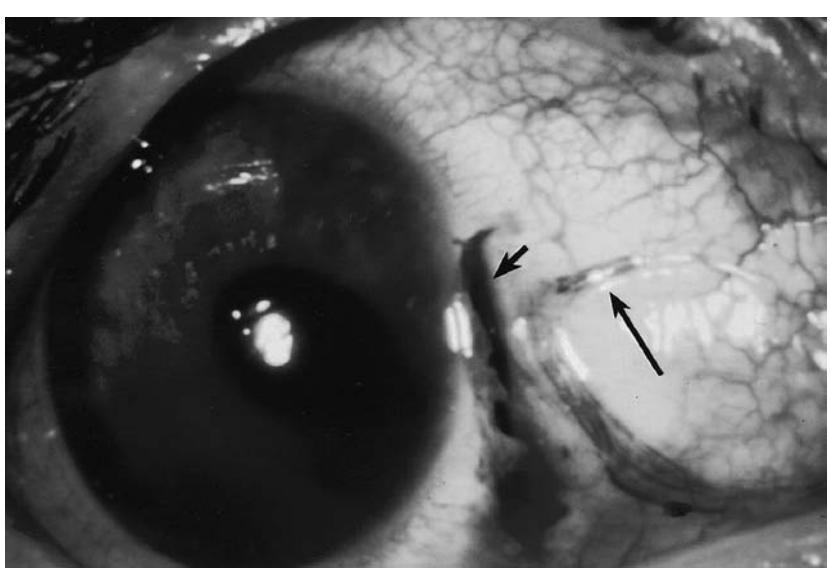

FIGURE 117.7 Ruptured globe. The scleral laceration *(short arrow)* appears as a linear brown line on the white of the eye. The pupil has a teardrop shape, the apex of which points in the direction of the rupture. The *long arrow* points to the upper border of a large conjunctival laceration. Note that the underlying sclera is intact under the conjunctival laceration. There is a diffuse hyphema in the anterior chamber, which partially obscures the pupil.

FIGURE 117.9 Patient shielded for right ruptured globe that was caused by a thrown pen.

Severe eye trauma may cause sedation or vomiting without head trauma or brain injury. Every attempt should be made to keep the child calm, even if sedation must be used. Keep in mind that crying, screaming, and Valsalva maneuvers such as vomiting can result in further extrusion of intraocular contents through the rupture. Although broad-spectrum intravenous antibiotic coverage is desirable, this treatment must be weighed against the potential aggravation of the child, which might accompany the needle puncture for catheter placement, and delay that may occur before the patient sees an ophthalmologist. Even if a ruptured globe is not seen clearly on examination, any patient who has a high-risk history, severe lid swelling, and extreme resistance to examination should be given an eye shield and referred to an ophthalmologist as if a ruptured globe was confirmed.

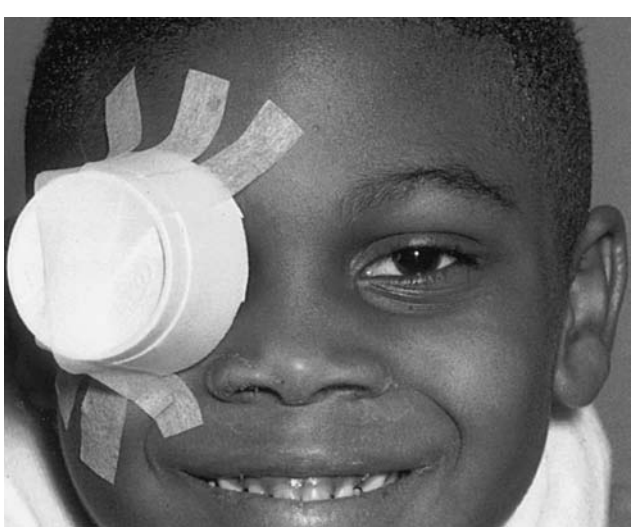

FIGURE 117.10 The bottom of a drinking cup is used as an eye shield.

BLOWOUT FRACTURE

Clinical Manifestations

The pathophysiology and diagnosis of blowout fractures are discussed in Chapter 24. Following blunt compressive eye trauma, the eyeball may be retroplaced in a manner that increases the pressure within the orbit and "blows out" one or more bones of the orbital wall. Direct blunt trauma to the orbital rims may also cause bony fractures that extend back into the orbit. Therefore, orbital fractures may occur after facial trauma with or without eyeball trauma.

The most common orbital fracture is an inferior and/or medial wall fracture. The lateral wall is the least commonly fractured. The intraocular contents often sink back into the fracture, giving an enophthalmic appearance (sunken eye). Conversely, proptosis can occur from orbital hemorrhage. Superior wall fracture (roof fractures) may be associated with pulsating proptosis as a result of communication between the orbit and intracranial cavity. Fractures of the inferior wall may be associated with numbness of the ipsilateral malar region caused by injury to the infraorbital nerve, which travels along the floor of the orbit. Palpation of the bony rim of the orbit is often remarkably normal, contrary to the common teaching about point tenderness and "step off" signs.

The hallmark sign of orbital fracture is a restriction of extraocular movement. Usually, the eye is unable to look away from the fracture site because of a tethering of intraocular muscle or other orbital tissues in the fracture (see Chapter 24, Fig. 24.4). Conversely, orbital hemorrhage at the fracture site can less commonly displace the eyeball away from the fracture and make it difficult for the eye to look in the direction of the fracture.

Management

Approximately 20% of orbital fractures are associated with eyeball injury. Therefore, ophthalmology consultation for complete dilated retinal examination and slit lamp biomicroscopy is indicated in virtually every case. Some controversy exists among ophthalmologists, otorhinolaryngologists, and craniofacial surgeons regarding the urgency for radiologic evaluation and surgical intervention in the management of orbital wall fractures. Axial (proptosis) or coronal displacement of the eyeball is an ominous finding because it may be a sign of orbital hemorrhage, which can cause compression of the optic nerve, requiring emergency surgical intervention. Some would argue that enophthalmos is also a sign that should lead to more urgent radiologic evaluation and surgical intervention. If a decision is made to proceed with radiologic imaging, the optimal test is computed tomography (CT) scan of the orbit with both axial and coronal views. The brain should be included, particularly when a roof fracture is suspected. Plain skull radiographs have little role in the management of orbital wall fractures and need not be ordered.

EYELID LACERATIONS

Clinical Manifestations

Although eyelid lacerations are usually easy to detect, the clinician must remember that the underlying eyeball might also have been lacerated or injured. Seemingly superficial lacerations of the eyelid may be associated with penetration into the orbit or intracranial cavity, particularly when the injury was caused by a pointed implement such as a tree branch or pencil. If possible, the eyelid should be everted to look for a conjunctival wound indicating that the laceration is actually a complete perforation of the eyelid. Puncture wounds of the upper lid with an implement such as a stick or pencil can result in perforation of the orbital roof and entry into the intracranial subfrontal space, with surprisingly little in the way of signs or symptoms. CT scan should be considered in all cases of full-thickness perforation of the upper lid. Likewise, it is remarkable how easily and apparently atraumatically a perforating implement can reach the orbital apex and optic nerve. Visual field defects may be the only sign, other than the small lid perforation, that the nerve has been injured. CT scan should be considered for all lid perforations.

Oblique lacerations that extend into the medial canthal area (juncture of the upper and lower lids medially) may involve the proximal portion of the nasolacrimal system (Fig. 117.11). Sometimes, the lid margin puncta, which drains tears into the system, is displaced laterally as a result of the laceration (Fig. 117.11). Lacerations in this area should usually be referred for ophthalmology consultation if any question exists regarding whether the tear drainage system is intact.

Management

Lacerations of the periorbital skin and superficial eyelid skin may be managed by standard skin closure techniques discussed elsewhere in this book. It is important that sutures not grasp deep tissue within the eyelid because this may result in cicatricial eversion of the eyelid margins. Table 117.2 summarizes those findings that, when associated with eyelid lacerations, should prompt ophthalmology consultation for wound closure.

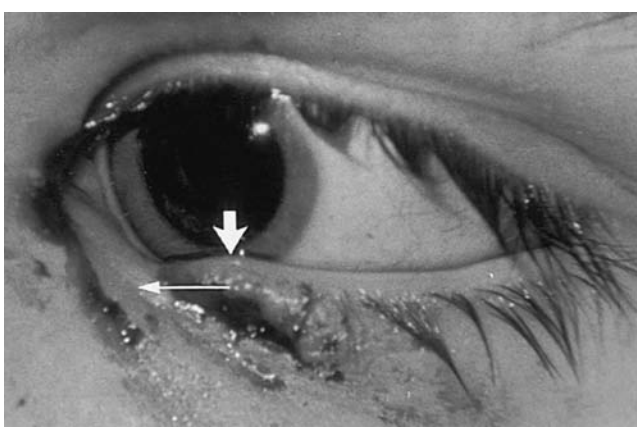

FIGURE 117.11 Lower lid laceration involving tear drainage system. *Thick arrow* indicates lower lid punctum, which has been displaced laterally. *Thin arrow* indicates normal course of canaliculus, which drains tears from the puncta to the lacrimal sac located medially.

TABLE 117.2

EYELID LACERATIONS

Consult ophthalmology if laceration is associated with:
- Full-thickness perforation of lid
- Ptosis
- Involvement of lid margin
- Possible damage to tear drainage system
- Tissue avulsion
- Eyeball injury

PERIORBITAL ECCHYMOSIS

Clinical Manifestations

Periorbital ecchymosis is usually a benign finding, although it may be associated with bony fracture or eyeball injury. Because of the loose connection of the eyelid skin and underlying tissues, dramatic ecchymosis can occur with mild blunt trauma. Bilateral ecchymosis may occur from midline forehead injuries. It is of forensic importance that the dating of injuries should not be made on the basis of the color of periorbital ecchymosis. Because accumulation of blood tends to be more dramatic in the eye than in other body sites, periorbital ecchymosis often looks much darker than what might be expected elsewhere for a bruise of similar age.

Management

No treatment is routinely needed for periorbital ecchymosis. Ice packs applied to the area, with the eyelids closed, can be helpful in reducing swelling.

Anticipatory guidance may be given to inform the family that the ecchymosis may persist for more than 2 weeks. An ongoing color change from purple to green and yellow may occur as the blood is resorbed and broken down. A hyperpigmented area may be left for several weeks or months thereafter.

CORNEAL AND CONJUNCTIVAL INJURY

Clinical Manifestations

The conjunctiva can be abraded or lacerated (Fig. 117.7), although the management of this problem is usually identical to that of corneal abrasion because the tissues heal so rapidly. Corneal or conjunctival abrasions may occur even

from mild surface trauma. Self-inflicted abrasions may occur accidentally.

Corneal abrasion can be painful and accompanied by dramatic photophobia and resistance to opening of the eyes. Yet, some children have remarkably few symptoms. They may complain of a foreign-body sensation even though no foreign body is present. A drop of topical proparacaine 0.5% or tetracaine 0.5% may have both diagnostic and temporary therapeutic usefulness. Any patient who is made more comfortable by the instillation of either of these drops must have an ocular surface problem (conjunctiva or cornea) as the cause of pain. The child who is crying and refusing to open the eyes may be compliant and easy to examine just a few minutes after the instillation of a topical anesthetic. Onset of action is approximately 20 seconds, and duration is approximately 20 minutes.

Topical fluorescein is used as a diagnostic agent to stain the affected area. Fluorescein is available as impregnated paper strips and as a solution combined with a topical anesthetic (Fluress®, Akorn Pharmaceuticals, Lake Forest, Illinois). Considering the limited use in an ED setting, strips may be a more practical method because bacterial contamination over time is more likely with the solution. When impregnated strips are used, they must be wet before instillation. Otherwise, the strip itself may cause a corneal abrasion, thus preventing the examiner from correctly identifying the patient's problem. Topical anesthetic or saline may be used to wet the strip. The lower eyelid should be pulled down, exposing the pink inner surface (palpebral conjunctiva) against which the strip may be touched. The solution then diffuses off the strip into the area between the lower eyelid and the eyeball (inferior fornix), where it is then displaced across the ocular surface with the next blink. The clinician must avoid placing too much fluorescein because the tear film can be so oversaturated that it may be difficult to find a small abrasion.

Fluorescein, which is orange, fluoresces yellow–green when exposed to blue light. Many modern ophthalmoscopes have a blue light. The examiner can view through the peephole of the direct ophthalmoscope, spinning the focusing dial to allow the ocular surface to be in focus with the examiner 5 to 10 cm away from the patient, inspecting the cornea and conjunctiva for an area that is stained. A Wood's or Burton lamp can also be used. Some of these devices have handheld magnifying windows attached. Although the staining may not be as dramatic, white light from a direct ophthalmoscope or penlight can also be used because some blue wavelengths are incorporated in white light. Green light (red free), available on most direct ophthalmoscopes, may make identifying stained areas more difficult than white light. When a superficial abrasion may actually represent penetration into the deeper corneal tissues, a teardrop or irregular pupil may be seen. Urgent ophthalmic consultation is indicated.

If the staining pattern reveals one or more vertical linear abrasions, the examiner should suspect the presence of a retained foreign body under the upper lid. This foreign body may be viewed by upper lid eversion (Fig. 117.12). The patient should be asked to look down repeatedly throughout this procedure. With the eye in downgaze, a cotton swab should be placed against the midbody of the upper eyelid and gently rotated downward toward the eyelashes so the skin is rolled with the swab by friction. This procedure causes the eyelashes to turn out toward the examiner so they may be grasped between the examiner's thumb and forefinger. It may be necessary to grab the entire lid margin in some children. If a topical anesthetic is instilled before lid eversion, this procedure is virtually painless although some patients do not enjoy the unusual sensation. After the lashes (or margin) are grabbed, lift vertically while the cotton swab is used to apply gentle downward pressure in the opposite direction. The eyelid then flips around the cotton swab. If a foreign body is identified, it can be gently lifted away using a cotton swab or forceps. To revert the eyelid, simply

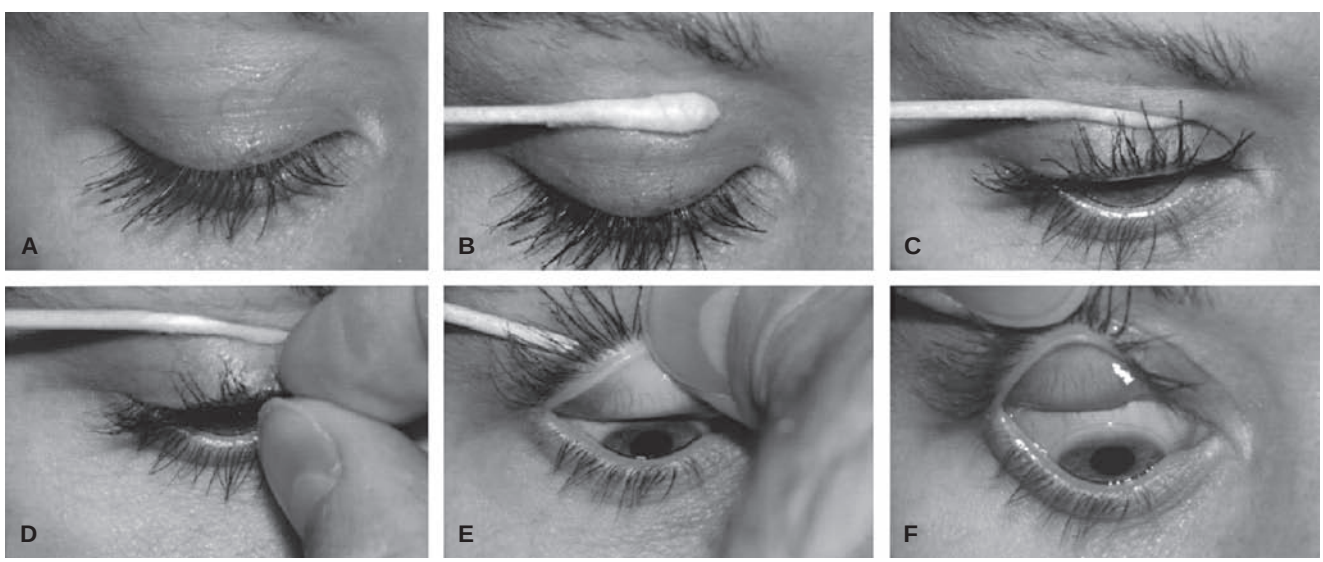

FIGURE 117.12 Upper lid eversion. Note that patient is looking down throughout procedure. In frame **C**, the swab is being rolled clockwise to engage skin and indirectly lift lash line. In frame **E**, the swab is being pushed downward as the examiner lifts the lashes upward in the opposite direction. In **F**, note that patient is wearing a contact lens.

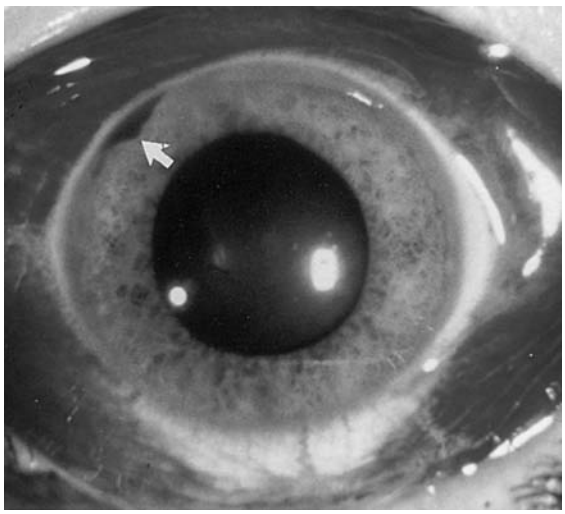

FIGURE 117.13 Subconjunctival hemorrhage extending for 360 degrees. Note the small hyphema *(arrow)*.

have the patient look upward or the examiner can massage the lid down with his or her forefinger.

Subconjunctival hemorrhage is uncommon in children. It may result from blunt trauma, conjunctivitis, chemical irritation, and increased intrathoracic pressure (e.g., chest trauma, suffocation). Although usually focal, the lesions may be multiple or diffuse. Petechia of the surrounding periorbital skin may or may not be present if the cause is airway obstruction. Hypertension, coagulopathy, or anticoagulant medications may result in subconjunctival hemorrhage out of proportion to the injury. After blunt eyeball trauma, a 360-degree subconjunctival hemorrhage may mask an underlying ruptured globe (Fig. 117.13). No treatment is needed for isolated subconjunctival hemorrhages. They may take up to 2 weeks to resolve, turning yellowish in the process.

Chemical injuries of the cornea and conjunctiva may also occur. These injuries are discussed in Chapter 127.

Management

Several studies have suggested that patching corneal abrasions, especially in children with small abrasions, may not accelerate healing or decrease symptoms. Although some controversy exists in this regard, many physicians prefer to apply a lubricating antibiotic ointment (e.g., bacitracin, erythromycin, Polysporin®) to the ocular surface with or without a light pressure patch over the closed eyelid. If used, the patch should be worn overnight. Another alternative for pain management may be the use of topical nonsteroidal antiinflammatory agents, although this has been researched only in adults. For patients who are relatively asymptomatic with corneal or conjunctival abrasions that are small and do not involve the visual axis (i.e., not involving the central cornea over the pupil), management with antibiotic or artificial tears alone may be sufficient with no patch. For patients who are in significant pain, a drop of cyclopentolate 1% can be instilled to relieve spasm of the eye's ciliary muscle. Ointments containing steroids or neomycin should not be used. If the patient is asymptomatic within 48 hours after patch removal (by the parents at home or by the physician), no follow-up is required. Larger corneal abrasions and those involving the visual axis should be seen on the day following trauma by an ophthalmologist. For any size of corneal abrasion, if pain or foreign-body sensation continues for more than 2 to 3 days, or if there is increasing pain and redness, the patient should be instructed to seek ophthalmologic care. A topical antibiotic ointment may be prescribed for use after patch removal two to three times daily for approximately 3 to 4 days.

Any patient with a fluorescein staining corneal defect who has a history of ocular herpes or who wears contact lenses should be referred urgently for ophthalmology consultation. Fluorescein should not be instilled while patients have their soft contact lens in place as this may result in permanent discoloration of the contact lens. Patients who wear contact lenses should never be patched for abrasions even if the contact lens has been removed. Patching an eye that often wears contact lenses may create a microenvironment that predisposes to bacterial ulceration of the cornea. The contact lenses should be removed immediately and left out until the cornea is documented by an ophthalmologist to be healed.

HYPHEMA

Clinical Manifestations

The presence of blood between the cornea and iris is a sign of severe ocular trauma. Although the entire anterior chamber may be filled with blood (8-ball hyphema), clots may also be small, requiring careful inspection for detection (Fig. 117.13). Sometimes the blood is more diffuse throughout the anterior chamber (Fig. 117.7) or may even be microscopic, requiring slit lamp examination for detection (microhyphema). The size of the hyphema is directly proportional to the incidence of secondary glaucoma and is inversely proportional to visual prognosis. Patients with hyphema are in a vulnerable period for the first 5 days after injury when spontaneous rebleeding may occur. Patients with hemoglobinopathies are also at particular risk for ocular complications of hyphema. Therefore, all patients who are in a high-risk ethnic group should receive a screening test or formal hemoglobin electrophoresis at presentation unless their status is already known.

Management

All patients who have hyphema must be seen by an ophthalmologist. Although microhyphemas and perhaps some small hyphemas may be managed in select clinical situations as outpatients with careful daily follow-up, hospital admission is often recommended. The eye trauma itself may result in some degree of physiologic sedation. The eye should be shielded, not patched (Figs. 117.9 and 117.10), and the patient should be placed on bed rest with the head elevated 45 degrees. This position helps allow blood within the anterior chamber to settle inferiorly, thus allowing clearance of the visual axis, improvement of vision, and a better view for the ophthalmologist looking into the eyeball. If an ophthalmologist is not readily available, the examining physician

may recommend admission and the use of a dilating agent to paralyze the ciliary muscle within the eye but it is desirable for ophthalmology consultation to be performed at least within 24 hours. The ophthalmologist may prescribe topical steroids, but they should not be prescribed by a nonophthalmologist. In some cases, oral antifibrinolytics may be used to prevent spontaneous rebleeding, but these agents should be used only under the supervision and recommendation of an ophthalmology consultant.

TRAUMATIC IRITIS

Clinical Manifestations

Inflammation within the anterior chamber of the eye often does not present for 24 to 72 hours after blunt trauma to the eyeball. The patient may complain of eye pain, redness, photophobia, and sometimes, visual loss. The pupil on the affected side may be constricted (see Chapter 25). The ocular injection may be confined to a ring of redness surrounding the cornea (ciliary flush). Definitive recognition of traumatic iritis requires slit lamp biomicroscopy.

A beam of light projected from a light source can be seen only as it reflects from surfaces. For example, the light from a movie projector in a movie theater would not be visible unless smoke and dust were present in the air to reflect the light as it passes between the projector and the screen. Likewise, the slit beam of light projected from the slit lamp is normally visible only as it reflects off (and through) the cornea and then passes unseen through the optically clear fluid of the anterior chamber (aqueous humor), landing on the iris and lens (within the pupil), where it is again visible as it reflects from their surfaces. When white blood cells are floating within the anterior chamber fluid, along with protein that has leaked from inflamed blood vessels, the beam of light from the slit lamp then becomes visible as it passes through the aqueous humor. The white blood cells appear as small specks floating within the beam of light. Red blood cells from microhyphema can also be detected in this manner. Recognition of iritis at the slit lamp requires skill and experience. Ophthalmology consultation is recommended when the diagnosis of iritis is suspected and if the emergency physician is not expert in slit lamp examination.

Management

Traumatic iritis may be an indicator that other ocular injuries have occurred. Ophthalmology consultation should be obtained in the diagnosis and management of this condition. The ophthalmologist often recommends dilating drops and topical steroids for treatment. Because of the risks associated with the use of topical steroids, they should not be prescribed by nonophthalmologists.

TRAUMATIC VISUAL LOSS

Clinical Manifestations

Some techniques for recognizing true traumatic visual loss are discussed at the beginning of this chapter. Occasionally, the emergency physician is faced with a child who is feigning visual loss. These situations seem to be more common after motor vehicle accidents or other injuries in which legal action may be involved. Functional visual loss can also be idiopathic and transient or associated with other overt or covert stress in the child's life. In the absence of other signs of ocular or head trauma, this diagnosis should be suspected. It then becomes necessary to "trick" the child into demonstrating that he or she can actually see. Patients who are truly acutely blind should demonstrate some degree of anxiety and virtually complete inability to navigate in the new surroundings of the ED. When asked to write their names on a piece of paper, truly blind patients can do so accurately, unlike children who are functionally blind who assume they are unable to write. When a mirror is held before a truly blind eye and then tilted in the vertical and horizontal planes, the eye will not follow. Any eye that truly has enough sight to recognize its own image moves involuntarily with the motion of the mirror.

Children who are feigning visual loss but not complete blindness can be more difficult to "trick." Sometimes, by placing a drop of saline or topical anesthetic in the eye while giving the child the suggestion that these "magic drops" will cause a return of vision, the child then begins to see better. The pinhole test (discussed above) can also be used in this manner. Ophthalmology consultation is sometimes critical in discovering whether a child has truly sustained visual loss.

A rare cause of visual loss after head trauma is transient cortical visual impairment/blindness. As a result of a direct or contrecoup occipital contusion, a child may experience acute blindness despite an otherwise normal eye examination. This centrally mediated phenomenon may resolve spontaneously. Ophthalmology consultation can be useful to rule out other causes of visual loss.

A multitude of intraocular injuries, including traumatic cataract, vitreous hemorrhage, retinal bruising (commotio retinae), retinal detachment, and optic nerve injury, can result in true visual loss or blindness. Although the pediatric emergency physician is often the first to meet a child with acute traumatic visual loss, in most of these circumstances, ophthalmology consultation is then required. For the emergency physician, the best screening tests for intraocular injury are vision testing, the examination of the red reflex, and direct ophthalmoscope examination.

CHILD ABUSE

Clinical Manifestations

Virtually any eye injury can be the result of child abuse. Unusual types of ocular trauma, such as the covert instillation of noxious substances onto the conjunctiva, should also be considered in the differential diagnosis of recurrent red eyes in the absence of an apparent cause. Perhaps the most common ocular manifestation of child abuse is the finding of retinal hemorrhages associated with the abusive head injury (Fig. 117.14, see also color plate). Although these hemorrhages can be seen with the direct ophthalmoscope, ophthalmology consultation is required. Children who present to the ED before the age of 5 years with a history of head trauma or sudden unexplained cardiorespiratory arrest should have a full dilated

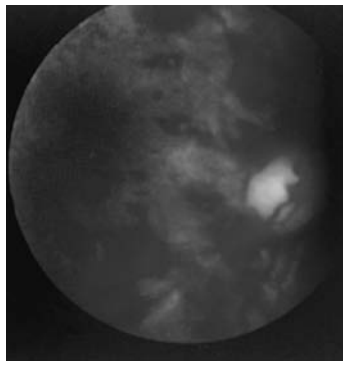

FIGURE 117.14 Retinal hemorrhages in abusive head injury.

examination conducted by an ophthalmologist to look for retinal hemorrhages that may indicate that a nonaccidental head injury has occurred. There are other cuases of retinal hemorrhage which must be differentiated based on systemic findings, laboratory evaluation where appropriate, and ophthalmology examination. The eye examination by a nonophthalmologist should not be used to decide whether or not ophthalmology consultation or neuroimaging is indicated, especially when there are sufficient historical or clinical indicators to raise a concern about possible child abuse.

CHAPTER 118 ■ THORACIC TRAUMA

HOWARD A. KADISH, MD, MBA

INTRODUCTION

Thoracic trauma in the pediatric population is relatively uncommon and only in the last two decades has it received careful scrutiny. Included in thoracic trauma are injuries to the chest wall, trachea, bronchi, lungs, heart, thoracic aorta and great vessels, esophagus, and diaphragm. The report of the National Pediatric Trauma Registry contains a detailed analysis of major thoracic trauma in children. In the United States, only 4% to 6% of children admitted to pediatric trauma centers have thoracic injuries; however, because of the severe mechanism, many patients never reach a hospital and die at the scene. In patients who do reach the hospital, most thoracic injuries do not require operative intervention other than tube thoracostomy.

When thoracic trauma occurs in isolation, the mortality rate is relatively low. The mortality rate triples when thoracic trauma occurs concurrently with head or abdominal trauma. In one study, 82% of patients with thoracic trauma had a multisystem injury, and 58% of those patients had a concomitant head injury. In the same study, children with thoracic trauma had a lower mean trauma score and a higher mean injury severity score. Mortality rates were 20 times higher for children with thoracic involvement than for those without. Another study showed that children with a pediatric trauma score of four or less had a significantly higher mortality rate than those with a score of five or greater. Most scene fatalities result from lacerations of the lung, heart, blood vessels, and bronchi. In the hospital, cardiac tamponade, injuries to the aorta and great vessels, and tension hemothorax/pneumothorax carry the greatest potential for death.

As with other types of pediatric trauma, blunt thoracic injuries are more common than penetrating. Motor vehicle–related accidents account for at least 75% of all blunt thoracic injuries. Other common mechanisms include falls, assaults, and bicycle accidents. Penetrating wounds occur in approximately 15% of children sustaining major thoracic trauma. Gunshot wounds followed by stab wounds are the most common causes of penetrating thoracic trauma, although mechanism varies with geographic location.

The most common injuries in blunt thoracic trauma include lung contusions (53%), pneumothorax or hemothorax (38%), and fractures (38%). Pneumothorax or hemothorax (64%) occur more frequently in penetrating thoracic trauma, but diaphragmatic (15%), cardiac (13%), and vascular injuries (10%) are also common.

Isolated rib fractures have a mortality rate of only 10%. The mortality rate approximates 20% in blunt thoracic trauma when only the lung or pleural space (pneumothorax or hemothorax) is involved. This increases to 30% if the diaphragm is injured; if the heart or great vessels are involved, it rises to 40% to 50%. In penetrating thoracic trauma, the mortality rate is less than 10% when only the pleural cavity is injured. Cardiac and vascular injuries carry a mortality rate of 50%.

PATHOPHYSIOLOGY

Children with thoracic trauma may present in respiratory or circulatory failure. Children in respiratory failure, more commonly seen than circulatory failure, may present with tachypnea, chest wall retractions, and agitation secondary to hypoxia.

Respiratory Failure

Because approximately 80% of thoracic trauma occurs as part of a multisystem injury, the most common cause of respiratory failure is neurologic compromise. If left untreated, patients will develop anoxic brain injury and a respiratory acidosis due to hypercarbia. Immediate control of the airway with positive-pressure ventilation followed by treatment of the neurologic emergency is indicated.

Airway obstruction, external compression of the pulmonary structures, direct injury to the pulmonary parenchyma, and chest wall injuries, all due to thoracic trauma, will also affect oxygenation and ventilation if left untreated.

Airway Obstruction

Blood, vomit, or foreign bodies (teeth) may obstruct the airway. Failure to remove or bypass the foreign body will lead to hypoxia and anoxic brain injury. Initial treatment includes repositioning and suctioning of the airway, along with cervical spine immobilization. If initial treatment fails, endotracheal intubation is indicated. If the endotracheal tube cannot bypass the obstruction or a foreign body cannot be extracted, a cricothyroidotomy or surgical tracheostomy should be performed.

External Compression of the Pulmonary Structures

External compression of the lungs, most commonly caused by air or blood within the pleural cavity, will cause respiratory distress. Initially patients may present with tachypnea, retractions, and hypoxia. As more lung segments are involved, ventilation is affected and the patient's carbon dioxide begins to rise. Tube thoracostomy is the treatment of choice for a pneumothorax or hemothorax.

Diaphragmatic hernia and gastric dilation can also cause respiratory distress by external compression of the lungs. Patients with a diaphragmatic hernia that compromises ventilation need

prompt surgical intervention. A nasogastric or oral gastric tube helps decompress the stomach and decreases the likelihood of aspirating vomit or swallowed blood.

Pulmonary Parenchyma Injury

Aspiration of blood or vomit into the terminal bronchi and alveoli will cause a chemical pneumonitis. Direct trauma to the lung parenchyma (pulmonary contusion) will also cause a leakage of blood and fluid into the alveolar space. Both of these injuries lead to shunting of deoxygenated blood into the systemic circulation. Endotracheal intubation with positive-pressure ventilation is indicated if the patient's respiratory status worsens. Patients with a severe chemical pneumonitis or pulmonary contusion may require high inflation pressures to maintain adequate oxygenation. These patients are at risk for a pneumothorax because of high inflation pressures coupled with an already injured lung.

Although not as common as a chemical pneumonitis or pulmonary contusion, penetrating thoracic trauma may cause direct pulmonary parenchymal damage but is associated more often with a hemothorax or pneumothorax.

Chest Wall Injuries

Chest wall injuries such as rib fractures or a flail chest may cause hypoventilation, as well as hypoxia secondary to pain and inadequate air exchange. Endotracheal intubation with positive-pressure ventilation is the treatment of choice in those patients with rising carbon dioxide levels or severe hypoxia.

Circulatory Compromise

Thoracic hemorrhage, obstruction of venous return to the heart, or direct injury to the heart can cause circulatory compromise and shock.

Thoracic Hemorrhage

Laceration of the hilum of the lung, a great vessel, or the heart itself will cause a significant amount of bleeding. A patient can hemorrhage more than 50% of his or her total blood volume into the pleural cavity. The body's compensatory mechanisms for the blood loss include an increase in both heart rate and total peripheral vascular resistance. Relying solely on a decrease in systemic blood pressure to detect hemorrhage in children may be deceiving because children may lose up to 25% of their total blood volume before their systemic blood pressure is affected. Children with significant bleeding may have a normal blood pressure but be tachycardic and poorly perfused with a prolonged capillary refill time. Treatment should be initiated prior to the onset of hypotension. Therapy includes fluid resuscitation, blood transfusion, and surgical repair if the patient continues to require multiple blood transfusions.

Obstruction of Venous Return to the Heart

A tension pneumothorax or hemothorax occurs when there is progressive accumulation of air or blood within the pleural cavity, which will cause a shift of the mediastinal structures. The trachea and mediastinum are shifted to the contralateral side. Venous return to the heart is reduced because the inferior vena cava is relatively fixed in place and becomes obstructed. Diastolic filling is reduced, and the stroke volume of the heart drops. Patients with a tension pneumothorax or hemothorax will be tachycardic, peripherally vasoconstricted, and if left untreated, will progress to shock. Initial treatment consists of needle decompression. If there is a tension pneumothorax, an immediate release of air should be noted and the patient's hemodynamic status should improve. The needle decompression is only a temporizing measure and must be followed by tube thoracostomy.

Direct Injury to the Heart

Myocardial contusion, ventricular or atrial rupture, and valvular disruption may produce cardiogenic shock. Circulatory compromise results from a decrease in cardiac output, usually from impaired in myocardial contractility. Patients may present in congestive heart failure with an enlarged liver, a gallop heard on cardiac examination, and rales with auscultation of the lungs. Echocardiography, especially transesophageal, is helpful in identifying the type of injury. Positive inotropic agents are the drugs of choice for improving myocardial contractility.

Pericardial tamponade, due to air or blood inside the pericardium, will also decrease cardiac output and cause circulatory collapse. If the patient is decompensating and a pericardial tamponade is suspected, then a pericardiocentesis should be performed. Where possible, ultrasonic confirmation and guidance are helpful.

DIFFERENCES BETWEEN CHILDREN AND ADULTS

Pediatric thoracic trauma differs from adult thoracic trauma in the mechanism of injury, type of injury, and frequency of other organ systems involved.

Falls are the most common mechanism of injury in the infant and child. Older children are often injured as pedestrians or as unrestrained passengers in motor vehicle accidents. Adolescents are more likely to be involved as occupants in motor vehicle–related accidents. Penetrating injuries secondary to violence are more common in the adolescent and young adult population.

Lung contusion is the most common pediatric thoracic injury, with intrapleural injury second. Lacerations of the heart, great vessels, and lungs are relatively uncommon, occurring in less than 10% of thoracic trauma cases. A cooperative study in adults sustaining thoracic trauma showed that 50% had a chest wall injury and that a flail chest injury occurred in 5% of those with chest wall injuries. Injuries to the lung parenchyma occurred in 26% of patients. Simple rib fractures are the most common type of thoracic injury in adults. Only 30% of pediatric patients, as compared with 50% to 75% of adults, sustain rib fractures because of increased compliance in the pediatric thoracic cage secondary to the greater cartilage content and the greater elasticity of the bones. Because of this increased compliance, kinetic energy is transferred more readily to the underlying organs. Thus, a pediatric patient may have an internal injury (lung contusion) without external evidence of trauma (rib fracture, laceration, bruising). Air and fluid within the pleural space (pneumothorax/hemothorax) more easily displace the mediastinum, compromising venous return and cardiac output in children (Fig. 118.1). Adults

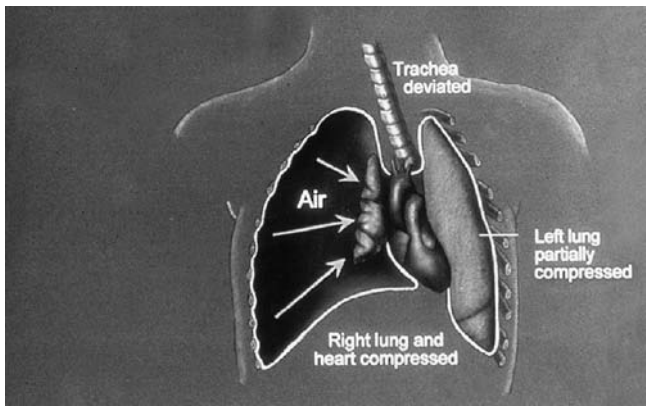

FIGURE 118.1 Tension pneumothorax with a mediastinal shift.

tolerate greater mediastinal shift and compromised venous return than do pediatric patients. The internal diameter of the pediatric trachea is smaller than the adult trachea (Fig. 118.2). In the quiet child, resistance to airflow is inversely proportional to the fourth power of the airway radius; therefore, any small amount of obstruction secondary to blood, secretions, or edema can cause significant respiratory distress and hypoxia. In the agitated child, airflow becomes turbulent and resistance to airflow is inversely proportional to the fifth power of the airway radius. Thus, in the pediatric patient with respiratory distress, it is important to keep him or her calm and quiet. The younger child is also more sensitive to hypoxia and may develop a reflex bradycardia or asystole.

Because approximately 80% of thoracic trauma occurs as part of a multisystem injury, the physician must also consider head, neck, and intraabdominal injuries when treating a child with chest trauma. Thoracic trauma is routinely associated with abdominal trauma in children because the chest and

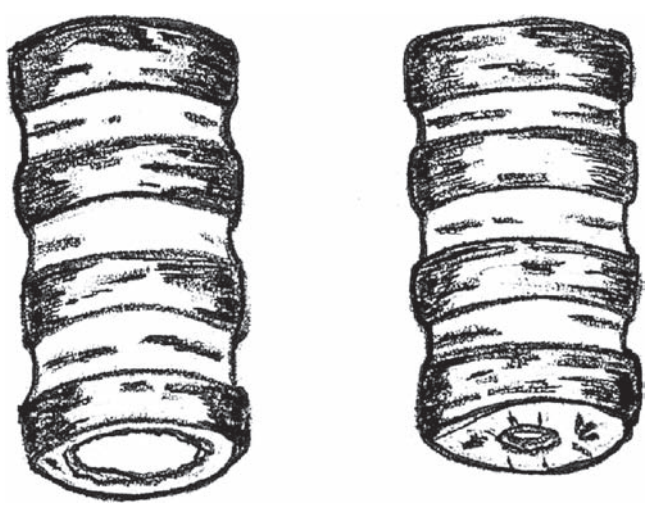

FIGURE 118.2 With swelling or edema, the internal diameter of a pediatric trachea (**A**) is much more compromised than the internal diameter of an adult trachea (**B**).

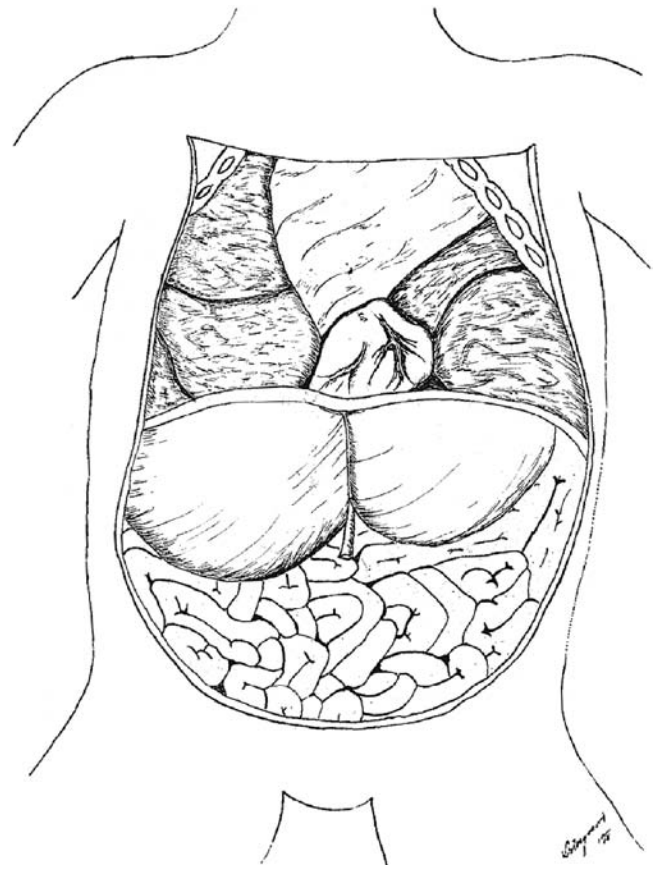

FIGURE 118.3 Drawing demonstrating the close proximity of the chest and abdominal cavities in the pediatric patient.

abdominal cavities lie in close proximity (Fig. 118.3). Gastric distension may also impede pulmonary function, and a nasal or oral gastric tube may relieve this distension (Fig. 118.4).

Mortality rate in thoracic trauma significantly increases with each organ system involved. Children with an isolated chest injury have a mortality rate of 5%. Children with chest and abdominal injuries have a mortality rate of 20%. The mortality rate increases to 35% in children with head and chest trauma, with more than 50% of those patients dying from their head injury. In an adult study, 43% of patients with thoracic trauma had a concomitant head injury, but the overall mortality rate was only 15.5%. Because children have a higher incidence of head trauma, the probability of survival in a pediatric patient with thoracic trauma is lower when compared with an adult thoracic trauma patient.

Thermoregulation is a concern in the small child. The pediatric patient can lose significant heat and become hypothermic secondary to large surface area compared with small body mass. Because most trauma patients need to be undressed and exposed, heating lights, warm fluids, and warming mattresses can all help stabilize the temperature.

Finally, the developmental stages of the pediatric patient must be taken into account in the evaluation of thoracic trauma. Younger children are not able to communicate effectively. They may be tachycardic and tachypneic from the injury itself or because they are frightened. The patient's agitation may make his or her respiratory status worse. A team

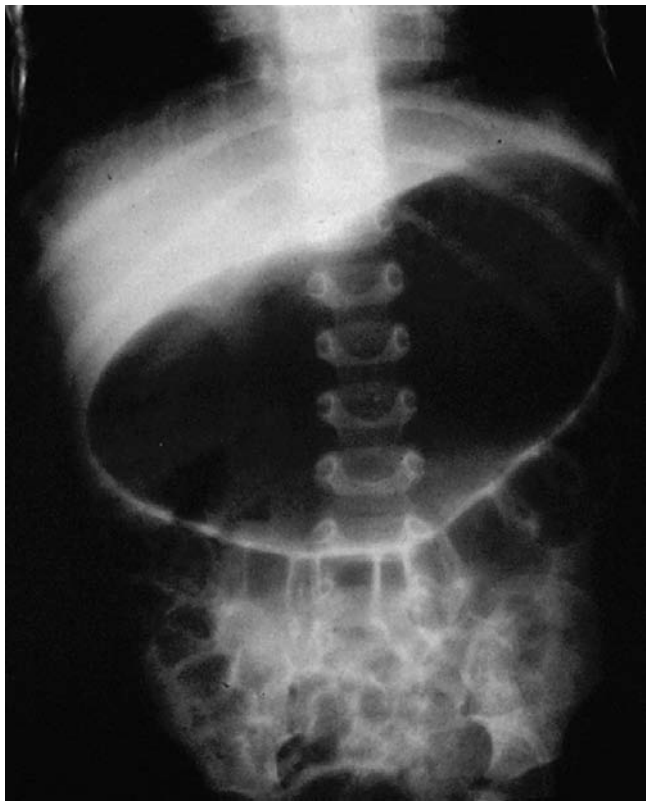

FIGURE 118.4 Radiograph of a patient with gastric distension. The patient's respiratory distress resolved once a nasogastric tube was inserted.

approach of including the families is helpful in calming and reassuring children.

CLINICAL MANIFESTATIONS AND EVALUATION

Injuries to the chest can be divided into four main categories: pulmonary, cardiac, vascular (great vessel), and other intrathoracic injuries. Pulmonary injuries are the most common. Cardiac and vascular injuries are less common but have a higher mortality rate. Diaphragmatic hernia and esophageal and tracheobronchial disruptions comprise the other intrathoracic injuries. When evaluating a patient who has sustained blunt thoracic trauma, one study showed that clinical predictors of thoracic injury included a low systolic blood pressure, an elevated respiratory rate, an abnormal examination of the thorax, an abnormal chest auscultatory examination, a femur fracture, or a Glasgow Coma Scale score of less than 15.

Pulmonary Injuries

Pulmonary injuries consist of contusions, lacerations, pneumothoraces, hemothoraces, and/or pneumohemothoraces. Contusions are more common in blunt trauma, as opposed to lacerations in penetrating trauma, but crossover occurs.

Patients may complain of chest pain and/or difficulty breathing but may have no symptoms. Physical findings may include tachypnea, asymmetric breath sounds, and/or chest wall tenderness. Patients with a tension pneumothorax may develop tachycardia, muffled heart sounds, hypotension, and/or distended neck veins. Pneumothorax and hemothorax are potentially life threatening, but greater than 90% of these patients will respond to simple interventions (needle aspiration and/or chest tube placement). In the stable patient, chest radiography and thoracic computed tomography (CT) scan are helpful in the evaluation of pulmonary injuries.

Pulmonary injuries may initially cause hypoxia and respiratory distress, or the patient may present with minimal symptoms but progress to severe respiratory distress. Therefore, all patients with a pulmonary injury need to be observed for clinical deterioration.

Cardiac Injuries

Cardiac injury in blunt thoracic trauma is rare, occurring in less than 5% of pediatric patients. The majority of patients with structural damage to the heart secondary to blunt trauma never reach a hospital because they die at the scene. Cardiac contusions far outnumber lacerations. Contusions are usually self-limited unless ventricular fibrillation, which is rare, develops. In contrast, there are case reports of sudden death following a single, isolated forceful precordial blow (commotio cordis). In commotio cordis, prompt cardiopulmonary resuscitation/defibrillation is the only identifiable factor associated with a favorable outcome.

Patients with cardiac injuries may complain of chest or sternal pain. Physical examination may reveal tachycardia, an irregular heart rhythm, a new heart murmur, signs of congestive heart failure, or in the case of cardiac tamponade, muffled heart tones. Evaluation for suspected cardiac contusion should include a 12-lead electrocardiogram (EKG), which may show ST-T-wave changes or arrhythmias, and short-term observation. Creatine phosphokinase (CPK-MB) or troponin I or T levels are not useful screening tools. Symptomatic patients should be further evaluated by either a transesophageal or transthoracic echocardiogram.

Vascular (Great Vessel) Injuries

Life-threatening injuries to the great vessels of the thorax are rare and carry a high mortality rate. In blunt and penetrating trauma, the aorta is most commonly involved. Early detection of such injuries is vital for survival. Clinical signs and symptoms may include hypotension, paraplegia, anuria, absent or diminished femoral pulses, or excessive chest tube bleeding. Radiographic findings may include a widened mediastinum, blurred aortic knob, pleural cap, or tracheal or nasogastric tube deviation. The gold standard for diagnosis is angiography, although CT scanning has been used to detect aorta injuries in selected stable patients. In the unstable patient, a transesophageal echocardiogram may be diagnostic.

Other Intrathoracic Injuries

Diaphragmatic, esophageal, and tracheobronchial disruptions are rare and are often overlooked in the initial evaluation of

thoracic trauma. The chest radiograph may initially appear normal in 30% to 50% of diaphragmatic hernias. When abnormal, the chest x-ray may show a bowel gas pattern in the lungs, a displaced nasogastric tube, or an elevated hemidiaphragm. The patient may complain of chest pain or difficulty breathing. The examination may be normal or show decreased breath sounds, respiratory distress, or a scaphoid abdomen. Surgical exploration is indicated in all suspected cases because a diaphragmatic hernia does not improve without surgical correction.

Patients with esophageal and tracheobronchial disruptions may present with a continuous air leak from the chest tube, pneumomediastinum, subcutaneous emphysema, and, for those patients with esophageal disruption, gastric contents from the chest tube. Bronchoscopy and/or esophagoscopy are indicated in suspected cases.

INITIAL MANAGEMENT

The airway, breathing, and circulation (ABCs) of trauma management apply regardless of the organ system injured. A top priority in any patient with respiratory or circulatory failure should be airway stabilization (see Chapter 5) and identification and treatment of shock (see Chapter 3). The injured child should be evaluated according to the primary survey of trauma management. The first priority in trauma patients with or without thoracic injury is establishing a secure, patent airway. Indications for endotracheal intubation in the thoracic trauma patient include depressed neurologic status, inadequate oxygenation or ventilation, compromised circulatory status, or an unstable airway, as seen in selected patients with burns.

After the airway is secured, breathing is assessed. Inspection (symmetry, adequate chest rise, neck vein, fullness trachea position) and auscultation (equal breath sounds, heart tones) of the chest provide information about ventilation. The ideal site for auscultation of the lungs is in the midaxillary line. Oxygen saturation by oximetry serves to evaluate oxygenation.

If a patient has an abnormal examination, but appears to be oxygenating and ventilating well and is not in shock, then chest radiography is indicated. If breathing is inadequate after endotracheal intubation and there is asymmetry of breath sounds, intervention is required prior to a chest radiograph. The patient with absent breath sounds on one side and tracheal shift to the opposite side requires immediate needle decompression and subsequent tube thoracostomy. It is only after the patient is stabilized that the chest radiograph should be obtained.

The patient's circulatory status is evaluated after airway and breathing have been stabilized. Pericardial tamponade and a tension pneumothorax or hemothorax should be considered in the poorly perfused, shock patient where other sources of blood loss have been excluded and where volume resuscitation has not improved the patient's status. Physical examination may reveal muffled heart or breath sounds with decreased or absent pulses, and ultrasound if available may show blood in the pericardial pleural space. Pericardiocentesis or thoracentesis and subsequent tube thoracostomy are lifesaving procedures and should be performed in the unstable trauma patient prior to going to the operating room for definitive treatment.

Once the patient is stabilized and the immediate life-threatening injuries such as airway obstruction, tension pneumothorax, hemothorax, and pericardial tamponade are treated, the chest radiograph and thoracic CT scan will provide valuable information regarding other potentially life-threatening and operative injuries. The ATLS (Advanced Trauma Life Support) protocol recommends a chest radiograph for all patients with significant trauma, though in one study, patients with either an abnormal respiratory rate for age, chest tenderness, or back abrasions were much more likely to have an abnormal chests radiograph than those patients without these findings (95% confidence interval, 0.86–1.0). The authors of that study advocated for a more judicial use of the chest radiograph. Thoracic injuries requiring operative intervention are described in Table 118.1. Indications for surgery in thoracic trauma are shown in Figure 118.5. The use of ultrasound is

TABLE 118.1

THORACIC TRAUMA INJURIES REQUIRING OPERATIVE INTERVENTION

Injury	Signs and symptoms
Tracheal/bronchial rupture	Active chest tube air leak
Lung parenchyma, internal mammary artery laceration, intercostal artery laceration	Chest tube bleeding greater than 2–3 mL/kg/h or hypotension unresponsive to transfusions
Esophageal disruption	Abnormal esophagogram (leak) or esophagoscopy Gastric contents in the chest tube
Diaphragmatic hernia	Abnormal gas pattern in the hemithorax Displaced nasogastric tube in the hemithorax
Pericardial tamponade	Positive pericardiocentesis
Great vessel laceration	Widened mediastinum Tracheal or nasogastric tube deviation Blurred aortic knob Abnormal aortogram (gold standard)

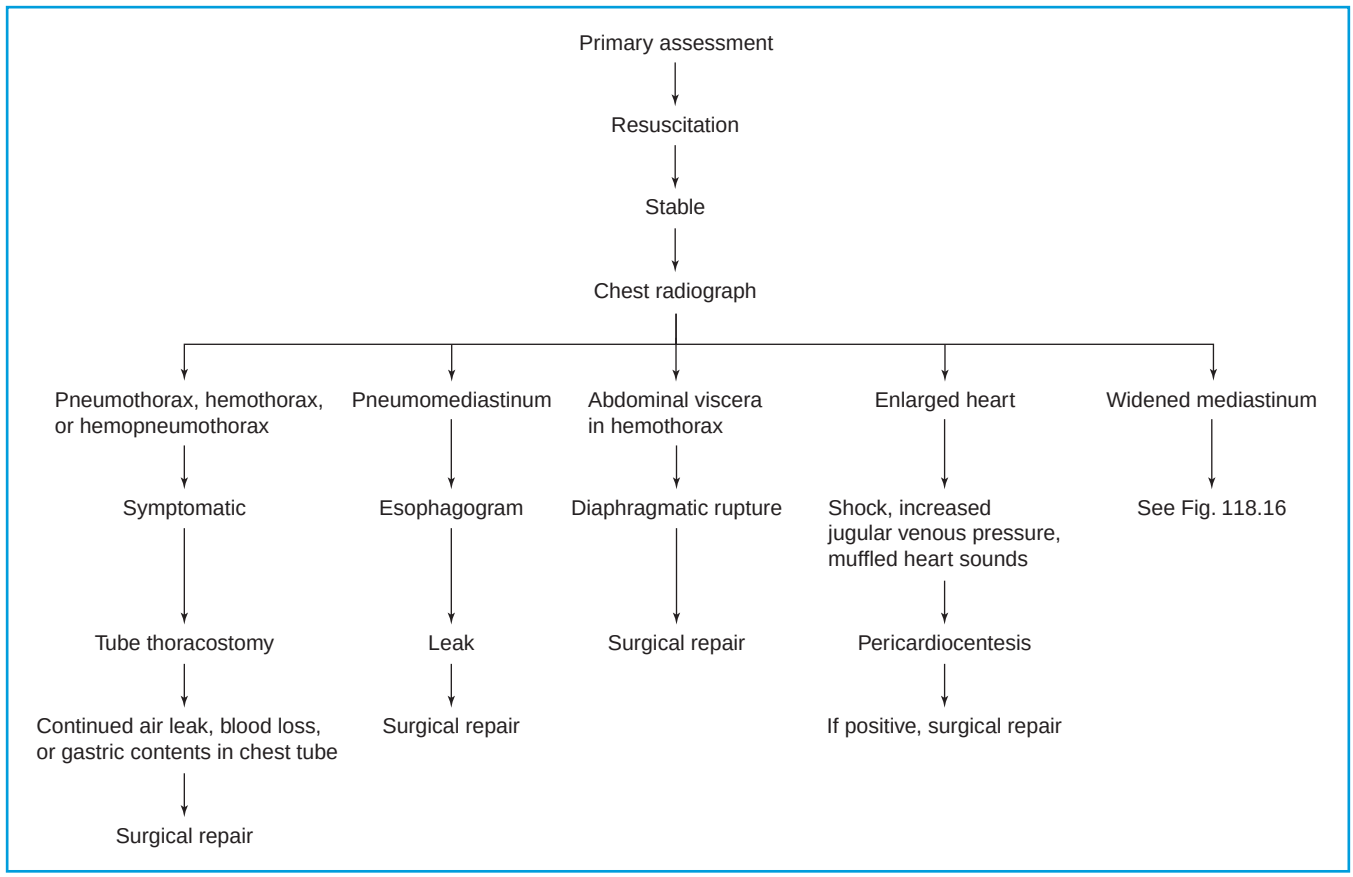

FIGURE 118.5 Indications for surgery in thoracic trauma.

rapidly becoming a standard diagnostic modality in the evaluation of the adult trauma patient. One adult study demonstrated that thoracic ultrasound was as sensitive and specific in identifying a hemothorax as a chest radiograph. Another adult study showed that thoracic ultrasound was as sensitive as thoracic CT scan in the detection of traumatic pneumothoraces. The utility of ultrasound in the pediatric trauma patient has yet to be determined. There has been no study specifically looking at its usefulness, except in the evaluation of cardiac injuries. Numerous studies have shown thoracic CT scan to be superior to routine chest radiograph in identifying pulmonary contusions, pneumothoraces, and hemothoraces. In one adult study, more than 50% of blunt chest trauma patients with a normal chest x-ray showed multiple injuries on the CT scan, among which were two potentially fatal aortic lesions. Therefore, thoracic CT scan should be part of the evaluation of pediatric trauma patients if a lung contusion, pneumothorax, or hemothorax is suspected either clinically or noted on the chest radiograph, or if the etiology of the patient's respiratory distress is unknown. Thoracic CT scan is also indicated in the asymptomatic patient with chest x-ray findings suggestive of a traumatic rupture of the thoracic aorta (TRA).

Chest Wall Injuries

The elasticity and flexibility of a child's thoracic cage make chest wall injuries less common than internal organ injuries, such as a pulmonary contusion. When chest wall injuries do occur, the patient is at increased risk for intrathoracic injuries. Included in chest wall injuries are rib, sternal, and scapular fractures, as well as flail chest.

Rib Fractures

Rib fractures may occur from either a direct blow to the rib or compression of the chest in an anterior–posterior direction. In a direct blow to the rib, the rib will fracture inward and may puncture the pleural cavity, causing a pneumothorax (Figs. 118.6A and 118.6B). A hemothorax is caused by a rib lacerating an intercostal artery, an internal mammary artery, or the lung parenchyma. Compression of the chest wall can cause the lateral portions of the ribs to fracture outward. Intrathoracic injury is seen less commonly with this type of fracture.

In one study, rib fractures occurred in 32% of all children admitted with thoracic trauma. Motor vehicle accidents were the most common mechanism of injury, as in adult studies. Single rib fractures did not correlate with the severity of injury, but as the number of fractures increased, so did the likelihood of multisystem and intrathoracic injuries. Children with rib fractures and both head and thoracic injuries had a doubling of mortality rate compared with children with rib fractures and an isolated thoracic injury.

Because of the relatively protected nature of the first rib and the amount of force required to fracture it, first rib fractures should be approached with a high index of suspicion for other serious injuries, such as vascular disruption or tracheal

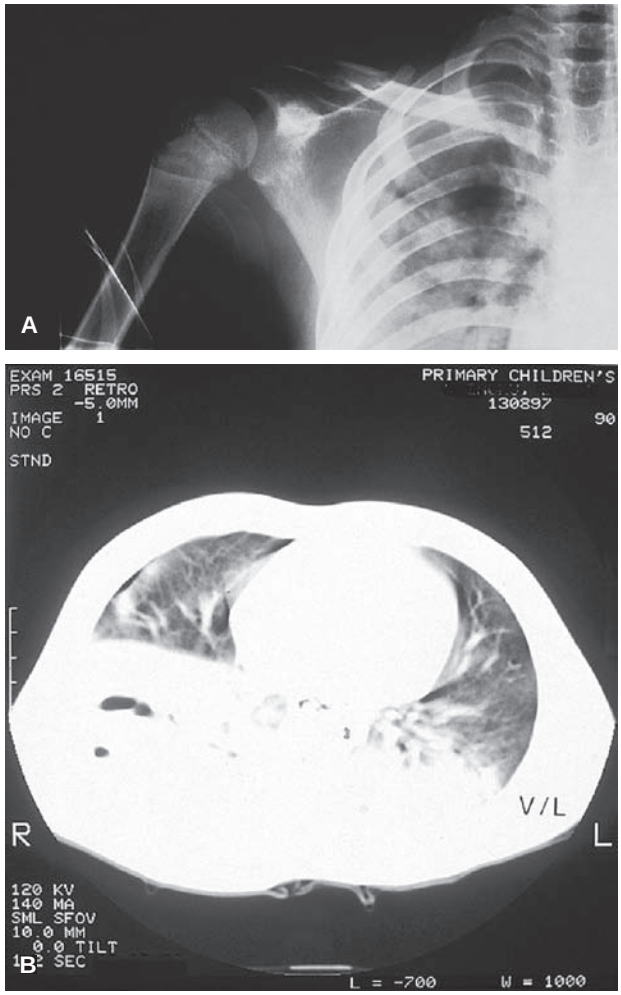

FIGURE 118.6 A 7-year-old involved in an automobile–pedestrian accident. Crepitus and decreased breath sounds were noted on the right side. Chest radiograph (**A**) shows rib fractures, clavicle fracture, and a pulmonary contusion. A pulmonary contusion and a pneumothorax are seen on the thoracic computed tomography (**B**).

laceration. Usually patients with these injuries are symptomatic (hypotension, pulse differences or deficits). In one study, all patients with a first rib fracture and injury to the great vessels exhibited physical examination abnormalities such as loss of the radial pulse on the involved side, discrepancy in blood pressure between the upper extremities, a flail chest, and/or hypotension. No patients with an isolated first rib fracture and a completely normal physical examination had an injury to a great vessel. In this and other studies, there was no correlation between level of rib fracture and associated vascular injury in the otherwise asymptomatic patient.

The pediatric patient with a rib fracture may splint and hypoventilate secondary to pain. Physical examination may reveal point tenderness, and if the pleura has been involved, crepitus. If the patient has any respiratory or circulatory compromise, a tube thoracostomy is indicated for a pneumothorax or hemothorax. The tube should be placed at a separate site from the area of the fracture. If the patient is stable, then relief of pain, monitoring the respiratory status, and further evaluation (chest radiography, thoracic CT scan) for underlying injury is indicated. Wrapping or binding the chest wall is contraindicated because these measures may impair ventilatory function. Analgesics are helpful but should be used with caution because they may also cause respiratory depression. Epidural analgesia may be administered, especially for lower rib fracture. Intercostal nerve block is another useful modality that should be performed carefully to avoid puncturing the pleura.

Patients with rib fractures, especially more than one fracture, are usually admitted to the hospital for pain control, pulmonary physiotherapy, and observation for worsening respiratory status. Prognosis for isolated rib fractures is excellent, with most healing within 6 weeks. The chest wall will remodel leaving no permanent disability.

Sternal and Scapular Fractures

Sternal and scapular fractures are uncommon in children, secondary to the marked compliance of the chest wall (Fig. 118.7). Although a thorough evaluation for other thoracic injuries is recommended routinely because of the significant force required to fracture these bones, only rarely are vascular or brachial plexus injuries detected. In one adult study, scapular fracture alone was not a significant marker for mortality or neurovascular injury. In another adult study looking at 37 patients with sternal fractures, the authors found that only one patient had a minor blunt cardiac injury (BCI) and that this patient had an obvious abnormal EKG. They concluded that the routine use of echocardiography in the assessment of isolated sternal fractures is not indicated. In another study looking at patients with BCI, only 2% had an associated sternal fracture.

Flail Chest

Fracturing two or more ribs on the same side may result in that particular chest wall segment losing continuity with the thoracic cage causing a flail chest. Direct impact to the ribs, as in a crush injury, is the most common mechanism for a flail chest. Flail chest is uncommon in children, owing to the marked compliance of the chest wall. In published series, flail chest occurred in approximately 10% of patients as compared with less than 1% in the pediatric population. When a flail chest does occur, it is usually associated with an intrathoracic injury, most often pulmonary contusion, because of the force involved.

The pediatric patient may develop respiratory distress and failure due to a flail chest from numerous mechanisms. In the early 1900s, Bauer described the pendelluft theory, which attributes inefficient ventilation and oxygenation to a pendulum-like

FIGURE 118.7 A 10-year-old child evaluated after a fall of more than 10 feet. The patient was asymptomatic except for shoulder pain. The only abnormalities noted were a scapular and clavicle fracture.

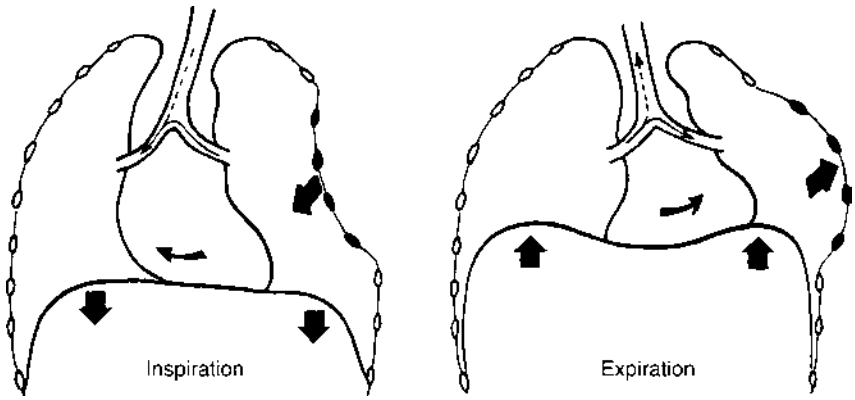

FIGURE 118.8 Pathophysiologic consequence of flail chest with paradoxical motion. (From Fleisher GR, Ludwig S, Henretig FM. *Textbook of pediatric emergency medicine*. 3rd ed. Baltimore: Williams & Wilkins, Fig. 101.4, reprinted with permission.)

movement of air from the injured lung to the uninjured lung. The harder and faster a patient works to breathe, the more shifting of air from one side to the other occurs. The paradoxical movement of the chest also impairs the normal inspiratory/expiratory function of the lung (Fig. 118.8). Another mechanism for respiratory distress is the association of underlying pulmonary injury with a flail chest. Edema within the airways will alter alveolar ventilation:perfusion ratios and produce pulmonary arteriovenous shunting with hypoxemia and subsequent respiratory distress. Finally, the pain associated with rib fractures will cause voluntary and involuntary splinting. These patients are at increased risk for atelectasis and pneumonia secondary to poor pulmonary function.

The goal of treatment should be to stabilize the involved portion of the thoracic cage. At the scene of an accident, the patient can be placed with the injured side down, thus improving tidal volume and ventilation. Any patient with respiratory distress should be intubated and placed on positive-pressure ventilation. This serves two purposes. First, the patient's airway is well protected and the effectiveness of breathing is maximized. Second, the positive pressure provides optimal expansion and splinting of the injured segment. Unfortunately, high inflating pressures can cause a pneumothorax and care must be taken when delivering positive pressure to the injured child. If the patient does not need to be intubated, aggressive pulmonary physiotherapy, along with pain control, is the treatment of choice. In patients with an underlying pulmonary contusion, fluids must be carefully monitored. Fluid may leak out of the injured capillary bed, worsening the pulmonary contusion.

Pulmonary Contusions and Lacerations

Pulmonary contusion is the most common thoracic injury in children. Pulmonary contusion occurs when a blunt force, such as a crush injury, is applied to the lung parenchyma. As in any contusion or bruise, the capillary network becomes damaged, leaking fluid into the surrounding tissues. A ventilation: perfusion mismatch will occur because of the extravasation of fluid, interfering with oxygenation. As the edema and swelling worsens, the patient's respiratory status will also deteriorate. When compared with a chest radiograph, a chest CT scan is more sensitive in detecting pulmonary contusion (Figs. 118.9A and 118.9B) and often lung parenchymal injuries are noted when a few cuts of the thoracic cavity are imaged while obtaining an abdominal CT scan. A pulmonary contusion may initially be invisible on a chest radiograph or a chest radiograph may underestimate the size of the pulmonary contusion. In one study, pulmonary contusions seen on chest CT scan were 2 to 3 times the size as seen on a chest radiograph. In another study, children with both a positive chest radiograph and a chest CT scan for a pulmonary contusion were more likely to require a prolonged hospital stay, an intensive care unit admission, and ventilator support when compared to those children with only a positive chest CT scan for pulmonary contusion and a negative chest radiograph. In the same study, a positive chest CT scan with a normal chest radiograph did not affect the need for ventilator support and prolonged hospital admission.

In one study, tachypnea, abnormal breath sounds, external thoracic wall contusion, and fracture of the bony thorax were each absent in more than 50% of patients with a pulmonary contusion. Interestingly, the chest radiograph in these patients did not dramatically worsen from time of admission. Nonetheless mild contusions require close hospital observation for worsening respiratory status and supportive care.

Patients with moderate-to-severe pulmonary contusions may be tachypneic and have an oxygen requirement secondary to shunting within the lung. If the patient can no longer maintain oxygenation, endotracheal intubation and mechanical ventilation with positive pressure is the treatment of choice. Fluid restriction is helpful to avoid exacerbation of pulmonary edema. Many of these patients will have associated injuries, making fluid restriction difficult; intensive care management with measurement of central venous and pulmonary arterial pressure may be helpful in fluid management. Double lumen endotracheal-endobronchial tubes can be used in patients with severe lung contusions refractory to normal ventilatory management.

Pulmonary lacerations usually result from penetrating trauma but can occur in rapid deceleration injuries. Rib fractures secondary to blunt trauma may also puncture the lung. Patients are usually tachypneic and have abnormal breath sounds. Large lacerations may cause hemoptysis. Chest radiograph will show pneumothorax or hemothorax. Treatment includes endotracheal intubation for those patients in respiratory distress and tube thoracostomy for pneumothorax or hemothorax. Adequate intravenous access and blood for transfusion should be available prior to chest tube placement unless the tube must be placed emergently for respiratory distress.

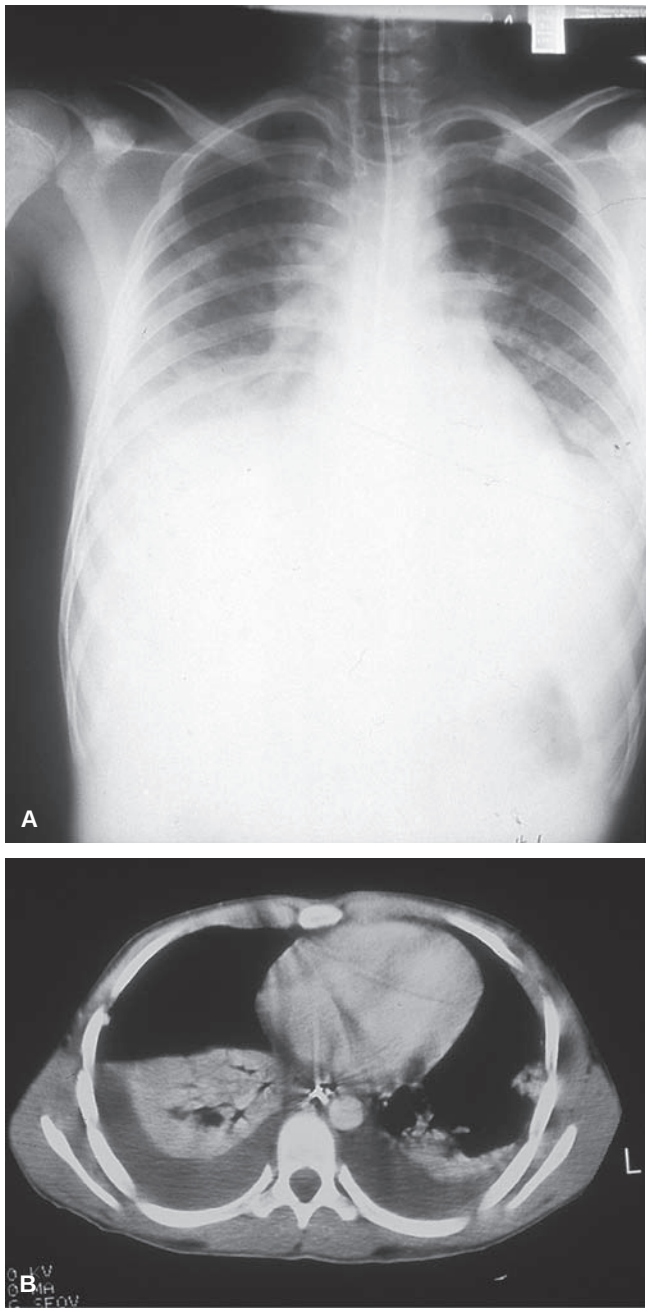

FIGURE 118.9 A 15-year-old child involved in an automobile–pedestrian accident. Vital signs were stable at the scene, but the child had decreased breath sounds bilaterally. **A:** Chest radiograph showed bilateral hemothorax and pulmonary contusions. **B:** Computed tomography confirmed and better delineated the hemothorax and pulmonary contusions.

Insertion of the chest tube can disrupt hemostasis in the chest cavity, and the patient may exsanguinate. Indications for surgery include continuous hemorrhage or air leak through the chest tube, massive hemoptysis, or air embolism.

Air embolism is usually fatal, but it should be considered when a patient deteriorates suddenly after endotracheal intubation, focal neurologic findings develop without evidence of a neurologic injury, or frothy blood is withdrawn from an arterial puncture. Treatment includes open thoracostomy with either occlusion of the hilar structure on the affected side or direct aspiration of the air. Neither of these treatment options is very successful.

Intrapleural Injuries

In one study, intrapleural injury occurred in 40% of children with thoracic trauma. Hemopneumothorax, hemothorax, and pneumothorax were evenly distributed. Pneumothorax was associated with the lowest mortality rate (15%), whereas hemothorax had the highest (57%). Auscultation is helpful, but not 100% accurate in diagnosing a hemothorax, pneumothorax, or hemopneumothorax. A more recent report found that auscultation to detect hemothorax, pneumothorax, or hemopneumothorax had a sensitivity of 58% and a specificity of 98%. The majority of intrapleural injuries do not need surgical intervention and can be managed either by hospital observation or tube thoracostomy (Fig. 118.10).

Pneumothorax

Pneumothorax is the second most commonly encountered entity in blunt thoracic trauma and most common in penetrating thoracic trauma. Air within the pleural cavity can arise from penetration of the chest wall, disruption of the lung parenchyma, a tear of the tracheobronchial structures, or esophageal rupture.

Patients may be asymptomatic, complain of pleuritic chest pain, have tachypnea, or be in severe respiratory distress. Physical examination may be normal or may reveal diminished or absent breath sounds, crepitus, or hyperresonance to percussion on the side of the pneumothorax. In the asymptomatic or mildly symptomatic patient, a chest radiograph is helpful in diagnosing and determining the type of treatment necessary (Fig. 118.11). Plain radiographic signs of a pneumothorax may include a hyperlucent hemithorax, pleural air at the lung base, and/or an unusually well-defined heart and mediastinal outline due to pleural air rising anteriorly. If the pneumothorax is small and the patient asymptomatic, hospital observation and administration of 100% oxygen is all that is necessary. A small pneumothorax is classically described as being less than 15%, although it is common to underestimate the size of a pneumothorax on plain films, only to find a much more extensive lesion on CT scan. Tube thoracostomy is indicated in the symptomatic patient, any patient undergoing positive-pressure ventilation, or those requiring air transport. An asymptomatic patient may rapidly become symptomatic if a small, simple pneumothorax progresses to a tension pneumothorax; therefore, even asymptomatic patients with a pneumothorax should be admitted to the hospital for observation.

Tension Pneumothorax

A tension pneumothorax is the most common complicated intrapleural injury. Tension pneumothorax develops in up to 20% of children after simple pneumothorax. A tension pneumothorax occurs when there is progressive accumulation of air within the pleural cavity. A laceration to the chest wall, pulmonary parenchyma, or bronchial tree may function as a one-way valve, allowing air to enter but not leave the pleural

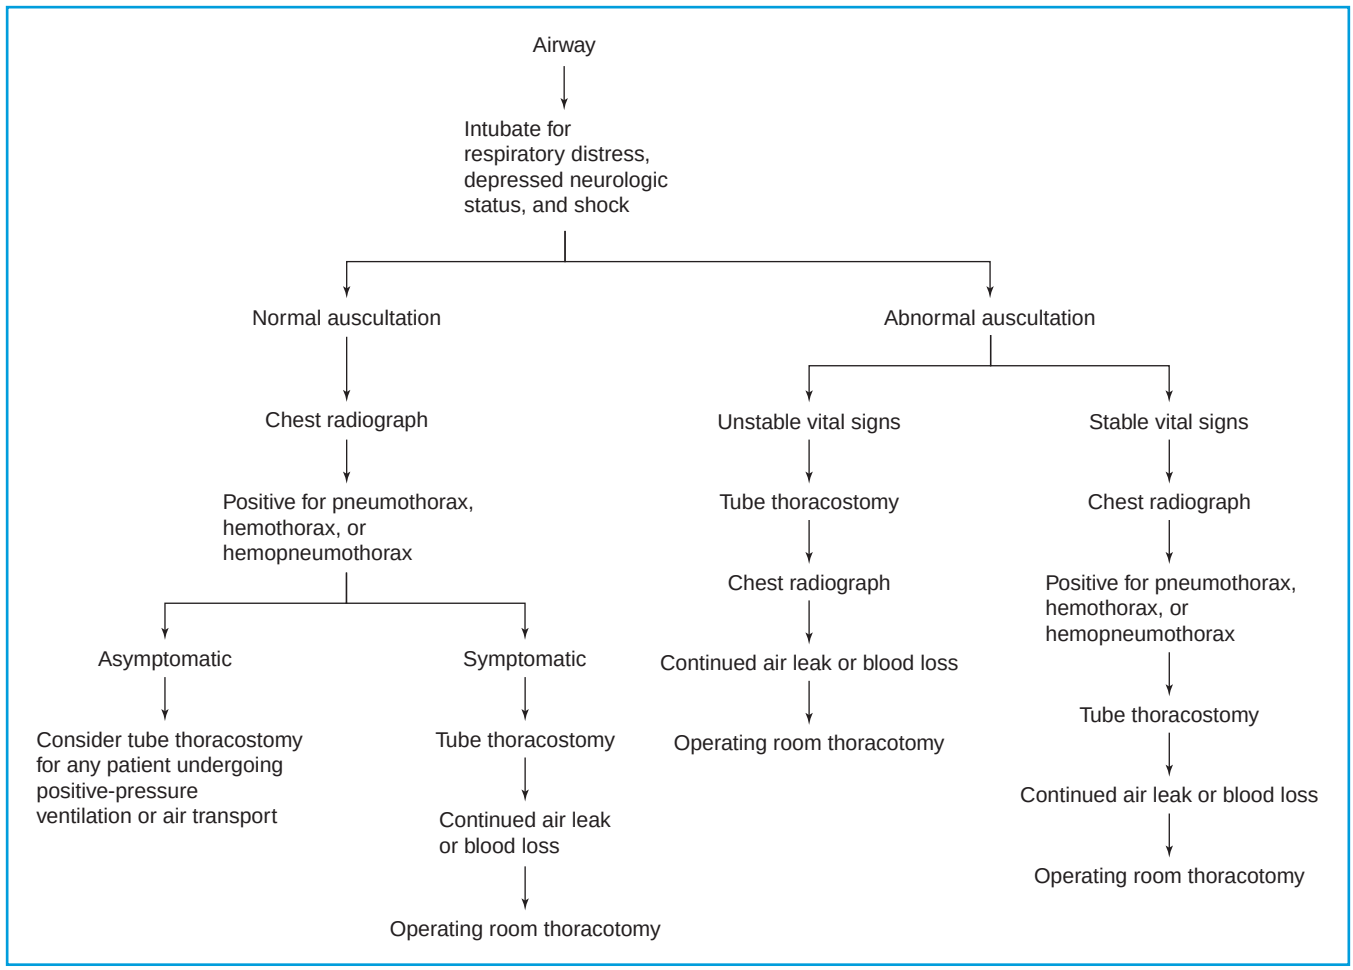

FIGURE 118.10 Algorithm for the management of intrapleural injuries.

space. The progressive accumulation of air within the pleural cavity not only collapses the ipsilateral lung, but it also compresses the contralateral lung. These patients may present in severe respiratory distress with decreased breath sounds on the side of the pneumothorax. There is also a shift of the mediastinal structures to the contralateral side (Fig. 118.12). Two thirds of the blood supply to the body is returned to the heart via the inferior vena cava. Because the inferior vena cava is relatively fixed in place and cannot shift as much as the superior vena cava, venous return to the heart is reduced and the patient may appear tachycardic, peripherally vasoconstricted, and in hypotensive shock. This underscores the importance that whenever a trauma patient suddenly deteriorates, the treating physician must return to airway and breathing, before jumping to circulation.

Initial treatment consists of needle decompression performed in the midclavicular second intercostal space of the ipsilateral side. If there is a tension pneumothorax, an immediate release of air should be noted. If positive, the needle decompression is only a temporizing measure and must be followed by tube thoracostomy. Tube thoracostomy is usually done in the midaxillary line at the level of the fifth intercostal space (nipple level). Chest x-ray is only performed after the insertion of the chest tube and should not be used to diagnose a tension pneumothorax in the symptomatic patient. If a significant air leak continues after chest tube placement, a tracheobronchial rupture must be considered.

Open Pneumothorax

An open pneumothorax is the result of penetrating trauma. There is a direct connection between the pleural space and the outside atmosphere. As in a bronchial tear or lung parenchymal injury, air may enter but not leave the pleural space.

Initial treatment includes placement of an occlusive dressing at the wound site. This is best done when the patient is in full expiration. A chest tube should be placed immediately to prevent development of a tension pneumothorax. The chest tube should be inserted at a site different than the open wound. Larger open wounds may need surgical closure. Any patient in respiratory distress should be intubated and receive positive-pressure ventilation.

Hemothorax

Hemothorax is much more common in penetrating than blunt thoracic trauma. In blunt thoracic trauma, a hemothorax can occur from rib fractures lacerating the lung, pulmonary parenchymal injuries without rib fractures, lacerations of the internal mammary arteries or intercostal arteries, or disruption of the major vascular structures in the mediastinum or hilum. A hemothorax secondary to a major injury of the great

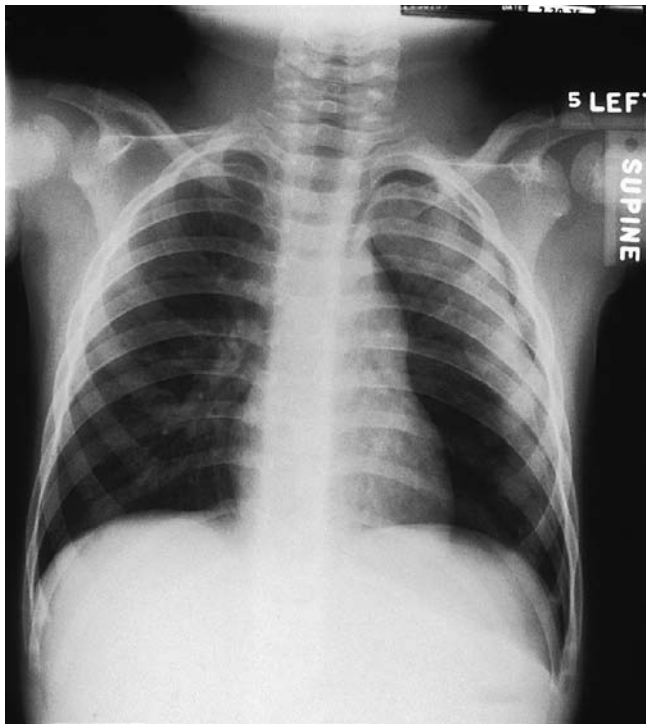

FIGURE 118.11 This 3-year-old child was an unrestrained passenger in a motor vehicle accident. The patient was tachypneic and had decreased breath sounds on the left side but was otherwise asymptomatic. Chest radiograph revealed a left pneumothorax with a pulmonary contusion.

FIGURE 118.12 A 5-year-old girl fell off and was then kicked in the chest by a horse. Upon arrival of the life-flight team, the patient was found to be in both respiratory and cardiovascular distress. Chest radiograph demonstrated a left-sided tension pneumothorax. The patient was intubated, and a chest tube was placed before the patient was transported. After the intubation and chest tube insertion, both the patient's respiratory and cardiovascular status improved.

vessels usually results in death. Liver and spleen injuries can also cause a hemothorax with disruption of the diaphragm. The most common cause of a hemothorax is injury to the intercostal or internal mammary arteries, whereas injuries to the lung or great vessels causing a hemothorax are much less common, but more serious.

Patients may present in respiratory distress or in profound shock secondary to obstruction of venous return or massive blood loss. Decreased breath sounds are noted on the affected side, and there may be tracheal or mediastinal deviation. Thirty percent to 40% of the patient's blood volume may be rapidly lost in the pleural cavity. This usually occurs with major vessel lacerations. Bleeding from the intercostal or internal mammary arteries stops secondary to low systemic pressures and also when reexpansion of the lung produces effective tamponade. A chest radiograph will confirm the diagnosis. If a hemothorax is suspected clinically and the patient is in severe respiratory or circulatory distress, immediate tube thoracostomy should be performed prior to a chest radiograph.

Treatment of a major hemothorax should include aggressive airway and circulatory management, as well as evacuation of the pleural blood. Endotracheal intubation and positive-pressure ventilation should be initiated in any unstable airway. Patients should be typed and crossed for packed red blood cells and adequately volume resuscitated, preferably with two large intravenous lines in place. When time permits, O-negative blood, if type-specific blood is not available, should be at the patient's bedside prior to tube thoracostomy.

Tube thoracostomy is performed to evacuate blood within the pleural cavity, reexpand the lung, and prevent or treat any mediastinal shift. The chest tube is placed in the midaxillary line at the level of the fifth intercostal space (nipple level). This is the same location as in a pneumothorax. Many hemothoraxes may actually represent hemopneumothoraxes. After placement of a chest tube, blood should be slowly evacuated from the pleural space. Blood within the pleural cavity may tamponade a significant bleeding source within the chest and evacuating that blood may cause new bleeding to occur. Patients can exsanguinate rapidly, which is why intravenous access, adequate volume resuscitation, and blood available for transfusion should be a priority. Thoracostomy drainage needs to be closely monitored. Large ongoing blood loss from a chest tube should be collected in a system that allows autotransfusion. Thoracostomy is indicated for continued bleeding (greater than 1 to 2 mL per kg per hour), inability to expand the lung, or retained blood within the pleural cavity. Failure to adequately drain a hemothorax may result in restrictive lung disease from a fibrothorax or an empyema from the clotted material becoming infected.

Chylothorax

A chylothorax is rare in thoracic trauma and most commonly occurs secondary to iatrogenic complications. It can occur from penetrating injuries or a hyperextension injury to the spine. Disruption of the thoracic duct will lead to chyle draining into the mediastinum and pleural space. Diagnosis is confirmed when chyle is aspirated from the pleural cavity. Infection is rare because chyle is bacteriostatic, and treatment consists of tube thoracostomy, dietary manipulation, and, if all else fails, thoracic duct ligation.

Tracheobronchial Injuries

Injury to the tracheobronchial tree in children occurs rarely, with an incidence of less than 1%. This injury is most commonly caused by acceleration or deceleration forces. Major vessels or pulmonary parenchyma are more likely to be injured in penetrating trauma than the tracheobronchial tree. Cervical tracheal rupture may be caused by a direct blow to the trachea or from the patient's head violently traveling forward and backward. This whiplash effect can cause a tear between two cartilaginous rings. Lower tracheobronchial injury usually occurs from a sudden increase in intrabronchial pressure. Because the child's chest wall is elastic, the trachea and main bronchi can be compressed between the chest wall and the vertebral spine. Compression of the chest with a closed glottis can cause a sudden increase in intrabronchial pressure, resulting in a tracheobronchial tear. Shear forces, traction, and crushing the airway between the chest and vertebral column may also cause a tracheobronchial injury. Approximately 80% of tracheobronchial injuries occur near the origin of the main stem bronchus.

The diagnosis of tracheobronchial injury may be difficult in the pediatric population. Mechanism of injury (fall, crush, direct blow) provides an important clue. Symptoms such as chest pain and dyspnea are common but nonspecific. Unlike the adult population, rib fractures are rare because of the elastic nature of the child's chest. Clinical signs include cyanosis, hemoptysis, tachypnea, and subcutaneous emphysema (cervical, mediastinal, or both). Pneumomediastinum and cervical emphysema are seen commonly in airway rupture (Fig. 118.13). If a pneumothorax is present with these findings, a bronchial rupture should be suspected. A continued air leak after insertion of a thoracostomy tube should also alert the physician to the possibility of a bronchial tear. Because of anatomic differences, ruptures of the bronchi occur on the right side more frequently than the left. In the absence of a pneumothorax, tracheal rupture should be suspected if a pneumomediastinum or cervical emphysema is present.

The treatment includes initial airway stabilization and then bronchoscopic evaluation of the airway. Numerous reports in the literature record a partial tracheal tear becoming complete after endotracheal intubation. Therefore, if the airway is stable and a presence of a tear is known or strongly suspected, oral tracheal intubation should be performed in the operating room under bronchoscopic guidance. This prevents further trauma to the airway, and if a complication arises, emergency surgical access to the airway is readily available. If the airway is unstable and emergent endotracheal intubation needs to be performed, efforts should be made to prepare for backup measures such as cricothyroidotomy, tracheostomy, or fiberoptic bronchoscopy. An advantage of early bronchoscopy is exact identification and location of the lesion. The best surgical results are achieved when operative exploration is performed early. In the stable patient, CT scan of the chest can also help confirm the diagnosis and identify other injuries.

Esophageal Injuries

Esophageal injury is rare in children, but presents a diagnostic challenge when it does occur. Timely and accurate diagnosis of an esophageal injury is paramount. The complications include mediastinal sepsis and death. The most common cause for esophageal perforation in the pediatric population is iatrogenic, followed by penetrating trauma (gunshot wound, stab wound). Esophageal perforation can occur in blunt trauma if there is a significant amount of chest compression. The cervical and thoracic regions are more commonly affected, with the thoracic region having the highest mortality rate (35%).

The patient's signs and symptoms will depend on the region injured. Patients with an esophageal rupture in the cervical region may complain of neck stiffness or neck pain. They may regurgitate bloody material and have cervical subcutaneous emphysema or odynophagia. A lateral neck x-ray may show retroesophageal emphysema. In the thoracic region, patients may present with abdominal spasms and guarding, chest pain, subcutaneous emphysema, tachycardia, or dyspnea. A chest x-ray may show a pneumothorax, pneumomediastinum, subcutaneous emphysema in the neck, a left pleural effusion, or an air-fluid level in the mediastinum. Perforation of the intraabdominal esophagus may cause retrosternal, epigastric, or shoulder pain.

Patients with suspected esophageal perforation should be adequately volume resuscitated, have a nasogastric tube placed, and receive antibiotics covering gram-positive, gram-negative,

and anaerobic organisms. The diagnosis of an esophageal perforation can be made by either esophagography, esophagoscopy, or both. In one study, flexible esophagoscopy had a sensitivity of 100% and specificity of 96%. Depending on the expertise at each institution and the stability of the patient, these studies may be paired to lessen the chance of a misdiagnosis. Once the diagnosis is made, prompt surgical correction is mandatory. If the diagnosis is made within 24 hours, mortality rate is approximately 5%. Delayed diagnosis for more than 24 hours after injury is associated with a mortality rate of 70%.

Diaphragmatic Injuries

In the sixteenth century, diaphragmatic rupture was described by Ambrose Paré. He noted "the stomach and intestines are sometimes drawn into the thoracic cavity" after diaphragmatic injury. Diaphragmatic injuries are more common in blunt trauma. A crushing force will produce a sudden increase in the intrathoracic and intraabdominal pressure against the fixed diaphragm. Because of the flexible nature of the child's chest wall, rib fractures are rare. Even though penetrating thoracoabdominal trauma is uncommon in children, a diaphragmatic injury should be suspected in any thoracic or abdominal penetrating injury. The level of the diaphragm fluctuates greatly with respirations, and injuries of the diaphragm have been reported with penetrating wounds as high as the third rib and as low as the twelfth rib. Early reports of blunt traumatic diaphragmatic rupture were mostly left sided. Because of a greater awareness of diaphragmatic injuries, right and bilateral diaphragmatic injuries have been reported more recently. Approximately 80% of diaphragmatic injuries still occur on the left, and 20% occur on the right. The left diaphragm is relatively unprotected, whereas the liver protects the right side. Right-sided diaphragmatic injuries are associated with increased mortality rate; patients usually have a greater physiologic insult and more numerous associated injuries.

Motor vehicle accident is the most common mechanism of injury and some authors believe the direction of impact may play a role in the side and type of diaphragmatic rupture. A lateral torso impact has been shown to be three times more likely to result in a ruptured diaphragm than a frontal impact. The rupture tends to be on the same side as the impact. Right-sided diaphragmatic ruptures may be associated with right-sided impact to the passenger side of the vehicle. Associated injuries such as pulmonary contusions, hepatic or splenic lacerations, and fractures of the extremities are present in more than 75% of patients. Thoracic aortic injuries have been reported in up to 10% of adults with diaphragmatic injury and should be considered in children with diaphragmatic trauma.

Patients may present in respiratory distress and have a scaphoid abdomen, although they are more likely to be symptomatic from associated injuries than from the diaphragmatic rupture itself. The verbal child may complain of chest pain or ipsilateral shoulder pain. The presence of bowel sounds within the thoracic cavity is nonspecific because bowel sounds can be transmitted from the abdominal cavity in children. More commonly, bowel sounds are absent because of an associated ileus. A nasogastric tube may be difficult to pass in patients with a diaphragmatic injury and gastric herniation. In left-sided diaphragmatic tears, the tip of the nasogastric tube may be seen looping into the chest. Even though the diagnosis is usually made upon initial review of the chest x-ray (Fig. 118.14), some series reported that up to 30% to 50% of initial chest x-rays were normal with a diaphragmatic injury. Right-sided diaphragmatic injury and herniation is more difficult to diagnose because the herniated organs are more likely to be solid. The chest x-ray may just show opacification of the right lung fields. This emphasizes the importance of serial evaluations and chest x-rays in patients suspected of having a diaphragmatic injury. Other diagnostic studies such as chest and abdominal CT scan with contrast or upper and lower gastrointestinal tract series can help confirm the diagnosis.

FIGURE 118.14 This 5-year-old boy was on a snowmobile when it crashed into a tree. Initially there was no respiratory distress, but upon arrival at the emergency department, the patient became tachypneic and required oxygen. Breath sounds were reportedly normal. Chest radiograph showed a left-sided diaphragmatic hernia. This injury was surgically repaired in the operating room, and the patient did well postoperatively.

Prior to performing a tube thoracostomy for a pneumothorax or hemothorax, diaphragmatic injury should be considered to avoid injury to herniated intraabdominal organs. In patients who clinically appear to have a diaphragmatic injury (scaphoid abdomen, bowel sounds auscultated in the thoracic cavity), a finger should be inserted in the chest tube incision site and the diaphragm should be palpated before placing a chest tube.

Herniation and strangulation of bowel may result from a delayed diagnosis. Diaphragmatic defects will not spontaneously heal because of motion associated with respirations and cyclical tension. Exploratory laparotomy or laparoscopy should be performed in cases where a diaphragmatic hernia is strongly suspected.

Traumatic Asphyxia

Traumatic asphyxia results from direct compression of the chest or abdomen. The most common mechanism is a child

run over by a motor vehicle or pinned underneath a heavy object. In anticipation of impending injury, the child may inspire, tensing the thoracoabdominal muscles and closing the glottis. Traumatic asphyxia also occurs in patients with asthma, seizures, persistent vomiting, and pertussis.

Positive pressure is transmitted to the mediastinum, and blood is forced out of the right atrium into the valveless venous and capillary system. The clinical manifestations occur because the increase in pressure dilates the capillary and venous system. Areas drained by the superior vena cava are particularly affected, explaining the marked difference between the patient's head and neck as opposed to the lower body. Patients with traumatic asphyxia usually present with the clinical picture of subconjunctival and upper-body petechial hemorrhages, cyanosis, periorbital edema, respiratory distress, altered mental status, and associated injuries.

The primary goal of treatment is to stabilize the patient and evaluate associated injuries. The external appearance of a child with traumatic asphyxia is quite impressive, but initial attention should be paid to the cardiopulmonary status of the child. Pulmonary contusions and hepatic injuries are commonly seen with traumatic asphyxia, and CT scan is helpful in identifying head, chest, and abdominal injuries. Because the most severe injuries cause immediate death, the prognosis is good for any patient surviving the first few hours. Cutaneous manifestations will resolve with time, and neurologic sequelae are rare. Neurologic injury usually results from hypoxia, not intracranial hemorrhage.

Aortic and Other Vascular Injuries

TRA is uncommon in children but carries a high mortality rate (75% to 95%). It is associated with sudden deceleration forces, commonly from automobile accidents, causing a sheering stress. The aortic arch remains fixed, but the descending aorta is mobile. With deceleration, bending or sheering will take place at the level of the ligamentum arteriosum, which is the most common site of aortic tears in adults and children.

TRA occurs in approximately 10% to 30% of adults sustaining severe blunt trauma but is much less common in the pediatric population. In one study, TRA occurred in only 2.1% of pediatric patients with thoracic trauma. The overall mortality rate was 93%. It is unclear why pediatric patients have a lower incidence of TRA than adults. One reason may be the mechanism of injury. In adults, most TRAs occur when the driver of an automobile forcibly strikes the steering wheel. The sudden deceleration force is isolated to the chest. Children who are passengers in a motor vehicle are less likely to strike an object that can deliver deceleration forces centrally to the chest. In children, one of the most common causes of blunt trauma is automobile-pedestrian accidents, which produce forces distributed over a much wider area.

Children are usually symptomatic from associated injuries, and TRA can easily be missed. Clinical signs may include difference in pulses between the arms or arms and legs, thoracic ecchymosis, thoracic and back tenderness, paraplegia, and anuria. Patients with paraplegia and back pain may be initially diagnosed with a spinal cord injury. Unfortunately, 50% of patients may have no signs pertaining directly to a TRA. A normal chest radiograph has been reported to have a 98% negative predictive value in excluding aortic tear, but an abnormal radiograph is in no way diagnostic. More than 90% of patients will have an abnormal chest x-ray (Fig. 118.15). Widened mediastinum, loss of the aortic knob, left-sided pleural cap, tracheal deviation, and nasogastric tube deviation may be seen on a chest x-ray. Much has been written in the adult literature about the association of TRA with first rib fractures. More recent studies have shown that isolated first rib fractures without any other signs or symptoms do not correlate with TRA.

FIGURE 118.15 This 12-year-old girl was an unrestrained passenger involved in a motor vehicle accident. The patient was hypotensive at the scene and could not move her legs. In the emergency department, she had no motor or sensory function to her lower extremities and was anuric. Chest radiograph showed a widened mediastinum from traumatic rupture of the aorta.

Early diagnosis is imperative in patients with TRA (Fig. 118.16). Morbidity and mortality increase threefold if operative intervention is delayed more than 12 hours. The gold standard for diagnosing TRA is aortography (Fig. 118.17). Thoracic CT scan is only 55% to 65% accurate but helpful in diagnosing associated injuries. In one study, transesophageal echocardiography was shown to be a highly sensitive and specific method of detecting injury to the thoracic aorta. In contrast, another study showed transesophageal echocardiography to be only 63% sensitive and 84% specific in identifying patients with a TRA. Pediatric patients were not included in either of these studies. If the patient is stable and TRA is of significant concern, aortography should be performed. Life-threatening intracranial,

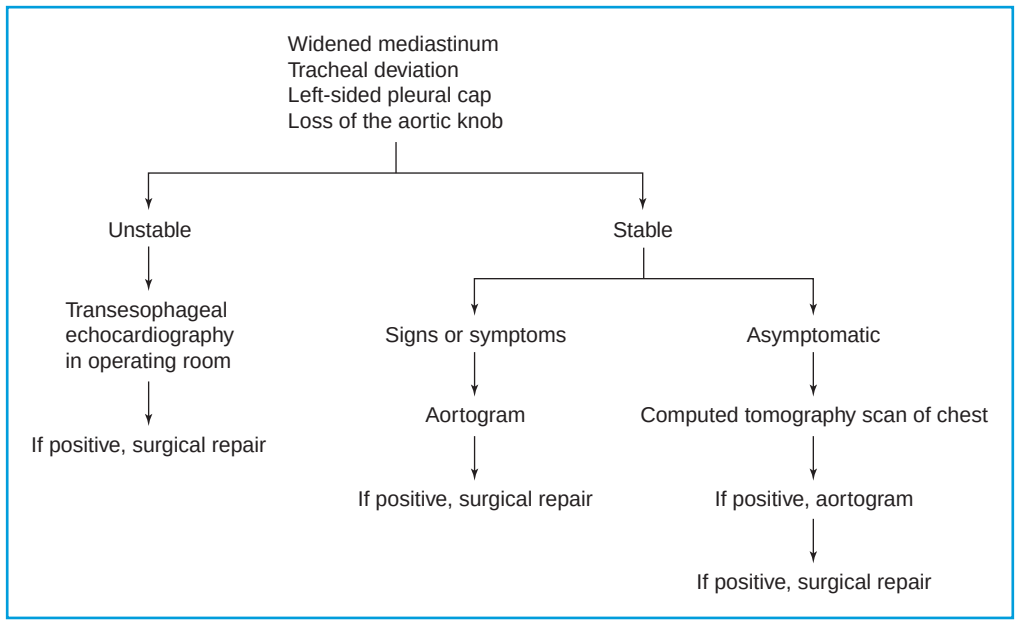

FIGURE 118.16 Algorithm for the evaluation and diagnosis of traumatic rupture of the thoracic aorta.

thoracic, or intraabdominal injuries must first be evaluated and stabilized prior to aortography. If the patient is unstable, a transesophageal echocardiography can be performed in the operating room while the patient's other life-threatening injuries are being treated.

Pericardial Tamponade

Pericardial tamponade occurs when there is injury to the myocardium and blood accumulates in the pericardial sac. Because of the nondistensible pericardium, pressure is exerted on the heart. Cardiac output decreases secondary to a decrease in venous return and stroke volume. The body will initially try to compensate with an increase in the pulse rate and peripheral vascular resistance. As the pressure within the pericardial sac increases, the systolic blood pressure will decrease, causing a narrowing of the pulse pressure and subsequent hypotension and cardiogenic shock.

FIGURE 118.17 Emergency pulmonary angiography confirmed an aortic transection distal to the left subclavian artery with a pseudoaneurysm and narrowing of the proximal descending thoracic aorta in a 12-year-old girl.

Pericardial tamponade may initially be difficult to diagnose because of associated injuries obscuring the clinical signs and symptoms. Patients may present with distant heart sounds, low blood pressure, poor perfusion, a narrow pulse pressure, or electromechanical dissociation (Fig. 118.18). Pulsus paradoxus, blood pressure falling more than 10 mm Hg during inspiration, occurs in less than one half of patients with pericardial tamponade and should not be relied on to make the diagnosis of pericardial tamponade. Chest x-ray may show an enlarged heart (Fig. 118.19) and an EKG may show low-voltage QRS waves. Neither of these tests is diagnostic for pericardial tamponade, and neither should delay treatment in the unstable patient. In the stable patient, an echocardiogram can demonstrate fluid within the pericardial sac.

In the unstable patient in whom pericardial tamponade is suspected, treatment includes control of the airway, intravascular volume resuscitation, and pericardiocentesis (Fig. 118.20). Pericardiocentesis is performed by inserting a 20-gauge spinal needle below the xiphoid process at a 45-degree angle toward the left shoulder. If time permits, an ultrasound (if available) may be performed or an EKG monitor can be attached to the spinal needle. If the needle touches the heart, a current will be noted on the EKG monitor. Blood aspirated from the pericardial sac can be differentiated from intracardiac blood because pericardial blood is defibrinated and does not clot. Even though patients may show transient improvement after removal of blood from the pericardial sac, the patient should be taken to the operating room immediately

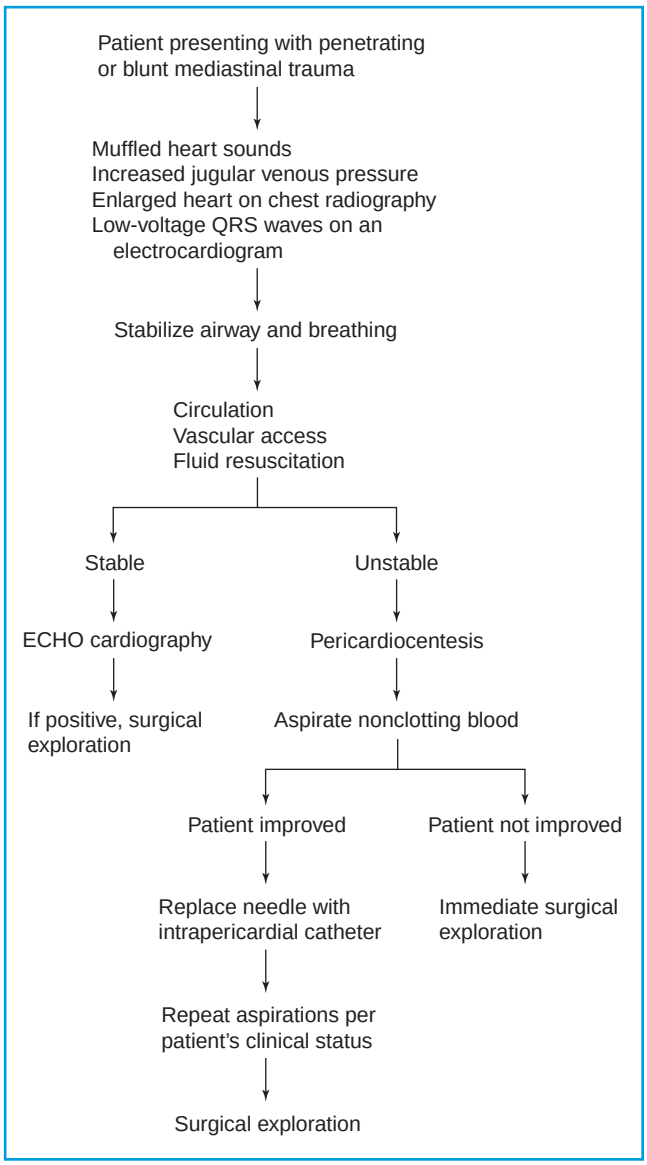

FIGURE 118.18 Algorithm for the evaluation and diagnosis of pericardial tamponade.

for a pericardial window or other surgical intervention. A catheter should be placed into the pericardial sac over a wire guide for continual drainage of blood until surgical correction can be performed.

Blunt Cardiac Injuries

BCI occurs more commonly with associated injuries than in isolation and represents a spectrum of injuries. Myocardial contusion, ventricular or atrial rupture, and valvular disruption are considered BCIs. Myocardial contusion is the most common and ventricular rupture the most lethal of injuries. In one study of 1,288 patients with blunt thoracic trauma, 60 (4.6%) had a diagnosis of BCI. Other series have reported the incidence of BCI to range from 0% to 43%. Complications of

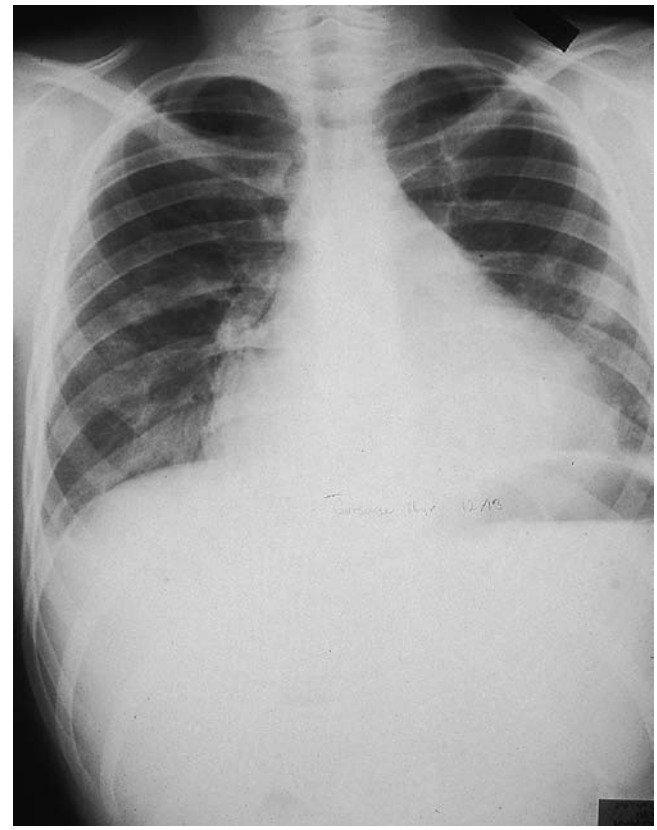

FIGURE 118.19 A 16-year-old boy had a steel bar strike him in the chest. Initially, he was hemodynamically stable but had muffled heart sounds. The patient quickly decompensated and required emergent pericardiocentesis after the chest radiograph. In the operating room, the patient was noted to have a small epicardial laceration on the surface of the heart.

BCI include arrhythmias, pump failure, congestive heart failure, and shock.

Cardiac rupture is the most common cause of death in blunt cardiac trauma. The right ventricle is the chamber most commonly ruptured because of its location directly beneath

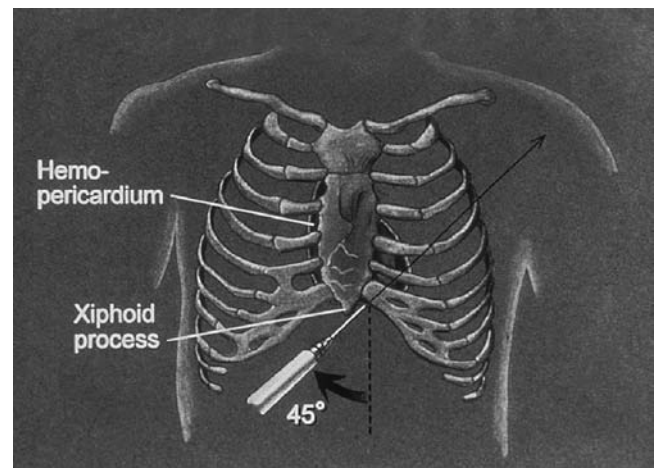

FIGURE 118.20 Pericardiocentesis is performed by inserting a 20-gauge spinal needle below the xiphoid process at a 45-degree angle toward the left shoulder.

the sternum. Septal rupture can also occur, with the condition of the patient correlating with the size of the rupture. Patients with cardiac rupture may demonstrate one or all the components of Beck's triad (jugular venous distention, low blood pressure, and muffled heart tones). Patients with valvular injury may present in congestive heart failure with a new regurgitation murmur. Coronary artery injury is rare but should be considered in patients with persistent EKG changes consistent with ischemia following blunt thoracic trauma.

Unlike adults, pediatric patients with BCI often have few presenting signs or symptoms. Approximately 70% of adults with BCI will complain of chest pain, whereas in one pediatric study less than one half of the awake patients with BCI complained of chest pain, and external evidence of thoracic injury was present in only 60% of these patients. In the same study, cardiac examination was abnormal in less than one fourth of the patients. BCI should be considered in any patient with thoracic trauma who develops a cardiac arrhythmia or a new murmur, or is in congestive heart failure.

Evaluation of suspected BCI remains controversial. In one study, all children who developed heart failure or serious cardiac arrhythmias during their hospital course initially presented to the emergency department (ED) either in shock or with a serious arrhythmia. Patients with suspected myocardial contusion can be monitored in the ED or hospital, and if no arrhythmias develop on EKG, can be safely sent home. CPK-MB ratios have a high false-positive rate and are not a helpful screening tool. Troponin I and T have low sensitivity and low predictive values in diagnosing myocardial contusion so they are not recommended as screening tools. Transesophageal echocardiography should be performed in thoracic trauma patients with an abnormal EKG, arrhythmia, or a new heart murmur. Transesophageal echocardiography has been shown to be more sensitive in detecting myocardial injury than transthoracic echocardiography.

Some general guidelines regarding patients with suspected BCI include the following:

- If a pediatric patient with suspected BCI is hemodynamically stable and has not experienced any arrhythmias, a serious life-threatening arrhythmia or pump failure is unlikely.
- Any patient with suspected BCI who is hemodynamically unstable or has arrhythmias should undergo transesophageal echocardiography and be admitted to the intensive care unit.
- All patients with suspected BCI need close follow-up.

Penetrating Thoracic Trauma

Although not as common as blunt thoracic trauma, penetrating thoracic trauma is becoming more frequent in the pediatric population. In one study, penetrating thoracic trauma occurred in 20% of pediatric patients evaluated for a thoracic injury. The most common mechanism of injury was gunshot; second was stab wounds (Fig. 118.21). Pediatric patients with blunt thoracic trauma are more likely die from associated intracranial and intraabdominal injuries. In contrast, penetrating thoracic trauma is usually a single-system disease and more than 95% of deaths are because of the thoracic wound.

The most common penetrating thoracic injuries are hemothorax and pneumothorax, almost always requiring tube thoracostomy. Intraabdominal injuries should always be suspected

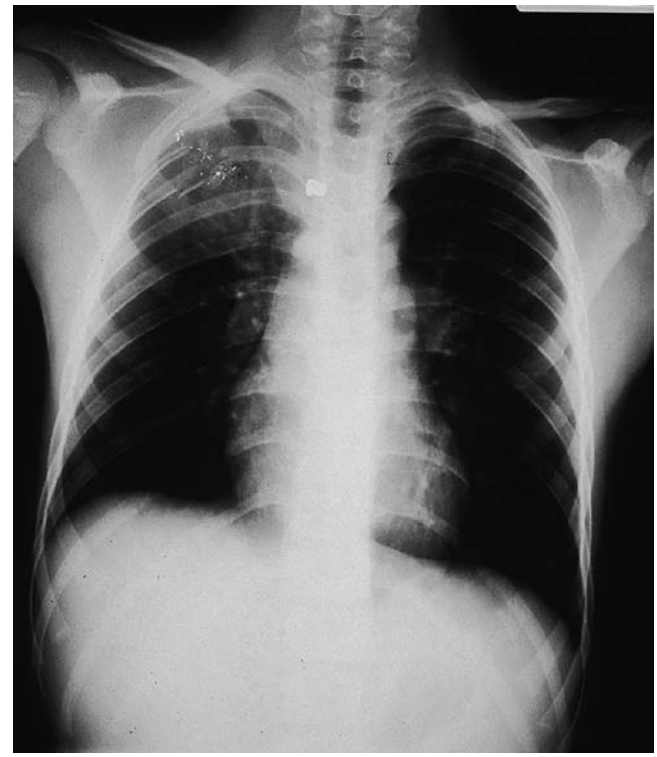

FIGURE 118.21 A 12-year-old boy playing with his father's loaded gun when it accidentally discharged. There was no cardiac or great vessel involvement, and the patient did well postoperatively.

because of the close proximity of abdominal contents to the thoracic cavity. In one study, intraabdominal injuries occurred in 20% of patients with penetrating thoracic injury. More than one half of children with penetrating thoracic injury will require operative intervention. This is higher than the 15% reported in the adult literature. It is unclear why children have this higher rate of operative intervention, but it may be because of the close proximity of the vital organs in the thoracic cavity as compared with adults.

Evaluation and treatment includes airway stabilization, fluid resuscitation, and management of the chest wound. Radiopaque markers (paper clips) may be placed by the entry and exit sites to help determine the course of the missile. Penetrating injuries near the mediastinum may be critical, especially if the patient is hemodynamically unstable. Pericardial tamponade should be considered and treated in the unstable patient. In the stable patient, transesophageal or transthoracic echocardiogram is helpful in evaluating the heart and determining if there is fluid within the pericardial sac. Diaphragmatic lacerations are difficult to diagnose and sometimes require exploratory laparotomy or laparoscopy for diagnosis and treatment.

Emergency Department Thoracostomy

Emergency department thoracostomy (EDT) is one of the most aggressive resuscitative measures for patients with thoracic trauma. With the advancement of transport systems and the regionalization of trauma centers, patients who would have

died at the scene are arriving at trauma centers for evaluation and treatment. EDT allows the physician to evaluate and evacuate the pericardial sac, perform open cardiac massage, and temporarily control bleeding from the heart, hilum, or lung. Catheters can also be placed directly into the right atrium, helping with fluid resuscitation, and the thoracic aorta can be compressed, improving central circulation to the brain and heart.

Anecdotal reports have been published, suggesting EDT may be useful in the pediatric patient who has vital signs but loses them during transport or resuscitation. Other studies have shown poor outcome of EDT in pediatric blunt trauma victims. The more recent literature has reevaluated the need for EDT and tried to select a more specific population. In one study, none of the 17 pediatric patients undergoing EDT after thoracic trauma survived, although 15 of the 17 patients had blunt trauma and only 2 had isolated penetrating thoracic trauma. The authors concluded that EDT was not indicated in the blunt thoracic trauma patient arriving in the ED without any vital signs or EKG tracing. Another study of thoracic gunshot wounds in the pediatric population found no survivors in patients undergoing EDT and advocated a reappraisal of the indications for EDT among pulseless pediatric victims of thoracic gunshot wounds.

The one accepted indication for EDT is the patient with penetrating thoracic trauma who had and then lost vital signs prior to arrival or during ED resuscitation. In addition, EDT may be useful for the patient with blunt thoracic trauma who acutely deteriorates in the ED during resuscitation, but the chance of survival is dismal. Lifesaving interventions such as airway management, fluid resuscitation, and pericardiocentesis should not be delayed while waiting for EDT to be performed. The pediatric patient with vital signs, but not responding to initial treatment such as tube thoracostomy and pericardiocentesis, is a candidate for thoracostomy in the operating room, rather than the ED.

The outcome is directly dependent on the patient's status prior to arrival in the ED and mechanism of injury. In blunt thoracic trauma, essentially 100% of patients who present to the ED without vital signs have a fatal injury, regardless of whether EDT is performed. Pediatric patients who present with cardiac arrest or tamponade caused by penetrating trauma, and in whom vital signs were present either in the field or in the ED, have the best chance of survival, although small, if EDT is performed.

STEPHEN LUDWIG

CHAPTER 119 ■ MINOR LESIONS AND INJURIES

SARITA CHUNG, MD

A variety of minor lesions in children may prompt an emergency department (ED) visit. Most visits are the result of acute injury, infection, or combination of the two mechanisms (e.g., hair tourniquet, felon paronychia). Some formerly quiescent abnormalities (e.g., thyroglossal duct cyst, pyogenic granuloma) become clinically apparent after rapid enlargement secondary to infection or direct trauma. Alternatively, asymptomatic minor lesions (e.g., lipoma, pilomatrixoma) may be noted during the evaluation of an unrelated complaint. Regardless of the presentation, a systematic approach is necessary for proper diagnosis and subsequent management of these lesions. Although most "lumps and bumps" in children have a benign cause, the examiner should bear in mind the possibilities of associated systemic illness and future complications.

HAND AND FOOT LESIONS

Eponychia and Paronychia

Infections and/or minor trauma of the digits are the major etiologies of hand lesions in the ED. The most common infections of the digits involve the eponychium (cuticle) as a result of a breakdown of the epidermal border due to trauma such as a traumatized hangnail or, particularly in children, finger sucking or nail biting. In its initial stage, the infection consists of a superficial cellulitis that remains localized to the cuticle and is termed an *eponychia*. Symptoms include erythema and localized pain at the nail margin. With progression, pus collects in a single thin-walled pocket under the cuticle, forming an acute paronychia (Fig. 119.1A). Patients typically present with localized tenderness and have an area of fluctuance and purulence around the nail margin (Fig. 119.1B). This may progress, extending under the skin at the base of the nail, and along the nail fold. Less commonly, the pus burrows beneath the proximal nail, forming an *onychia* or subungual abscess. Causative organisms include *Staphylococcus aureus, Streptococcus pyogenes,* and anaerobic species. Chronic paronychia can be seen in patients repeatedly exposed to water or moist environments. Symptoms are present for weeks and are similar to those with acute paronychia. Eventually, the nail may become thickened and discolored. *Candida albicans* is the most frequent organism seen with chronic paronychia.

Treatment of a simple eponychia involves frequent warm soaks and attention to local hygiene. Topical antibacterial ointments may hasten resolution. Treatment of an acute paronychia is incision and drainage (see Section VII, Procedures). If an onychia has formed, removal of the proximal portion of nail overlying the abscess is essential to ensure adequate drainage and prevent destruction of the germinal matrix. When an onychia forms under the anterolateral aspect of a nail, treatment consists of elevation and excision of the overlying portion of the nail. The role of oral antibiotics after incision and drainage has not been clearly established but does represent common practice. If the infection is due to finger biting or sucking, antibiotics providing coverage against anaerobes should be considered. Oral antimicrobial therapy is definitely indicated for patients with associated lymphangitis. Oral antimicrobial therapy for methicillin-resistant *S. aureus* should be considered if there is clinical suspicion, high rate in the community or the infection is not improving. Treatment of chronic paronychia consists of topical steroids and/or antifungal agents.

A *herpetic whitlow* involving a finger is sometimes mistaken for a paronychia and is the major differential diagnostic consideration. The majority of cases are in children younger than 2 years. Clinically, this lesion is characterized by the appearance of multiple, painful, thick-walled vesicles on erythematous bases most commonly located at the pulp space of the digits but can also occur around the nail folds and lateral aspects of the digit. During the ensuing few days, vesicles begin to coalesce and their contents become pustular (Fig. 119.2). A Gram stain of pustular fluid is negative for bacteria. Tzanck prep of scrapings from the base of a lesion reveals multinucleated giant cells. Subsequently, ulceration and crusting occur. The process initially results from inoculation of herpes simplex virus into a small break in the skin. The source may be a parent with herpes labialis, or a child with herpetic gingivostomatitis or herpes labialis may inoculate his or her own finger.

If the infection is primary, fever and regional adenopathy are seen. With recurrences, these findings are usually absent. The course is usually self-limited. However, oral acyclovir may be given in the first few days of the infection to shorten the course. For the immunocompromised patient, parenteral acyclovir should be considered to prevent dissemination. A complication of herpetic whitlow is bacterial superinfection.

Felon

A *felon* consists of a deep infection of the distal pulp space of a fingertip. Felons are caused by introduction of bacteria into the pulp space, usually by punctures (which may be trivial) or splinters. Causative organisms are similar to those found in eponychial infections. A felon typically presents as an exquisitely tender and throbbing fingertip that is swollen, tense, warm, and erythematous. However, its evolution is usually relatively slow, beginning with mild pain and minimal swelling

FIGURE 119.1 **A:** Small paronychia located along nail fold, noted after minor trauma. **B:** Paronychias on toe and finger.

that progress over a few days. This process is in part caused by the anatomy of the pulp, which consists of multiple closed spaces formed by fibrous septae that connect the volar skin to the periosteum of the distal phalanx. With progression of infection, pressure buildup within these small compartments may cause local ischemia. In some cases, organisms may spread to invade the phalanx, resulting in osteomyelitis. In others, the process may point outward to the center of the touch pad, where the septae are least dense, producing an obvious area of fluctuation. Because the deep septal attachments are distal to the distal interphalangeal (DIP) joint and flexor tendon sheath, there is less risk of spread to these structures.

Treatment consists of incision, blunt dissection, and drainage. A longitudinal incision over the area of maximal tension or fluctuance is the procedure of choice. Care should be taken to extend the incision past the DIP joint to prevent formation of a flexion contracture (see Section VII, Procedures). After drainage, a course of oral antibiotics is indicated. Close follow-up is essential to assess response to therapy and identify complications, such as septic arthritis and suppurative tenosynovitis. Patients presenting with fever, lymphangitis, or evidence of osteomyelitis should be referred to the hand service for admission, parenteral antibiotics, and definitive care.

FIGURE 119.2 Herpetic whitlow of the thumb.

Subungual Hematoma

A *subungual hematoma* is a collection of blood located under a nail that arises after trauma to the nail bed, typically due to a crush injury. Because this mechanism is also a common cause of phalangeal fractures, radiographs are advisable. The patient experiences throbbing pain that worsens with increasing pressure as more blood collects. If the subungual hematoma involves more than 50% of a nail surface, is associated with a distal phalanx fracture, or the nail or its margins are disrupted, the presence of a significant nail bed injury should be suspected. Nail trephination provides drainage with relief of pressure and pain and suffices for uncomplicated subungual hematomas with intact nail margins, regardless of size of the hematoma. This procedure also reduces risk of secondary infection. The trephined opening should be large enough (larger than 3 to 4 mm) to allow for ongoing drainage without risk of closure by a new clot (see Section VII, Procedures). Sometimes producing two openings in the nail will promote more complete drainage. When the nail or its margins are disrupted and/or a displaced phalangeal fracture is present, the nail should be removed and the nail bed repaired. Antimicrobial prophylaxis for these injuries remains a source of controversy but is often prescribed by practitioners for patients with underlying fractures and those with severe soft-tissue injuries.

Subungual Foreign Body

Foreign bodies such as a wood splinter or metallic shaving become embedded under the nail and may be the source of pain and/or infection. When the foreign body is only partially embedded, the nail can be trimmed close to the nail bed, and the object's projecting end grasped with splinter forceps and gently extracted. If a portion remains or the foreign body is

deeply embedded from the outset, a digital block should be performed. Then the part of the nail overlying the object can be shaved down with a scalpel until the foreign body is exposed. Alternatively, the nail can be lifted and the object removed (see Section VII, Procedures). After splinter removal, the finger should be soaked in warm, soapy water, and an antibiotic ointment and protective dressing applied. Soaks should be repeated three times daily at home for the ensuing 3 to 5 days. In the unusual case of a child with multiple subungual splinters or fragments, it is best to remove the nail, clean out the foreign material, irrigate thoroughly, and then replace the nail (after trephining it to allow drainage).

Hair Tourniquet

A *hair tourniquet* injury is an entity unique to pediatrics. It involves strangulation of a digit (or occasionally the penis) by a hair or fine thread. It is seen most commonly in young infants and can be the cause of unexplained irritability or crying. The mechanism involves entwinement of the hair around an infant's digit. This may occur during a bath, during or as a result of wiggling of the toes in a sock, bootie, or mitten that inadvertently has a hair or loose thread in it. A hair shed from a parent during diapering is the probable source of penile tourniquets. As the hair or thread becomes more tightly entwined, it produces a tourniquet effect, impairing blood flow with resultant ischemic pain and distal swelling. When noted early, the hair is often visible in a crease just proximal to the swollen area. If seen later, the hair may have cut through the skin, making it difficult to visualize (Fig. 119.3). In rare cases, frank ischemic necrosis of the distal digit may be seen on presentation. Removal requires a fine-tipped forceps and the aid of a thin loupe or probe that is inserted proximally under the constricting hair. Usually the hair can be unwound from the digit intact or cut with scissors. When the hair is deeply embedded or there is any question of a remaining constricting band, a nerve block should be performed and a perpendicular incision made over the hair. To avoid damage to neurovascular structures, such an incision should be made on the lateral or ulnar aspect of a finger or toe at 3 or 9 o'clock or at 4 or 8 o'clock along the penile shaft. When the entire hair cannot be removed with certainty, plastic surgical consultation is indicated.

FIGURE 119.3 Hair tourniquets of third and fourth toes.

FIGURE 119.4 Ganglion cyst of the tendon sheath of flexor carpi radialis.

Ganglion

A *ganglion* is a cystic outgrowth or protrusion of the synovial lining of a tendon sheath or joint capsule. Common locations of ganglions include the dorsal or volar surface of the wrist (usually on the radial side), the dorsum of the foot, or near the malleolus of an ankle (Fig. 119.4). Occasionally, a flexor tendon sheath ganglion may present on the palmar surface of the hand at the base of a digit. The cause is believed to involve prior trauma that causes partial disruption of the synovium and subsequent herniation of synovial tissue. The cysts are soft, slightly fluctuant, and transilluminate. Most are painless or only mildly uncomfortable. However, those on the foot or ankle may cause pain when shoes are worn. Elective surgical excision with obliteration of the base is indicated only if function is impaired or the lesion is of cosmetic significance. Even then, up to 20% recur. Striking the cyst with a heavy object, an old fashion folk remedy, should be strongly discouraged because the cystic fluid may be dispersed through the surrounding soft tissue, inciting diffuse scar formation.

FACE AND SCALP LESIONS

Epidermal Inclusion Cyst

Among the most common postpubescent skin lesions is the *epidermal inclusion cyst* (EIC). These have also been termed *epithelial, sebaceous, and pilar cysts*. Most result from occlusion of pilosebaceous follicles, although some stem from inoculation of epidermal cells into the dermis via needlestick or other trauma. A few may arise from epidermal cells that become trapped along embryonic lines of closure. Lesions consist of firm, slow-growing, 1- to 3-cm, round nodules. Most are solitary lesions found about the scalp and face, although they also may be located on the trunk, neck, and scrotum. Histologically, these dermal and subcutaneous nodules consist of epidermally lined keratin-filled cysts. Presentation is that of a slow-growing painless lump that may provoke concerns of malignancy. At times, these cysts become acutely infected, and the patient complains of pain, erythema, and sudden increase in size. Infected cysts should be incised and drained, as well as treated with oral antibiotics before elective excision. Noninflamed cysts can be

referred for elective excision that must include the entire sac to prevent recurrence.

When a patient presents with multiple large EICs, Gardner's syndrome should be suspected. This autosomal dominant disorder is characterized by multiple EICs, intestinal polyposis, desmoid tumors, and osseous lesions. Early diagnosis is especially important because of a 50% risk of malignant transformation of the intestinal polyps.

Dermoid Cyst

Dermoid cysts are congenital, subcutaneous nodules derived from ectoderm and mesoderm. There is a male predominance. They, too, are lined with epithelium, but unlike EICs, they may contain multiple adnexal structures such as hair, glands, teeth, bone, and neural tissue, as well as keratin. The cysts usually present as solitary, round, firm nodules with a rubbery or doughy consistency on palpation, a smooth surface, and normal overlying skin. Lesions tend to grow slowly, and malignant transformation is rare. Whereas some dermoids may be mobile, many are fixed to overlying skin or underlying periosteum. Occasionally, dermoids may have deeper attachments extending intracranially or intraspinally, along with an accompanying sinus. Because these cysts form along areas of embryonic fusion, common sites include the nasal bridge, midline neck, or scalp; the lateral brow (Fig. 119.5, see also color plate); anterior margin of the sternocleidomastoid; and midline scrotum or sacrum. An external ostium may or may not be visible. A small percentage of patients with dermoid cysts may have other craniofacial abnormalities. Because the sinus tract can serve as a conduit for spread of secondary infection, all midline lesions should have appropriate imaging [computed tomography (CT) and/or magnetic resonance imaging (MRI)] followed by elective excision.

Nasal Bridge Lesions

Midline nasal masses in infants and children may be acquired (e.g., EIC) or congenital, the latter stemming from improper embryologic development (e.g., dermoid cyst, encephalocele, glioma).

FIGURE 119.5 Dermoid cyst abscess. (From Fleisher GR, Ludwig W, Baskin MN, eds. *Atlas of pediatric emergency medicine*. Philadelphia, PA: Lippincott Williams & Wilkins, 2004. Reprinted with permission.)

FIGURE 119.6 Preauricular surface pit. (Courtesy of David Tunkel, MD.)

Dermoids are the most common embryologically derived midline nasal lesions (see previous discussion). Clinically, a firm, round, subcutaneous mass is seen in the midline over the dorsum of the nose. Some have an overlying dimple, which may have an extruding hair (Fig. 119.6). Its attachment may extend only to the nasal septum or may go deeper through the cribriform plate into the calvarium. Because of their proximity to the nasopharynx, these dermoids are particularly prone to secondary infection and fistula formation. Hence, prompt excision is indicated after careful MRI or CT.

Gliomas are benign growths composed of ectopic neural tissue. The lesion usually consists of a firm, gray, or red-gray nodule, ranging in size from 1 to 5 cm and can be mistaken for a hemangioma. Most are extranasal (60%), occurring on the bridge of the nose. The remainders are either solely intranasal masses (30%) or have both intranasal and extranasal elements (10%). By definition, they do not have intracranial communication. They are composed of neural and fibrous tissue, covered by nasal mucosa. There is a male predominance. To prevent possible distortion of surrounding bone and cartilage, surgical excision is the treatment of choice.

Encephaloceles consist of neural tissue that has herniated through a congenital defect in the midline of the calvarium, and thus, always have an intracranial communication. Lesions appear as soft, at times pulsatile, compressible masses that enlarge with crying or straining. Compression of the jugular veins (Furstenberg test) may also cause the mass to expand in size. Some infants with nasal encephaloceles are born with overt craniofacial deformities and a rounded swelling at the base of the nose, whereas in others, the mass is confined to the nasopharynx, and external facial features

are normal. The latter may present with signs of persistent nasal obstruction. In these patients, a grapelike mass is found on nasopharyngoscopy. MRI is the modality of choice for differentiating encephaloceles from other midline nasal masses and for determining their size and extent. Neurosurgical evaluation and management is indicated for all encephaloceles.

Preauricular Lesions

Preauricular lesions, located just anterior to the tragus, may be the result of imperfect fusion of the first two branchial arches (sinus tract, pit) or may consist of first arch remnants (cutaneous tag). They may be unilateral or bilateral, single or multiple. Usually, they are seen as isolated minor anomalies, but on occasion they can be found in association with other developmental anomalies involving the first branchial arch or in infants with chromosomal disorders. Most lesions are evident shortly after birth. Some individuals simply have a surface pit or dimple, whereas in others, the overlying dimple represents the entrance to a sinus tract or blind pouch with a small cyst at its base (Fig. 119.6). The latter may contain hair and other epidermal elements. Sinuses are prone to infection and abscess formation, whereupon the child presents with sudden enlargement of a painful preauricular mass and overlying erythema. When this occurs, the patient should be treated with appropriate antimicrobial therapy before elective excision of the cyst and fistula tract. Cutaneous tags, also called *accessory auricles*, are flesh-colored pedunculated lesions that may or may not have a cartilaginous component (Fig. 119.7). Some with narrow bases may simply be tied off with silk sutures. Those with wider bases and those containing cartilage can be referred for elective excision for cosmetic reasons.

FIGURE 119.7 Multiple preauricular skin tags. (Courtesy of David Tunkel, MD.)

NECK LESIONS

Neck lesions in children may be of congenital origin or may be acquired as the result of an inflammatory process (Fig. 119.8). Although malignancy is a much rarer cause of neck masses in children, it must always be considered in the differential diagnosis. Neck masses or lesions are most conveniently divided into those occurring in the midline and those located in the lateral aspects of the neck (see Chapter 123).

Midline Neck Lesions

Submental lymphadenitis or *lymphadenopathy* occurs in the midline just beneath the chin. Nodal enlargement stems from drainage of primary infection of the lower lip, buccal floor, or anterior tongue.

Dermoid cysts (see "Face and Scalp Lesions" section) can occur throughout the midline of the neck but are usually found above the area of the hyoid. They may also be found more laterally along the anterior border of the sternocleidomastoid.

Thyroglossal duct cysts are among the more common midline neck masses in children. Approximately 40% present before 10 years of age. They are composed of an ectodermal ductal remnant that fails to regress after fetal descent of the thyroid gland. They may occur anywhere along the path of descent of the thyroid, from the foramen cecum at the base of the tongue to the sternal notch, although most are found near the level of the hyoid bone. Presentation is usually that of a painless, smooth, mobile, cystic mass that is located in the midline or just slightly off-center (Fig. 119.9). Because of its intimate association with the hyoid, the mass moves with protrusion of the tongue or swallowing. On occasion, an overlying pore is present. Some cysts go unnoticed until infection occurs, causing acute swelling, pain, and erythema of the overlying skin. Patients with asymptomatic thyroglossal duct cysts should be referred for elective surgical excision. If the thyroglossal duct cyst is infected on presentation, excision is deferred until appropriate antimicrobial therapy is completed and inflammation has subsided. If incision and drainage are required during treatment, the patient should be referred to a surgeon comfortable with thyroid anatomy. Elective excision involves removal of the cyst, the entire duct to the level of the foramen cecum, and the midportion of the hyoid bone. On rare occasions, ectopic thyroid tissue in a thyroglossal duct cyst is the patient's only functioning thyroid. Therefore, ultrasound or radioisotope scanning is recommended to confirm the presence of a normal thyroid gland before surgery.

Diffuse enlargement of the thyroid gland, or *goiter,* may be the result of infiltration, inflammation, or overstimulation of the gland. By far, the most common cause of pediatric thyroid enlargement is chronic *lymphocytic thyroiditis* (also called *Hashimoto's thyroiditis* or *autoimmune thyroiditis*). This disorder is characterized by a defect in cell-mediated immunity that results in lymphocytic infiltration of the thyroid gland. Female population is affected predominantly, and peak occurrence is during adolescence. Autoimmune thyroiditis has been associated with other autoimmune diseases such as chronic urticara and diabetes. Usual presentation is one of a slow-growing,

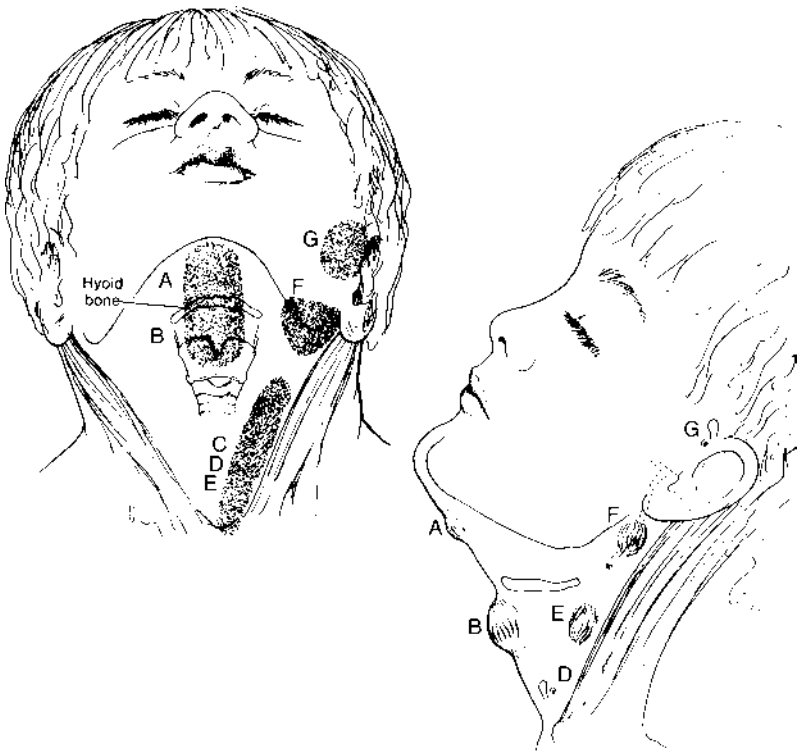

FIGURE 119.8 Head and neck congenital lesions seen in children in frontal and lateral views. The shaded areas denote the distribution in which a given lesion may be found. A, dermoid cyst; B, thyroglossal duct cyst; C, second branchial cleft appendage; D, second branchial cleft sinus; E, second branchial cleft cyst; F, first branchial pouch defect; G, preauricular sinus or appendage.

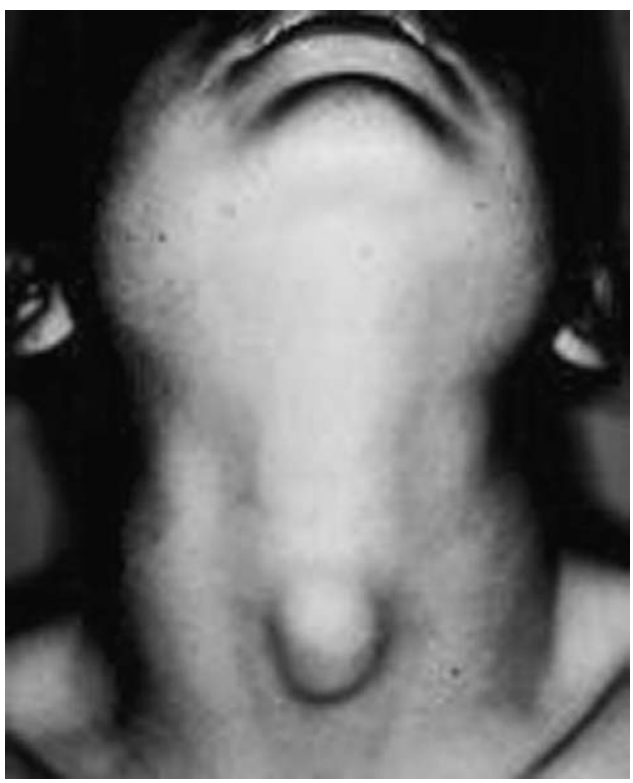

FIGURE 119.9 Thyroglossal duct cyst. (From Snell RS. *Clinical anatomy*, 7th ed. Baltimore, MD: Lippincott Williams & Wilkins; 2005:CD418. Used with permission.)

painless midline neck mass. Occasionally, a patient may complain of sore throat. Examination reveals a firm, nontender, diffusely enlarged gland in most affected children, but approximately one-third will have some lobular or nodular enlargement. Evaluation includes assessment of thyroid function and the detection of thyroid autoantibodies in the serum. Most patients with lymphocytic thyroiditis are euthyroid. When thyroid dysfunction is present, it usually takes the form of hypothyroidism. Any degree of nodularity of the gland warrants further investigation to rule out malignancy.

Inflammation of the thyroid gland secondary to infection, *acute suppurative thyroiditis*, is a rare cause of diffuse thyroid enlargement that can be associated with an underlying pyriform sinus fistula. Presentation usually follows an upper respiratory tract infection or otitis media and is characterized by abrupt appearance of a painful, tender, swollen mass in the region of the thyroid. Systemic toxicity in the form of fever and chills and severe dysphagia are often present. Flexion of the neck may alleviate pain, whereas extension worsens it. The etiologic agents include *S. aureus* and those in the oropharyngeal flora. Appropriate broad-spectrum parenteral antimicrobial therapy is usually sufficient to eradicate the infection. Abscess formation necessitates incision and drainage by a surgeon comfortable with thyroid anatomy. Evaluation with a CT or esophagography should include identification of a pyriform sinus fistula after resolution of infection to prevent recurrences.

Acute immune stimulation of the thyroid gland may also produce diffuse thyroid enlargement. In *Graves' disease*, autoantibody attachment to the thyrotropin receptor stimulates an increase in thyroid hormone synthesis and release.

Patients may initially have a history of changes of behavior, decrease in school performance, and/or increase in linear growth. On presentation, patients will have a symmetrically enlarged smooth nontender goiter and signs of thyrotoxicosis, including tachycardia, nervousness, tremor, hypertension, exophthalmos, and increased appetite. A thyroid bruit may be auscultated in half the patients. An elevated T_4 in the context of a low TSH level and presence of TSH receptor antibodies confirms the diagnosis. Consultation with a pediatric endocrinologist is indicated.

Solitary nodular thyroid masses deserve careful attention. Although most are secondary to chronic lymphocytic thyroiditis or consist of a benign adenoma, the incidence of malignant neoplasms is actually higher in children with thyroid nodules than in adults. Hence, every thyroid nodule found in a child merits a complete evaluation that may include a TSH level and ultrasound-guided biopsy.

Lateral Neck Lesions

Enlarged cervical lymph nodes constitute the most common lateral neck masses in children. Knowledge of the anatomy of the cervical lymphatics is of fundamental importance to understanding processes that cause enlargement of cervical lymph nodes. This section focuses mainly on local processes that cause nodal enlargement, but it is important to note that many systemic infections and inflammatory disorders can cause diffuse adenopathy that includes the cervical chain. Therefore, any child with a neck mass deserves a complete examination to look for the presence of generalized adenopathy and other signs of systemic disease.

Reactive cervical adenopathy refers to mild enlargement of cervical lymph nodes that accompanies a viral or bacterial upper respiratory tract infection. Involved nodes are typically located in the upper portion of the cervical chain. They are usually discrete, firm, mobile, and less than 2 cm in diameter. They may be mildly tender but have no overlying erythema, edema, or warmth. Regression within 1 to 2 weeks of resolution of the primary infection is the rule, although occasionally mild enlargement of the node may persist, if fibrosis has occurred.

Local infection of a lymph node itself is termed *acute suppurative lymphadenitis.* The involved node is solitary, typically 2 to 3 cm or larger in diameter, and extremely tender. As the infection proceeds, overlying swelling, erythema, and warmth develop and become more pronounced (Fig. 119.10). Initially the node is firm, but later it may become fluctuant. Acute suppurative lymphadenitis is most often caused by streptococcal or staphylococcal organisms. Because of the high incidence of β-lactamase production by *S. aureus*, β-lactamase stable antibiotics (dicloxacillin, cephalexin, or clindamycin) are the treatment of choice. Most patients respond to oral antimicrobial therapy and application of warm compresses. However, ultrasound may be indicated to establish if fluctuance has developed, and if so, incision and drainage are recommended. Other potential causative organisms of acute, subacute, or chronic lymphadenitis include anaerobic bacteria, *Pasteurella multocida* (following animal bites), *Haemophilus influenzae, Streptococcus agalactiae, Francisella tularensis, Brucella* species, *Bartonella henselae* (cat-scratch disease), mycobacteria, and actinomycoses. Oral antimicrobial therapy for methicillin-resistant *S. aureus* should be considered if there is clinical suspicion or high rate in the community or if the infection is not improving. Kawasaki disease may also present with an acutely enlarged cervical node and should be considered when other clinical criteria are present (fever for more than 5 days, rash, conjunctivitis, extremity and oral changes, and hyperirritability).

FIGURE 119.10 Suppurative lymphadenitis of an anterior cervical lymph node.

Salivary gland infections, *sialadenitis,* and *parotitis*, may cause lateral neck or submental swelling. When the parotid gland is involved, firm indurated swelling is found extending in an arc from the preauricular area down under the ear and behind it. The degree of swelling is often sufficient to blunt the angle of the jaw, and the mass is usually mildly tender (Fig. 119.11). Patients complain of mild pain in the region of the pinna, which increases with eating. Most salivary gland infections affect the parotid gland, with involvement of the sublingual and submandibular glands being much less common. Viral agents (e.g., mumps virus, parainfluenza types 1 and 3, influenza A, Coxsackie virus A, and rarely, human immunodeficiency virus) cause most of these infections. Less commonly, parotitis is due to a bacterial agent such as *S. aureus*. In these cases, patients present with rapid gland enlargement and severe pain, and they often have high fever and signs of systemic toxicity. On examination, overlying erythema and exquisite tenderness are present, and purulent material can often be expressed

FIGURE 119.11 Parotitis.

from Stensen's duct by massaging the gland. An elevated amylase level can help confirm the diagnosis of parotitis. Symptomatic treatment of sialadenitis includes close attention to hydration and avoidance of foods that require excessive chewing or induce rapid salivary flow (e.g., citrus fruits, sour foods). If bacterial sialadenitis or parotitis is suspected, β-lactamase stable parenteral antibiotics should be administered. Otolaryngologic consultation should be obtained if surgical drainage is needed because of the proximity of the facial nerve. Much less commonly, parotid gland swelling is of noninfectious origin. Causes include occlusion of Stensen's duct by a calculus and traumatic insufflation of the gland with forceful blowing (e.g., trumpet blowing) or, in rare instances, primary parotid neoplasms.

Cystic hygromas (lymphangiomas) represent malformations of the lymphatic system. They consist of dilated lymphatic channels and may be multiocular or unilocular. They occur most often in the posterior triangle of the neck (Fig. 119.12) but may be found in the axillae, groin, popliteal fossae, or on the chest or abdominal wall (Fig. 119.13). When found in the neck, extension of the mass into the anterior triangle, sublingual space, retropharyngeal space, or mediastinum is possible. Such infiltration can result in airway compromise and/or compression of vascular and neural structures. Most cystic hygromas are present at birth or become apparent shortly thereafter. Patients usually present with a slow-growing, painless neck mass that is soft and compressible, although some are brought for care because of sudden enlargement caused by secondary infection or hemorrhage within the lesion. Anatomic delineation of the mass is best done using MRI or CT. When lesions are located in the neck, the potential risk to the airway and neurovascular structures, coupled with the possibilities of hemorrhage or lymphangitis, dictates the need for early intervention. Consultation with an otolaryngologist is indicated.

FIGURE 119.13 Lateral abdominal wall cystic hygroma (lymphangioma).

Branchial cleft anomalies consist of a group of congenital malformations, including subcutaneous cysts, sinus tracts, and cartilaginous remnants. They are caused by persistence of structures derived from the embryonic branchial arches. Of these anomalies, 90% arise from the second branchial arch and are found along the anterior border of the sternocleidomastoid muscle. Sinus tracts of second branchial arch remnants may end in an internal ostium located near the tonsillar fossa. Less commonly, first branchial arch anomalies may be noted as masses or sinus tracts near the mandibular ramus. Some first branchial arch remnants end in an internal ostium located in the external auditory canal. Branchial cleft anomalies may be noted shortly after birth either as a firm, mobile mass with or without an overlying pore or simply as an external ostium or pore without an underlying mass (Fig. 119.14). More commonly, branchial cleft cysts are detected later in childhood when they may present as an asymptomatic mass or with acute painful enlargement as a result of secondary infection. All branchial cleft anomalies should be

FIGURE 119.12 Lateral neck cystic hygroma (lymphangioma) in an infant.

FIGURE 119.14 Second branchial cleft pit that had an underlying sinus tract.

referred for surgical excision for cosmetic purposes and to avoid potential morbidity, which includes infection and the development of carcinoma in situ. When patients present with infection, excision must be deferred until antimicrobial therapy and incision and drainage (if needed) have quelled all signs of inflammation.

The combination of torticollis and a lateral neck mass in early infancy is highly suggestive of a *sternocleidomastoid tumor* that can be associated with primiparous births, breech presentations, and difficult labor. Clinically, a nontender, firm, ovoid 1- to 3-cm mass is found along the middle third of the sternocleidomastoid muscle. The mass represents local muscle hemorrhage or infarction that subsequently undergoes fibrosis. It is believed to be the result of traumatic extraction of the head during delivery or of fibrous dysplasia secondary to intrauterine positioning. Some are noted at birth, whereas others become apparent within the ensuing few weeks. The head is bent toward, and the chin away from, the affected side, and limitation of bending to the opposite side and rotation toward the involved side are noted. Initial treatment consists of passive stretching exercises and positioning of the infant so that he or she has to turn from the affected side to see others. If this fails, surgical release of the contracture is indicated to prevent secondary facial deformity with growth. Infants with this disorder should be carefully assessed for associated hip dysplasia, which coexists in up to 20% of cases.

The possibility of *malignancy* must be considered in the differential diagnosis of any child with a cervical mass. History regarding the presence of persistent fevers, malaise, night sweats, weight loss, and other constitutional symptoms should be sought, and the child assessed for presence of pallor, petechiae, generalized adenopathy, and hepatosplenomegaly. Primary lymphoid malignancies, such as leukemia and lymphoma, may present initially with a rapidly enlarging neck mass. In contrast to infectious adenopathy, involved nodes tend to be firm, matted, nontender, and poorly mobile. Posterior triangle and supraclavicular masses carry a much higher risk for neoplasm than do anterior triangle masses. Metastatic tumors, such as rhabdomyosarcoma and neuroblastoma, may also initially manifest as a neck mass. If malignancy is suspected, the ED workup should include complete blood cell count, electrolytes, uric acid, lactate dehydrogenase, liver function studies, heterophile antibody titer, and a chest radiograph. Further evaluation, including imaging and biopsy, should be performed in consultation with a pediatric oncologist.

SURFACE LESIONS

Vascular Malformations

Vascular malformations result from errors in vascular morphogenesis. Unlike hemangiomas, they are present at birth, grow only in proportion to the child, and do not undergo regression. They may be of capillary, venous, or arterial origin or combinations of vessel types may exist within the same lesion. *Port-wine stains* are among the more common capillary vascular malformations. They have a characteristic deep red to purple hue (Fig. 119.15, see also color plate). Children with facial port-wine stains that lie in the distribution of the ophthalmic branch of the trigeminal nerve (which includes the forehead, upper eyelids, and nose) merit careful evaluation for associated anomalies. Specifically, the *Sturge-Weber syndrome* is characterized by ipsilateral vascular angiomatosis of the leptomeninges and ocular vessels. Clinical manifestations may include seizures, mental retardation, hemiplegia, and glaucoma. Serial head CT scans performed on these children often demonstrate evolution of serpiginous calcifications and progressive atrophy of the cerebral cortex underlying the pial vascular malformations. Children with port-wine stains involving an extremity may develop hemihypertrophy of the affected limb because of an unusually rich underlying blood supply, the *Klippel-Trenaunay-Weber syndrome*. All cosmetically significant port-wine lesions should be referred to a dermatologist (see Chapter 85).

FIGURE 119.15 Facial port-wine stain. (From Weber J, Kelley J. *Health assessment in nursing*, 2nd ed. Philadelphia, PA: Lippincott Williams & Wilkins, 2003.)

Salmon patches, the most common form of vascular malformation seen in infancy, occur in 30% to 40% of all newborns. These flat pink lesions, which become more prominent with crying or exertion, are most commonly located on the nape of the neck (stork bites), on the glabella, or over the eyelids (angel kisses). They consist of distended dermal capillaries and almost always fade or disappear by the end of the first year of life, although nuchal salmon patches may persist into adulthood.

Hemangiomas

Hemangiomas, the most common benign neoplasm of infancy, occur in 10% or more of children younger than 1 year. Histologically, they are composed of hyperplastic vascular endothelium that develops from angioblastic tissue that has failed to connect normally with the vascular system during gestation. Although only a small portion of hemangiomas is evident at birth (2.5%), most become apparent within the first month of life. There is an increased incidence in female and premature infants. Sixty percent of all hemangiomas are located in the head/neck region. Lesions tend to undergo a period of rapid growth over the ensuing 6 to 12 months, then

FIGURE 119.16 Superficial hemangiomas of hip and buttock. (Courtesy Joseph Glustein, MD.)

plateau. Subsequently, a slow process of involution begins, usually by 18 months. Approximately 50% of lesions involute completely by 5 years of age, and 95% by 9 years of age. Hemangiomas can be subdivided into three types as follows:

1. *Superficial hemangiomas* are confined to the upper dermis. Formerly called *capillary* or *strawberry hemangiomas*, these lesions are red, raised, well demarcated, and compressible (Fig. 119.16).
2. *Deep hemangiomas*, previously called cavernous hemangiomas, lie in the lower dermis. They tend to have indistinct margins, and the overlying skin often has a bluish hue (Fig. 119.17).
3. On close inspection, many hemangiomas have a combination of both superficial and deep elements, and thus should be called *mixed hemangiomas*.

Because of their natural history of ultimate regression, a combination of watchful waiting and parental reassurance remain the standard of care for most hemangiomas. However, active intervention is indicated for lesions that compromise vital structures (airway, eyes, nose); lesions that are susceptible to trauma, hemorrhage, or infection; and those that grow at an alarming rate. Extremely large cavernous hemangiomas pose a risk for development of *Kasabach–Merritt syndrome*, which is characterized by sequestration of platelets with secondary thrombocytopenia and high-output cardiac failure. Infants who present with stridor at 6 to 12 weeks of age may have an undiagnosed laryngeal hemangioma. More than 50% of infants with laryngeal hemangiomas have cutaneous hemangiomas along the mandible and neck region in a "beard" distribution. Infants with liver hemangiomas are at risk for congestive heart failure. Decisions regarding treatment are best made in consultation with a specialist in vascular anomalies.

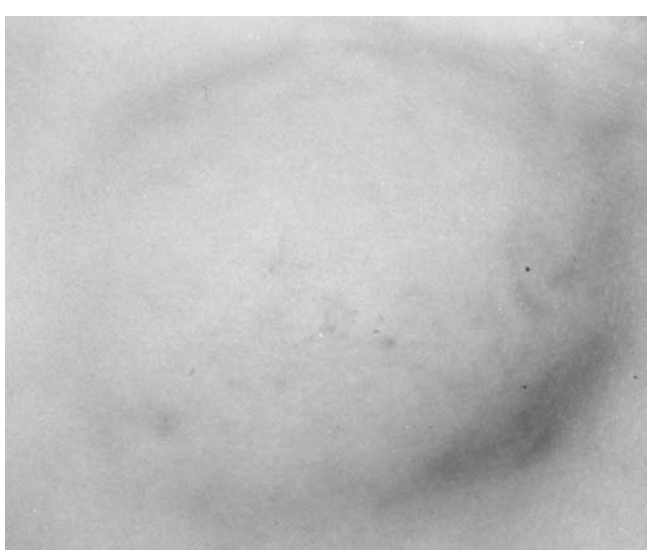

FIGURE 119.17 Deep hemangioma of upper lateral chest.

Lipoma

Lipomas are benign subcutaneous tumors composed of mature adipose cells. They often present in adolescence as painless and usually solitary nodules. They may be located anywhere on the body. Clinically, lipomas are nontender and have a soft, rubbery consistency, often with lobulations. Overlying skin is normal and easily slides across the mass, which helps distinguish lipomas from other skin nodules such as pilomatricomas. *Angiolipomas* are a variant of lipoma that have a component of capillary proliferation. Unlike lipomas, they tend to be painful. Lesions that are cosmetically significant, large, or painful warrant elective surgical excision.

Pilomatricoma

Pilomatricomas (calcifying epitheliomas) are relatively common lesions, accounting for 10% of superficial nodules seen in children. These benign tumors arise from cells of the hair matrix, hair cortex, or inner root sheath. Most are found on the head and neck, but some arise on the trunk and extremities. They appear as firm (resulting from calcification), solitary nodules ranging in size from 0.5 to 5 cm. An overlying bluish hue may help distinguish the lesion from other benign nodules such as epidermal or dermoid cysts. When pinched, the overlying skin "tents," providing another distinguishing feature. Multiple pilomatricomas have been associated with Gardner's syndrome, Steinert's disease, myotonic dystrophy, and sarcoidosis. Familial occurrences have been reported but are rare. If the lesion is located in a cosmetically sensitive area, elective surgical excision is the treatment of choice.

Pyogenic Granuloma

A *pyogenic granuloma* (also called *lobular capillary hemangioma*) is a benign vascular lesion most commonly found on exposed skin surfaces such as the face, hands, and forearms. Occasionally, lesions form on oral or nasal mucosal surfaces. They are composed of granulation tissue with significant vascular overgrowth and are considered the result of an exaggerated vascular growth factor response after local trauma. Lesions are usually solitary and pedunculated, measuring from

FIGURE 119.18 Large pedunculated umbilical granuloma that responded to suture ligation and repeated silver nitrate applications.

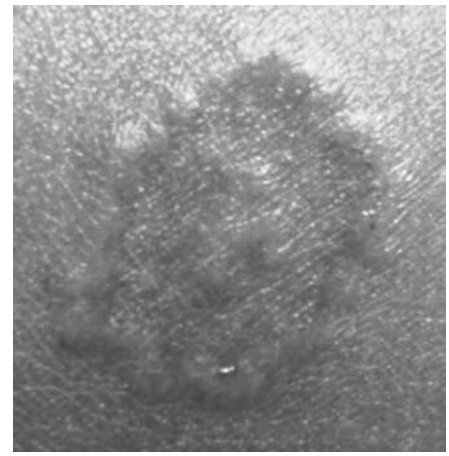

FIGURE 119.19 Granuloma annulare.

0.5 to 2 cm. At times, multiple satellite lesions are found around a central granuloma. The color and character of a pyogenic granuloma varies according to its stage of growth. Early on, the lesion appears as a glistening, red, polypoid nodule with a friable surface that bleeds easily. Later (weeks to months), the lesion becomes fibrotic and shrinks, taking on a reddish-brown hue. The most common reasons for presenting to the ED are bleeding or chronic oozing of an early lesion. Treatment consists of excision followed by silver nitrate cauterization of vessels at the base. Recurrence merits referral to a dermatologist.

Umbilical Granuloma

An umbilical granuloma presents as a soft, friable, polypoid mass that is pink or dull red. It arises from the base of the umbilical stump and at times may be pedunculated with a short stalk (Fig. 119.18). It is the product of an exuberant granulation tissue reaction, probably secondary to excessive moisture and/or low-grade infection. Treatment of most lesions consists of cauterization with a silver nitrate stick. During this procedure, care should be taken to cover the skin of the umbilical rim with gauze to protect it from burns. Following cauterization, the lesion should be blotted dry to avoid seepage of excess silver nitrate to surrounding tissue. Home care consists of keeping the umbilicus clean and dry. Large granulomas may require repeated cautery at intervals of several days. Pedunculated granulomas are candidates for suture ligation (3-0 nylon). The parent is then instructed to return for follow-up for cauterization of the base (once the granuloma has necrosed and dropped off) to prevent recurrence. Umbilical granulomas must be differentiated from persistent embryonic remnants such as an *omphalomesenteric duct* or *patent urachus*. The presence of a central lumen or chronic discharge should prompt the clinician to consider these rare umbilical anomalies. The distinction is of great clinical significance because these problems may be associated with other congenital malformations, and surgical excision of the entire remnant is necessary to prevent sequelae, such as infection.

Granuloma Annulare

The lesions of *granuloma annulare* are composed of infiltrates of lymphocytes and altered collagen within the dermis. They first appear as raised nodules that gradually expand centrifugally to form annular rings ranging from 1 to 5 cm in diameter. They have a firm, fibrous, sometimes-lumpy consistency on palpation. Overlying skin is usually normal or slightly hyperpigmented (Fig. 119.19). Although most are asymptomatic, a patient occasionally may report mild pruritus and present with superficial excoriation caused by scratching. The lack of an active microvesicular border, firm consistency on palpation, and the deeper dermal location of these lesions help distinguish them from *tinea corporis*. Lesions are commonly found on the extensor surfaces of the lower portions of legs and the dorsum of the hands and feet and, less often, on the trunk or abdominal wall. Although granuloma annulare may present at any age, more than 40% of cases appear before age 15. Because most lesions undergo resolution within 1 to 2 years, reassurance is usually all that is necessary. In the rare case of a patient with severe or widespread lesions, dermatologic consultation should be sought.

Juvenile Xanthogranuloma

Juvenile xanthogranulomas (JXG) present as nodular or plaquelike lesions with a firm or rubbery consistency. Initially reddish in color, they evolve to have a distinct yellow or orange hue (Fig. 119.20). Many are noted at birth, whereas others appear within the first several months. They range in diameter from 0.5 to 4 cm. Like hemangiomas, they tend to grow rapidly in infancy, then spontaneously regress in early childhood. Common sites include the scalp and face, proximal extremities, and occasionally, the subungual area of a digit or a mucocutaneous junction. Lesions may be solitary but are often present in groups. Histologically, xanthogranulomas are composed of lipid-laden macrophages or histiocytes within a granulomatous matrix whose inciting source is unknown. In rare cases, giant or disseminated lesions may occur. Patients who have multiple or diffuse lesions may also have ocular lesions, specifically lesions of the iris that have been associated with spontaneous anterior chamber hemorrhage and glaucoma. On occasion, ocular lesions have been misdiagnosed as retinoblastoma. A systemic form of JXG exists, and affected

FIGURE 119.20 Yellow nodular lesion typical of juvenile xanthogranuloma.

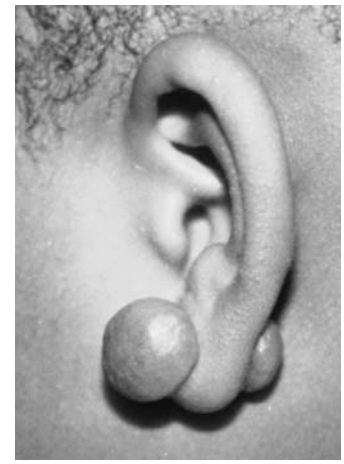

FIGURE 119.21 Large keloid that formed after ear piercing in a susceptible child.

patients may or may not have concomitant cutaneous findings. In this variant, noncutaneous lesions may involve the brain, heart, liver, spleen, and lungs. Children who have both JXG and neurofibromatosis are at a much higher risk for unusual forms of leukemia and thus should be appropriately monitored. Last, unlike children with disseminated xanthomas, there is no relationship between JXG and lipid abnormalities. All children with suspected xanthogranuloma should undergo biopsy. An ophthalmologic evaluation is necessary if JXG is confirmed, and careful observation for evidence of systemic involvement is warranted.

Neurofibroma

A neurofibroma may present as a solitary lesion in an otherwise normal patient or as a feature of neurofibromatosis type I. Cutaneous neurofibromas arise from nerve sheath cells located in the dermis. They appear as pink or flesh-colored nodules that are soft and range in size from 0.5 to 3 cm. Most do not appear until adolescence. Lesions may be confused with angiolipomas and hemangiomas; however, a distinguishing feature is the tendency of neurofibromas to be especially soft centrally and invaginate with digital pressure, described as "buttonholing." Elective excision is indicated only if the lesion is compressing a nerve, causing nerve root pain, because excision is often followed by recurrence of an even larger lesion.

Keloid/Hypertrophic Scar

Exaggerated proliferation of fibrous connective tissue in the process of cutaneous wound healing results in formation of *hypertrophic scars* and *keloids*. Wounds involving areas of skin that are thick or under high tension (shoulders, back, chest, or chin) are at greatest risk. The ear lobe is another commonly affected site. Individuals with dark skin are much more susceptible to abnormal scarring, which has its highest incidence in adolescence and early adulthood. Hypertrophic scars remain confined to the area of original injury. They are rarely painful and tend to undergo slow regression over 6 to 12 months. In contrast, keloids extend beyond the original wound margins and rarely regress spontaneously. Initially, keloids may be painful and tender or pruritic. They have a rubbery consistency on palpation and a smooth pink surface (Fig. 119.21). Ear piercing, tattooing, and elective cosmetic procedures should be avoided in persons who have a tendency to form keloids. Severe keloids should be referred to a dermatologist or plastic surgeon for further treatment.

Lumbosacral Lesions

Pilonidal dimples, typically located in the midline in the sacrococcygeal area, are benign lesions of no clinical significance. On close inspection, there is no evidence of a central pore or opening. In contrast, pilonidal sinuses, which are found in the same area, do have a small surface opening to a tract lined by stratified squamous epithelium that extends toward, but not into, the spinal canal. In some instances, sinuses appear to be of embryonic origin, stemming from either an abnormality of midline fusion or invagination of ectodermal elements. The base of such a lesion may consist of a small cyst containing products of skin cells and epithelial appendages, including hair. In other cases, the source may be a distorted hair follicle. Pilonidal sinuses and cysts are asymptomatic until the sinus becomes obstructed and/or infected. This phenomenon is most likely to occur during adolescence or early adulthood. Male population is much more commonly affected than female population. Excess weight, hirsutism, and a sedentary lifestyle or occupation that requires prolonged sitting also appear to be predisposing factors.

Infecting organisms usually gain access through the external sinus tract. Once infection occurs, an abscess forms and tends to enlarge rapidly. Because the overlying skin is thick, expansion tends to occur deep to the skin surface, and acquired sinus tracts may form external to the postsacral facia. Patients typically complain of low back pain, increased on

FIGURE 119.22 Infected pilonidal cyst.

sitting, and local tenderness. On examination, a tender, indurated swelling is noted overlying the sacrococcygeal area with the original sinus at its cephalad end (Fig. 119.22). Treatment consists of incision and drainage with careful probing to break up loculations and extract any hairs present because these act as foreign bodies. Cultures grow mixed organisms, including staphylococci, anaerobes, and fecal flora. Home care includes sitz baths and oral antimicrobial therapy. Elective excision of the entire cyst and all associated sinus tracts is indicated once inflammation has resolved.

Cutaneous Manifestations of Spinal Dysraphism

A number of midline cutaneous abnormalities found in the lumbosacral area are associated with underlying vertebral or spinal cord defects that are the result of defective closure of the caudal neural tube, *occult spinal dysraphism*. Skin findings include *hairy patches* (Fig. 119.23), *skin tags*, *port-wine stains*, *hemangiomas,* and *congenital dermal sinuses*. The latter tend to be more cephalad than pilonidal sinuses, and their sinus tracts often extend to the spinal column. Underlying intraspinal lesions include dermoid tumors, lipomas, and diastematomyelia. In the latter condition, the lower cord is divided sagittally by an osseous or fibrocartilaginous septum, which tethers the cord at that level, impeding its normal ascent within the spinal canal as the child grows. Patients with tethering may present with lower-extremity neurologic deficits at birth or may insidiously develop symptoms later in infancy or childhood, especially during a period of rapid growth. Complaints may include back or leg pain or stiffness, buttock pain, weakness or numbness, and bowel and bladder complaints. Physical examination may reveal decreased tone and decreased deep tendon reflexes in the lower extremities.

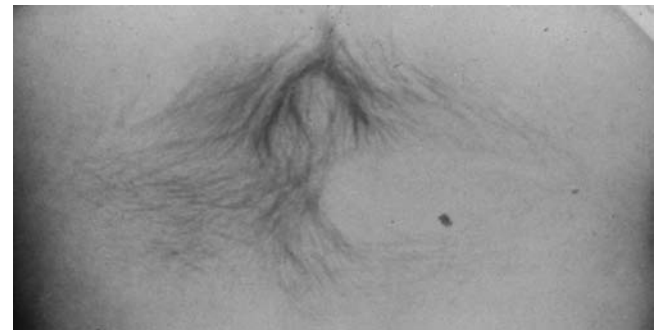

FIGURE 119.23 Lumbosacral hairy patch in a patient with diastematomyelia.

Any child found to have one of the midline cutaneous findings just described should undergo radiologic imaging to detect and delineate underlying vertebrospinal defects because early neurosurgical intervention enables substantial reduction in morbidity.

Perineal Lesions

Urethral prolapse is a phenomenon seen primarily in obese prepubescent girls (see Chapter 90). Two-thirds or more are African American. In this condition, the urethra prolapses through the urethral meatus and is seen as a red or purplish red, friable, edematous mass overlying the anterior portion of the introitus (Fig. 119.24). It often has a doughnut shape, and close inspection reveals a central orifice. The prolapsed mucosa is usually mildly painful and tender and tends to bleed easily. Presenting complaints may include perineal pain, dysuria, and blood spotting on underwear. Urination is not impaired. The precipitating event is characterized by increased intraabdominal pressure, usually

FIGURE 119.24 Typical doughnut appearance of urethral prolapse.

severe straining with constipation, a severe coughing spell, or prolonged crying. Because the red friable mass often overlies the hymenal orifice, it can be mistaken for traumatized hymenal folds, raising suspicion of sexual abuse. Correct diagnosis is made by examination under magnification after applying a topical anesthetic. This enables visualization of the central orifice and elevation of the mass to visualize the hymen. Management consists of treating the predisposing condition, oral analgesics and topical antibiotic/anesthetic creams for symptomatic relief, and twice-daily application of estrogen cream.

Hemorrhoids, internal and external, are dilated veins arising from the superior and inferior hemorrhoids veins. While very uncommon in children, incidences of hemorrhoids increase during adolescence. Development of hemorrhoids is associated with children with portal hypertension, chronic constipation, or excessive straining. Symptoms include painless bleeding (internal hemorrhoids), prolapse, pruitus, and pain secondary to vascular thrombsis. Treatment initially starts with medical management, increased fiber consumption or use of stool softeners, and topical care corticosteriods and analgesics. Refractory hemorrhoids may be managed nonoperatively with ablation or ligation. If unsuccessful, then hemorrhoidectomy should be considered. Due to the rarity of hemorrhoids in children, any presentation should prompt a careful and thorough evaluation of the underlying etiology.

Perianal skin tags are common sequelae of anal fissures and thus tend to be seen in children with a history of large, hard stools. They consist of pedunculated masses on short stalks that form during the process of healing of an anal fissure, probably in part caused by frictional forces common to this area. They are usually asymptomatic. They also can be seen in association with hypertrophic scars, another common sequela of the healing of an anal fissure. Although most patients with these lesions are otherwise normal, a small percentage have them as manifestations of perianal disease, internal fissures, and/or fistula, which may be the primary problem or one manifestation of inflammatory bowel disease. Management is directed at treating the predisposing or underlying condition. Bothersome pedunculated lesions can be tied off with silk suture.

Rectal prolapse, herniation of the rectum through the levator and then the anal orifice, is a phenomenon typically seen in children between 1 and 2 years of age (Fig. 119.25). The most common predisposing conditions, severe constipation and severe diarrhea, are characterized by repeated straining on defecation, which stretches pelvic suspensory structures, facilitating herniation. Patients with spina bifida may have prolapse as a consequence of deficits in perineal innervation with attendant atrophy of the supporting perineal muscles. Rectal prolapse may be the first presenting symptom in children with cystic fibrosis. Occasionally, an apparent rectal prolapse represents the lead end of a sigmoid intussceptens. In these cases, patients have a history of antecedent, intermittent, abdominal pain or irritability and may have vomiting, lethargy, and/or rectal bleeding as do other infants and children with intussusception. Clinically, a cylindrical mass with a central orifice and a glistening red surface is seen protruding through the anus. Acutely, the mass can be reduced with gentle pressure. Attention is then directed at identifying and treating the underlying condition to prevent recurrences. The need for operative intervention for persistent recurrences is rare and is largely limited to neurodevastated patients with intractable constipation.

Acute Thromboplebitis

Because of technological advancements and treatments for diseases such as cancer and congenital heart disease, the incidence of venous thromboembolism has increased in the pediatric population. The annual incidence is 0.07 to 0.14 per 10,000 children. For hospital admissions of children, the incidence is 5.3 per 10,000, and for neonatal intensive care unit admissions, it is 0.24 per 100,000. Incidence peaks during the neonatal period and then during adolescence. Acute thrombophlebitis is increasingly recognized as a medical complication that can cause significant morbidity and mortality if not diagnosed early.

There are many medical conditions that increase the risk of thromboplebitis. In the pediatric population, one of the major causes is the presence of an indwelling central catheter. Other associated conditions that increase the risk of thromboplebitis are cancer, particularly acute lymphoblastic leukemia, chemotherapy such as asparaginase, congenital heart disease, trauma, infection, nephritic syndrome and systemic lupus erythematous.

Pathophysiology

Virchow's triad (venous stasis, endothelial injury, and hypercoagulability) illustrates the underlying mechanisms for developing thromboplebitis. Conditions that contribute to venous stasis include prolonged immobilization due to an underlying medical condition or recent surgery. Central venous lines, while crucial for many therapies, are thrombogenic as they can cause damage to the endothelium and disrupt blood flow. Hypercoagulable states include inherited thrombophilia, such as antithrombin III, protein C or S deficiency, and Factor V Leiden mutation, and acquired thrombophilia, such as infection and sepsis. Hormonal replacement and pregnancy can also contribute to increased risk of thromboplebitis.

Clinical Findings

Clinical characteristics for superficial thromboplebitis include pain, induration, and erythema along the superficial vein. Palpating a palpable cord should raise suspicion for thrombosis. If accompanied by fever or surrounding erythema or

drainage, a septic thromboplebitis should be considered. Any presence of a superficial thromboplebitis should prompt a search for deep venous thrombosis, given that both are results of the same pathophysiology.

For deep venous thrombosis in the upper chest, initial clinical presentation can be asymptomatic. Initial clinical signs include repeated loss of patency of the central venous line, or line sepsis. Late findings include swelling of the face or neck, periorbital edema, headache, discoloration of the related limb, chylopericardium and/or chylothorax. Patient may exhibit signs of superior vena cava syndrome.

In the lower extremities, patients can develop unilateral leg swelling and tenderness. The absence of a palpable cord or negative Homans' sign does not rule out a deep venous thrombosis. Accompanying signs include inguinal and abdominal pain, discoloration of the affected leg, and prominent collateral circulation.

For clinical findings of pulmonary embolism, please see chapter "Pulmonary Emergencies."

For evaluation of thromboplebitis, consider obtaining complete blood cell count and coagulation studies. In postpubertal girls, a urine pregnancy test is warranted. In adults, D-dimer, a marker for endogenous fibrinolysis, has been shown to be an effective screening tool in combination with a clinical prediction model in evaluating lower-extremity deep venous thrombosis. Factors used in the clinical model include immobilization, malignancy, extremity physical findings (calf circumference, leg swelling, and edema). Unfortunately, the clinical prediction model has not been validated in children and the use of D-dimer as a screening tool in children is debated. Thus, even with a negative D-dimer, one cannot exclude the diagnosis of a venous thrombosis. A persistently elevated levels of D-dimer and/or Factor VIII have been shown to predict a poor outcome in children with thrombosis.

In children with no other risk factors for venous thrombosis, or repeated episodes of venous thrombosis, consider screening for an inherited hypercoagulable state such as an antithrombin III, protein C or S deficiency, factor V Leiden mutation, antiphospholipid antibody, and lupus anticoagulant.

While venography is the gold standard for diagnosis of venous thrombosis, its use in children is limited due to its invasiveness and technical difficulties. Compression ultrasound is the imaging technique of choice for the diagnosis of venous thromboembolism in the proximal lower extremity. For evaluation of the upper chest, compression ultrasound is limited due to bony structures such as the clavicle and thoracic cage. Therefore, a combination of venography and ultrasound is recommended for evaluation of upper venous system.

Spiral CT has been shown to be accurate for diagnosis in adults, but its use in children should be limited given the radiation exposure. Currently under development, magnetic resonance venography has been shown to have high sensitivity and specificity for diagnosis of venous thrombosis in adults but has not been studied as well in children.

Management

Initial management is directed at reestablishing blood flow through the occluded vessel, resolving thrombus, and preventing embolization of the thrombus. Therapies consist of anticoagulants and thrombolytic agents. Treatment should be initiated in the ED with consultation with a hematologist.

Unfractionated heparin can be started with a loading dose of 75 units/kg and a maintenance dose of approximately 20 to 28 units/kg/hr, depending on age. Risks of unfractionated heparin include bleeding and heparin-induced thrombocytopenia.

Low-molecular-weight heparin can also be used and dosing is age-dependent. Advantages of low-molecular-weight heparin include subcutaneous administration and minimal laboratory monitoring.

Thrombolytic agents such as Recombinant tPA (alteplase) can be administered as a continuous infusion for catheter-directed thrombolysis (0.01 to 0.2 mg per kg per hour) or for systemic thrombolysis (0.1 to 0.6 mg per kg per hour for 6 hours). Use of thrombolytic agents should be reviewed in consultation with a hematologist.

CHAPTER 120 ■ APPROACH TO THE CARE OF THE TECHNOLOGY-ASSISTED CHILD

JOEL A. FEIN, MD, MPH, KATHLEEN M. CRONAN, MD, AND JILL C. POSNER, MD, MSCE

Up to almost one-fourth of the visits to a pediatric emergency department (ED) are for complaints associated with chronic illness. Many children with chronic illness have indwelling medical devices, such as cerebrospinal fluid (CSF) shunts, venous catheters, and gastrostomy tubes (G-tubes). Medical technology has enabled these children, who in the past would have required specialized inpatient or intensive care, to thrive at home. Emergency physicians must be able to diagnose and treat the common problems associated with these new technologies and recognize when it is appropriate to consult other specialists familiar with these children.

Devices most commonly found in the pediatric population include CSF shunts, tracheostomy tubes, venous catheters, and percutaneous gastrointestinal (GI), and urologic catheters. This chapter familiarizes the emergency clinician with the equipment and with the clinical manifestations and management of the problems related to these apparatuses. In addition, the clinician can advocate more effectively for the patients if he or she is aware of the emotional and social issues that may accompany these patients and families.

APPROACH TO THE CARE OF THE TECHNOLOGY-ASSISTED CHILD

The technology-assisted child who visits the ED may pose a challenge for the practitioner. Because of several factors, the evaluation of these patients may, at times, seem overwhelming. These children are often assisted by several pieces of equipment, the history can be difficult to obtain because of its inherent complexity, and a thorough physical examination may be impeded by the technology. When a common illness is superimposed on a chronic condition, the illness may appear more complex, misleading the examiner. In addition, the ED visit may have been prompted by multiple reasons. The more involved the equipment and problems, the more challenging the situation becomes.

When a technology-assisted child arrives in the ED, early contact to the primary care provider may be helpful. The primary care provider may be able to offer suggestions about the management of the child, potentially avoiding unnecessary tests and admission. In many situations, a home health nurse may accompany the patient and the family to the ED and can be a valuable source of information.

In recent years, the American College of Emergency Physicians and the American Academy of Pediatrics have provided a data form, the Emergency Information Form, for children with special health care needs that can be accessed at the time of the ED visit for patients who have subscribed to the service. This form can be located at www.aap.org/ advocacy/epcparent.htm or http://www.acep.org/patients.aspx?id=26276. A Medi-Alert bracelet provides a patient identification number that enables procurement of information about the patient. By accessing the Medi-Alert hotline, relevant medical information about the patient can be faxed rapidly to the ED for immediate use. Deriving an accurate history is imperative and greatly improves the quality of care administered.

When caring for the technology-assisted child, several important principles emerge that should be used in the acute care setting (Table 120.1).

First, *common things are common*; common pediatric illnesses may afflict these children as they do others. This point is always important to remember when evaluating a seemingly complicated child who presents with the routine signs and symptoms characteristic of typical childhood diseases. For example, a child with a CSF shunt may have vomiting caused by gastroenteritis.

Second, the presence of indwelling devices *predisposes the patient to infection*. When a child presents with symptoms associated with a specific piece of equipment, the clinician must be suspicious of infection of that equipment. For example, if a child with a tracheostomy presents with fever, cough, and increasing secretions, it is crucial to evaluate for the possibility of tracheitis. At the same time, the equipment has a tendency to become colonized with commensal organisms. Therefore, all bacterial growth does not indicate acute infection and other sources of infection should be considered.

Above all, *families should be relied on* for important information because the parents or caregivers of technology-assisted children have become sophisticated in their knowledge of specific illnesses and equipment. This information becomes crucial when an acutely ill patient presents to the ED with several forms of technology and an involved medical history. Parents are sensitive to subtle changes in their children because they provide most of the home medical care. *Families are experts* and should play an integral role in the evaluation, management, and ultimate disposition of their child in the ED setting.

Children with chronic illnesses have a higher likelihood of being admitted to the hospital, resulting in longer lengths of stay in the ED. The practitioner should realize that the families of technology-assisted children often have sufficient equipment and trained personnel available in the home setting to care for an exacerbation of a chronic problem or an unrelated acute problem. For example, family members whose child has a chronic respiratory illness often have supplemental oxygen in the home and are facile with its use. Knowing that families

TABLE 120.1

APPROACH TO THE TECHNOLOGY-DEPENDENT CHILD IN THE EMERGENCY DEPARTMENT

Common pediatric illnesses can afflict chronically ill children
Presence of foreign bodies or hardware predisposes the patient to infection
Families are the experts in their children's problems—rely on them for important information
Consider altering the usual criteria for admission

of technology-assisted children are compliant and likely to return to the ED if their child's degree of illness exceeds the capabilities of the home care is reassuring. Thus, the practitioner should consider *altering the usual criteria for admission* in this specific population.

Having a technology-assisted child in the home creates a stressful situation for family members and other caregivers. A visit to the ED for an acute problem exacerbates this level of stress. These families may be more likely to question the diagnostic tests and therapies offered during the evaluation of their child because of their level of medical knowledge, as well as the constant illness-related anxiety that intrudes upon their lives. The ED visit is more effective if the practitioner recognizes the psychosocial issues associated with this population of patients.

Tracheostomy Care

Background

Advances in neonatology and pediatric critical care medicine have enabled children to survive the complications of premature birth, congenital anomalies, and severe life-threatening illnesses. Yet, a significant number of children are unable to be weaned immediately from respiratory support. As home care has become more widely recognized as an alternative to prolonged and costly hospitalization, the number of children managed at home with tracheostomies and mechanical ventilation has increased dramatically. Consequently, these children seek care more often in the ED when acute problems arise. To approach these situations calmly and systematically, the emergency physician should (i) appreciate the physiologic differences in a patient with chronic respiratory insufficiency (CRI), (ii) be familiar with the equipment used in the care, and (iii) understand the commonly encountered complications and their management.

Pathophysiology

In healthy people, respiration is maintained via a complex mechanism involving the alveolocapillary network, the diaphragm and intercostal musculature, and the central respiratory centers in the brainstem. Respiratory compromise results when one or more components of this mechanism are affected by disease. Chronic respiratory support may be a part of the management plan for children with a diversity of disease processes, including neurologic and neuromuscular disorders, central hypoventilation syndromes, obstructive apnea, congenital facial and airway anomalies, and others. Processes such as bronchopulmonary dysplasia once accounted for the majority of CRI (up to 65%); however, recent epidemiologic studies have demonstrated a shift in the proportion of CRI due to chronic lung disease. More recent trends indicate that congenital or perinatally acquired neurologic or neuromuscular diseases are now the leading indication for chronic ventilatory support (54% in a study by Graham et al) and chronic lung disease seems to be playing a significantly lesser role (7% in that same study). Survival and decannulation rates depend on the nature and severity of the underlying disease.

Equipment

The complexity of the many tubes and attachments extending from the patient's airway can be overwhelming, especially in the emergent situation. Familiarity with the equipment used in caring for a patient with a tracheostomy ensures the emergency physician's adept management of these situations. Starting from the patient's neck, each piece of equipment can be easily identified (Fig. 120.1).

Tracheostomy Tubes. Modern tracheostomy tubes are made of polyvinylchloride, a soft substance that conforms to the shape of the trachea, but is rigid enough to avoid collapse. Unlike their metal predecessors, they have little tissue reactivity, causing less tracheal wall irritation. Several manufacturers, under sterile conditions, package tracheostomy tubes for one-time use. Intensivists directing the long-term airway management of their patients may prefer one manufacturer to another, but the emergency physician does not need to know the minor differences among the products. The emergency physician should, however, know what types of tracheostomy tubes are stocked by the ED's facility and how to convert from the patient's brand and size to an available tube with suitable dimensions.

Three dimensions determine the size of a tracheostomy tube: the inner diameter, the outer diameter, and the length. The inner diameter refers to the same measurement used in describing the size of an endotracheal tube, ranging from 2.5 to 10 mm. This measurement is generally imprinted on the flanges of the tracheostomy tube and is standardized among manufacturers. The outer diameter and length are often not

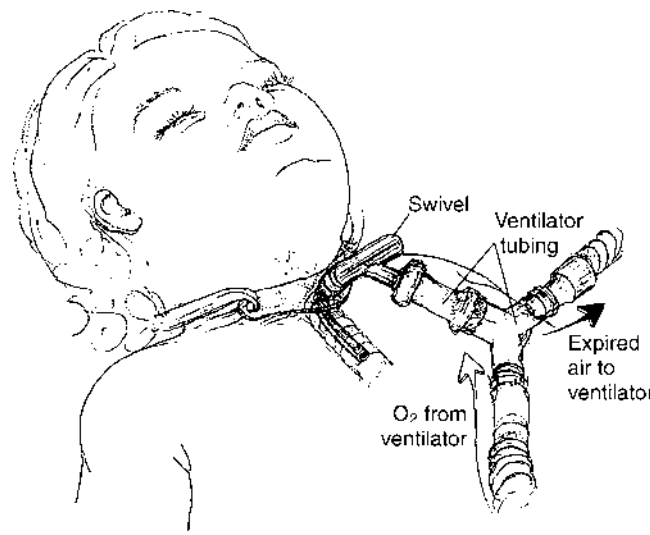

FIGURE 120.1 Tracheostomy parts.

identified on the tube and can vary considerably among manufacturers. The chart in Table 120.2 lists the dimensions of various tubes. When a tracheostomy tube change is indicated and an identical replacement is not available, this chart can be used in selecting the appropriate size tube of an available type.

A tracheostomy tube may be cuffed or uncuffed. An infant or young child may have a cuffed tracheostomy tube, especially if he or she has an airway anomaly or has developed tracheomegaly. Checking for the presence of a cuff in all patients and deflating it before removing the tube are important.

	5.5	5.5	8.0	52

Some tracheostomy tubes are fenestrated. The hole in the posterior aspect of the tube facilitates retrograde movement of air through the larynx, allowing vocalization. In addition, some tracheostomy tubes have an inner cannula that is positioned within the lumen of the tracheostomy tube (i.e., the outer cannula) so that it can be removed for cleaning while the airway is maintained by the outer cannula. Importantly, the proximal portion of the inner cannula is required to connect the tracheostomy to the manual resuscitator bag; therefore, the inner cannula must be in place when bag-valve ventilation is performed.

Swivel. A swivel is often attached to the end of the tracheostomy tube. Some unique characteristics of children make the swivel particularly useful. First, children have a natural inclination to move and explore. The swivel device accommodates movement in the ventilator-assisted child, so traction is not placed on the ventilator tubing or on the tracheostomy tube. Second, the short neck and bulky soft tissues of young children can obstruct the tracheostomy tube opening. The swivel provides additional length, so the tube opening extends beyond the soft tissues of the neck.

Heat–Moisture Exchanger. Air inspired directly into the trachea through a tracheostomy tube bypasses the important warming and humidification mechanisms provided by the natural upper airway. Therefore, a humidification system is an important component of the equipment used in a patient with a tracheostomy. A home ventilator setup includes a stationary humidification system that is used when the child is connected to the circuit. Similarly, a heat–moisture exchanger is attached to the end of the tracheostomy tube in patients who do not require the ventilator. The device is composed of a hydrophilic material that captures the patient's own heat and humidity on exhalation so that it can be inspired on inhalation. It should be placed between the tracheostomy tube and the manual resuscitator when prolonged bag-valve ventilation is performed.

Clinical Findings/Management

The approach to the ill patient with an artificial airway is the same as that for any patient who comes to the ED. The initial evaluation consists of a review of the patient's ABCDs (airway, breathing, circulation, and disability). Certainly, particular attention must be paid to the airway and breathing. An emergency physician who knows how to anticipate common problems and to recognize them early is able to institute appropriate therapy without delay.

Obstruction and Decannulation. The most life-threatening complication in a patient with an artificial airway is cannula obstruction or dislodgment. Younger children are more likely to experience accidental decannulation because of the short length of the trachea and tracheostomy tube. Some infant tubes are as short as 3 to 4 cm. In addition, the small lumen is more easily occluded by a mucous plug or by an accumulation of secretions. Infants with less developed intercostal muscles and children with neuromuscular disorders may be unable to generate an adequate cough to keep the airway clear of debris.

The presentation is similar to that of other children with respiratory compromise. The child may appear distressed with tachypnea, cyanosis, accessory muscle use, and/or nasal flaring. Alternatively, the child may be lethargic or obtunded as a result of prolonged respiratory effort or an elevated carbon dioxide level.

Any child with an artificial airway and respiratory distress is assumed to have an obstruction. The patient should be placed immediately on high-flow humidified oxygen. The physician should determine whether the tracheostomy tube appears to be in place, recognizing that a tube in the stoma does not necessarily indicate a tube in the trachea. If a cannula change was attempted before the child's arrival in the ED, a false passage into the paratracheal soft tissues may have occurred. Auscultation for the presence and symmetry of bilateral breath sounds should be performed and the quality of the patient's respiratory effort should be assessed. Immediate suctioning is appropriate in an attempt to assess tube patency and to clear the airway of secretions.

The physician should not hesitate to change the cannula. All the necessary equipment for the change should be present, including a replacement tracheostomy tube, an endotracheal tube one-half size smaller, and a bag-valve-mask ventilation circuit with oxygen flow, scissors, and tracheostomy ties. The change is best accomplished with the participation of two people; one secures the patient and removes the old tube, whereas the other inserts the new tube.

Infection. Bacterial colonization of the trachea usually occurs in a child with a tracheostomy. Common colonizing organisms include gram-positive cocci (*Staphylococcus aureus*, *S. epidermidis*, *Streptococcus pneumoniae*, α- and β-hemolytic streptococci), gram-negative bacilli (*Klebsiella*, *Pseudomonas*, *Escherichia coli*, *Serratia marcescens*, *Haemophilus influenzae*), and anaerobes (*Peptostreptococcus*, *Bacteroides*). These same organisms can become pathogenic, causing tracheitis or pneumonia.

A peristomal cellulitis can result from infection with skin flora. Good tracheostomy care and regular cleaning with dilute hydrogen peroxide solution can prevent most peristomal infections. Similarly, inadequate padding of the neck area beneath the tracheostomy ties can result in a contact or monilial dermatitis. Differentiating between bacterial colonization of the trachea and clinical infection can be difficult. The physician should elicit a history of any changes in the quantity, thickness, or odor of the tracheal secretions, and any systemic signs of infection or respiratory distress. Along with physical examination, there should be a determination of oxygenation by pulse oximetry. A Gram stain and bacterial culture, and a rapid viral detection assay of the tracheal secretions, may be helpful in determining the presence and cause of an infection. Leukocytosis in the tracheal secretions and a predominant organism by Gram stain may be suggestive of bacterial tracheitis; radiographic evidence of a new infiltrate indicates pneumonia.

If the child appears well and follow-up can be ensured, outpatient antibiotic therapy may be appropriate. For children with increased oxygen or ventilatory requirements, hospitalization should be considered for intravenous (IV) antibiotic therapy, aggressive pulmonary toilet, and close monitoring.

Erythema of the peristomal skin is usually caused by irritation and should be managed by increasing the frequency of the tracheostomy care at home. The additional findings of

warmth, tenderness, purulent drainage, or fever may suggest the presence of a peristomal cellulitis. Depending on its severity, this condition should be treated with oral or IV antibiotics.

The skin of the neck under the ties securing the tracheostomy tube can also become inflamed. Generally, this situation can be treated by increasing the amount of padding and by keeping the area dry. An erythematous rash with satellite lesions classic for a monilial dermatitis should be treated with topical antifungal creams.

Asthma. The incidence of asthma in children with chronic lung disease has increased. Many children are maintained at home on inhaled β-agonists and inhaled steroids therapy. The usual viral and environmental triggers, such as dust, pets, and smoke, precipitate exacerbations of asthma in these children.

The presentation is similar to that of other asthmatic patients, with varying amounts of respiratory distress, wheezing, and hypoxemia. As previously mentioned, the physician must consider the possibility of cannula obstruction or dislodgment in all cases. Treatment with oxygen, bronchodilators, and steroids should be initiated promptly. Emergency clinicians should recognize, however, that children with chronic lung disease have less pulmonary reserve. Chest radiography and arterial blood gas analysis should be performed as clinically indicated. Increased ventilatory support or continuous positive airway pressure may be required to overcome fatigue and atelectasis.

Bleeding and Granuloma. The tracheal mucosa located adjacent to the stoma, the cuff, and the distal tip of the tracheostomy tube is prone to bleeding or granuloma formation. The most common reason for bleeding is inadequate humidification causing drying and friability of the tracheal mucosa. Infection or granuloma formation can also result in small amounts of bleeding. Large amounts of blood coming from the tracheostomy tube opening can signify erosion of the tube into the brachiocephalic artery. The incidence of tracheoarterial fistula formation is rare (approximately 0.7%) but commonly results in death due to massive hemoptysis and blood loss. The risk for development of this life-threatening complication is highest during the postoperative period (i.e., within 4 weeks of tube placement); it occurs with a similar incidence in patients with chronic ventilatory support.

Small amounts of bleeding from the tracheal stoma usually resolve with increased humidification of the inspired air. The persistence of minor bleeding might indicate an intratracheal granuloma, which should be evaluated by direct visualization. This procedure is best performed by an otorhinolaryngologist.

A large amount of bleeding is a surgical emergency. IV access should be obtained immediately and volume replacement should be initiated. The tracheostomy tube should not be removed because it may be the best way to ensure an airway. Frequent suctioning aids in preventing aspiration. If the site of bleeding can be identified, direct pressure should be applied to the area. Overinflating the cuff may tamponade a bleeding vessel and provide a temporary treatment until it can be ligated.

Peristomal granulomas can usually be treated with topical antibiotics. In refractory cases, cauterization with silver nitrate is indicated.

Cerebrospinal Fluid Shunts

Background

CSF shunt placement is the most common neurosurgical procedure performed in children. More than 4,400 CSF shunts were placed in 2003; that same year, CSF shunt-realted problems accounted for almost 15,000 hospital admissions and almost $300 million were charged for shunts malfunctions. CSF shunts are placed to divert CSF from the brain to another area of the body, most commonly the peritoneal cavity. The clinician evaluating a child with a CSF shunt should be aware of associated complications such as infection, obstruction, and overdrainage because certain complications can be disastrous if unrecognized and untreated. However, children with CSF shunts may often exhibit symptoms of their chronic illnesses that are unrelated to shunt malfunction.

Pathophysiology

CSF is an ultrafiltrate of plasma produced at a rate of 500 mL per day in a 70-kg adult and proportionally less in children and infants. The fluid is mainly produced by the choroid plexus and various extrachoroidal sites within the brain. CSF travels from the lateral ventricles into the third ventricle through the foramen of Monro and then again through the aqueduct of Sylvius to the fourth ventricle. The CSF then enters the subarachnoid space via the foramina of Luschka and Magendie and travels through the brain and spinal canal. CSF is reabsorbed and enters the venous system through the "one-way valves" of arachnoid villi that penetrate the dura.

Hydrocephalus can result from oversecretion, impaired absorption, or blockage of CSF pathways. *Oversecretion* can occur in some choroid plexus tumors. *Impaired absorption* can occur as a result of increased CSF protein, often a result of perinatal hemorrhage or meningitis or less commonly etiologies such as subarachnoid hemorrhage, or Guillain-Barré syndrome. Severe congestive heart failure or any other condition that raises venous pressure may impair CSF absorption as well. Impaired absorption is the cause of communicating hydrocephalus, in which flow from the lateral ventricles to the foramina of Luschka and Magendie is not obstructed. *Blockage of CSF pathways* is the most common cause of hydrocephalus in children and is often located at the narrow aqueduct of Sylvius proximal to the fourth ventricle and is referred to commonly as aqueductal stenosis. Conditions that can cause obstruction are intraventricular bleeding or scarring, tumors, or congenital malformations. Dandy-Walker cysts cause obstruction of the foramina of Luschka and Magendie and therefore may result in enlargement of all four ventricles.

Equipment

Different types of CSF shunts, which vary mostly by the location of the distal tubing and the type of reservoir or valve system, are available. The choice of CSF shunt type and the method of placement (endoscopically or nonendoscopically) depend on the individual patient's anatomy and cause of hydrocephalus and the experiences and preferences of the neurosurgeon performing the procedure. Commonly, the patient or caregiver knows the location and type of shunt and is able to provide details regarding prior shunt placement and problems. Palpation of the hardware and plain radiographs may be used

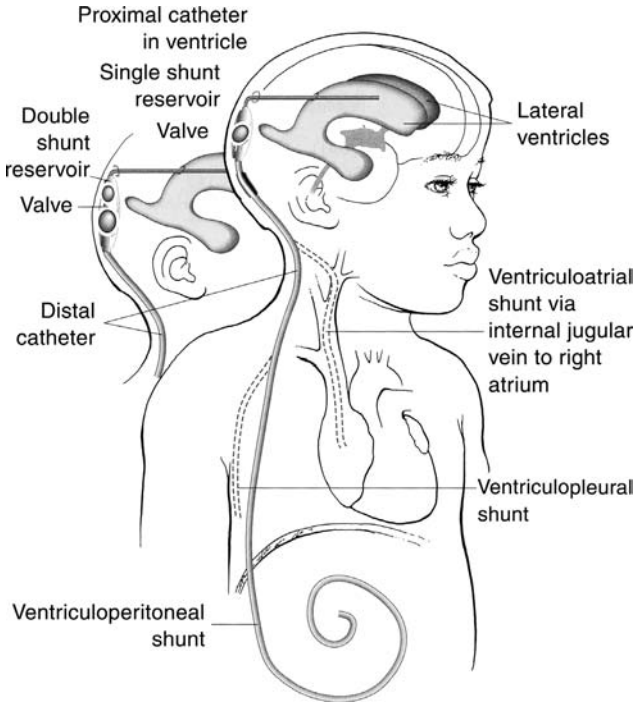

FIGURE 120.2 Diagram of typical ventriculoperitoneal shunt.

to acquire more information regarding the specific location of the shunt components. Most CSF shunts have the following three components: (i) proximal shunt tubing, (ii) reservoir system, and (iii) distal shunt tubing (Fig. 120.2). Occasionally, the system will not contain a reservoir and only the one-way valve can be palpated and noted on cranial radiograph.

The *proximal shunt tubing* has a fenestrated tip that is usually located in the ventricle but may also be located inside a noncommunicating cyst or in the lumbar subarachnoid space. This tip allows free passage of CSF into the shunt system. More than one proximal catheter may be present if multiple, noncommunicating areas of the brain require shunting. The *reservoir system* consists of one or two "domes" or "bubbles." Reservoirs may be placed directly over or slightly distal to the burr hole. This information is crucial when emergent access to the burr hole is needed. The *distal shunt tubing* leads from the reservoir unit to a part of the body that can accept the drained CSF, usually the peritoneum. The distal tubing may also be located in the vascular system or pleural cavity. Ventricular–atrial shunts are less commonly inserted because of the serious infectious complications that have occurred with these types of shunts but are often necessary due to severe scarring in the peritoneum from prior peritonitis either from a CSF infection or from unrelated causes. All modern shunt tubing is made of 1/8-in diameter Silastic elastomer, which causes minimal omental reaction and is resistant to cracking.

CSF shunt systems contain a one-way valve to prevent backflow of CSF into the ventricles. These valves are designed to operate at high, medium, or low pressure. Externally programmable valves, which can vary the opening pressure setting, are also available but are less commonly used in the pediatric population when compared with adults. An antisiphon device may be inserted into the distal portion of the system to prevent overdrainage of CSF and concomitant low-pressure complications.

Clinical Findings/Management

Mechanical Malfunction. Malfunction of a CSF shunt can be caused by the obstruction of the catheter lumen or disconnection of the various components. The proximal catheter lumen is usually obstructed by choroid plexus, but floating debris or hypercellular CSF can result in the same obstruction; the distal catheter can be obstructed by the surrounding omentum or can be kinked or coiled awkwardly impeding smooth drainage. Both proximal and distal portions can be occluded by the products of infection or by migration of the catheter tip into the brain parenchyma or intraabdominal structures. Particularly in neonates, poor absorption of excess fluid in the peritoneum due to decreased surface area can create the appearance of luminal obstruction. In addition, as the child grows, the tension on the shunt system can lead to disconnection of the distal tubing.

Up to 60% of patients with CSF shunts experience a shunt malfunction in their lifetime, most commonly within the first 6 months and half within 2 years of initial shunt placement. Parental history is paramount in deciding whether a child is experiencing symptoms of shunt malfunction. The parent often notices that the child "just isn't acting right" or is less active or thinking less clearly than usual. The statement, "This is exactly how he acted the last time his shunt was obstructed," is suggestive of another malfunction, regardless of the presence or absence of the symptoms listed in the following section.

Common signs and symptoms of mechanical shunt failure include headache, visual disturbances, vomiting, lethargy, and irritability (Table 120.3). The astute parent or clinician may note mild ataxia, increased head circumference or bulging fontanel in an infant, swelling at the reservoir site, poor cognition, or abnormal behaviors. A classic sign is "sunsetting

TABLE 120.3

CONCERNING FINDINGS IN PATIENTS IN CEREBROSPINAL FLUID SHUNT MALFUNCTION

Symptoms
Fever
Headache
Altered mental status
- Irritability
- Lethargy/difficult arousal
- Confusion

Vomiting
Visual disturbances
Seizures (rare to be the only manifestation)

Signs
Papilledema
Bulging fontanel/enlarged head
Engorged head veins
Macewen's sign (cracked pot sound during percussion)
Abnormal neurologic examination
- Increased deep tendon reflexes or lower-extremity tone
- Positive Babinski's sign
- Cranial nerve palsy—lateral (sixth) or upward (fourth) gaze (sunsetting)
- Respiratory compromise

eyes," which is really an upgaze paresis and eyelid retraction associated with Parinaud's syndrome from pressure on the quadregeminal plate by a dilated suprapineal recess in direct communication with the third ventricle. Increased tone, hyperreflexia, or Babinski's reflex represents stretching and disruption of the corticospinal fibers originating from the motor cortex and can suggest shunt malfunction in a patient with a previously normal examination, although these symptoms are rarely present in a child without a severe alteration of consciousness and thus add little to the diagnosis. Patients with true, raised intracranial pressure (ICP), as manifest through Cushing's triad (hypertension, bradycardia, and abnormal respiratory pattern), require immediate maneuvers to decrease ICP and guide them quickly toward operative repair of the shunt. Seizures are uncommon as the sole manifestation of CSF shunt malfunction. However, seizures can occur in children who have predisposing brain lesions, and many patients with CSF shunts have epilepsy. Shunt infection must be considered in the child with symptoms of shunt malfunction, especially if the child has a history of recent shunt revision. Ronan et al reported that more than one-third of patients with shunt infection presented with symptoms of malfunction.

If the history and physical examination of the ill child with a CSF shunt suggest a possible shunt malfunction, further evaluation includes a noncontrast computed tomographic (CT) scan with comparison to the most recent prior study, if available. A plain radiograph of the skull, chest, and abdomen ("shunt series") is helpful both in assessing the integrity of the shunt connection and in identifying the components of the working system. The clinical suspicion of a shunt malfunction based on a history and physical examination may outweigh the data obtained from radiographic studies.

Much discussion and controversy surround the clinician's ability to assess CSF shunt function by "pumping" the shunt reservoirs. In a single reservoir system, this procedure involves depressing the reservoir bubble. Resistance to depression suggests distal catheter malfunction. Poor filling suggests either proximal catheter malfunction or small ventricles. The maneuver in a double-bubble shunt requires the initial depression of the proximal bubble, depression of the distal bubble to check for resistance, and subsequent release of the proximal bubble to check for poor filling. Pumping the shunt to test for obstruction is not always reliable. Piatt found that this maneuver had a positive predictive value of 21% and a negative predictive value of 78% in patients for whom the diagnosis of shunt patency or malfunction was definite. In addition, pumping of the shunt can cause entrapment of choroid plexus in the proximal shunt tubing and lead to proximal catheter obstruction where none previously existed.

If subsequent evaluation is still necessary to diagnose malfunction, a neurosurgeon should be consulted. It may be necessary to "tap" the shunt (Fig. 120.3). The patient's hair is either shaved or trimmed. The scalp is cleansed first with alcohol and then with three applications of Betadine® that are allowed to dry after each application. The shunt tap is performed by inserting a 23- or 25-gauge butterfly obliquely into the reservoir and holding the butterfly tubing perpendicular to the floor. The height that the CSF rises into the butterfly tubing, measured in centimeters, is the ICP. Normal pressure is between 5 and 10 cm; pressure of more than 20 cm is indicative of distal shunt malfunction requiring urgent revision. Slow

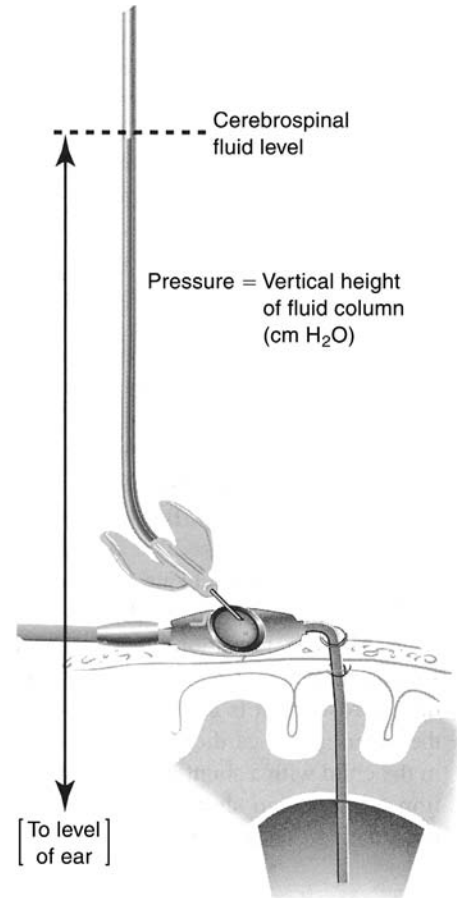

FIGURE 120.3 Tapping the cerebrospinal fluid shunt.

or absent flow from the proximal reservoir (especially with occlusion of the distal reservoir of a double-reservoir shunt) is highly predictive proximal shunt obstruction. In this case, the physician may notice that the reservoir collapses when gentle suction is applied to the butterfly with a syringe. It is important to avoid further suctioning of this reservoir because this could lead to aspiration of debris into the proximal catheter, causing a blockage where one did not previously exist. Poor flow during the shunt tap can also indicate slit ventricles and is therefore rarely the only data required to commit a patient to an operative shunt revision.

The shunt tap can be therapeutic and diagnostic. The child with a distal shunt obstruction or partial proximal obstruction may be eligible for urgent, rather than emergent, shunt revision if symptoms of increased ICP are alleviated after the tap. However, removal of too much fluid should be avoided because abrupt fluid shifts within the cranial vault can lead to disruption of subdural vessels. It is prudent to remove just enough fluid to decrease the ICP below 20 cm and repeat the procedure if symptoms return before definitive surgical management.

The child with complete obstruction of the proximal catheter does not obtain relief of symptoms after a shunt tap because the obstruction prevents adequate aspiration of fluid from the ventricles. These children usually respond temporarily to medical management that decreases their ICP; however, it should be stressed that restoration of shunt integrity and function is the permanent treatment of shunt obstruction. This

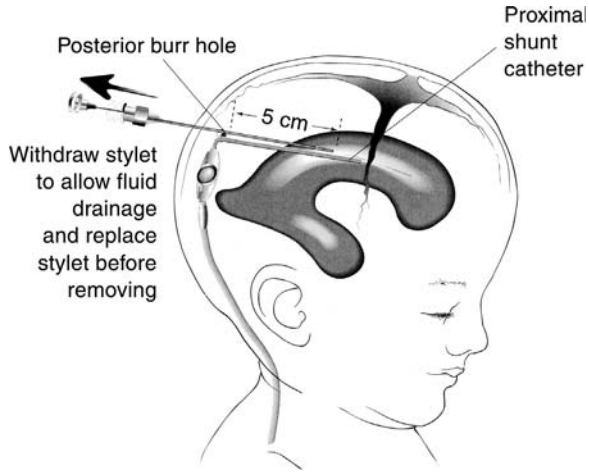

FIGURE 120.4 Burr-hole puncture.

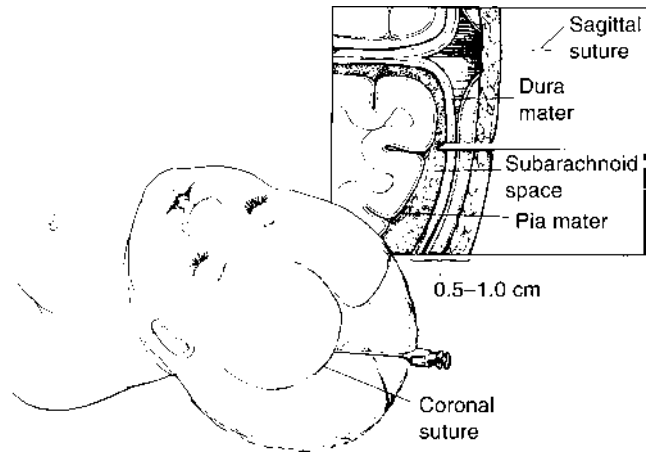

FIGURE 120.5 Ventricular tap through open fontanel.

treatment includes the administration of acetazolamide (Diamox®) 30 to 80 mg per kg per day and Decadron® 1 mg per kg per day and hyperventilation in the unstable patient. If the child is experiencing life-threatening symptoms from proximal obstruction, is unable to undergo immediate surgical repair, and is unresponsive to medical management, a burr-hole puncture procedure may be performed (Fig. 120.4) only in dire circumstances, as the procedure has attendant life-threatening risks such as disruption of intraparenchymal vessels and tissue. By nature of the procedure itself, the proximal shunt catheter is torn and urgent revision is therefore mandatory. The burr hole is best identified by direct palpation and confirmation with the skull radiographs. For example, a Rickham reservoir is located directly over the burr hole, whereas standard shunt valve/reservoir systems are usually, although not always. A 3½-in spinal needle is inserted perpendicular to the skull through the burr hole to a depth of no more than 5 cm. After the stylet is removed, fluid should drain spontaneously and should be allowed to do so until flow slows down. The patient's condition should stabilize sufficiently for transport to an operating suite or tertiary care institution.

Another method of temporarily relieving a lumen obstruction is to flush a small amount of sterile saline through the clogged tubing in an attempt to dislodge the obstruction. This method can be used for distal or proximal obstructions, with the caveat that instilling a few more milliliters into the ventricles may in fact worsen the patient's condition. In this procedure, the double-bubble reservoir that is not being used must be compressed to allow the fluid to go in only one direction.

In an infant with an open fontanel, the physician can aspirate fluid through a direct ventricular puncture (Fig. 120.5). This procedure carries as great if not greater risk of parenchymal injury as the burr-hole puncture procedure and likewise should be performed only when prompt surgery is impossible.

Infection. The reported incidence of CSF shunt infections ranges between 5% and 10% and depends on the center performing the study and the criteria used to define infection. The majority of infections are perioperative in nature. More recent advances, such as allowing fewer operating room personnel, soaking the shunt in antibiotics before insertion, and the administering prophylactic antibiotics have reduced the rate of infection. Infections generally occur within 2 months of shunt placement, with a higher incidence of infections in children younger than 4 years. Other risk factors include insertion of the shunt into a premature infant and insertion after a previous infection. The common organisms cultured from infected CSF shunts are gram-positive bacteria (Table 120.4). Staphylococci adhere well to Silastic® tubing, and these infections are often difficult to eradicate without removal of the catheter. Infections with *S. epidermidis* and *S. aureus* are common within the first few weeks after surgery. Infections that occur more than 6 months after shunt placement are more likely due to gram-negative infections such as *H. influenzae* infection, bowel erosion, or pressure necrosis from the shunt apparatus. Fungi are rare pathogens occasionally seen in premature infants.

External infection of skin and subcutaneous tissue overlying the shunt hardware can occur; however, these superficial infections may not lead to shunt infection if treated promptly. Necrosis of the area around the reservoir can occur as a result of the constant pressure in infants or nonambulatory patients. Skin breakdown leading to visualization of the shunt mechanism is, by definition, a shunt infection and must be treated accordingly.

The peritoneal portion of the shunt may become infected through the shunt mechanism or via a primary peritoneal infection. Peritoneal infection can result in loculated, cystic pools of infection around the terminal portion of tubing (pseudocysts). These infections may be indolent in their presentation, and the shunt tap from the reservoir may not show evidence of infection.

Shunt nephritis is a rare but serious complication of ventricular–atrial shunts. Renal deposition of antigen–antibody

TABLE 120.4

COMMON ORGANISMS INVOLVED IN CEREBROSPINAL FLUID SHUNT INFECTIONS

Gram positive	Gram negative
Coagulase-negative staphylococci (*Staphylococcus epidermidis*)	*Escherichia coli*
Staphylococcus aureus	*Enterococcus* species
Streptococcus species	*Haemophilus influenzae*

TABLE 120.5

SIGNS AND SYMPTOMS OF SHUNT INFECTION IN PATIENTS WITHOUT WOUND INFECTION

Change in sensorium	Shunt malfunction
Fever	Vomiting
Irritability	Abdominal pain

complexes leads to complement activation, which damages the renal tissue.

Unfortunately, the child with an infected CSF shunt may present with nonspecific signs and symptoms (Table 120.5). Children commonly develop symptoms of shunt malfunction, such as lethargy or irritability. Meningismus is not often present. Infection may also manifest as abdominal complaints, such as pain or vomiting, especially when the infection involves the distal catheter tip.

Fever is not always present in patients with shunt infections and is uncommonly the only sign. As previously mentioned, infection is most common within a few months of the shunting procedure, is uncommon after 6 months, and is rare more than 1 year afterward. These rules are less applicable in patients with gram-negative infections, which can occur later after shunt placement. Children with gram-negative infections are more often bacteremic, if not septic appearing.

A wound infection overlying any portion of the shunt mechanism can manifest as erythema and tenderness or swelling along the shunt tract or over the reservoir. A reddened tract of skin paralleling the shunt tubing from the head to chest is often detected and is virtually diagnostic of shunt infection.

In the absence of overlying infection, aspiration of a small amount of CSF from the shunt system should be performed to identify the presence of a bacteriologic cause of shunt infection. This procedure is usually performed by a neurosurgeon, if possible. The results of this procedure are sometimes helpful but not always determinate: the white blood cell (WBC) count can range from 0 to 2,600 if the shunt is infected, and patients without infection can have up to 500 WBCs per mm^3. In the absence of a positive culture result, many clinicians use more than 50 WBCs per mm^3 in the presence of fever, shunt malfunction, and neurological or abdominal symptoms to arrive at the diagnosis. Gram stain of the fluid may be helpful in broadening antibiotic coverage if gram-negative organisms are present. However, the Gram stain should not be used to narrow the usual antibiotic coverage until the culture and sensitivities of the causative organisms are obtained. Most neurosurgeons are reluctant to perform shunt taps in patients with subtle neurologic complaints and vague infectious signs because of the purported risk of "seeding" the shunt with skin flora. This risk has never been clearly defined prospectively, but in a neurologically normal child, it is prudent to perform a thorough fever workup for common infectious sources to avoid even a small risk of causing a shunt infection.

Patients with ventriculoperitoneal shunt (VPS) who complain of abdominal pain, with or without fever, may benefit from abdominal radiographs and ultrasound to search for a loculated CSF collection or pseudocyst, or visceral perforation.

Various permutations of medical and surgical therapy have been suggested for the treatment of proximal CSF shunt infections. Medical therapy alone has been found to have a relatively low success rate compared with a combined medical–surgical approach. Potential surgical interventions include immediate shunt replacement or the insertion of an extraventricular drainage (EVD) catheter, followed by delayed shunt revision. The latter method improves the bacteriologic cure rate significantly, although it must be performed in an institution that is facile in managing and preventing infection of EVD catheters. Distal shunt infections are treated with antibiotics and temporary externalization of the distal shunt catheter.

Medical therapy provided in the ED for children with suspected CSF shunt infections is limited to the administration of broad-spectrum IV antibiotics. The antibiotics should be effective against *S. epidermidis*, *S. aureus*, and gram-negative organisms, as well as any organisms identified from previous infections. A reasonable choice of empiric therapy is vancomycin and cefotaxime. Therapy can be expanded to treat *Pseudomonas aeruginosa* infections in severely ill patients or those who are unresponsive to initial therapy. Eventually, antibiotic therapy may be narrowed on the basis of culture results of the shunt fluid. In patients with gram-negative or fungal infections, intrathecal antibiotics may be used; however, this procedure is not considered appropriate in an ED setting.

Overdrainage. Occasionally, children with CSF shunts experience symptoms related to the system working too well, resulting in low ICP. "Overshunting" is more common in infants who have had initial shunting before 6 months of age. One consequence is the slit ventricle syndrome, in which the ventricles collapse around the proximal catheter port and block further drainage. The best means of diagnosing intracranial hypotension is the patient's history rather than physical examination or radiographic analysis. Young infants may exhibit sunken fontanels, microcephaly, or overriding parietal bones. Older children may exhibit intermittent symptoms of headache, nausea, vomiting, and lethargy. The drainage of CSF shunts increases when the patient is upright and decreases when supine. In contrast to the classic timing of symptoms related to increased ICP, patients with intracranial hypotension are often worse when in the standing position or after they are awake for several hours. Lying supine for a few hours tends to relieve symptoms of slit ventricle syndrome. Many patients with CSF shunts have CT scans that reveal small ventricles; however, only a small proportion of these patients have slit ventricle syndrome. Therefore, the CT scan is best used to differentiate between shunt malfunction and other causes of symptoms rather than to diagnose an overdrainage problem.

Chronic or recurrent episodes of slit ventricle syndrome can be addressed surgically by upgrading the resistance of the valve or by insertion of an antisiphon device. Oral analgesics may be helpful in managing mild cases.

Other Complications. Numerous other complications related to CSF shunts deserve mention. The most common of these complications is a benign postoperative leakage of CSF around the proximal shunt tubing into the subgaleal space around the reservoir. The resulting extracranial fluid collection resolves spontaneously, so drainage of this fluid should be avoided. In nonpostoperative patients, a new extracranial fluid collection

can suggest shunt malfunction, as the CSF takes the newest "path of least resistance."

Patients with CSF shunts have an increased risk of seizures compared with the general population. These seizures often begin years after shunt placement and are caused by epileptogenic scars. They are more common in patients with other abnormalities correlated with seizures, such as porencephalic cyst or intracranial hemorrhage.

Overdrainage can lead to shrinkage of brain tissue and concomitant subdural accumulations (hematomas or CSF effusions referred to as hygromas). Similarly, a decreased rate of head growth because of overdrainage can result in craniosynostosis in the infant.

Some important, albeit rare, complications are related to specific types of CSF shunts. The distal portions of a VPS can migrate and cause perforation of the colon or genital tract. This section of tubing can act as a fulcrum for intestinal volvulus. Ascites and abdominal cysts can form as a result of drainage of excess fluid into the peritoneum. Increased intraabdominal pressure can precipitate the formation of an inguinal hernia through a patent processus vaginalis.

Ventricular–vascular shunts can be associated with an increased risk of bacteremia. Shunt nephritis can result from complement activation and renal deposition of bacteria. Patients with ventriculoatrial shunts can experience cardiac arrhythmias or atrial perforation, usually perioperatively. Bacterial endocarditis, cardiac foreign body, and mural thrombus are rare but notable complications of vascular shunts.

After ventriculoatrial shunt, the pleural cavity is the third most common site for distal catheter placement. These can lead to pleural effusions and related complications. Often, they are placed temporarily to allow "bowel rest" after peritonitis but then revised to a standard VPS when the infectious peritoneal issues have resolved.

Avoiding Pitfalls with New Endoscopic Technology. Neurosurgeons are increasingly using endoscopic techniques in the management of pediatric hydrocephalus, particularly in obstructive hydrocephalus and the treatment of intracranial cysts. Children who have previously been shunt dependent may undergo endoscopic third ventriculostomy (ETV), which is effectively an "internal shunt" that bypasses a stenosed aqueduct of Sylvius. Parents and emergency clinicians should be cognizant that these children are still subject to the same manifestations of shunt failure; the presence of appropriate signs and symptoms of raised ICP should initiate the same evaluation and criteria for possible intervention outlined earlier in this section. It should be noted that while not subject to the myriad malfunctions that befall patients with implanted hardware such as infection, erosion, disconnection, and clogging, patients with ETVs can suffer restenosis of their fenestration site, with reports of closure as late as 8 years after the initial procedure.

Indwelling Venous Access Devices

Background

In 1973, Broviac designed the first Silastic tunneled central venous catheter (CVC). These devices provide children with relatively permanent and secure venous access during chemotherapy, total parenteral nutrition, or prolonged IV antibiotic therapy. Pediatricians, family practitioners, and emergency physicians have increasingly been called on to access and assess these catheters. Clinicians must be familiar with the procedures for establishing patency, drawing blood, dealing with catheter occlusion or breakage, and assessing for infection. In 1983, the first totally implanted central venous access device, often referred to as a chest port, was developed and introduced.

Pathophysiology

The distal tip of tunneled venous catheters is located at the junction of the right atrium and the superior vena cava. The site of venous entry is usually the subclavian or internal jugular vein; however, access is occasionally obtained through the external jugular, cephalic, and brachiocephalic veins. The catheter is tunneled under the skin to a site in the chest away from the venous entry site and then either externalized or connected to a subcutaneous reservoir.

Equipment

Tunneled CVCs come in various types, such as Broviac, Hickman, Leonard, Raaf, Hermed, Groshong, and Corcath (Fig. 120.6). These catheters are made of Silastic elastomers

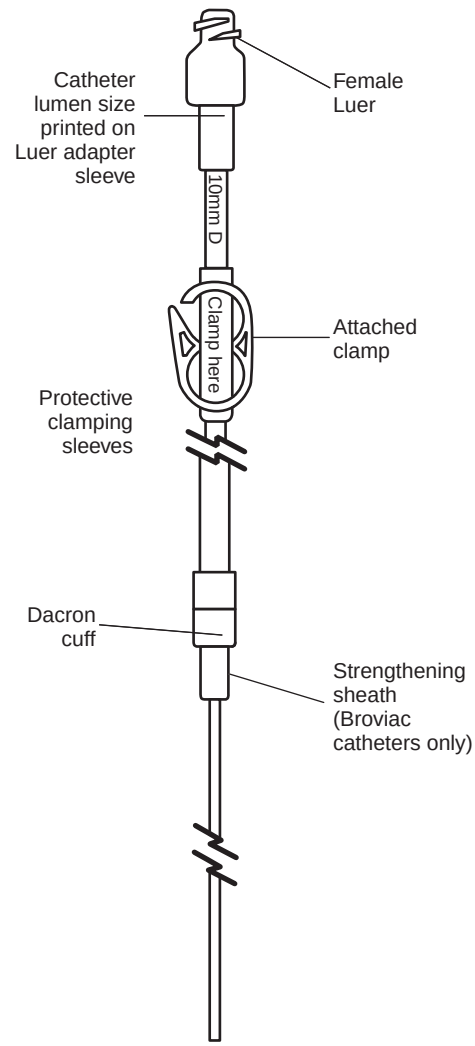

FIGURE 120.6 Partially implantable ("tunneled") venous catheter.

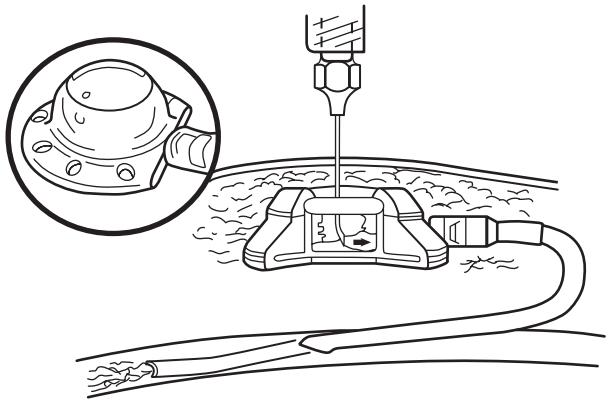

FIGURE 120.7 Totally implantable venous access device.

and are tunneled under the skin a few centimeters before externalization. A Dacron® cuff, located around the catheter, anchors the catheter after it stimulates fibrosis of the surrounding tissue. This also serves to inhibit migration of bacteria into the catheter tract. The most proximal portion of the catheter contains a female Luer lock tip, which is usually covered with a removable needleless cap, allowing a direct and solid connection to most syringes and IV tubing. A clamp is present just before this tip, under which a reinforced sleeve protects against catheter breakage. The catheters can vary in length, diameter, and numbers of lumen and access ports. The Groshong-type catheter is valved at the distal tip to keep blood out of the lumen and therefore requires only saline flushes and does not require clamping. A kit is available that contains the equipment necessary to repair broken external catheters (Invacare, Inc, Holliston, MA).

Totally implantable venous access devices (Infusaport, Port-A-Cath) are *internalized* under the skin (Fig. 120.7). Like the tunneled CVCs, they use a Silastic catheter with the distal tip located in the distal SVC. However, the proximal end is tunneled and connected to a subcutaneous reservoir chamber, which is implanted in a pocket under the skin. The reservoir has a self-sealing silicone septum and a hard metal or plastic back surface, with suture holes to secure it to the muscle wall. The chamber is accessed by inserting a tapered 20- or 22-gauge Huber noncoring needle through the skin over the port. The noncoring needle is angled at 90 degrees for ease of insertion and stabilization. If emergency access is required, a straight needle can be used, although this may core a portion of the device's septum.

Specific equipment is available for accessing tunneled and totally implanted indwelling CVCs (Table 120.6). The medical office or ED that occasionally sees these children should have a prepared kit containing these items at hand.

Procedures that can be accomplished by the generalist or ED personnel include establishing access, performing phlebotomy, and infusing fluids or medications. The general procedure for establishing access and patency is similar for both tunneled and totally implanted devices (Table 120.7). Aseptic technique is mandatory. Because tincture of iodine solution can damage Silastic catheters, 2% chlorhexidine gluconate or povidone-iodine solution is used to clean the site. Recent studies have demonstrated lower bloodstream infection rates with the use of 2% tincture of chlorhexidine. Clamps or hemostats with teeth can also damage the external portion of the catheter. In addition, smaller (less than 3 mL) syringes can generate too much pressure inside the catheter, causing catheter breakage. Therefore, 5- or 10-mL syringes are recommended to flush the system; never force flush against resistance. Fluid or medications should never be infused until patency is established because the risk of administering these solutions into a nonvascular space is high. To prevent air emboli from occurring, all clamps must remain closed when any part of the circuit is open. For accurate blood test results, the amount of blood that needs to be withdrawn unused is 3 mL from a tunneled CVC and 5 mL from a totally implanted CVC. Recent literature has demonstrated that compared with heparin, tissue-type plasminogen activator (tPA) is more successful in reducing the chances of clot formation in central venous hemodialysis catheter. However, further research on other types of catheters and cost analyses remain to be performed to determine if tPA should replace heparin in this regard.

When a tunneled CVC is accessed, these steps should be followed:

1. Before accessing the system, prime the intended IV circuit, including connection tubing, with saline to remove air. Clamp the IV tubing closed.
2. Clamp any external portions of central catheter on the protected area near the hub.

TABLE 120.6

EQUIPMENT NEEDED TO ACCESS CENTRAL VENOUS CATHETERS

Clamp or hemostat *without* teeth, possibly with rubber tips	Povidone-iodine ointment
T-extension tubing with clamp	Alcohol swabs
10-mL syringe of normal saline	Sterile drapes and gloves
10-mL syringe of heparin 100 U/mL	Dressing gauze and tape
(4) Injection caps	Tegaderm sterile dressing
Povidone-iodine solution with sterile gauze	(2) Tapered Huber noncoring needles, 20- and 22-gauge

TABLE 120.7

TIPS FOR THE ROUTINE USE OF INDWELLING VENOUS ACCESS DEVICES

- Aseptic technique
- Do not use
  - Clamps or hemostats with teeth
  - Tincture of iodine solution
  - Small (≤3 mL) syringes
- Flush entire intravenous circuit before accessing system
- Always close clamps when any part of the circuit is open
- Do not infuse fluids or medications until patency is established
- Flush the catheter with 10 mL of saline between medications
- Flush cap or reservoir with heparin when procedure is complete

3. Clean the cap on the end of the system with alcohol, povidone-iodine, or chlorhexidine and allow the solution to dry.
4. Flush the system with 3 to 5 mL of saline in a 5- to 10-mL syringe and then aspirate 3 to 5 mL of blood to check patency; do not use this as a blood sample—discard. Absence of blood return may indicate the formation of fibrin sheath on internal catheter tip or malpositioning of the tip. If no blood return, consider a dye study and do not use the catheter for vesicant infusion.
5. Draw off blood needed for laboratory analysis and administer medications or fluids as needed. Flush again with saline and then either flush the device with heparin or connect the IV tubing to the needleless cap using Luer lock connections.
6. If the catheter is to be heparin locked, clamp the line prior to removal of the flush syringe; this maneuver is not necessary for the saline-flushed Groshong device.
7. If the needleless cap is removed, discard the old needleless cap and replace it with a new one using sterile technique.

The procedure differs slightly when accessing a totally implanted CVC or port. Because intact skin is penetrated, the use of a topical anesthetic cream before access should be considered when feasible. After leaving the topical anesthetic on for the manufacturer's recommended time, it should be wiped off and the skin should be cleansed with 2% chlorhexidine gluconate, alcohol, or povidone-iodine. Povidone-iodine should not be cleaned off with alcohol. Using sterile technique, a Huber needle should be inserted through the skin directly into the reservoir diaphragm and stopped when resistance is met at the back of the reservoir. The needle should be secured in place and patency should be established with aspiration and flushing. After use, the totally implanted device must be flushed using 3 to 5 mL of heparin (10 units per mL) or similar solution. When the port is not being used, patency is maintained with 3 to 5 mL of 100 units per mL flush on a monthly basis.

Complications resulting from accessing CVCs include occlusion, air embolus, catheter breakage or displacement, and infection. Although most of these complications can be avoided if care is taken to maintain aseptic technique, the clinician should be aware of their diagnosis and management.

Clinical Findings/Management

Catheter Occlusion. Difficulty drawing blood or infusing fluid through a CVC can be the result of catheter malposition or occlusion. The catheter may be positioned against a vessel wall, or fibrin or blood may clot in the lumen. In addition, various precipitates can occlude the lumen of the catheter. Waxy precipitates can result when parenteral nutrition solutions contain combinations of fat, protein, and carbohydrate, and particulate precipitates can result from the poor solubility of calcium and phosphorus. IV phenytoin (especially when administered in a glucose-containing solution) and diazepam can also get precipitated.

Children who require IV medications or fluids at home may present for short-term management of catheter occlusions. The problem is often noted only when the acute care nurse or physician cannot access the catheter during the evaluation of another problem.

Increasing the venous pressure gradient along the catheter can facilitate phlebotomy. These maneuvers include having the patient hold his or her arms above the head, cough or perform Valsalva maneuver, and placing the patient in reverse Trendelenburg position. If blood still cannot be drawn, 3 mL of saline should be used to gently irrigate the clot and aspirate it into the syringe. Two to 3 mL of fluid should be forced back and forth to avoid pushing the clot into the venous system. A number of complications can result from this maneuver. The pressure can force the clot into the bloodstream or rupture the catheter, particularly if the practitioner uses too much force or too small a syringe. Care should be taken to observe the catheter for a balloon "aneurysm," a sign of impending rupture.

Totally implanted systems are much less likely to clot than are tunneled catheters. This situation is fortunate because irrigating the clot is admittedly more difficult, if not impossible, to perform on a totally implanted system.

Specific agents may help dissolve precipitates or clots. For waxy precipitates, 70% ethanol should be used. For particulate precipitates, 0.1N hydrochloric acid (HCl) or 8.4% sodium bicarbonate should be used depending on the pH of the drugs/solutions infusing prior to the precipate formation. Fibrinolytic agents such as urokinase (0.5 to 1 mL of a 5,000 units per mL solution) or tPA (up to 2 mg, dependent on catheter size) may dissolve a blood clot, and similar to HCl, may be used up to three times if necessary. Ethanol should be used only one time per episode. Urokinase infusions may be started at the suggestion of the surgical or interventional radiology consultants, who should be involved in the treatment plan if initial attempts are unsuccessful.

Air Embolism. Failure to maintain a closed system during manipulation of indwelling venous catheters can result in embolism of air into the chambers of the heart. Passage of the embolus to the systemic or pulmonary circulation can result in severe and irreversible tissue damage.

Air embolus can cause a patient to experience sudden onset of tachypnea, tachycardia, hypotension, or loss of consciousness. Other diagnoses that should be considered in patients with these symptoms are pneumothorax, liberation of septic emboli, and direct cardiac insult. If an air embolus is suspected, the patient should be placed in the left-sided Trendelenburg position and oxygen should be administered. In addition, the indwelling catheter should be clamped and remain unused as other peripheral access is obtained.

Catheter Breakage. The family members and physicians caring for the child with a tunneled catheter may have considered the nightmare of catheter breakage and subsequent exsanguination. Although catheter breakage is a distinct possibility, most events occur during routine care rather during playtime and therefore the blood loss is easily apparent and correctable. A tunneled catheter can acquire a small hole from inadvertent needle puncture or even ordinary wear and tear. Totally implanted catheters, in contrast, are less susceptible to local events or wear and tear. However, trauma to the area can result in detachment of the proximal portion of the catheter from the implanted port.

Leakage of blood or fluid from the externalized portion of a tunneled catheter is easily noticed. Externalized catheters must be immediately clamped proximal to the break, cleaned with povidone-iodine solution, and covered with sterile dressing until repaired. Repair kits are available for each catheter size (Fig. 120.8). These kits contain a new external catheter

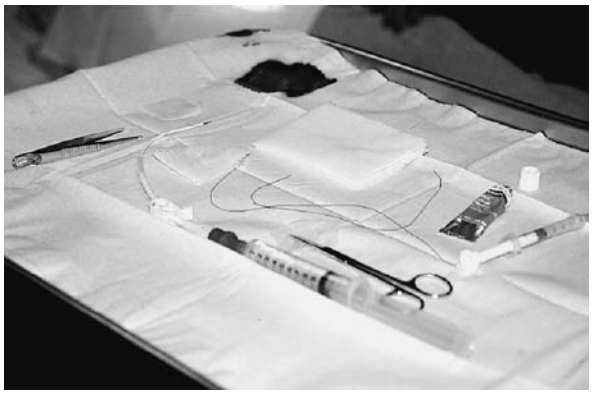

FIGURE 120.8 Repair kit for tunneled catheters.

segment with a hollow male connector that fits into a cleanly sliced proximal end. The kits also contain a syringe and needle to apply the glue to the male connector. Optimally, a person familiar with the procedure will be available within a short time of clamping the catheter. If the externalized portion is too small to clamp, hemostasis may be achieved by putting pressure on the site of venous entry. A scar is usually apparent at this site. However, if the scar is not apparent, the catheter should be palpated from the exit site on the skin to the location at which it can no longer be palpated and pressure should be applied at that site.

If an implantable catheter leaks, fluid or blood that collects subcutaneously may cause a bulge or painful swelling at the site. A broken implanted catheter must undergo prompt surgical management. The broken segment can often be easily visualized by chest radiography.

Catheter Displacement. Occasionally, the patient or caregiver inadvertently pulls on the externalized portion of a tunneled catheter. The venous portion of the catheter may eventually be displaced from the venous system. Externalized catheters are at higher risk for dislodgment within a few weeks of insertion, because the cuff is not fully anchored by fibrosis. Exsanguination after catheter dislodgment is a rare event because of the advancement of the tip inside the vein and the natural tendency toward venous hemostasis. However, children with clotting disorders are at increased risk of life-threatening blood loss after catheter displacement. Totally implanted devices are at risk of dislodgment at both ends; however, few events apart from major thoracic trauma place enough tension on the catheter to dislodge it from the vein. Migration of the venous catheter tip is rare but can lead to cardiac arrhythmias, pneumothorax, cardiac tamponade, and superior vena cava syndrome.

Detecting catheter dislodgment is easier in patients with externalized catheters. If the Dacron cuff is noted outside the skin surface, the catheter must be considered dislodged and should not be used until the tip's location can be confirmed by chest radiography. Failure to draw back free-flowing blood from the device increases the suspicion that the catheter is no longer in the central vein. In this situation, the catheter should be clamped and secured close to the skin and immediate surgical or interventional radiology consultation should be obtained. A dye study may be necessary to locate the catheter tip. For totally implanted devices, dislodgment of the catheter from the vein should be suspected if the device no longer functions after thoracic trauma. If the catheter is disconnected from the reservoir, fluid or blood may collect subcutaneously and cause a bulge or painful swelling at the site. Prompt surgical management is required.

Catheter migration should be considered in patients with totally implanted venous catheters who experience respiratory distress or palpitations. Radiologic evaluation of catheter location should rapidly ensue, with subsequent surgical consultation if the catheter tip has migrated.

Infection. The presence of an indwelling venous catheter places a patient at higher risk for infection, which can occur at the catheter exit site, the tunnel through which the line is placed, the catheter itself, or in the patient's bloodstream. Tunneled catheters carry a higher overall risk of infection than do fully implanted devices. The presence of erythema, tenderness, or purulent drainage at any skin site related to an indwelling catheter suggests a catheter infection. Less commonly, infection can also occur at the subcutaneous pocket of a patient's fully implantable catheter. The entire dressing must be removed for these sites to be inspected. Fever is common in patients with catheter-related bacteremia or sepsis but may be absent in early, localized infection. Immunocompromised patients can exhibit rapid deterioration, and more commonly acquire fungal, gram-negative, and polymicrobial infections. Patients receiving parenteral alimentation are also at higher risk for gram-negative infections. Still, the most common pathogens in patients with indwelling catheters are gram-positive organisms such as *S epidermidis*, *S aureus*, and *S viridans*. The signs of infection may be more subtle or absent in neutropenic patients. Catheter-related bacteremia can also occur without apparent skin manifestations. It is sometimes difficult to tell if the catheter itself is infected or simply seeded the bloodstream, and many consider both to have occurred in the presence of a positive culture result. If this differentiation is necessary, it is possible to compare the extent of the colony-forming units between the peripheral and central cultures and the timing between the central and peripheral culture growth.

Blood cultures should be obtained from the catheter and, in most cases, from a peripheral vein as well. At least 1 to 2 mL of blood should be used for this purpose. More than 90% of blood cultures will yield positive results within 36 hours; gram-negative pathogens will be discovered within 24 hours after culture is obtained. Fungal cultures are appropriate in immunocompromised patients or those who have had prior invasive fungal infections. Cultures of any purulent fluid are helpful. A complete blood cell count with differential count is warranted, although a normal result should not dissuade the clinician from suspecting an invasive bacterial infection. Other blood tests, such as coagulation studies, should be considered if the patient is ill appearing.

Initial treatment consists of IV antibiotic therapy and supportive measures. Bacterial catheter infections can be eradicated without catheter removal, although infections with *S. aureus* and fungi usually necessitate catheter removal. Persistent infection, infection of the subcutaneous tunnel, critical illness, endocarditis, and thrombophlebitis are also indications for removal. Initial antibiotic therapy should include agents active against both gram-positive and gram-negative infections. Many centers use oxacillin and gentamicin as the first choice;

local antibiotic resistance patterns should determine the use of vancomycin instead of oxacillin. Ceftazidime or cefepime should be added for presumptive treatment of *Pseudomonas* infection in neutropenic patients or in those who appear to be severely ill. Local bacterial resistance patterns may alter these choices, such that centers may reserve the use of vancomycin for culture-positive resistant strains or use netilmicin in place of gentamicin. These issues should be discussed with the patient's personal physicians and the local infectious disease consultants. Persistent colonization of CVCs may respond to installation of antibiotic or ethanol into the lumen for 12 to 24 hours (antibiotic lock or ethanol lock).

Other Complications. Other complications related to indwelling catheters can occur, albeit rarely. Direct injury to the exit site can be a result of either erosion of tissue by the Dacron cuff of an externalized catheter or breakdown of the skin site from vigorous cleansing. This condition can lead to a localized infection. On physical examination, excoriation, erythema, tenderness, or purulent drainage is present at the exit site of the catheter. Select patients with a localized site infection who are afebrile and well appearing, have a normal leukocyte count, and have prearranged follow-up may be managed as outpatients with oral antibiotic therapy.

As previously mentioned, phenytoin and diazepam can interact with the silicone lining of the catheters and the administration of these medications through Silastic catheters should be avoided if possible. In addition, a large volume of saline flush should be administered between medications that are incompatible with each other, such as calcium and bicarbonate.

Enteral Feeding Tubes

Background

A stoma, derived from the Latin word for "mouth," is an opening from the GI or urinary tract to the outside of the body. A gastrostomy is a surgically or endoscopically created stoma that provides access to the stomach from the level of the skin. A jejunostomy is a surgically created stoma that brings the jejunum to the skin surface. Gastrostomy is performed most typically in children who are predicted to be unable to take adequate oral nourishment for a prolonged period. The inability to tolerate sufficient oral feedings can be related to numerous conditions, including esophageal atresia, chronic malabsorptive syndromes, significant craniofacial abnormalities, neurologic impairment, severe gastroesophageal reflux, esophageal burns, chronic systemic diseases, and rarely anorexia nervosa. Jejunostomy feedings are used when postpyloric feeding is required and carried out in such patients as those with delayed gastric emptying, recurrent aspiration pneumonia, or severe gastroesophageal reflux. Gastric feedings are much more common than jejunal feedings.

Enteral feeding via gastrostomy and jejunostomy tubes (J-tubes) has become more common in recent years. Therefore, ED physicians should become comfortable with the various types of G-tubes and jejunal tubes, the supporting types of apparatus, and the complications inherent in the use of these lifesaving enteral feeding devices.

Pathophysiology

G-tubes are inserted via percutaneous endoscopic gastrostomy (PEG), open gastrostomy, laparoscopy, or radiologic percutaneous gastrostomy. The PEG technique is the most common. It involves placing a percutaneous hole in the anterior abdominal wall. An endoscope is used to provide light at the exact site on the anterior abdominal wall as a guide for needle puncture. A long guide wire with a feeding tube is then passed through the mouth and distally until the pointed dilator is seen pushing its way through the skin of the anterior abdominal wall. In open gastrostomy, a left upper quadrant or midline incision is used to place the G-tube through the abdominal wall. The G-tube then passes through a purse string suture placed on the anterior wall of the stomach and into the lumen of the stomach at the level of the fundus. The purse string suture is then tightened around the tube to prevent gastric leakage, and the wall of the stomach around the suture is sewn to the abdominal wall where the tube makes its exit. Laparoscopic and radiologic percutaneous gastrostomies are evolving techniques of enteral tube placement.

Jejunostomy can be performed via an open technique or percutaneously. Jejunal feeding can also be accomplished by placing a jejunal tube via the gastrostomy. This method allows jejunal feeding and enables venting of gastric air.

Equipment

Gastrostomy Tubes. Several types of G-tubes are available. Most are made of polyurethane, silicone, or rubber. These devices may vary in length, the number of ports, the type of catheter tip, the number of lumens, and the manner of securing to the patient's skin (Fig. 120.9). The *mushroom* types (Button by Bard Interventional Products Division, Billerica, MA) have soft flexible tips that require an obturator or stylet to stretch the tip. These devices have a single lumen. The *balloon tip devices* (MIC-KEY, Medical Innovations Corporation, Draper, UT) have become most popular and have begun to replace the mushroom tip devices. The inflatable balloon is located at the tip, similar to a urinary Foley catheter. They are easy to secure and do not dislodge as easily. These tubes may have multiple ports and lumina. The most recent advance in G-tubes is the introduction of the low-profile G-tube, commonly referred to as buttons (Fig. 120.10). The advantage of this type of apparatus is that no long piece of tubing arises from the stoma. They may have either mushroom or balloon tips. Replacement devices need to be matched for both the size of the stoma (the external diameter of the tube) and the length of the stoma tract. These buttons have unidirectional antireflux valves that are fragile. In some centers, button devices are placed at the time of the initial gastrostomy.

Jejunal Tubes. Jejunal tubes that pass through the gastrostomy are usually small-diameter tubes (8F), an example of which is the Frederick Miller feeding tube set manufactured by Cook (Bloomington, IN). These tubes have a small mercury weight at the distal tip and are placed under fluoroscopy. Several types of surgical jejunostomy feeding tubes are available, including Malecot and MIC-KEY jejunal tubes.

Clinical Findings/Management

Patients with G-tubes or J-tubes who present with symptoms that appear to be related to the tube require a full evaluation.

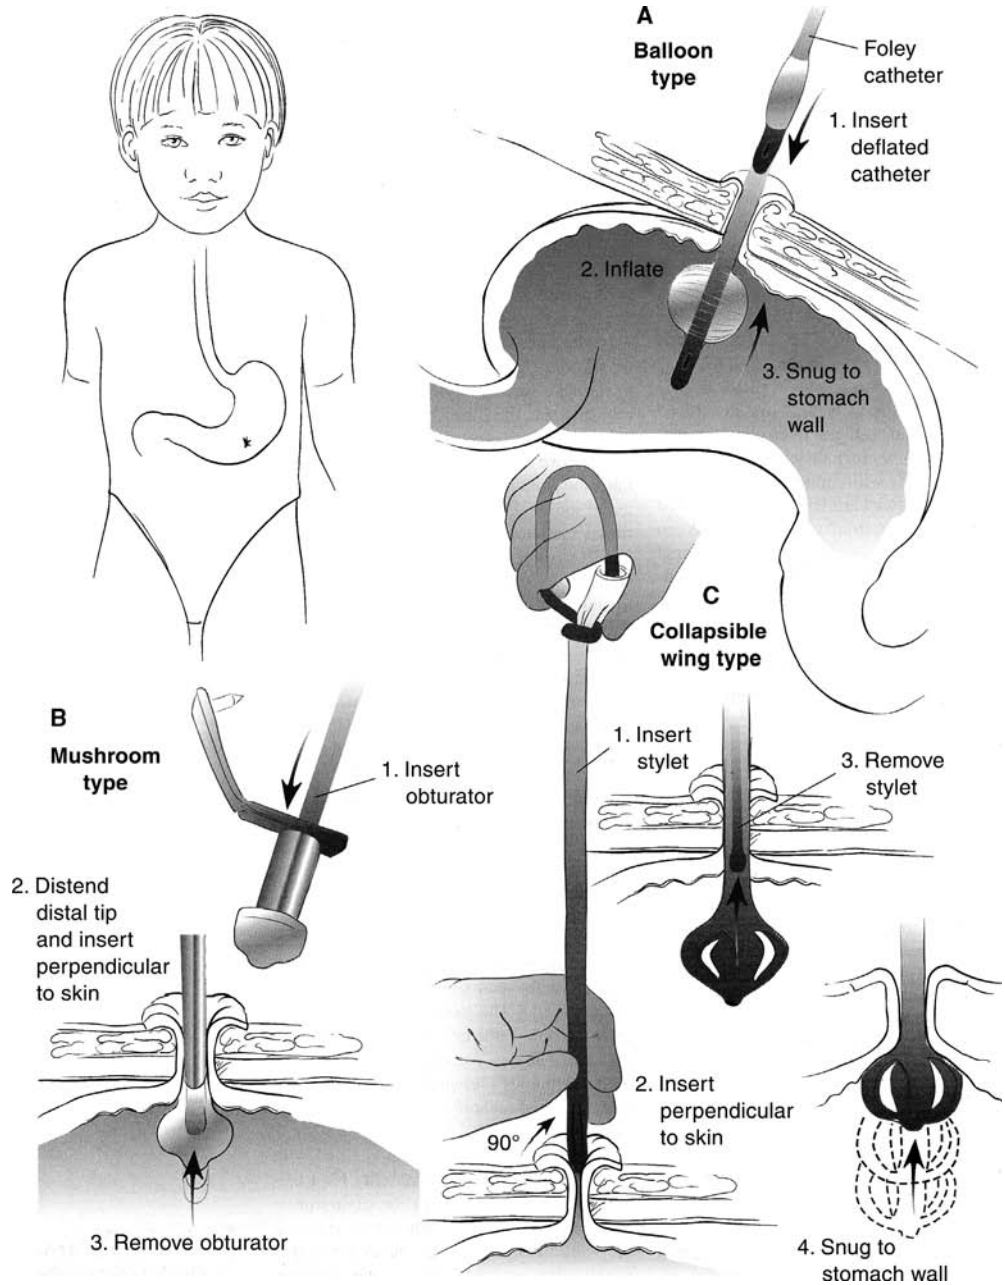

FIGURE 120.9 Gastrostomy tube replacement for balloon-type (**A**), mushroom-type (**B**), and collapsible wing-type (**C**) catheters.

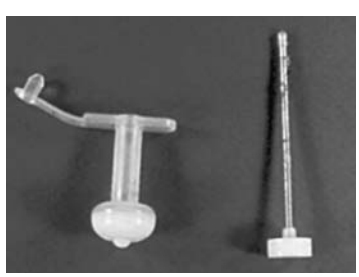

FIGURE 120.10 The button: replacement gastrostomy device.

If the problem is directly related to the G-tube or J-tube, the emergency physician can offer efficient evaluation and therapy if he or she is familiar with potential complications. Complications related to gastrostomy and jejunostomy can be divided into mechanical tube–related problems and problems with the stoma.

Tube-related Problems

Dislodgment. Dislodgment is one of the most common complications of G- and J-tubes. This situation may occur as a result of a traumatic event, such as accidental tension on the external tubing, occult balloon deflation, or rupture of the balloon leading to extrusion of the entire tube. When G-tube dislodgment precipitates an ED visit, many parents either recall

the size of the tube or bring one along to the ED. If neither of these occurs, the patient's medical record usually provides the most recent tube size.

The patient with tube dislodgment may present with a benign stoma or with active bleeding secondary to trauma. If the tube size is unknown or if various tube sizes are not available, the most common temporizing method of replacement is insertion of a Foley catheter. A crucial consideration is the interval of time since the dislodgment. If hours have elapsed, the stoma may be constricted and require insertion of a smaller replacement tube.

The interval since *initial* placement of the gastrostomy is important. Perioperative displacement (within 1 month of initial placement) is treated differently than dislodgment of a tube from a mature stoma. If a G-tube dislodges, temporary replacement with a smaller Foley catheter may prevent pushing the recently fixed stomach away from the anterior abdominal wall. A series of progressively larger Foley catheters, beginning with one to two sizes smaller than the original tube, may be used to dilate the stoma if it is partially closed. A gastroenterologist or surgeon should then be consulted for definitive care. An older tube that has dislodged should be replaced urgently with the same size and type of the tube to avoid narrowing of the stoma. The physician must use caution when reinserting a G-tube because extreme force can lead to tube insertion into the peritoneal cavity through a false tract.

A jejunal tube that has dislodged needs to be replaced by the subspecialist who placed it initially. For example, a J-tube that was inserted via the gastrostomy should be replaced by the interventional radiologist under fluoroscopy. A surgical J-tube requires replacement by a surgeon.

Clogging. Clogging or obstruction of the lumen of the G-tube or J-tube can occur as a result of dried, solidified formula or twisting or kinking of the tube. Tube obstruction is discovered when the caregivers cannot infuse fluids. If formula is suspected as the cause, aspiration of the clot and gentle flushing of the lumen should be attempted. Warm water is recommended as the most effective fluid. Despite reports of the success of various carbonated drinks in this situation, their effectiveness is controversial. When the G-tube becomes clogged, insertion of a stylet is not recommended because this technique may result in perforation of the tubing beneath the skin level. Repositioning of the tube should be attempted next; if this procedure is not effective, removal and replacement are necessary. If the gastrostomy is fresh (within 1 month), the surgeon or gastroenterologist should be consulted before removal of the clogged tube. Caregivers should be reminded of the need for proper flushing with each use. If the patient has a button, the extension tubing should be removed from the button before flushing it.

Leaking. Leaking can occur directly from the lumen of the tube or from the peristomal area. Leaking from the stoma often indicates that the stoma has widened and now exceeds the size of the tube. Determining whether the leaking substance is formula, pus, or gastric fluid is important in the management. If purulent drainage is coming from the stoma, the physician needs to look further for signs of stomal cellulitis or peristomal abscess (see the next section). If formula is leaking from the lumen of the tube, the physician must assess the tube position and check the balloon. In the case of a leaking button, problems with valve patency could occur. If fluid is leaking from the stoma, the stoma may have become larger than the tube. One approach to this problem is removing the tube for a short period, thus allowing constriction of the stoma. The stoma may also have become disrupted and therefore requires surgical evaluation.

Reflux. Gastroesophageal reflux may be a complication of G-tube placement. An increase in prior reflux disease can occur when a Nissen fundoplication is not performed simultaneously. The patient may present with an increase in episodes of vomiting and symptoms of esophageal irritation after G-tube placement. Patients in this category may benefit from continuous enteral feedings. If continuous feedings are not effective in reducing symptomatic reflux, fundoplication may be indicated.

Gastric Ulceration. Gastric irritation leading to ulceration may occur as a complication of gastrostomy in several scenarios. If the tip of the G-tube is too long, it may abrade the opposite surface of the stomach mucosa, resulting in bleeding or traumatic ulceration. Similarly, the balloon may accidentally become overinflated and cause friction, especially when the stomach is empty. Balloon overdilation can occur if medications or flushes are erroneously administered via the balloon port.

A patient with gastric ulcer caused by mechanical trauma presents with symptoms similar to other ulcer patients. Common symptoms are abdominal pain, irritability, hematemesis, hematochezia, and coffee ground gastric drainage from the G-tube lumen. Saline lavage should be performed. If the fluid obtained is nonbloody, medications such as H_2-blockers, antacids, and sucralfate may be administered and upper endoscopy should be scheduled. The G-tube should be changed and the patient's symptoms should be monitored carefully.

Gastric outlet obstruction. Gastric outlet obstruction is a rare but serious complication of G-tubes. It is usually the result of the migration of the tube tip into the pyloric channel. Occasionally, the G-tube can migrate superiorly and block the esophagus. In very rare cases, the entire apparatus can migrate distally, resulting in gastric outlet obstruction. The child complains of retching or sudden onset of emesis and appears uncomfortable. The G-tube needs to be pulled back to its proper location until it is snug against the abdominal wall. If this procedure is not successful, the tube must be removed completely.

Stomal Complications

Irritant dermatitis/allergic hypersensitivity. Skin irritation around the stoma may result from chronic leakage of gastric or jejunal fluid around the tube. If the stoma widens, the leakage may become excessive, resulting in more significant dermatitis. Various brands of adhesives and cleansing solutions may result in an allergic rash around the stoma.

The peristomal skin should be thoroughly cleansed and dried before assessment. Small vesicular lesions with surrounding erythema suggest irritant dermatitis. Local treatment includes keeping the area as dry as possible and using barrier creams to protect the skin from further breakdown. Stomahesive Power (Convatec, Princeton, NJ) is useful for molding to the skin

surface and keeping the area dry and free of debris. In addition, identifying and treating the cause of the leakage are important. If the leakage is caused by an enlarged stoma, surgical intervention may be required in the near future.

Hypergranulation tissue. Children with G- and J-tubes may develop hypergranulation tissue in the peristomal area, extending beyond the wound bed. Although these granulomatous lesions may be harmless, they can be distressing to caregivers. There is often drainage associated with the granulation tissue; however, this does not uniformly indicate the presence of infection. Hypergranulation tissue may begin to cause occlusion of the stoma and should be treated. Treatment options include the application of silver nitrate swabs (though this may be uncomfortable to the patient), triamcinolone cream (0.5%) twice a day, and polyurethane foam dressings.

Cellulitis. When peristomal skin surrounding the G-tube or J-tube is irritated by recurrent or intermittent exposure to drainage or other irritants, cellulitis may occur. The infection may begin as superficial skin irritation or contact dermatitis and then evolve into a deeper infection. The surrounding peristomal area may become reddened, warm, tender, and edematous. These symptoms and signs may occasionally be accompanied by systemic symptoms and fever. The patient with a G- or J-tube may become resistant to tube feedings because of the discomfort associated with manipulation of the apparatus. Once cellulitis is present, the patient requires systemic antibiotics for resolution of this infection. The common organisms, staphylococci and streptococci, usually respond to a first-generation cephalosporin. Occasionally, a peristomal abscess, heralded by a localized area of fluctuance, can complicate the cellulitis. This abscess requires incision and drainage before antibiotic administration.

Fungal infection. Recurrent moisture caused by gastric or jejunal leakage in the stomal area can predispose the patient to fungal infection. The most common causal organism is *Candida albicans*, appearing as fiery red plaques at the stoma site. Topical clotrimazole is curative in most situations. Keeping the area as dry as possible is imperative.

Gastrointestinal and Genitourinary Diversion

Background

Pediatric patients may have a GI or genitourinary diversion for one of many reasons. Congenital causes include Hirschsprung's disease, imperforate anus, cloacal exstrophy, bladder exstrophy, meningomyelocele with a neurogenic bladder, and posterior urethral valves. Acquired lesions may include ulcerative colitis, Crohn's disease, and necrotizing enterocolitis. Traumatic injuries leading to GI or genitourinary diversion include penetrating wounds and falls.

GI diversions consist primarily of colostomy and ileostomy. A colostomy brings the colon to the skin; these patients usually have semiformed stools because the absorptive and storage function of the bowel is preserved. An ileostomy brings the ileum to the skin. Since these patients do not possess large bowel function, they consequently have a watery, frequent stooling pattern.

The major forms of chronic urinary diversions consist of ureterostomy, vesicostomy, pyelostomy, and ileal conduits. In addition, there are temporary urinary diversions that may be established by percutaneous means and maintained with a drainage catheter. Ureterostomy brings the dilated ureter to the level of the skin, whereas pyelostomy brings the dilated renal pelvis to the skin. In contrast, an ileal conduit implies that the ureters are attached to a short segment of the ileum, which is then externalized. A vesicostomy opens the bladder to the skin. Nephrostomy or cystostomy necessitates that a tube be placed into the renal pelvis or bladder via a percutaneous approach and left in place as a temporary diversion. The percutaneous nephrostomy is typically placed by the interventional radiologist. These temporary diversions are most often used to allow for minimally invasive management of stone disease. Urinary undiversion indicates that the patient has undergone a surgical procedure that internalizes the urine passage via a "neobladder" composed of the original bladder and/or a combination of large and small bowel.

In general, a stomatherapist is crucial to the physicians and families of all patients with stomal sites and appliances. However, patients continue to present to the ED with ostomy-related problems, and the emergency physician should become facile with the various types of GI and genitourinary diversions and their specific complications.

Pathophysiology

The nature of the disease and the location of the lesion(s) guide the surgeon when choosing the type of diversion to use. An ileostomy is usually performed in newborns for conditions such as meconium ileus, necrotizing enterocolitis, and intestinal atresia. It may be required in older children and adolescents because of ulcerative colitis or polyposis. The surgical method used depends on the predicted length of time required for the ostomy, as well as the location of the disease.

Colostomy in infants is required for complications of colonic atresia, high forms of imperforate anus, and Hirschsprung's disease. The level of the colostomy is related to the disease type and to anticipated future procedures. Some of the ostomy complications that occur in patients with genitourinary and GI diversions are similar. In both types of diversions, many complications relate to the actual stoma. These conditions are discussed in the previous enteral feeding section. Other complications are metabolic or mechanical in nature.

A vesicostomy is usually performed for patients with myelomeningocele, posterior urethral valves, prune belly syndrome, and spinal cord injury resulting in a neurogenic bladder. This procedure consists of bringing the dome of the bladder up to the skin below the umbilicus to serve as a vent for high bladder pressure, and it is protective of the upper urinary tract.

Ureterostomy is accomplished by bringing the ureter to the surface of the skin either in the groin (low) or in the flank (high). Most high ureterostomies are of the loop variety, in which a loop of the ureter is incised on one side and passed upward to allow the edges to be anastomosed to the skin. This path allows ureteral continuity from the kidney to the bladder, with a vent to the skin. Low ureterostomies are more common and are performed for obstructed ureters such as ectopic

ureters or megaureters. To decompress an obstructed system and prevent urinary tract infection, the ureter is divided, the distal end is ligated, and the proximal edges are anastomosed to the skin.

Ileal loop conduits are created with a resected 10- to 20-cm bowel segment of the ileum and anastomosing both ureters to one end. The other end of the bowel loop is brought out to the skin. Ileal loop conduits are preferable in older children who can wear an appliance to collect the urine.

Equipment

Standard ostomies are commonly managed by placing an ostomy pouch over the stoma to collect the effluent. In young infants, sigmoid colostomies may be managed without an external pouch if the effluent is not caustic to the skin and fluid is therefore collected in the diaper. Urinary flow can also be collected in a diaper and may be preferable because some appliances do not adhere well to the skin for long periods.

Ostomy pouches for children are manufactured in various sizes. One- and two-piece configurations are available, and pouches may be soft or rigid. Supplemental adhesives are crucial to enhance adhesion, especially if the effluent is more liquidlike.

Clinical Findings/Management

Gastrointestinal Diversions. Patients with colostomies and ileostomies may present with complications that are common to both types of ostomies. Ileostomies also have metabolic complications that are specific to this type of ostomy.

Cutaneous complications. Peristomal cutaneous complications are common in patients with ostomies, and stem from the effect of chronic stool and other drainage on the peristomal skin. This chronic drainage compromises the skin integrity surrounding the stoma. The most effective management is the maintenance of a good seal between the ostomy pouch and the stoma. Contact dermatitis may occur either from leakage around the stoma or from allergy to stomal materials such as tape or pouches. Removing the offending material often successfully treats this condition. Infection with *C albicans* is fairly common because of the persistent moisture and the frequent use of prophylactic antibiotics. Treatment with antifungal agents such as clotrimazole, especially powders, is effective. The powder can be mixed with a small amount of water and painted onto the skin to enhance adherence of the pouch. Ointments and creams should be avoided in fungal infections. Skin bleeding resulting from prolonged irritation of the peristomal area is usually minor. The cellulitis that can occur if the skin excoriation worsens is treated with systemic antibiotics.

Stomal complications. Stomal stenosis is not always detectable to the parent or practitioner and may present with reduced or absent output, diarrhea, or cramping abdominal pain. When severe stenosis occurs, it usually presents as obstruction. To assess the degree of stenosis, the physician should gently examine the stoma digitally unless the stoma is too small. In this case, a catheter should be carefully passed. If abdominal obstruction is suspected, radiographs of the abdomen and urgent surgical consultation are indicated.

Prolapse of the stoma occurs in more than 20% of patients with stomas and is usually not an emergency. However, skin excoriation, bleeding, and incarceration of the bowel may occur. The situation becomes more urgent if the prolapse is associated with pain, decreased output, or a dusky stoma color that represents circulatory compromise and requires immediate surgical management. This includes easing the prolapsed contents back into the stoma using both hands. This procedure may need to be done repetitively until such time that definitive surgical repair is undertaken.

Retraction of the stoma because of excessive tension may cause the stoma to recede beneath the skin. This condition occurs more often than prolapse in patients with ileostomies. Stomal retraction makes it difficult for a pouch to adhere to the skin. Retraction can also result in cellulitis or even peritonitis, depending on the location of the detachment and the flow of the effluent. Management usually includes antibiotics and if the retraction is extensive, surgical correction is indicated.

A hernia of the peristomal contents occurs when there is a protrusion of the colon or ileum into the subcutaneous layers of skin surrounding the stoma. This complication may impede adherence of the ostomy pouch but does not usually represent an emergency. Elective surgical revision provides definitive management.

Complications specific to ileostomy. Patients with ileostomies occasionally develop metabolic derangements. In the face of large volume losses, children tend to deplete salt and water. If large fluid losses persist, the biochemical profiles of these patients are significantly altered. Determining the cause of the exceptionally high fluid losses from the ileostomy is crucial. Some possibilities are obstruction, gastroenteritis, and dietary indiscretion. Treatment is aimed at restoring normal fluid and electrolyte balance and may require hospital admission.

Patients with ileostomies are prone to acquiring urinary stones. The chemical composition of stones in this scenario is different than that in normal patients; uric acid stones constitute 60% and calcium oxalate makes up the remainder. Treatment is directed at decreasing ileostomy output and increasing urine output.

Urinary Diversions

Vesicostomy. In patients with a vesicostomy, eversion of a large portion of the bladder can occur and appear like an exstrophy. When the posterior aspect of the bladder prolapses through the stoma, the patient presents with a red mass, which may change to purple if not treated promptly. Applying an index fingertip to the bladder and gently pushing inward may manage this condition. Nonlatex gloves are required because children with urologic abnormalities are often allergic to latex. Sedatives may be required to facilitate reduction of the prolapse. A prolapsed vesicostomy should be surgically revised emergently if the manual reduction is unsuccessful.

Patients with stomal stenosis of the vesicostomy usually present with a palpable bladder, a history of unwanted urethral voiding, or with symptoms of urinary tract infection. As the bladder fails to empty at low pressures, the mean storage pressure rises and the chance for seeding bacteria into the upper urinary tract increases. These patients often have a pinpoint opening to the bladder, and the parents usually comment on how much smaller the stoma has become over time. If

possible, these patients should have a catheter placed via the vesicostomy using a small (6F or 8F) catheter. If it is not possible to catheterize the vesicostomy, an attempt must be made at urethral catheterization assuming the patient has been left anatomically intact. If the vesicostomy is successfully catheterized, the catheter should be left in place until surgical revision is carried out.

Many vesicostomies are colonized with bacteria via stomal contamination. Therefore, a catheterized specimen through the stoma is sometimes unreliable. Patients with constitutional symptoms such as fever should have their urine culture carried out via vesicostomy. If no other source of fever is discovered, treatment should commence after the culture has been obtained. In an asymptomatic patient, a positive culture result may represent asymptomatic bacteriuria and is not always of concern.

Skin irritation in the area of the vesicostomy is unusual. The most important preventive measure is frequent diaper changes, even if highly absorbent diapers are used. If urine seeps onto the patient's clothes repetitively, skin breakdown may ensue. In severe cases, temporary urinary diversion with a Foley catheter while applying a barrier ointment allows time for healing.

Ureterostomy. Stenosis is the most common complication in the patient with a ureterostomy. These patients often present with fever and symptoms suggestive of pyelonephritis. The stoma should be catheterized with an 8F catheter, and urine should be sent for culture. Surgical revision of the stoma or definitive urologic reconstruction must be considered. Ureterostomy prolapse is rare.

Ileal loop conduits. Inflammation of the peristomal skin arises when the appliance fits poorly around this bud of ileum, allowing urine to seep under the protective wafer. Prolonged contact with skin causes irritation and ulceration. The use of paste to create a better seal around the bud is often all that is needed to avoid such a complication. In some cases, surgical revision is necessary, especially when the bud has retracted.

Prolapse of the ileum occurs occasionally and can be striking, especially if too long a segment was used in creating the loop initially. Prolapsed segments 20 to 30 cm long have been seen and require surgical revision. If the prolapse is minor, the clinician should perform the same gentle manual reduction technique previously described in the "Stomal Complications" section under "Gastrointestinal Diversions."

Peristomal hernia can occur when fascial defects adjacent to the ileal loop allow loops of bowel to herniate outside the abdominal wall. This condition requires urgent surgical consultation.

Stenosis of the ileal stoma may occur in these patients. Symptoms may include pain, but the usual presenting complaint for these patients is fever. This finding necessitates a workup for pyelonephritis. Stomal stenosis can also lead to the formation of urinary calculi. In this setting, surgical revision of the ileal stoma must be undertaken.

Urinary undiversions. As the child with a vesicostomy or ileal loop grows older, the social stigma of a diaper motivates many of these patients to seek urinary continence. For patients with spina bifida or exstrophy, this goal may be achieved by the use of an intestinal segment to augment bladder capacity (enterocystoplasty). In addition, a procedure to tighten the bladder neck and create resistance to leakage and creation of a channel through which the patient can perform intermittent catheterization is indicated. For all patients with spina bifida and most patients with exstrophy, continence comes at the expense of daily clean intermittent catheterization (CIC) for the rest of their lives. Careful patient and family selection is necessary for this procedure; compliance with CIC is crucial. Nevertheless, the enhanced self-esteem and improved quality of life these patients report are gratifying.

Perforation is the worst complication of intestinal augmentations to create neobladders. Most bladder perforations result from overdistension of the augmented bladder, which then diminishes perfusion to the bowel segment. In addition, the urine in these neobladders is chronically colonized secondary to the use of intermittent catheterization. Patients may present anywhere from 1 month to many years after surgery with a history of acute abdominal pain. Fever may be present within a few hours of perforation. Because many patients with spina bifida have decreased or absent abdominal sensation, peritonitis may be fairly advanced before pain is experienced. The presence of abdominal pain in a patient with a urinary diversion should prompt an immediate call to the patient's urologist. The urologic evaluation generally consists of a fluoroscopic gravity cystogram with views during filling and emptying, or a CT cystogram. Small perforations may be obscured with the full bladder and become apparent only during bladder emptying. Prophylactic antibiotics should be administered before the cystogram. Once this diagnosis is established, the patient is prepared for emergency laparotomy.

Patients may present to the ED with a sudden inability to pass a catheter into their neobladder. This situation may be because the appendiceal conduit through which they pass their catheter contains a false passage. A fluoroscopic study is warranted to delineate the passage and allow catheterization under radiographic control. The same situation is often true for patients catheterizing per urethra. In some cases, the urologists may opt to take a patient to the operating room for emergency endoscopy in order to define the obstruction point. When all else fails and the patient's bladder continues to distend, it is safest to pass a suprapubic drainage catheter into the neobladder.

Because the creation of a neobladder is an intraperitoneal operation, these patients are at risk for developing small bowel obstructions. A patient with abdominal pain and a neobladder merits radiographic evaluation.

Up to 30% of patients with a neobladder develop stones within their pouch and require either endoscopic or open surgical removal. These stones rarely cause pain by obstruction, but rather they produce foul urine that can be so irritating to the neobladder that the patient presents with a vague lower abdominal pain. These stones are calcified and show up on an abdominal radiograph. Treatment with antibiotics is palliative until surgical removal is undertaken.

The insertion of bowel segments into the urinary tract carries with it certain fluid and electrolyte complications that may not be a problem under normal circumstances. However, with GI viral infection and superimposed diarrhea and dehydration, the patient may not be able to compensate. For example, a patient with a gastric augmentation who presents with diarrhea

and lethargy may have a severe, hypochloremic, hyponatremic, metabolic alkalosis. Thus, any patient with a bladder augmented with bowel who is obtunded requires careful consideration of an electrolyte disturbance as the underlying cause.

CHAPTER 121 ■ ABDOMINAL EMERGENCIES

RICHARD G. BACHUR, MD

Pediatric abdominal complaints are common presentations in the emergency department (ED), mostly due to innocent gastrointestinal (GI) problems. However, ED physicians are challenged to identify those patients with more serious disorders, including surgical emergencies. The etiology of abdominal emergencies vary by age of the child, and the presentation of even common problems such as appendicitis may vary greatly based on the maturity of the child and stage of the disease. Clinicians should be aware of the variation of presentations, as well as the proper approach to diagnosis and management. Many conditions, for example, bowel obstruction, may have the same initial approach regardless of the specific etiology. Logical diagnostic schemes and prompt recognition of surgical emergencies should be the goal of the evaluation.

This chapter reviews the common, acute nontraumatic surgical conditions of the abdomen in the following categories: (i) diseases that produce peritoneal irritation; (ii) acute intestinal obstruction; (iii) chronic, partial intestinal obstruction; (iv) problems that produce rectal bleeding; (v) intraabdominal masses; (vi) abdominal wall defects; and (vii) foreign bodies of the GI tract. Nonsurgical GI emergencies are covered in Chapter 89. Chapter 107 deals with major trauma to the abdomen. Chapter 49 reviews the diagnostic approach to the child with abdominal pain.

EVALUATION

History

Once the concern of an acute abdominal process is considered, the clinician should focus on specific elements of the history: (i) presence and character of abdominal pain, (ii) history and character of emesis, (iii) bowel history, (iv) systemic symptoms, (v) associated symptoms attributable to the lower respiratory tract or urinary system, and (vi) past medical history.

Abdominal pain is a common feature of many acute surgical abdominal conditions. Unfortunately, abdominal pain can also be nonspecific and associated with many common entities such as gastroenteritis, constipation, mesenteric adenitis, nephrolithiasis, urinary tract infection, ovarian cysts, pleuritis, and pneumonias. Key elements of the history regarding pain include sudden versus gradual onset; the duration, whether it is persistent or intermittent; radiation to other areas; and whether the pain migrated. Pain that begins vaguely throughout the abdomen and then localizes to more severe, sharper pain is the classic description with appendicitis as pain transitions from a *visceral*, diffuse, and nondescript pain to a more defined, localized *peritoneal* pain. Mild intermittent pain without associated symptoms is rarely a serious condition. Persistent pain with progressive symptoms requires a thorough evaluation for more severe conditions such as appendicitis. Sudden onset of severe pain might be seen with relatively innocent conditions such as constipation but could also represent a perforated ulcer, bowel obstruction or ischemia, renal obstruction, ovarian torsion, or ectopic pregnancy. In preverbal patients, history of irritability or "fits" of crying may be indicative of abdominal pain. Flexing the hips and crying in young infants might be indicative of abdominal pain. Paradoxical irritability, more often associated with meningeal irritation, may also be a sign of peritonitis in young infants.

Vomiting is associated with many surgical conditions. The number and frequency of the episodes along with the character of the emesis should be elicited. Specifically, questions regarding the presence or absence of bile or blood need to be determined and may substantially influence the initial management and approach to the patient. Acute onset of bilious emesis should raise concern for bowel obstructions, although some bilious emesis may also be seen with persistent emesis and ileus associated with viral gastroenteritis. Bilious emesis in a newborn infant is indicative of a surgical emergency. Bowel history should be reviewed along with the presence of blood either as fresh blood or melena. Bloody diarrhea is more likely to be seen with forms of colitis or infectious enteritis, whereas blood per rectum is more consistent with bowel ischemia, a bleeding lesion in the bowel such as a Meckel's diverticulum or polyp, or lower tract trauma. Although bloody stool may or may not be surgical in nature, it warrants a thorough assessment (see Chapters 18 and 29). In the absence of recent stool, the additional absence of flatus may suggest an ileus or obstruction. Diarrhea is not a typical feature of acute surgical processes; therefore, if the illness begins with nonbloody diarrhea, it is unlikely to represent a surgical process. However, the presence of diarrhea does not automatically exclude surgical processes because many patients with intussusception had preceding gastroenteritis. Likewise, the development of diarrhea in a child who has several days of abdominal pain may be secondary to appendiceal perforation with abscess formation.

Other systemic symptoms may help suggest the etiology of the abdominal emergency or the severity of illness. Presence of fever in the well child with abdominal pain may support viral gastroenteritis, whereas fever in the patient with concerns for acute appendicitis may suggest bowel perforation. In general, fever prior to abdominal pain is unlikely to be an acute surgical process. Distinct episodes of pain associated with profound lethargy and diaphoresis might lead to the diagnosis of intussusception. Associated weight loss, pallor, and fatigue can be seen with inflammatory bowel disease or malignancies. Associated, nonsystemic symptoms or a constellation of complaints may point toward specific etiologies of abdominal pain: cough, fever,

and pleuritic pain may suggest pneumonia; fever and flank pain may be indicative of pyelonephritis; fever, dyspareunia, and vaginal discharge are seen with pelvic inflammatory disease.

Prior surgical history should always be ascertained when evaluating a patient with an acute abdomen. Abdominal complaints might indicate a complication of surgery in the immediate postoperative period, whereas more remote surgical history might indicate intestinal obstruction from adhesions.

Examination

Children vary in their ability to cooperate during the abdominal examination, and often the physician must make patient, repeated efforts to perform an adequate evaluation. A few minutes spent gaining the child's confidence will often allow a better examination. Observing the patient's ability to move in the parent's arms or bed is helpful. Patients with peritoneal signs might only get comfortable when lying still. In cases of extreme patient anxiety, watching the parents palpate the abdomen can give a general sense of tenderness and peritoneal signs. Occasionally, if an initial examination is suboptimal due to crying, repeat examinations, especially if the child falls asleep, might prove invaluable. Narcotics should not be routinely used to sedate a child for examination, but narcotics should be used to treat severe pain—knowing that subsequent examinations may be affected.

Once the child relaxes, the physical examination should follow an orderly progression: inspection and observation, abdominal palpation, auscultation, examination of nonabdominal areas, and rectal examination (Table 121.1).

The initial step of inspection should focus on the presence of distension, visible bowel loops, and asymmetry. Inspection is easily done because of the relative prominence of the child's abdomen, and thinness of the overlying muscles and subcutaneous tissue. The child should be observed in motion—for example, when moved in the parent's arms, changing position in the bed, or, in older children, when walking or hopping on command. Changes in facial expression or clutching their abdomen with motion imply significant pain. Inspection should include the oropharynx (streptococcal pharyngitis), lower chest, flanks, genitalia (testicular torsion, hernia, hematocouplos), and inguinal areas.

Palpation is the most difficult, yet most informative, aspect of physical examination. In young infants and toddlers, making the child, and hence the abdominal muscles, relax prior to the examination is important. Flexing of the hips, use of a pacifier, or providing a small sip of sugar water may change the tense abdomen of a screaming infant to an examinable abdomen. In older children, trying to engage them prior to palpation is beneficial. Ask the child to point to the place where the pain is most severe. Avoid the tender area initially, but return to palpate it last. A number of "tricks" can be used to facilitate the palpation, such as distracting the child with conversation, palpating with the head of the stethoscope in hand, and palpating while asking the child to take a deep breath. Palpation should identify any tenderness as noted by the verbal patient or change in expression or crying in the younger child. Along with tenderness, guarding and rebound should be appreciated. In addition, masses or organomegaly should be noted. Palpation should include the genitalia of males, and pelvic examination should be considered in postpubertal, sexually active females. Generally, pelvic examination is not required in non–sexually active females unless specific gynecological diagnoses are probable; of note, hematocolpos does present as significant abdominal pain and possible lower abdominal mass, which can easily go unrecognized without proper examination of the genitalia.

TABLE 121.1

ABDOMINAL PHYSICAL FINDINGS AND THEIR MEANING

Physical findings	Meaning
Abdominal distension	Peritonitis, intestinal obstruction, ileus
Visible bowel loops	Intestinal obstruction, intussusception
Asymmetry	Appendiceal abscess tumor, constipation
Point tenderness	Appendicitis, cholecystitis
Guarding	Peritonitis, appendicitis, abscess
Rebound	Peritonitis, infarcted bowel
Rovsing's sign	Appendicitis
Palpable mass	Tumor or cyst, intussusception, chronic constipation
High-pitched bowel sounds	Intestinal obstruction
No bowel sounds	Peritonitis, infarcted bowel, ileus
Psoas sign	Appendicitis (especially retrocecal), psoas abscess retroperitoneal hematoma
Rectal examination—tenderness or bogginess on right	Appendicitis

Next, auscultate for bowel sounds. The presence of normal bowel sounds may not rule out surgical pathology, but a silent abdomen or one with high-pitched tinkles and rushes suggests the possibility of ileus or obstruction. Auscultation of the lung fields is also necessary to identify either the primary cause of pain, such as pneumonia, or associated pulmonary findings, as with pleural effusions with pancreatitis or peritonitis.

The final step in the evaluation should be a rectal examination. The important technical aspects include use of generous amounts of lubricant, slow insertion of the examiner's finger as the patient takes slow deep breaths, and the palpation of the presumed painful area last. If done carefully and gently, the rectal examination is usually well tolerated by the child. Any stool on the examiner's glove should be tested for blood.

Laboratory

Laboratory and radiographic studies vary, depending on the diagnoses that are being considered. When considering surgical

diagnoses, a complete blood count (CBC) with differential is essential. As with other diagnostic workups, CBC will add information to help guide the physician toward or away from diagnoses—it will rarely make a diagnosis. A urinalysis is an important part of the evaluation of any abdominal symptoms in children: white blood cells (WBC) to suggest a urinary tract infection, blood to possibly suggest a urologic etiology such as nephrolithiasis or ureteral obstruction, and tests for glucose and ketones knowing that many patients with diabetic ketoacidosis present with abdominal pain and emesis, and finally specific gravity to help gauge hydration of the patient. Depending on the child's condition, history, physical examination, and diagnostic considerations, other tests may be ordered: serum electrolytes, blood urea nitrogen (BUN), serum amylase or lipase, liver enzymes, bilirubin, sickle cell preparation, β-HCG, erythrocyte sedimentation rate, and C-reactive protein.

An abdominal radiograph is rarely helpful for nonspecific pain in the well child, but it is very useful for consideration of obstruction, constipation, nephrolithiasis, and perforation of the bowel. An upright, lateral decubitus, or cross-table lateral radiograph should be obtained when "free air" is suspected. In evaluating possible appendicitis, look for a fecalith in the right lower quadrant. Ultrasound (US) and computed tomography (CT) have varying roles, depending on the diagnosis. Upper GI series can be done to identify upper obstructions, and dye or air enemas can be diagnostic for lower obstructions such as ileocolic intussusception.

Assessment

Once the history, physical examination, and laboratory data are available, the emergency physician must synthesize them into an overall assessment and treatment plan. The following sections detail the symptoms and signs of the common acute surgical problems in children. Initial ED management is discussed, but in all cases of presumed surgical disease, the definitive treatment requires surgical consultation. Consultation with a surgeon should be considered after the initial evaluation if the patient appears ill or serious surgical conditions are being considered; laboratory evaluation and radiologic studies should not delay surgical evaluation in such children.

DISEASES THAT PRODUCE PERITONEAL IRRITATION

The physician must perform a careful examination to elicit accurate signs of peritonitis. Tenderness is not necessarily an indication of an intraabdominal surgical problem in a child. A child with localized peritonitis may have only minimal findings, whereas a patient with a nonsurgical condition may have severe pain and generalized tenderness. The typical features of peritonitis—rigidity, involuntary guarding, and rebound—are the same in children and adults but may be more difficult to elicit or interpret in younger children and infants. Reproducible peritoneal tenderness in the same location is much more suggestive of peritonitis than deep abdominal tenderness that shifts in location with reexamination of the child. In infants and young children, irritability or screaming with any movement of the child may indicate peritonitis.

Acute Nonperforated Appendicitis

Background

Acute appendicitis is the most common, nontraumatic surgical emergency in children. There is a slight male predominance with a peak incidence of 9 to 12 years of age. Although neonatal cases have been reported, appendicitis rarely occurs in children younger than 2 years. Predictably, the diagnosis is very difficult in children younger than 5 years. The emergency physician must accurately evaluate the child and promptly consult a surgeon when the diagnosis is clear or when appendicitis cannot be safely ruled out. Such consultation is especially urgent in younger children, in whom perforation occurs more frequently and can occur within 8 to 24 hours of the onset of symptoms.

Clinical Manifestations

Usually the child with appendicitis complains initially of poorly defined and poorly localized midabdominal or periumbilical pain. Unfortunately, this symptom is common to many other intraabdominal, nonsurgical problems. In the young and, to a lesser extent, the older child, vomiting and a low-grade fever often occur soon thereafter. Characteristically, the pain then migrates to the right lower quadrant (Table 121.2).

Because the position of the appendix may vary in children, the localization of the pain and the tenderness on examination may also vary. An appendix that is located in the lateral gutter may produce flank pain and lateral abdominal tenderness; an inflamed appendix pointing toward the left lower quadrant may produce hypogastric tenderness and pain with urination

TABLE 121.2

PROGRESSION OF SYMPTOMS AND SIGNS OF APPENDICITIS

Nonperforated Appendicitis
Poorly defined midabdominal or periumbilical pain
Low-grade fever
Anorexia
Vomiting
Migration of pain to right lower quadrant
Localization depends on position of appendix
Appendix in gutter → lateral abdominal tenderness
Appendix pointing toward pelvis → tenderness near pubis may cause diarrhea or bladder irritation
Retrocecal appendix → tenderness elicited by deep palpation
Pain on coughing, hopping, or to percussion
Rectal examination: pain on palpation of right rectal wall
WBC count: 11,000–15,000/mm^3
Urinalysis: ketosis, few WBCs
Perforated Appendix
Increasing signs of toxicity
Rigid abdomen with extreme tenderness
Absent bowel sounds
Dyspnea and grunting; tachycardia
Fever: 39–41°C (102.2–105.8°F)
WBC count: >15,000/mm^3 with shift to left
Eventual overwhelming sepsis and shock

WBC, white blood cell.

(from bladder contraction). An inflamed low-lying, pelvic appendix may not cause pain at McBurney's point, but instead may cause diarrhea from direct irritation of the sigmoid colon. Anorexia and nausea are common; vomiting is more common in younger children. In early stages, the patient may complain of pain with motion, for example, bumps in the road on the drive to the ED or walking, and as peritoneal irritation worsens, the child will prefer to lay motionless in the bed.

When obtaining the history, the physician needs to consider other causes of abdominal pain, which may appear as appendicitis but, in fact, are nonsurgical. Concurrent GI illness in other family members or friends suggests the possibility of an infectious gastroenteritis. Constipation, streptococcal pharyngitis, urinary tract infection, lower lobe pneumonia, mesenteric adenitis, and ovarian cyst are common conditions often masquerading as appendicitis. Although the presentation is generally more rapid and severe, torsion of the ovary and ectopic pregnancy should be considered in female patients with sudden onset of severe pain.

On examination, palpation is usually reliable in demonstrating focal peritoneal signs at the site of the inflamed appendix. If the appendix is in the pelvis or retrocecal area, however, typical anterior peritoneal signs may be absent. When the inflamed appendix is not close to the anterior abdominal wall, as in the case of retrocecal appendix, tenderness may be more impressive on deep palpation of the abdomen or palpation of the flank. Percussive tenderness, shake tenderness, pain with coughing, or hopping suggests peritoneal irritation. A properly performed rectal examination can contribute to the clinical impression: the examining finger should be inserted as fully as possible without touching the area of presumed tenderness and then, when the child is relaxed and taking deep breaths, the examiner can indent an area high on the right rectal wall. A sudden involuntary reaction implies localized tenderness. In a child with a history of probable appendicitis for more than 2 or 3 days, a boggy, full mass may also be in this location, suggesting an abscess.

A CBC in a child with appendicitis usually shows an elevated WBC count in the range of 11,000 to 15,000 per mm^3 in the first 12 to 24 hours of the illness. As the appendix becomes more gangrenous, the WBC count rises further, and the differential demonstrates more and more neutrophils and an increasing number of bands. Urinalysis often shows ketosis. If the inflamed appendix lies over the ureter or adjacent to the bladder, a few WBCs may be found in the urine. The presence of numerous WBCs and bacteria on a freshly spun specimen may indicate an acute urinary tract infection. An abdominal radiograph may show an appendicolith (8% to 10%), localized ileus with air–fluid levels, or a gaseous loop in the right lower quadrant, or more commonly, a nonspecific bowel gas pattern. Subtle radiographic findings include a blurred psoas margins and thickened cecal wall. Rarely, pneumoperitoneum may be seen with perforated appendix.

If the clinical and laboratory diagnosis of acute appendicitis is convincing, no further studies are indicated. For patient with equivocal findings, patients should be monitored with serial examinations or have radiologic studies to aid diagnosis. CT and US have both been used for diagnosis. US has a reported sensitivity of 80% to 92% with a specificity of 86% to 98%. Technically, a noncompressible enlarged appendix is diagnostic of appendicitis, although the study must be considered unhelpful if the appendix is not specifically identified. Focal CT has a diagnostic sensitivity of 87% to 100% with a specificity of 83% to 97%. CT can identify an enlarged appendix, focal thickening of the cecum, periappendiceal inflammation, mesenteric nodes, and fluid collections associated with perforation. Protocols using intravenous (IV) contrast plus rectal contrast or oral contrast vary by institution. In general, US has less utility in patients with a high body mass index, and CT is most interpretable in patients with adequate periappendiceal fat. US may be preferred in adolescent females as an initial study if gynecological conditions are suspected such as ovarian cyst, tuboovarian abscess, ovarian torsion, or ectopic pregnancy (see Chapter 90).

Management

The preoperative preparation of a patient with acute appendicitis should include electrolytes if the patient has been vomiting or has had poor fluid intake for more than a few hours. IV fluids should be started with the goal of rapid intravascular expansion and then correction of further fluid deficits. Protracted GI losses, as with vomiting, may lead to potassium depletion. Initial fluids should include a bolus of isotonic fluid (10 to 20 mL per kg), then changed to D5% 0.5 NS with 10 to 20 mEq per L of potassium. These fluids can then be altered, if necessary, once the serum chemistries are known.

The emergency physician must keep in mind the many variations in the way appendicitis can present. Patients with equivocal findings should be admitted for monitoring and serial examinations or have imaging studies to demonstrate a normal appendix. If the imaging studies are equivocal, the surgeon will decide to operate or continue to monitor. Patients who have a typical history for appendicitis but suddenly have diminished pain may actually represent perforation of the appendix. Such patients should be observed for several hours prior to declaring an improved condition. Even in the presence of negative imaging studies, the emergency physician should arrange close follow-up for any patient with abdominal pain. For those patients with progressive pain or persistent emesis, admission for further care and subsequent evaluation might be necessary.

Perforated Appendicitis

Ideally, once the diagnosis of appendicitis is considered seriously, the patient will have accurate diagnosis and surgery before the appendix has perforated. Unfortunately, some patients, particularly younger children and infants, may arrive for emergency care with an already perforated appendix because of a delay in seeking treatment or in making the diagnosis. Once the appendix has perforated, there are usually signs of generalized, rather than localized, peritonitis. In a young child, the omentum is thin and often incapable of walling off the inflamed appendix. As a result, perforation occurs more quickly, and secondary dissemination of the infection occurs more widely. Although the mortality from appendicitis has decreased, the incidence of perforation in children has remained the same over the last several decades.

Clinical Manifestations

Within a few hours after perforation has occurred, the child begins to develop increasing signs of peritonitis and toxicity. First, the lower abdomen and then the entire abdomen become

FIGURE 121.1 Perforated appendicitis with abscess and fecalith. The upright abdominal roentgenogram shows numerous dilated loops of bowel and a calcified fecalith *(arrow)*. Note that the space between the individual loops indicates the presence of intraperitoneal fluid.

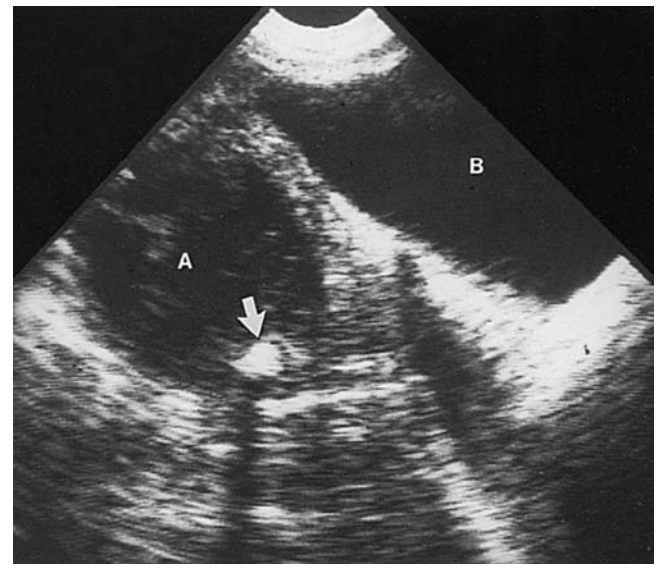

FIGURE 121.2 Perforated appendicitis with abscess and fecalith. Ultrasonography of the pelvis shows a complex mass *(A)* with a fecalith *(arrow)* producing characteristic acoustic shadowing to the right of the bladder *(B)*.

rigid with extreme tenderness. Bowel sounds are sparse to absent. Other signs include pallor, dyspnea, grunting, significant tachycardia, and higher fever [39°C to 41°C (102.2°F to 105.8°F)]. Rarely, the patient may develop septic shock (see Chapter 3) from the overwhelming infection.

Initially, the findings may be confused with those of pneumonia because the extreme abdominal pain may cause rapid shallow respirations, painful respirations associated with grunting, and decreased air entry to the lower lung fields. In young children, the findings may also be confused with meningitis because of paradoxical irritability—any motion of the child, even trying to comfort the child, may cause pain and irritability.

The laboratory findings in the child with perforated appendicitis often suggest this diagnosis. The WBC count is significantly elevated, usually greater than 15,000 per mm^3, with a marked shift to left; leukopenia may be seen in perforation associated with overwhelming sepsis. The radiologic evaluation of suspected perforated appendicitis should include plain abdominal radiographs and either ultrasonography or CT. The plain film of the abdomen may show free air or evidence of peritonitis (Fig. 121.1). The US of the pelvis may show a complex mass with or without a calcified fecalith or free fluid within the abdominal cavity (Fig. 121.2). CT can better define the size and location of an associated abscess (Fig. 121.3).

Management

Initially, therapy should be directed toward proper resuscitation with assessment and management of the airway, breathing, and circulation (see Chapter 1). Extremely ill children may require endotracheal intubation to control ventilation and maximize O_2 delivery in cases of shock. Hypovolemia should be rapidly corrected with normal saline or Ringer's lactate solution. An initial bolus of fluid starting at 20 mL per kg is given rapidly until vital signs are improved and the patient produces urine. Vasopressor therapy should be considered for patients who do not have sufficient response to 60 to 80 mL per kg of isotonic fluids. Broad-spectrum antibiotics targeting bowel flora (gram-negative enterics as well as anaerobes) should be given. Immediate surgical consultation is necessary. Placement of a bladder catheter and central venous access with measurement of central venous pressure may be necessary to monitor response to therapy. Once the emergency physician is certain that the airway can be controlled and the circulation is adequate, relief of pain can be accomplished by using narcotic agents (e.g., morphine 0.1 mg per kg). The patient's fever can usually be controlled by antipyretics or cooling blanket. A nasogastric tube should be

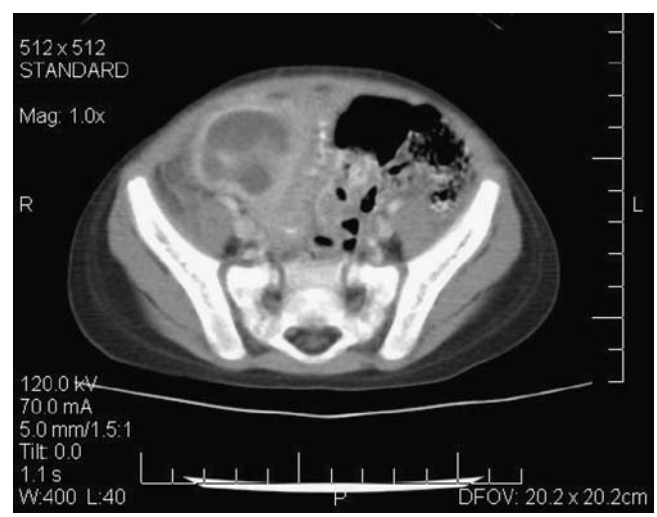

FIGURE 121.3 CT scan of perforated appendix with abscess.

placed to evacuate the contents of the stomach and to drain ongoing gastric secretions. For ill patients, blood products should be readied.

Children with perforated appendicitis can deteriorate quickly. Therefore, emergency resuscitation should be quickly followed by operative intervention. At surgery, the appendix is removed, the area is drained, and other appropriate treatments are given. For patients with minimal systemic signs, abscesses may be drained percutaneously using radiologically guided procedures—with the expectation of a delayed appendectomy.

Meckel's Diverticulitis with and without Perforation

Meckel's diverticulum is a vestige of the omphalomesenteric duct and occurs in 2% of the population. Most patients with a Meckel's diverticulum are asymptomatic or, if symptomatic, have rectal bleeding from ulceration at the junction of the ectopic gastric mucosa and the normal ileal mucosa (see the "Diseases that Produce Rectal Bleeding" section.). Classically, the bleeding is painless. Less commonly, Meckel's diverticulum presents with symptoms of diverticulitis with or without perforation. A preoperative diagnosis of an inflamed or a perforated Meckel's diverticulum is rarely made but, nevertheless, should be considered in the differential diagnosis of a perforated viscus leading to generalized peritonitis. The diagnosis is usually made in the operating room by the surgeon who finds a normal appendix, and then an exploration of the bowel finds a diseased diverticulum approximately 2 ft. from the ileocecal valve.

Primary Peritonitis

Primary peritonitis is a bacterial infection of the peritoneal cavity, usually secondary to a bloodborne or lymphborne infection. Although rare, it can occur in children with nephrosis, cirrhosis, or other etiologies of ascites, and may mimic appendicitis. Primary peritonitis is usually caused by *Streptococcus pneumoniae*, *Streptococcus pyogenes*, or gram-negative enteric organisms. Blunt trauma may lead to perforated viscus. Lacerations to the vaginal vault or rectum from instrumentation or abuse can lead to vaginal or rectal bleeding and peritonitis. Hirschspring's disease may lead to toxic megacolon and perforation. Rarely, peritonitis can spontaneously occur in girls from 5 to 10 years old in whom the cervix is open and the vaginal fluid is not yet acidic enough to retard the ascent of infection. Patients with nephritic syndromes have an increased incidence of primary peritonitis.

The clinical manifestations include fever, vomiting, and abdominal pain. The physical examination includes findings of peritoneal irritation. An elevated WBC count (greater than 15,000 per mm^3) and left shift are also seen. Often, the symptoms, signs, and laboratory findings are indistinguishable from those for perforated appendicitis; thus, the diagnosis may be made at laparotomy. If the diagnosis is suspected before surgery, the patient should undergo paracentesis. The diagnosis may be confirmed by a Gram stain showing bacteria followed by a positive culture.

Pancreatitis

Although acute pancreatitis is common in adults, it occurs rarely in children. The most common cause is abdominal trauma. Pancreatitis produces upper abdominal or periumbilical pain, often radiating to the back. Occasionally, the presentation is that of a patient in shock. Findings that support the diagnosis include paralytic ileus, distension, and ascites. Serum amylase or lipase is usually elevated. When severe, the serum calcium is also decreased. When pancreatitis occurs in a child without a history of trauma, the physician should evaluate the patient for possible congenital abnormalities of the biliary tree or pancreatic ducts, such as abnormal insertion of the main pancreatic duct or the presence of a choledochal cyst. Surgical intervention is rarely indicated in the acute phase. However, early surgical consultation is essential in case the patient deteriorates (see Chapter 89). Signs of deterioration include persistently low serum calcium, a falling hematocrit, increasing toxicity, and deterioration of the patient's coagulation profile.

ACUTE INTESTINAL OBSTRUCTION

In any child with persistent emesis, especially with bilious emesis, acute intestinal obstruction must be considered. If the obstruction is high in the intestinal tract, the abdomen does not become distended; however, with lower intestinal obstruction there is generalized distension and diffuse tenderness, usually without signs of peritoneal irritation. Only if the bowel perforates or vascular insufficiency occurs will signs of peritoneal irritation be found. If complete obstruction persists, bowel habits may change, leading to complete obstipation of both flatus and stool. All patients with suspected bowel obstruction should have radiographs of the abdomen in supine, upright, and prone cross-table lateral views. In patients with acute mechanical bowel obstruction, multiple dilated loops are usually seen. Fluid levels produced by the layering of air and intestinal contents are seen in the upright or lateral decubitus radiographs (Fig. 121.4).

Intussusception

Background

Intussusception occurs when one segment of bowel invaginates into a more distal segment. This is the leading cause of acute intestinal obstruction in infants, and it occurs most commonly between 3 and 12 months of age. The most common intussusception is ileocolic but the small bowel may intussuscept into itself. Often, it will be ileoileal at a location close to the cecum. Typically, this small bowel intussusception then prolapses through the ileocecal valve (Figs. 121.5 and 121.6). The intussusception continues through the colon a variable distance, occasionally as far as the rectum, where it can be palpated on rectal examination. Colocolic intussusceptions are rare. In infants, the lead point for the intussusception may be hypertrophied Peyer's patches. In children older than 2 years, a specific lead point such as a polyp, a Meckel's diverticulum, a duplication, or a tumor is more likely. A diarrheal illness, viral syndrome, or Henoch-Schönlein purpura may occur several days to a week before the onset of abdominal pain and obstruction.

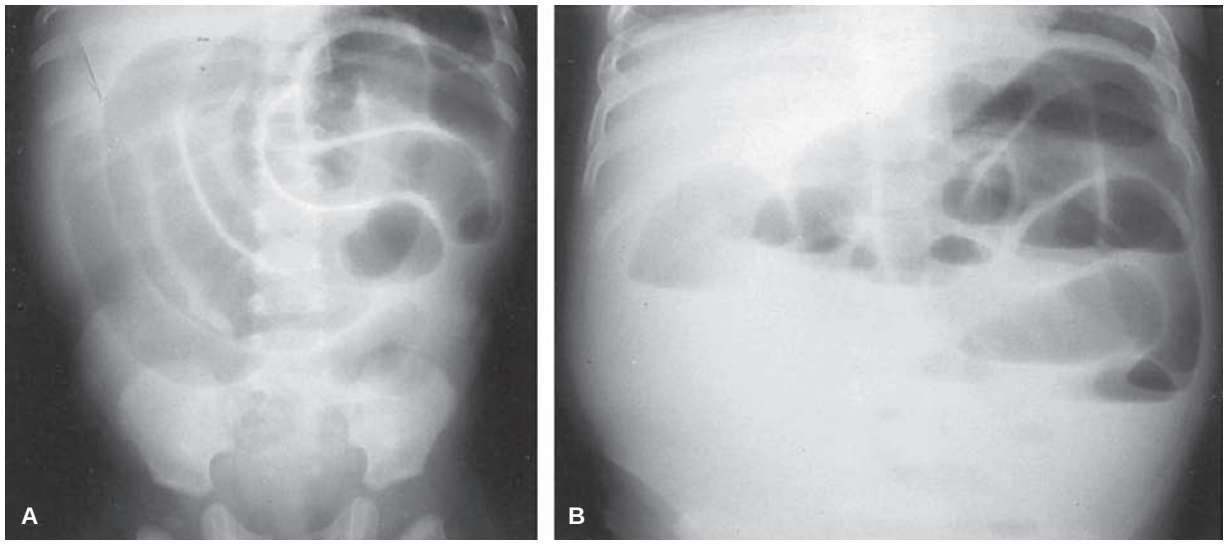

FIGURE 121.4 **A:** Small bowel obstruction. Numerous dilated small bowel loops occupy the midabdomen and have a stepladder configuration. Minimal air is seen in the rectum. **B:** Same patient as in **A.** The upright abdominal roentgenogram shows numerous dilated loops in the small bowel with differential fluid levels in one loop indicating mechanical bowel obstruction.

Clinical Manifestations

The primary manifestation of intussusception is colicky abdominal pain. This symptom may have been preceded by the symptoms and signs of a viral gastroenteritis or even an upper respiratory infection. Gradually, the child becomes more irritable and anorectic, and may vomit. The pattern of pain in a child with an intussusception is often consistent and characteristic, and the diagnosis is suggested strongly if a history of episodic pain is obtained. The child may appear to be comfortable and well between episodes. Occasionally, the infant may appear lethargic and listless. At times, patients with intussusception have been misdiagnosed as being in a postictal state or encephalopathic.

The localized portion of the intussusception leads to partial or complete obstruction and generalized abdominal distension. In some cases, the intussuscepted mass can be palpated as an ill-defined, sausage-shaped structure if the abdomen is not too distended. This mass is most often palpable in the right upper quadrant.

When children arrive in the ED early in the course of intussusception, there is often no history of having passed a currant jelly stool, although blood may be found on rectal examination (50% to 75% of cases have occult blood). However, the absence of bloody stools should not preclude making the diagnosis of a possible intussusception. Infants and young children

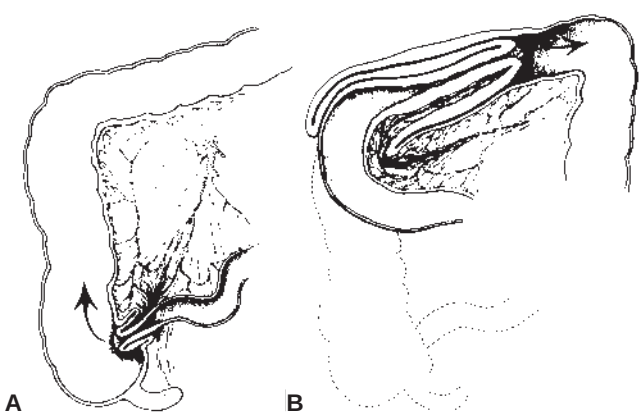

FIGURE 121.5 Ileocolic intussusception. **A:** Beginning of an intussusception in which terminal ileum prolapses through ileocecal valve. **B:** Ileocolic intussusceptum continuing through the colon. This can often be palpated as a mass in the right upper quadrant.

FIGURE 121.6 Ileocolic intussusception. Barium enema shows the intussusception as the filling defect within the hepatic flexure surrounded by spiral mucosal folds. Significant distended small bowel represents distal small bowel obstruction.

with colicky abdominal pain and emesis should be evaluated for intussusception. Only 20% of infants with intussusception have the triad of colicky abdominal pain, vomiting, and bloody stools.

As the bowel becomes more tightly intussuscepted, the mesenteric veins become compressed, whereas the mesenteric arterial supply remains intact. This leads to the production of the characteristic currant jelly stool, which may be passed spontaneously or found on the rectal examination. As the intussusception becomes swollen, the pressure of entrapment occludes the arteries. At this point, the bleeding lessens, but the bowel can become gangrenous and even perforate, leading to peritonitis.

Management

The patient should be prepared by inserting an IV line and a nasogastric tube. IV fluids should be given to correct dehydration. Nasogastric suction minimizes the risk of vomiting and aspiration. Once blood has been sent to the laboratory for a CBC electrolytes, and a cross-match, the patient should have radiologic studies.

Plain radiograph findings of intussusception are variable and depend primarily on the duration of the symptoms and the presence or absence of complications. In early cases, a normal gas pattern is seen. Distal colonic air cannot be interpreted as an absence of intussusception. Unless the radiograph exhibits air in the cecum, ileocolic intussusception cannot be excluded by radiograph. In the patient with symptoms longer than 6 to 12 hours, flat and upright films often show signs of intestinal obstruction, including distended bowel with air–fluid levels (Fig. 121.4). A characteristic "target" sign may be seen or more commonly a paucity of gas in the right lower quadrant. Occasionally, the actual head of the intussusception can be seen on a plain film as a soft-tissue mass. US can be used diagnostically with reported sensitivity of 98% to 100%.

In more recent years, air insufflation enema or hydrostatically controlled barium enema has been a successful therapy in up to 70% to 95% of cases with higher success rates reported with air reduction. Strict reduction guidelines must be followed to avoid perforation. The full reduction of the intussusception is confirmed only when there has been adequate reflux of barium or air into the ileum. Patients with peritonitis or free air on plain radiograph should not have an enema study or reduction attempt. In the seriously ill infant with signs of peritonitis or a frank small bowel obstruction, the diagnosis of intussusception should be made with isotonic water-soluble contrast media with no attempt at reduction. The reduction in such infants should be performed surgically. Perforation rates with enema reduction have been reported in up to 3%. Criteria that are linked to a lower reduction rate and a higher perforation rate, especially if more than one is present, are patient age younger than 3 months or older than 5 years; long duration of symptoms, especially if greater than 48 hours; passage of blood via the rectum (hematochezia); significant dehydration; and evidence of small bowel obstruction on plain radiograph.

Many children with intussusception require emergency surgery, especially if the intussusception has been of long duration or the child shows evidence of gangrenous bowel, including high fever, leukocytosis, significant distension, and general toxicity. If an enema reduction seems safe and appropriate, the operating room should be placed on standby and the operating team should be ready to commence immediate surgery if complications develop during the procedure or if unsuccessful. Preoperative preparation and resuscitation begins in the ED and continues during the enema. A general surgeon should be present or immediately available in case of perforation during the procedure. Barium enemas can lead to peritoneal contamination with barium, and air enemas can lead to massive pneumoperitoneum and sudden death unless the abdomen is decompressed (by needle decompression). Sedation has been associated with decreased rates of reduction. Delay in reduction can lead to gangrenous bowel.

The recurrence rate after enema reduction ranges from 1% to 3%. When there is a recurrence, a second attempt at reduction may be done by enema. This is usually successful in most cases, but with a third episode of intussusception, an exploratory laparotomy must be done. Recurrences are more common in older children and may be caused by a lead point such as a Meckel's diverticulum, an intestinal polyp, or an intraluminal tumor such as lymphoma. Therefore, it may be wise in an older child to operate with the first recurrence.

Incarcerated Inguinal Hernia

Incarcerated inguinal hernia is a common cause of intestinal obstruction in the infant and young child. Approximately 60% of incarcerated hernias occur during the first year of life. Incarceration occurs more often in girls than in boys, but usually involves the ovary rather than the intestine. Often, the patient or family has no previous knowledge of the presence of a congenital hernia. Incarceration does not necessarily mean that the nonreducible portion of intestine is compromised or gangrenous. However, strangulation can occur within 24 hours of a nonreduced incarcerated hernia because of progressive edema of the bowel caused by venous and lymphatic obstruction. This obstruction then leads to occlusion of the arterial supply with resulting necrosis of the bowel and perhaps perforation.

The clinical presentation of a child with an incarcerated hernia is irritability due to pain, vomiting, and occasionally abdominal distension. A firm, discrete mass can be palpated at the internal ring and may or may not extend into the scrotum. Occasionally, the testicle may appear dark blue because of pressure on the spermatic cord causing venous congestion, and in a prolonged incarceration, the testicle may be infarcted. Intestinal obstruction may develop quickly, and an abdominal radiograph exhibits signs of small bowel obstruction and possibly gas-filled loops of intestine in the scrotum. Lack of air in the inguinal region cannot be used to exclude a hernia because the intestine, especially when incarcerated, is often fluid filled. It is often difficult to differentiate a tense hydrocele in the scrotum from an incarcerated hernia. If the child has had a hydrocele, a sudden increase in fluid in the tunica vaginalis may produce discomfort, and the concern is that the child has developed an incarcerated hernia. However, it is uncommon for a hernia to appear in the presence of a communicating hydrocele because of the narrowness of the patent processus vaginalis that is associated with the hydrocele. The acute hydrocele presents only in the scrotum but may extend somewhat up into the inguinal canal. However, no mass can be felt

in the area of the internal ring, indicating that no intestine is exiting from the ring.

Unless the child is extremely ill with signs of intestinal obstruction or toxic from gangrenous bowel, a manual reduction of the incarcerated hernia should be attempted. The child should be sedated with morphine 0.1 mg per kg intravenously with standard monitoring of respiratory status. The mother should then cuddle the baby until it relaxes and falls asleep. An older child may be placed in the Trendelenburg position to allow gravity to facilitate the reduction. Once the child is asleep, gentle manipulation of the incarcerated mass should be attempted. Mild pressure should be exerted at the internal ring with one hand, while the other attempts to squeeze gas or fluid out of the incarcerated bowel back into the abdominal cavity. If the reduction is unsuccessful, the child should be taken immediately to the operating room.

After the hernia has been reduced manually, the child may be admitted for observation but not immediate repair. The hernia sac and spermatic cord are edematous after a reduction, making the repair difficult. Usually, it is done 24 hours after admission. If a child has persistent emesis after a manual reduction of a hernia, consider the possibility that the bowel was incompletely reduced. Children that develop peritoneal signs after manual reduction should be evaluated for possible perforation associated with gangrenous bowel. Rarely should a child be sent home after a manual reduction unless the parents are properly informed concerning signs of recurrence or intestinal obstruction and are thoroughly reliable (see the "Inguinal Hernias and Hydroceles" section).

Incarcerated Umbilical Hernia

Incarceration of an umbilical hernia is rare. If present, there is a persistent and tender bulge in the umbilical hernia sac. If the incarceration is of short duration, a gentle effort might be made to reduce it manually, but it is often necessary to prepare the child for urgent surgery. At the time of surgery, the loop of incarcerated bowel should be inspected, rather than letting it drop back into the abdominal cavity, to be certain that there has been no vascular impairment (see the "Umbilical Hernias" section).

Malrotation of the Bowel with Volvulus

Background

Malrotation of the bowel is a congenital condition associated with abnormal fixation of the mesentery of the bowel (Fig. 121.7). Therefore, the bowel has a tendency to volvulize and obstruct at points of abnormal fixation. Although malrotation with volvulus usually occurs either in utero or during early neonatal life, malrotation can be unrecognized until childhood (25% of cases present after 1 year of age). This is an extraordinarily dangerous situation because a complete volvulus of the bowel for more than an hour or two can totally obstruct blood supply to the bowel, leading to complete necrosis of the involved segment. When a volvulus involves the midgut, the entire small bowel and ascending colon may be lost. To prevent such a catastrophe, physicians should have a high index of suspicion for malrotation in any child with signs of obstruction and be prepared to get a child with a presumed volvulus to the operating room immediately.

Clinical Manifestations

Any child with bile-stained vomiting and abdominal pain may have malrotation with volvulus. The pain is usually intense and constant. Blood may appear in the stool within a few hours and suggests the development of ischemia and possible necrosis of the bowel. Clinically, malrotation can present in several different ways: first, and most dangerous, is the sudden onset of abdominal pain with bilious vomiting with no prior history of GI problems; second is a similar abrupt onset of obstruction in a child who previously seemed to have "feeding problems" with transient episodes of bilious vomiting; and third is a child with failure to thrive because of alleged intolerance of feedings.

On physical examination, there may be only mild distension of the abdomen because the obstruction usually occurs high in the GI tract. On palpation, the physician may discern one or two prominently dilated loops of bowel. The abdomen may be diffusely tender and yet not have signs of peritonitis early in the course. On rectal examination, the presence of blood on the examining finger is an alarming sign of impending ischemia and gangrene of the bowel.

Management

The key to management is to be suspicious of malrotation and to obtain flat and upright radiographs of the abdomen immediately. The presence of loops of small bowel overriding the liver shadow is suggestive of an underlying malrotation. When complete volvulus has occurred, there may be only a few dilated loops of bowel with air–fluid levels. Distal to the volvulus, there may be little or no gas in the GI tract. A "double-bubble sign" is often present on an upright film because of partial obstruction of the duodenum causing distension of the stomach and first part of the duodenum (Fig. 121.8A).

When a child is being assessed for possible malrotation, an upper GI series is the study of choice. The ligament of Treitz is absent in the malrotation anomaly; therefore, the C-loop of the duodenum is not present, the duodenum lies to the right of the spine, and the jejunum presents a coiled spring appearance in the right upper quadrant (Figs. 121.8B and 121.9). The cecum is not fixed and usually assumes a position in the right upper quadrant. However, because of its mobility, the cecum on barium enema may be seen in its normal position in the right lower quadrant. Therefore, a barium enema is not the most reliable study to rule out malrotation. In the neonate, the cecum sometimes takes a high position, and this could give a false impression of malrotation. If a US is obtained, as with possible pyloric stenosis or intussusception, an abnormal relationship between the superior mesenteric artery and vein should lead to an upper GI series.

As in the case of a child with an unreduced intussusception, a child with a possible volvulus should be prepared for immediate surgery. The operating room and operating team should be notified. IV fluid and electrolyte replacement should begin immediately. Laboratory studies should be obtained, but they do not add to the diagnostic evaluation. A nasogastric tube should be inserted and blood cross-matched. Because this entity can present even in adulthood, every physician should understand the pathogenesis and the need for surgical therapy

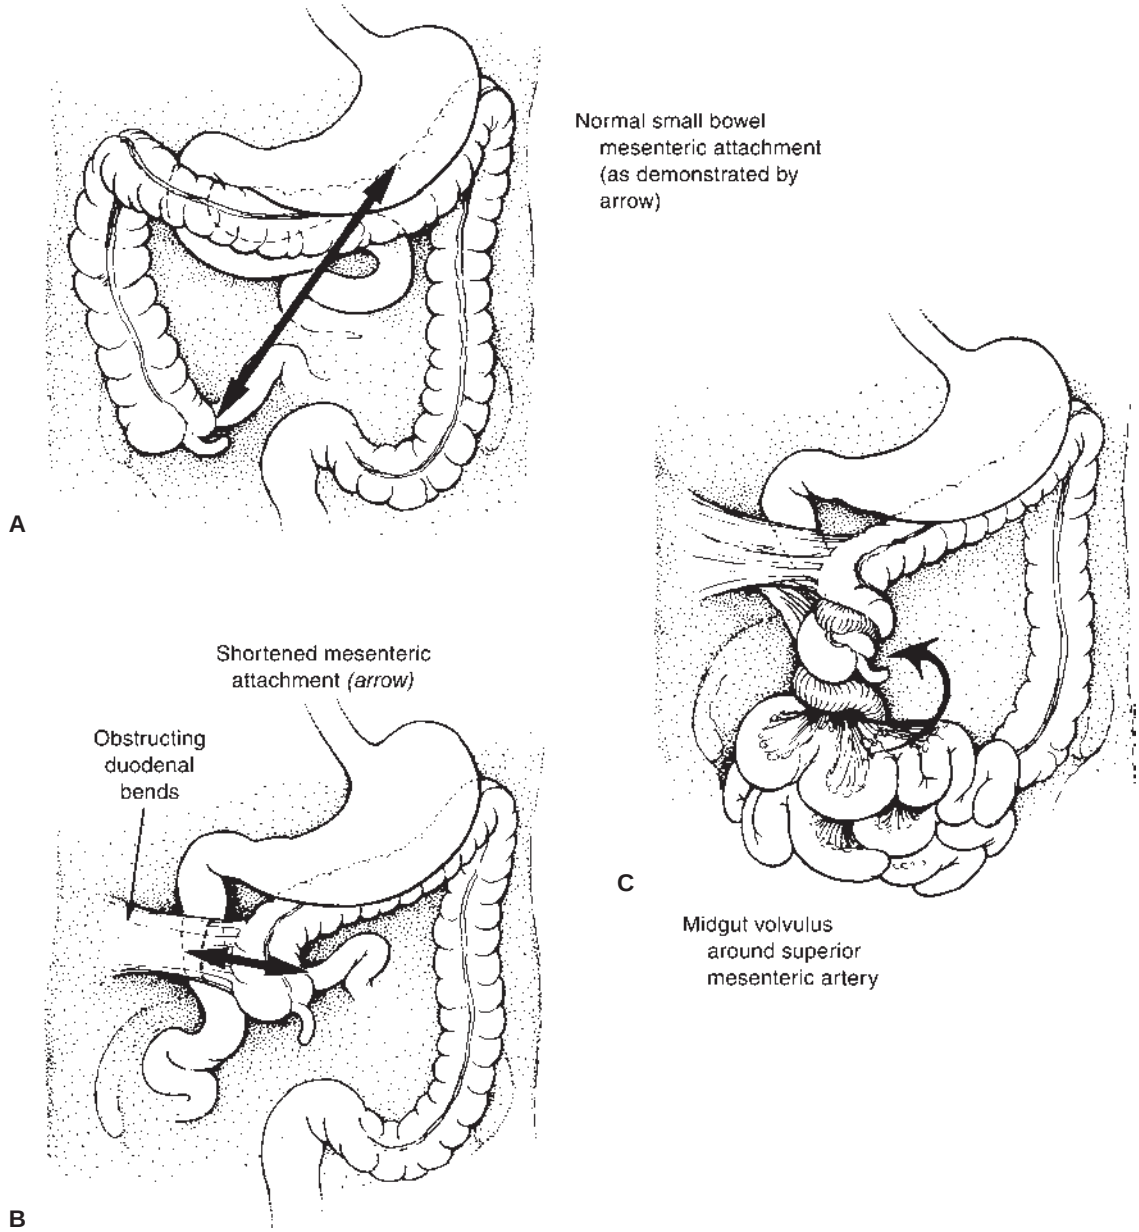

FIGURE 121.7 Malrotation with volvulus. **A:** Normal small bowel mesenteric attachment (as demonstrated by the *arrow*). This prevents twisting of small bowel because of the broad fixation of the mesentery. **B:** Malrotation of colon with obstructing duodenal bands. **C:** Midgut volvulus around the superior mesenteric artery caused by the narrow base of the mesentery.

of malrotation. If immediate transfer to a pediatric hospital cannot be accomplished within an hour, a laparotomy should be performed without delay.

Pyloric Stenosis

Pyloric stenosis refers to an idiopathic hypertrophy of the pyloric muscle and occurs in 1 in 250 births. There is a male:female ratio of 4:1, and first born males are at higher risk. A familial incidence has been shown, particularly if the mother had hypertrophic pyloric stenosis as an infant. The age of onset is usually 2 to 5 weeks. Rarely, the onset may be late in the second month of life. The cause of the muscle hypertrophy is unknown, but the symptoms, diagnosis, and therapy are well defined. A causal relationship has been established with macrolide therapy (often used for motility), but the extent is still unknown.

Clinical Manifestations

Characteristically, the infant does well, without vomiting, for the first few weeks of life and then starts vomiting, either at the end of feedings or within 30 minutes. The infant is hungry and will eat immediately after vomiting. The vomiting becomes more prominent and eventually becomes forceful, projectile emesis.

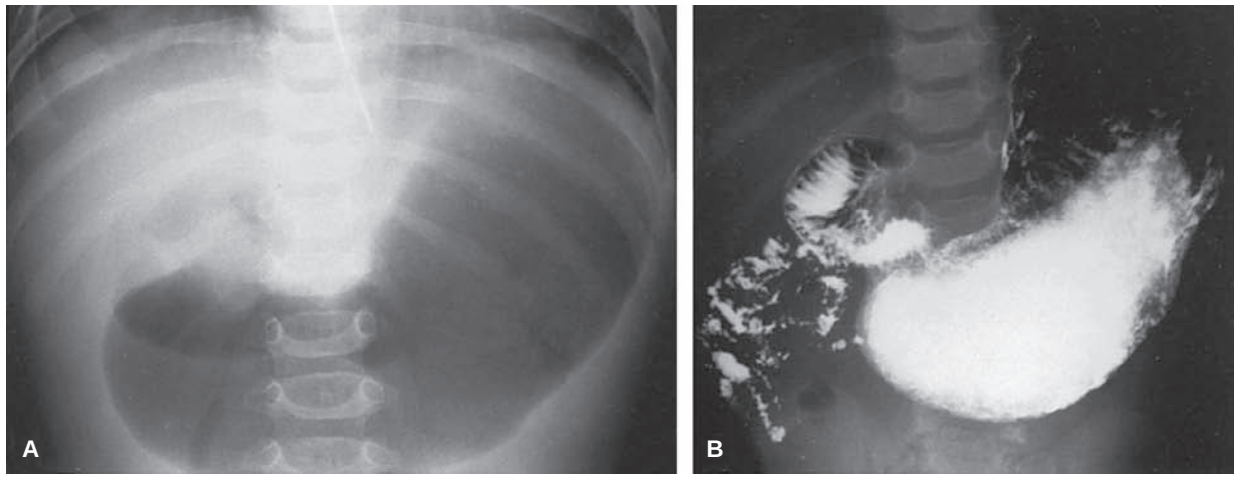

FIGURE 121.8 **A:** Malrotation of the bowel. Supine plain roentgenogram of the abdomen shows distended stomach and proximal duodenal loop. **B:** Same patient as in **A.** Upper gastrointestinal series shows dilated proximal duodenum with abrupt transition to normal caliber of small bowel. Abnormally placed ligament of Treitz. Proximal jejunum in the right abdomen.

The vomitus is always nonbilious. With protracted emesis, hematemesis can occur. Infants with pyloric stenosis may also become jaundiced with the onset of the other symptoms. The hyperbilirubinemia usually improves or abates postoperatively.

Early in the course, infants may appear perfectly active and well hydrated. In infants with protracted symptoms, moderate to severe dehydration may exist. The abdomen is soft and nondistended and if the infant is relaxed, an "olive" mass may be palpable in the midepigastrium. Sugar water can be used to help relax the infant for this part of the examination. Another diagnostic clue is the presence of prominent gastric peristaltic waves across the abdomen. If a nasogastric tube is placed, a large volume of gastric content may be retrieved and the "olive" more easily palpated.

FIGURE 121.9 Malrotation. Upper gastrointestinal study showing absence of the ligament of Treitz and coiled spring appearance of jejunum.

If the child has vomited for an extended period, he or she will show signs of growth failure. There may be loose, hanging skin and an absence of subcutaneous tissue. The infant may take on an "old man" appearance, with wrinkled skin on the face and body. Weight gain is inadequate, which may be calculated by knowing that the average child regains birth weight by 10 days of age and thereafter 15 to 30 g (0.5 to 1 oz) per day. With severe dehydration, the infant may be hypotonic and lethargic with poor feeding.

Serum electrolytes may be abnormal because of gastric losses. Accordingly, the potassium and chloride are low, and serum bicarbonate is high. This hypochloremic alkalosis may be profound with serum chlorides in the 65 to 75 mEq per L range. The patient can exhibit periods of apnea from the extreme metabolic alkalosis. When dehydration becomes severe, the patient may then develop acidosis, indicating an advanced and even more dangerous metabolic imbalance (see Chapter 100).

Management

Infants should be hospitalized and rehydrated with appropriate fluid and electrolyte replacement. Initially, IV fluids should be normal saline (lactated Ringer's solution is contraindicated) to replenish intravascular volume and supply adequate chloride. Potassium chloride should be added once urine output has been established. If hypotonic solutions are used, there is significant risk of causing hyponatremia (see Chapter 100). A volume of fluid appropriate to the patient's level of dehydration should be used.

Some pediatric surgeons will operate based on a typical history associated with a palpable pyloric mass. Commonly, US is used to confirm the diagnosis. The real-time US scanning not only increases the accuracy of the diagnosis of pyloric stenosis, but can also localize the "olive." The hypertrophic pyloric

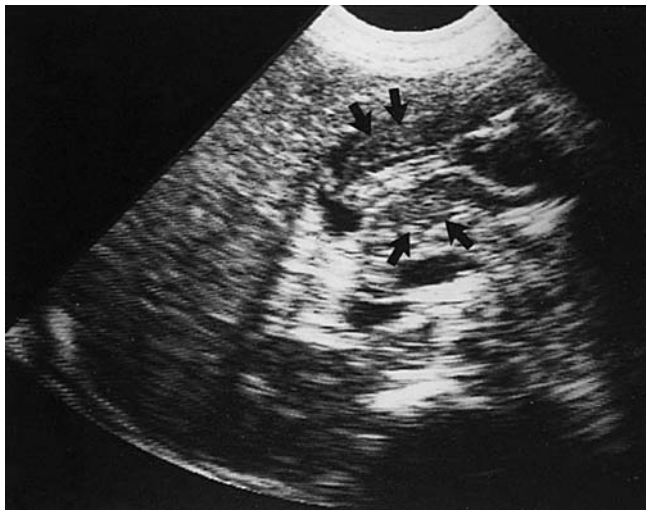

FIGURE 121.10 Hypertrophic pyloric stenosis. Ultrasonography of the abdomen shows thick pyloric muscle surrounding a centered echogenic mucosal and submucosal region *(arrows)*.

muscle is seen as a thick hypoechoic ring surrounding a central echogenic mucosal and submucosal region (Fig. 121.10). The quantitative criteria for the sonographic diagnosis of hypertrophic pyloric stenosis are 1.4 cm or longer length of the pyloric canal with 0.3 cm or greater thickness of the circular muscle.

If the US study does not show a hypertrophic pylorus, an upper GI series should then be done to eliminate gastroesophageal reflux, malrotation, and antral web as diagnostic possibilities. In general, pyloric stenosis can be identified by the presence of a "string sign" in the pyloric channel, seen best on oblique projections on the upper GI series (Fig. 121.11).

FIGURE 121.11 Pyloric stenosis. Long, narrowed, and tilting upward antropyloric canal. Parallel streaks of barium-producing typical string sign with complete obstruction *(arrows)* and eccentric lesser curvature indentation pyloric tilt *(arrow)*. The tilt is performed when the peristaltic wave meets the muscle mass.

FIGURE 121.12 Dilated loops of small intestine and absence of air in lower abdomen indicating a high intestinal obstruction caused by postoperative adhesions.

To lessen the risk of vomiting and aspiration, the barium should be evacuated from the stomach after the upper GI series has been completed. Surgical pyloromyotomy is a most successful form of therapy, and such infants can usually be discharged from the hospital 2 days after surgery. Some infants will have some regurgitation postoperatively as a result of a temporary relaxation of the gastroesophageal sphincter.

Postoperative Adhesions

Prior abdominal surgery or peritonitis places a child at risk for intestinal obstruction from adhesions (Fig. 121.12). Such obstruction can occur relatively early in the postoperative course or months or even years later. The child often has the sudden onset of abdominal cramps, nausea, vomiting, and abdominal distension. Although most intestinal obstructions from adhesions do not jeopardize the perfusion of the bowel, occasionally a loop of intestine, caught under a fibrous band, can become gangrenous. All such patients need to be admitted to the hospital and evaluated by a surgeon who should direct the complete management.

CHRONIC PARTIAL INTESTINAL OBSTRUCTION

Any child with intermittent abdominal distension, nausea, anorexia, occasional vomiting, or chronic constipation or obstipation may have partial intestinal obstruction. A number of diagnostic considerations exist.

Chronic Constipation

Chronic constipation is probably one of the most common causes for abdominal pain, distension, and vomiting in children. The history, if available from a reliable parent, may attest to chronic constipation; however, occasionally, such a child is diagnosed only by palpating a large mass through the intact abdominal wall or a hard fecal mass blocking the anal outlet on rectal examination. Such children may have a history of encopresis and appear malnourished. Chapter 13 covers the diagnostic approach to the child with constipation.

These children should be disimpacted manually or managed with saline enemas and a rectal tube passed above the obstruction. For children unable to tolerate disimpaction, oral or nasogastric bowel evacuants such as polyethylene glycol electrolyte solution can be used. If the process has progressed to partial bowel obstruction, in-hospital management is necessary to clean out the bowel adequately while monitoring and hydrating the patient adequately.

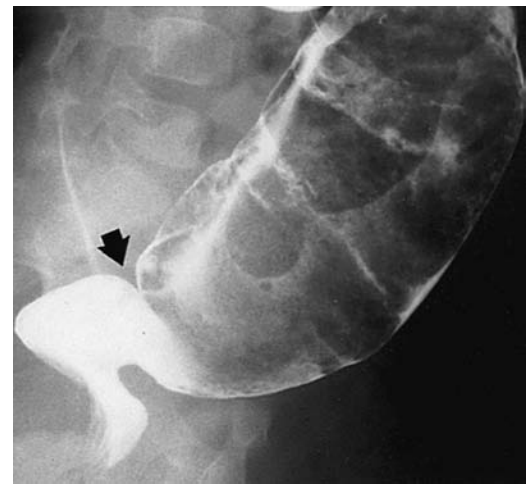

FIGURE 121.13 Hirschsprung's disease. Barium enema studies in lateral view show transition zone *(arrow)* with narrow rectum but dilated sigmoid colon.

Aganglionic Megacolon (Hirschsprung's Disease)

In patients with Hirschsprung's disease, the parasympathetic ganglion cells of Auerbach's plexus between the circular and longitudinal muscle layers of the colon are absent. The involved segment varies in length, from less than 1 cm to involvement of the entire colon and small bowel. The effect of this absence of ganglion cells produces spasm and abnormal motility of that segment, which results in either complete intestinal obstruction or chronic constipation.

These children have a lifelong history of constipation, so it is important to obtain an accurate account of the child's stool pattern from birth. A child with Hirschsprung's disease typically has never been able to stool properly without assistance (e.g., enemas, suppositories, anal stimulation). Normal stooling is not possible because of the failure of the aganglionic bowel and interval anal sphincter to relax. The child usually has no history of encopresis, as one would find in chronic functional constipation. These youngsters have chronic abdominal distension and are often malnourished. Vomiting is uncommon, as are other symptoms. Complete intestinal obstruction in Hirschsprung's disease is more likely to occur in early infancy and only rarely in the older age groups. It may present with signs and symptoms of acute bowel perforation.

Table 121.3 summarizes the pertinent diagnostic features differentiating functional constipation from Hirschsprung's disease.

After flat and upright abdominal roentgenogram radiographic studies have been obtained, a properly performed barium enema with a Hirschsprung's catheter is the best initial diagnostic procedure. There should be no preparation of the bowel. Ideally, the rectum should not be stimulated by enemas or digital examination for 1 to 2 days before the procedure. The key to diagnosis is seeing a "transition zone" (Fig. 121.13) between the contracted aganglionic bowel and the

TABLE 121.3

DIFFERENTIAL DIAGNOSIS OF FUNCTIONAL CONSTIPATION AND HIRSCHSPRUNG'S DISEASE

	Functional constipation	Hirschsprung's disease
Onset	<2 yr	Birth
History	Coercive training Colicky abdominal pain Periodic volume stools	Enemas necessary No abdominal pain Episodes of intestinal obstruction
Encopresis	Present	Absent
Abdominal distension	Absent or minimal	Present
Rectal examination	Feces-packed rectum	Empty rectum
Barium examination	Dilated rectum	Narrow segment
Motility	Normal	Abnormal
Biopsy	Ganglion cells	No ganglion cells

proximal dilated ganglionated bowel. Stimulation of the rectum shortly before the study may result in decompression of the proximal bowel, with loss of definition of the transition zone. When a clear-cut transition zone is seen, it is not necessary to fill the colon with barium more than 12 to 18 in above the transition point. It is important, however, not to empty the colon of barium at the end of the study. The presence of retained barium above the transition point 24 hours later strongly suggests the diagnosis of Hirschsprung's disease.

Anorectal manometry to determine the presence or absence of relaxation of the internal anal sphincter is helpful in establishing the neurogenic dysfunction of the bowel. Barium enema studies and manometry are clearly complementary in the diagnosis of Hirschsprung's disease. However, rectal manometric studies are more reliable than radiologic methods for short aganglionic segments that are usually not apparent on barium enema studies. Manometric studies are not dependable in infants younger than 3 weeks. If the barium enema and anal manometry studies indicate Hirschsprung's disease, rectal biopsy is not necessary to confirm the diagnosis.

In children of all ages, an adequately performed suction mucosal biopsy of the rectum 2 cm or more above the dentate line can be reliable in diagnosing Hirschsprung's disease. Because of the complicated evaluation and management of this disease, referral to a pediatric surgeon is recommended.

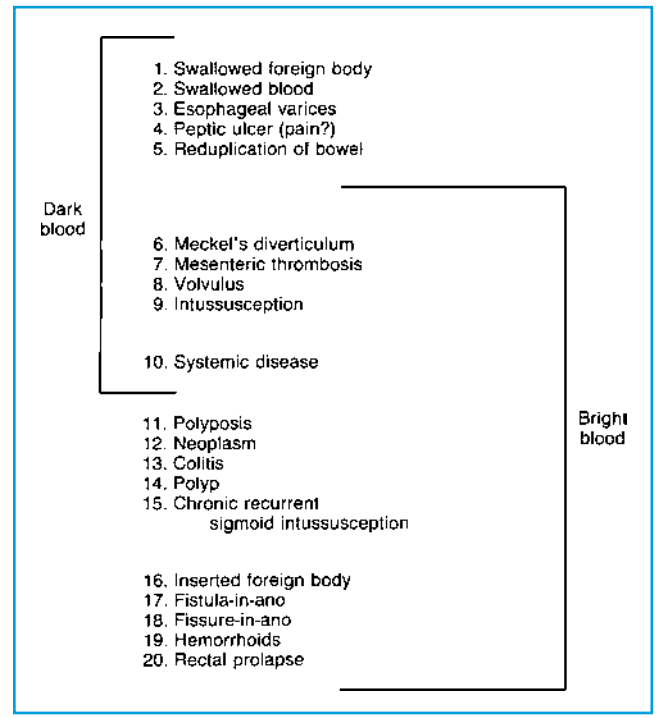

FIGURE 121.14 Causes of rectal bleeding in children.

Duplications

Duplications occur anywhere from the mouth to the anus and produce various symptoms. In the abdomen, there may be a noncommunicating cyst that gradually fills up with secretions and compresses the adjacent normal bowel, producing a palpable abdominal mass or chronic intestinal obstruction. Rarely, a marginal ulcer resulting from ectopic gastric mucosa may occur, and this produces painless bleeding. After appropriate radiographic diagnosis, surgery is indicated.

Inflammatory Bowel Disease

The older child or adolescent may develop either Crohn's disease or ulcerative colitis (see Chapter 89), and this must be included in the differential diagnosis of chronic intestinal obstruction. Usually, the child has a history of changing bowel habits, with mucus or blood in the stools, chronic abdominal pain, and weight loss. Chapter 89 covers inflammatory bowel disease in detail.

DISEASES THAT PRODUCE RECTAL BLEEDING

Rectal bleeding can be a sign of a serious condition. Blood on the outside of a formed stool is likely to originate from the distal large bowel, rectum, or anus. Blood mixed in the stool is generally from a higher source of bleeding. Blood associated with diarrhea is common with inflammatory bowel disease and infectious enteritis. A "tarry" stool suggests a source of bleeding in the proximal portion of the GI tract, and bright red blood suggests a more distal origin (Fig. 121.14). All patients with rectal bleeding should have a rectal examination. Those with significant hemorrhage require flexible colonoscopy. In some patients, no definite diagnosis may be reached despite extensive studies. In any patient with significant bleeding, however, surgical consultation is indicated. Chapters 29 and 89 further discuss the diagnosis and management of patients with GI bleeding.

Fissures

An anal fissure is probably the most common cause of bleeding, especially in infants. However, fissures may occur at any age. The child usually has a history of passing a large, hard stool with anal discomfort. Often, the child has a history of chronic constipation with progressive reluctance to pass stool because of the associated discomfort. If bleeding occurs, it usually involves streaking of bright red blood on the outside of the stool or red blood on the toilet tissues. The diagnosis can easily be made by inspection or anoscopic examination and appropriate measures taken to relieve the chronic constipation (see Chapter 13). Rarely does a child require hospitalization or surgery.

Juvenile Polyps

Older infants and children can develop either single or multiple retention polyps. Usually, the polyps occur in the lower portion of the colon and can often be palpated on rectal examination. Polyps bleed, but they rarely cause massive hemorrhage. They may intermittently prolapse at the anus or on

FIGURE 121.15 Juvenile polyp. Double air-contrast barium enema shows a single polyp with long stalk in transverse colon *(arrow)*.

occasion come free and be passed as a fecal mass associated with bleeding. Colonic polyps may be lead points for intussusception. Usually, however, polyps are asymptomatic except for the associated bleeding. These are not premalignant lesions, and they tend to be self-limiting (Fig. 121.15).

If a polyp can be felt on rectal examination or viewed through the sigmoidoscope, it may be safely removed. Polyps beyond the reach of the sigmoidoscope should be removed by colonoscopy.

Familial Polyposis

Families with multiple adenomatous colonic polyps are infrequently encountered. Bleeding is rare. More often, a colitis type of mucous discharge is present. Rectal examination and endoscopy reveal multiple "cobblestone" sessile polyps. These individuals are at risk for neoplasia because these are premalignant adenomatous polyps. The child should be referred to a pediatric surgeon and gastroenterologist for evaluation and long-term management.

Meckel's Diverticulum

Two percent of the population is born with a Meckel's diverticulum. This is the most common omphalomesenteric duct remnant. The diverticulum is usually located 50 to 75 cm proximal to the terminal ileum. Only 2% of persons with a Meckel's diverticulum manifest any clinical problems. The most common complication of a Meckel's diverticulum is a bleeding ulcer. Ectopic gastric mucosa in such patients is usually present in the diverticulum. The acid secretion produces ulceration at the junction of the normal ileal mucosa with the ectopic mucosa. Currant jelly stools or hemorrhage may be present. Other modes of presentation include diverticulitis, perforation with peritonitis, or intussusception as a result of the diverticulum's serving as a lead point.

Barium studies usually fail to outline a Meckel's diverticulum. The imaging modality of choice for detection of ectopic gastric mucosa in a bleeding Meckel's diverticulum is nuclear scintigraphy. A well-defined focal accumulation of radionuclide (^{99m}Tc pertechnetate) usually appears at or about the same time as activity in the stomach and gradually increases in intensity (Fig. 121.16). A duplication cyst with gastric mucosa shows the same focal accumulation of radionuclide. Preoperative differentiation between two lesions as a cause of GI bleeding is not important. The accuracy of scintigraphy in detection of ectopic gastric mucosa in Meckel's diverticula is approximately 95%. False-negative results may rarely occur in patients with rapidly bleeding Meckel's diverticula and with those diverticula that do not contain gastric mucosa.

In any child with a major rectal bleed and a negative scan, further workup, including an arteriogram if the bleeding continues to be active or colonoscopy when the bleeding is not active, is required.

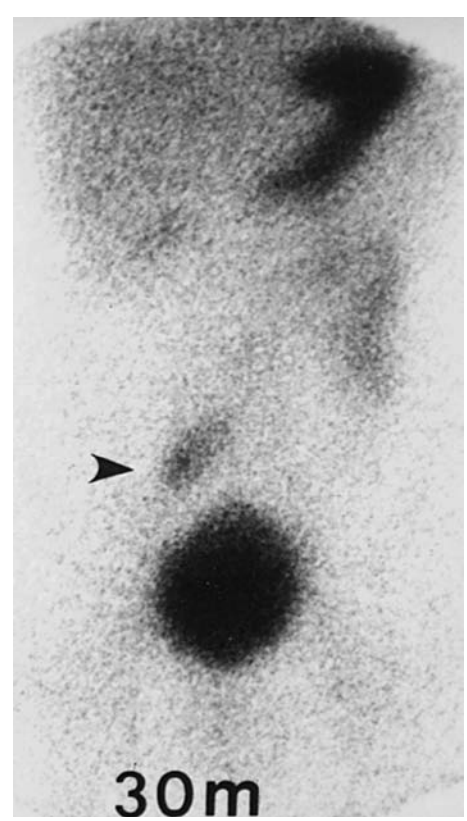

FIGURE 121.16 Meckel's diverticulum. Anterior image at 30 minutes shows an oval focal accumulation of ^{99m}Tc-pertechnetate in the right lower quadrant of the abdomen *(arrowhead)*.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura (see Chapters 91 and 85) is a vasculitic disorder that can produce asymptomatic rectal bleeding or abdominal pain. Usually there is a recognizable vasculitic rash with purpura, as well as petechiae mostly of the lower extremities and buttocks. Occasionally, a child will develop a small bowel intussusception from a submucosal hemorrhage that is acting as a lead point. Other common manifestations are hematuria, arthralgias or arthritis, purpuric rash, and testicular pain.

Other Causes of Rectal Bleeding

Other causes of rectal bleeding include intestinal vascular malformations, intussusception, duplications, inflammatory bowel disease, peptic ulcer with bleeding, portal hypertension with bleeding varices, foreign bodies of the rectum, and anal fistulas. These topics are covered elsewhere in this chapter and Chapters 29 and 89.

INTRAABDOMINAL MASSES

Background

Intraabdominal masses may be benign or malignant. Children are often asymptomatic even when the tumor is large; frequently, the mass is detected by the caregiver noticing a protuberant or lopsided abdomen.

It is difficult to feel an intraabdominal mass, as well as outline its limits and its degree of mobility, if an infant or child is crying. The physician should then make an effort to palpate the intraabdominal contents carefully. These masses can be fragile and prone to rupture. Therefore, palpation of the mass should be done gently and strictly limited to as few examiners as possible.

Retroperitoneal masses tend to be fixed, whereas masses attached to the mesentery or omentum are mobile and may be shifted to different locations by the examiner. Pelvic masses are commonly fixed and often can best be felt by rectal examination. A presacral mass may narrow the rectum and produce constipation. Abdominal masses present with various characteristics and may be smooth, nodular, cystic, or firm.

Initial evaluation in the ED may include flat and upright abdominal films. If, after such an examination, the origin of the mass is unclear or suggests a neoplasm, the patient should be admitted and a workup done without delay. Observation has no place in dealing with unexplained abdominal masses in children.

Diagnostic imaging should identify the precise anatomic location and extent of the pathologic process. The general location of a mass, with or without calcification, can be confirmed by plain abdominal roentgenograms. Ultrasonography has become increasingly popular as initial imaging because it does not require GI preparation or injected contrast, yet it is diagnostically accurate. Ultrasonography can differentiate a cystic flank mass (Fig. 121.17) that could be a hydronephrotic kidney from a solid tumor such as an adrenal neuroblastoma, and thus, facilitate the proper referral of the child to either a urologist or a pediatric surgeon. CT is superior to other modalities for anatomic detail, and it provides anatomic and physiologic information about organs and vascular structures despite overlying gas and bones. Renal scans are superior to excretory urography for determining renal function. Angiography is indicated for an abdominal mass only if a precise knowledge of segmental vascular anatomy is required or if interventional techniques are contemplated.

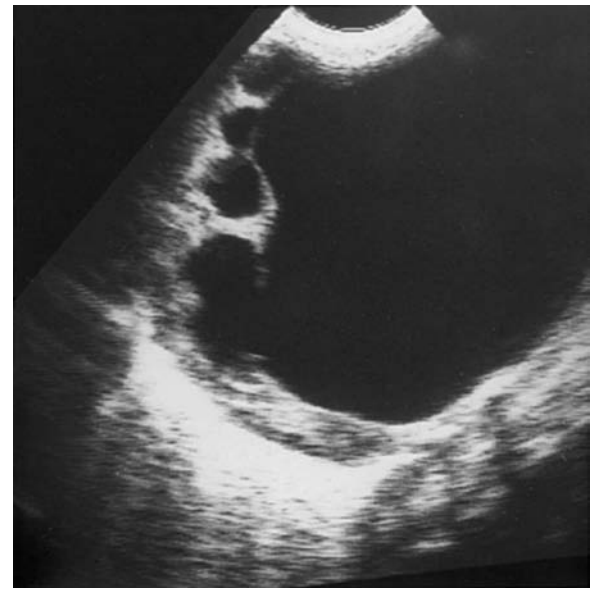

FIGURE 121.17 Ureteropelvic junction obstruction. A newborn with left flank mass. Ultrasonography of the left flank shows dilated pyelocalyceal system. The communicating dilated collecting systems are seen in the periphery of the significantly dilated renal pelvis.

Sacrococcygeal Teratoma

The presacral sacrococcygeal teratoma is the most common tumor of the caudal region in children and is more common in females than in males (4:1). Most tumors are benign and are noted at birth. Tumors in patients beyond neonatal age have a higher incidence of malignancy. Radiography shows a soft-tissue mass that arises from the ventral surface of the coccyx. Calcifications are present in 60% of presacral sacrococcygeal teratoma and are more common in benign tumors. US confirms whether presacral sacrococcygeal teratomas are cystic, solid, or mixed and can also determine impingement on the urinary tract. CT is helpful in confirming the diagnosis, particularly in older children, and demonstrates the content of a tumor, as well as its extent and bone anomalies. Tumors with more solid components are more often malignant than those with more cystic components (Fig. 121.18).

Nonmalignant Intraabdominal Masses

Fecaloma

A lower abdominal mass, particularly one on the left side, is most often related to retained stool and associated with chronic functional constipation than with Hirschsprung's

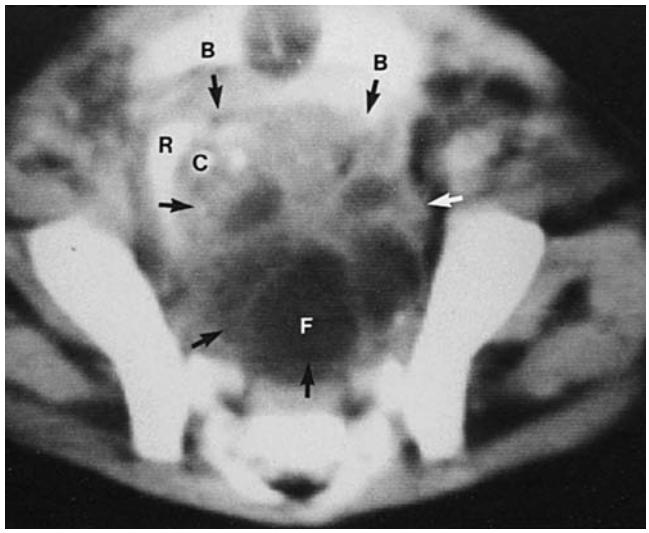

FIGURE 121.18 Presacral teratoma. Computed tomographic section of pelvis with contrast medium enhancement shows a large cystic mass *(arrows)*. The mass contains both fat and calcification, and displaces the rectum anteriorly and laterally, and the bladder anteriorly. B, bladder with Foley catheter; C, calcification; F, fat; R, rectum.

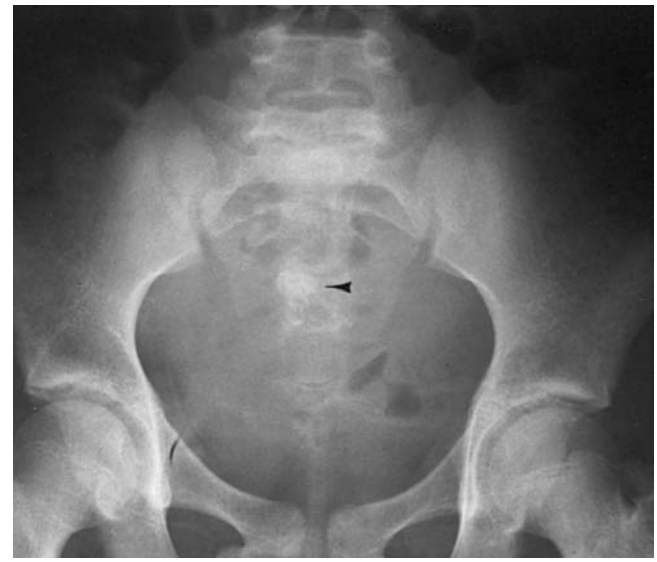

FIGURE 121.19 Ovarian dermoids. Note calcification *(arrows)* in superior aspect of a large pelvic mass in a 12-year-old girl.

disease. If a mass is found, a careful review of bowel habits is important. If an abdominal mass is a fecaloma, a large bolus of stool can usually be felt on rectal examination just inside the anus. The evaluation of the impaction, and irrigation of the upper sigmoid colon, should cause the mass to disappear. See Chapter 13 for the causes of constipation.

Ovarian Masses

Simple ovarian cysts and solid teratomas are not uncommon and may be asymptomatic even though they have reached a large size. Occasionally, the child presents with urinary complaints from the pressure on the bladder or urethra. Granulosa cell tumors of the ovary produce precocious puberty because they are hormonally active tumors. They may be malignant. The sudden onset of severe abdominal pain may indicate torsion of an ovarian mass, with resultant ovarian infarction.

Radiographs may show calcification in about half of patients with teratomas (Fig. 121.19). Because an occasional ovarian tumor is malignant in children, children with ovarian masses should be promptly evaluated and prepared for surgery (see Chapter 90).

Omental Cysts

Omental cysts are rare, are usually asymptomatic, and can fill the abdomen. It is often difficult to differentiate an omental cyst from ascites. Smaller cysts are more mobile and can be pushed freely into all quadrants of the abdomen. If a cyst volvulizes on its pedicle or has bleeding within it, it may cause abdominal pain or tenderness. Elective surgical excision is indicated.

Mesenteric Cysts

Mesenteric cysts can occur anywhere in the mesentery but are most common in the mesentery of the colon. They tend to be multilocular and are often discovered during a routine examination or after an episode of abdominal trauma with enlargement from bleeding. They are benign, but surgical therapy is indicated, both to confirm the diagnosis and to prevent complications. They can usually be removed with sparing of the bowel, or they can be marsupialized into the general peritoneal cavity where the fluid is absorbed.

Duplications

GI duplications within the abdomen can occur anywhere along the greater curvature of the stomach, the lesser curvature of the duodenum, or the mesenteric side of either the small or large intestines. They can also be pararectal, rising up out of the pelvis. Duplications that produce abdominal masses are either noncommunicating, and hence gradually enlarge, or communicating in that their secretory lining has a distal communication with the true lumen of the bowel. Except for the rare occurrence of massive rectal bleeding in a child with a communicating duplication, most duplications do not present as emergencies. Instead, they present in children either as unexplained abdominal masses or with symptoms of intermittent colic, resulting from partial obstruction of the true lumen of the adjacent bowel. The exact diagnosis is often unclear until the time of laparotomy.

Malignant Intraabdominal Masses

About 50% of the solid malignant tumors seen in children occur within the abdominal cavity. Most solid masses occur in the retroperitoneum. The most common is neuroblastoma, followed by Wilms' tumor and rhabdomyosarcoma. Other unusual tumors, such as embryonal cell carcinomas (yolk sac tumor) and lymphosarcoma, also occur in young children. Chapter 97 covers oncologic emergencies. As with most

malignant tumors, early diagnosis and treatment provide the best prospects for a cure.

Neuroblastoma

Neuroblastoma most often occurs as a tumor arising from the adrenal gland, but it can develop anywhere along the sympathetic chain or in the pelvis. It can grow extensively, often crossing the midline of the abdomen and enveloping key vascular and visceral structures. The best cure rates are generally in children who are younger than 1 year at the time of diagnosis and in whom the tumor is still localized to the point of origin. In such favorable cases, the tumor can be totally excised. When widespread dissemination occurs, complete resection is unwarranted because of the risk to other vital structures.

CT with contrast enhancement demonstrates precise anatomy, as well as renal function and organ vascularity. The CT characteristics of neuroblastoma include irregular shape, irregular margins, lack of well-defined capsules, and mixed low-density center. Neuroblastoma often displaces surrounding organs and encases vessels. Prevertebral midline extension is common. There are calcifications in at least 75% (Fig. 121.20). Ultrasonography has limitations in accurately determining tumor margins or local extension.

Wilms' Tumor

Wilms' tumor is the most common intrarenal tumor seen in children. The tumor can be massive before its discovery. Wilms' tumor should be considered in any child who has unexplained hematuria.

A solid renal mass demonstrated by US in infants and children is usually a Wilms' tumor. Because of the high frequency of tumor extension into the renal veins and inferior vena cava

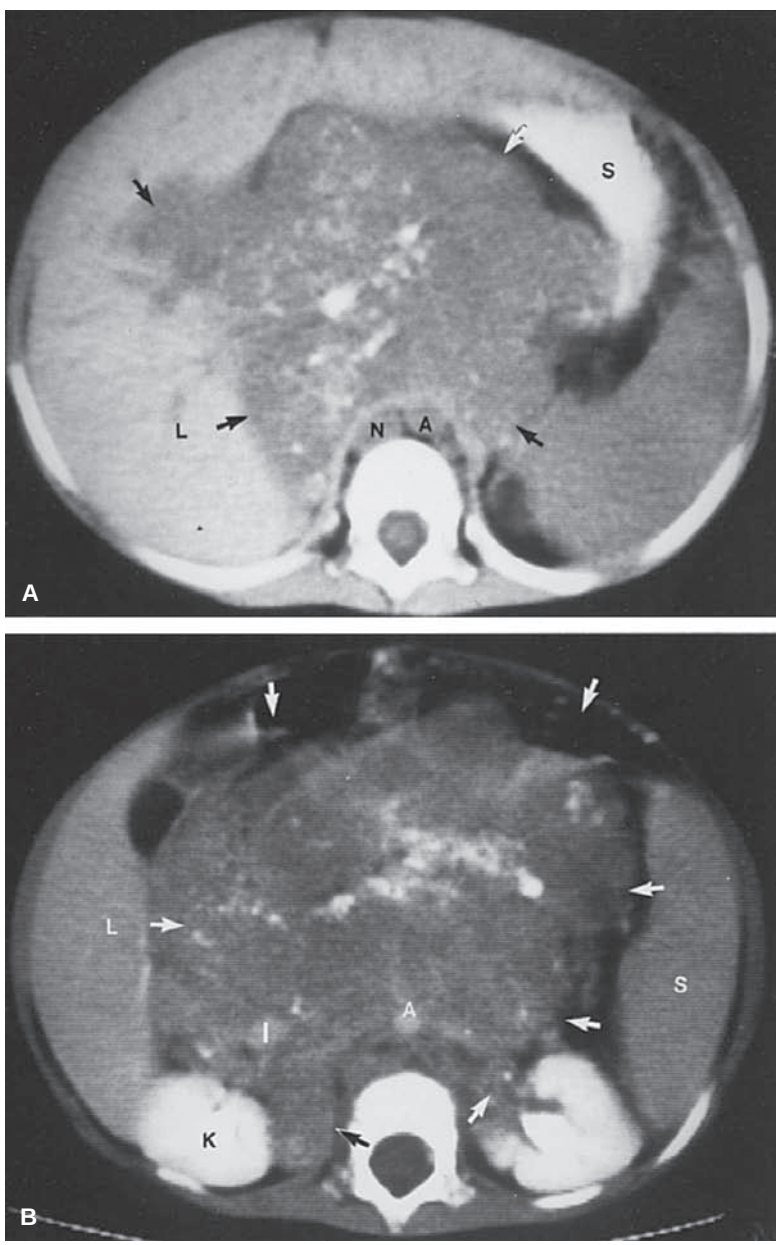

FIGURE 121.20 **A:** Celiac axis neuroblastoma. Computed tomographic (CT) section of the abdomen shows a large lobulated mass with multiple flakes of calcification displacing stomach and the liver *(white arrow)*. Note presence of retrocrural node *(black arrows)*. A, aorta; L, liver; N, node; S, stomach. **B:** Celiac axis neuroblastoma. Enhanced CT section of the abdomen at level of the kidney shows a large lobulated mass with irregular margins and calcification displacing the right kidney inferoposterior and laterally. Note encased inferior vena cava (IVC) and aorta. The IVC is displaced laterally and ventrally and to the right the superior mesenteric artery and celiac axis are completely surrounded by the mass. A, aorta; I, IVC; K, kidney; L, liver; S, spleen; *white arrows*, mass.

(IVC), these vascular structures should be examined by US. Because Wilms' tumors are usually large and expansive, the IVC often is extrinsically displaced by the tumor mass. CT with bolus contrast enhancement may be required for confirmation of equivocal invasion in a patient suspected of having Wilms' tumor. A CT scan can define the presence of an intrarenal mass and extent of tumor, visualizes vascular structures, identifies nodal involvement, defines internal hemorrhage and necrosis, evaluates the presence or absence of liver metastases, and provides some measure of renal excretory function. Also, CT can determine whether a tumor is initially nonresectable or bilateral (Fig. 121.21). Chest CT is also performed at the initial evaluation to identify pulmonary metastases. Patients with presumed Wilms' tumor require admission for coordinated approach by the surgeon and oncologists.

Rhabdomyosarcoma

Rhabdomyosarcoma can occur anywhere in the abdomen or pelvis where there is striated muscle. Tumors are particularly common in the pelvis, involving the prostate, uterus or vagina, and retroperitoneal structures, but they have also been found in the common bile duct and other unusual sites. These tumors can reach a large size before they become symptomatic, and each must be managed individually, depending on the site of origin, extent of growth, and the degree of spread. Modern selective therapy has greatly improved the survival rate of this highly malignant tumor.

Hepatomas

The most common primary GI tract neoplasm is hepatic in origin. Hepatoblastoma and hepatocellular carcinoma are the two main subgroups of liver tumors; they are clinically indistinguishable at presentation. Many are asymptomatic, but symptoms such as early satiety, weight loss, and abdominal pain may be seen especially with very large tumors. More often, the tumor is discovered after caregivers notice a change in the appearance of the abdomen. They are usually seen in older infants and young children. Increased levels of α-fetoprotein are associated

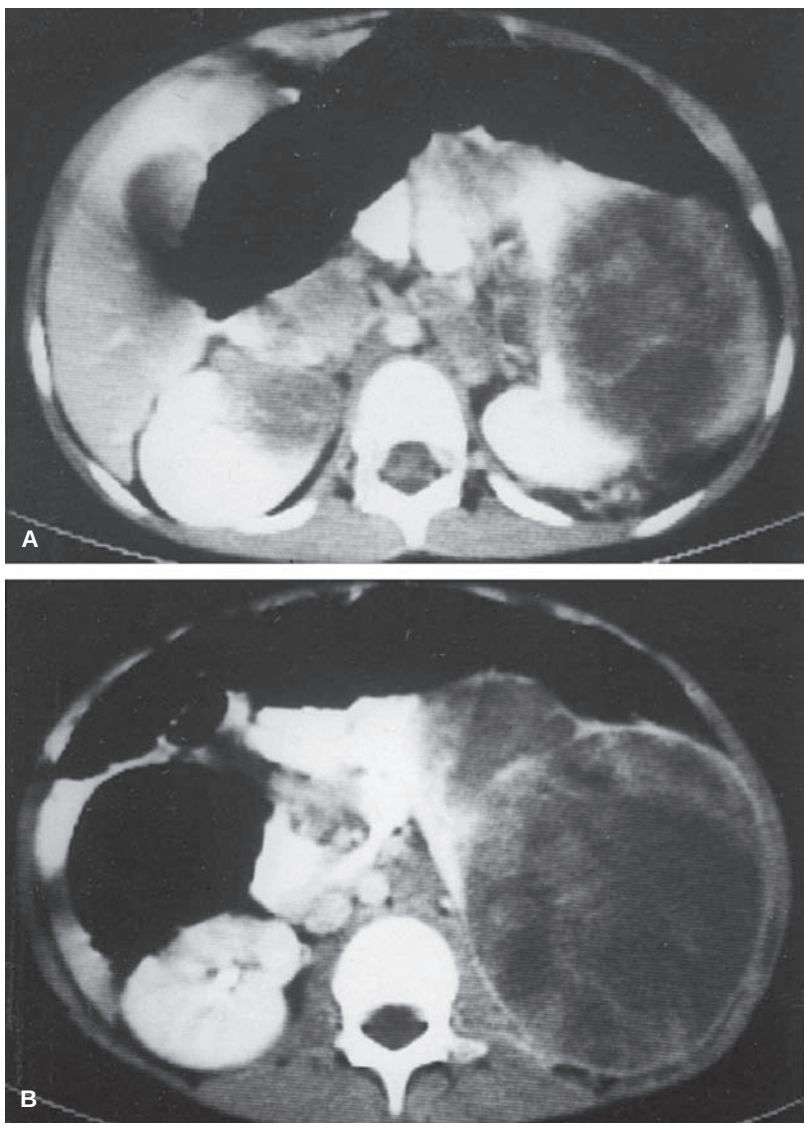

FIGURE 121.21 **A:** Bilateral Wilms' tumor. A 5-year-old girl with left flank mass. CT sections of the upper abdomen with contrast medium enhancement show a necrotic mass arising from superior aspect of the left kidney. Note a small mass in the superior medial aspect of the right kidney. **B:** Bilateral Wilms' tumor (same patient as in **A**). CT section of the abdomen with contrast medium enhancement shows extent of the large necrotic left Wilms' tumor with periaortic adenopathy.

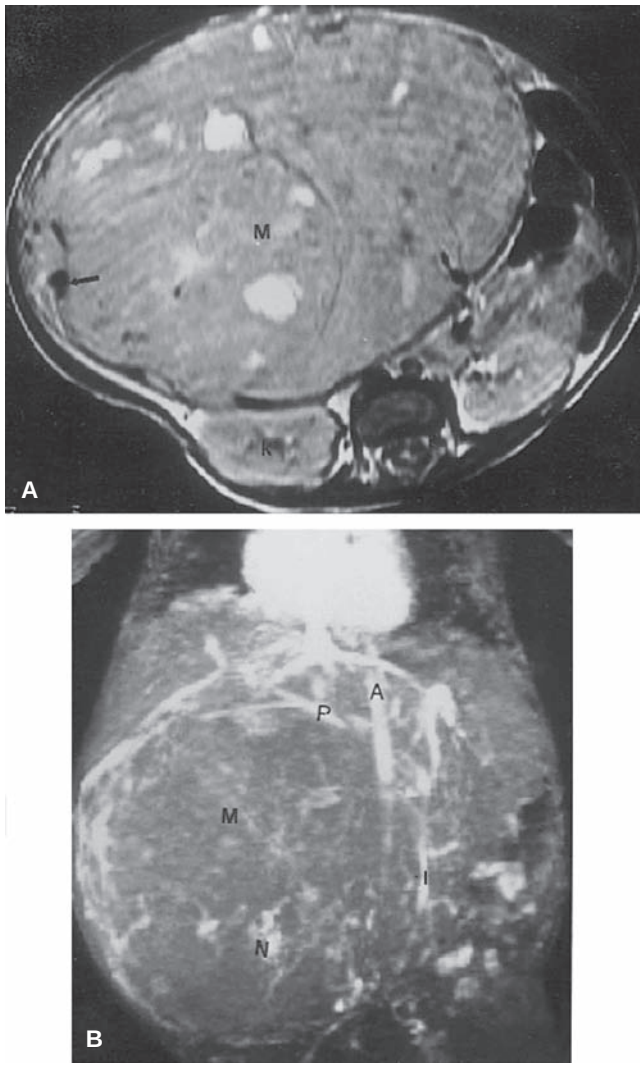

FIGURE 121.22 **A:** Hepatoblastoma in a 2-month-old boy. Axial T1 magnetic resonance imaging (MRI) shows a solid mass (M) occupying entire liver, gallbladder *(arrow)*, and right kidney (K). **B:** Coronal magnetic resonance angiography shows liver mass (M), with stretching of the hepatic vessels and multiple area of neovascularity (N). Note marked stretching and displacement of the inferior vena cava (I) with patent portal vein (P). A, aorta.

with both types. Differential diagnosis should include hemangioendothelioma, hamartoma, and renal and adrenal tumors.

Radiologic imaging is directed at diagnosis and the resectability of the tumor. CT or MRI with angiography is often required to determine surgical approach (Fig. 121.22). Long-term survival is poor unless complete resection is possible. Liver tumors commonly metastasize to the lungs, brain, and regional nodes.

ABDOMINAL WALL DEFECTS

Inguinal Hernias and Hydroceles

Indirect inguinal hernia is the most common congenital anomaly that is found in children. It is approximately 10 times more common in males than in females. There is a strong familial incidence.

Clinical Manifestations

The child with a hernia may present in different ways. The presentation is determined by the extent of obliteration of the processus vaginalis during development. A child may have a completely open hernia sac, which extends from the internal ring to the scrotum, or a segmental obliteration producing a sac that is narrow at its proximal end, creating a hydrocele of either the tunica vaginalis or the spermatic cord. The narrowing of the processus allows the abdominal fluid to seep into the distal portion of the sac. It then becomes entrapped and produces what is clinically recognized as a hydrocele. It is often difficult for this fluid to egress through the narrow patent processus vaginalis back into the abdominal cavity.

At the time of the embryologic closure of the processus vaginalis, many fetuses will have some fluid trapped around the testicle in the tunica vaginalis. This is called a physiologic hydrocele, which is a normal newborn finding. In such cases, the fluid is gradually absorbed in the first 12 months of life. If, however, an infant or child develops a hydrocele along the cord in the tunica vaginalis sometime after birth, it must be assumed the processus vaginalis is still patent and in communication with the peritoneal cavity. This patent processus vaginalis represents a hernia sac. Surgical closure of the sac and drainage of the hydrocele are then indicated on an elective basis.

Many infants and children manifest the classical bulge in the inguinal canal that occurs during straining or crying. This is caused by a loop of intestine distending into the hernia sac (or may represent the ovary in a female). Usually, the hernia sac contents reduce into the abdominal cavity when the straining ceases. If the prolapsing loop of intestine becomes entrapped in the hernia sac, an incarceration occurs. This is a true emergency that could eventually lead to intestinal obstruction and possibly strangulation of the bowel. For easily reduced hernias, elective herniorrhaphy should be done shortly after the hernia is diagnosed.

Hydroceles of the spermatic cord with associated communicating hernias are sometimes difficult to differentiate from an incarcerated hernia. If an empty hernia sac can be felt above the hydrocele, the physician can be assured that this is an asymptomatic hernia with an associated hydrocele. However, if there is fullness above the hydrocele and the mass cannot be reduced, the child should be taken to the operating room on the assumption that it probably is an incarcerated hernia that needs to be managed surgically. If there is any uncertainty, a US may be useful to define the hernia. Bowel gas in the hernia sac is not reliably present for diagnostic reasons.

Management

Fortunately, strangulation of the entrapped loop of bowel in an incarcerated hernia occurs relatively late so, contrary to adult practice, efforts to reduce the incarceration without surgery are usually warranted. When a child with an incarcerated hernia presents in the ED, the child should be given nothing to eat or drink, sedated if necessary with morphine 0.1 mg per kg, and placed in a Trendelenburg position. Often, this alone will reduce

the incarceration. If it does not, bimanual reduction should be attempted. The fingers and thumb of one hand should compress the internal ring area, while an effort is made with the other hand "to milk" either gas or fluid out of the entrapped bowel back into the abdomen. This relieves the pressure and usually allows the entire loop of bowel to reduce back into the abdominal cavity. Once the incarcerated hernia is reduced, the child should be admitted or scheduled for elective surgery at the surgeon's discretion. Patients who were vomiting, had guaic-positive stools, or had difficulty reducing hernias should be admitted for serial abdominal examinations. A day or two should be allowed to pass to lessen the edema of the area, as well as to allow an easier and safer elective herniorrhaphy.

Epiploceles (Epigastric Hernias)

If a discrete mass occurs intermittently about one third of the distance from the umbilicus to the xiphoid, it is usually the result of a weakness of the linea alba through which properitoneal fat protrudes. This defect is called epiplocele. Such defects are fairly common in infants and usually close spontaneously. In older children, the mass may occasionally be tender. If it becomes excruciatingly tender, it is a sign that fat has become incarcerated in the hernia. Although there is no great urgency, these small midline defects should be repaired surgically when they become symptomatic.

Umbilical Hernias

Umbilical hernias are common in small infants, particularly in African Americans. Fortunately, most of the hernias tend to close spontaneously, and only rarely does incarceration occur. Umbilical hernias can be large and unsightly, and families need reassurance that watchful waiting is the best course. However, if the umbilical hernia fails to close by the age of 5 to 6 years, surgical repair is indicated. Umbilical hernias may be repaired earlier if there is a large ring that shows no signs of diminishing in size over 1 to 2 years, if there is a thinning of the umbilical skin, or if an incarceration has occurred. Hernias that have a supraumbilical component tend not to close spontaneously and may be operated on at an earlier time of life.

Other Umbilical Defects

Omphalomesenteric duct remnants may persist in either of two forms. When the duct is patent from the ileum to the umbilicus, there is a release of small bowel contents via an opening in the umbilicus. A second form involves a remnant of the omphalomesenteric duct that contains a secreting mucosal patch that is attached to an opening in the center of the umbilicus. Passage of a sterile blunt probe or instillation of contrast dye under fluoroscopy via the umbilical opening will usually confirm either of these conditions. Once identified, these remnants must be excised surgically. In contrast, some infants present with umbilical granuloma in which an excessive amount of granulation tissue has built up after separation of the umbilical cord. In these patients, no opening in the granulation tissue can be seen or felt by means of a probe. These granulomas are usually best treated by application of silver nitrate to the granulation tissue. After each treatment, the area should be rinsed thoroughly to prevent burning of adjacent skin. If the granuloma is allowed to persist, it will eventually epithelialize and become an umbilical papilloma (Fig. 121.23).

If the urachus persists after birth, it can form a urinary fistula that drains at the umbilicus. This problem is ordinarily noted in the newborn period. Older infants or children may present with drainage at the umbilicus caused by persistence of part of the urachus, even though connection with the bladder may be obliterated. These urachal remnants also require surgical excision.

FOREIGN BODIES OF THE GASTROINTESTINAL TRACT

When a child ingests a foreign body, it causes great concern to the family. Most swallowed foreign bodies move through the GI tract without complication. Occasionally, a foreign body lodges in the esophagus, necessitating removal. Plain film roentgenograms for suspected foreign body should focus on the suspected area initially but then expanded to locate the object. Foreign bodies lodged in the esophagus should be removed promptly to prevent complications such as edema, ulceration, aspiration, pneumonia, or perforation. If initial radiographic studies identify a smooth, small object, such as a coin, a period of conservative observation may allow the foreign body to move into the stomach. If the history of radiographic appearance suggests a battery, emergency endoscopy and removal should be performed. Esophageal foreign bodies in the esophagus greater than 24 hours require removal. Patients with esophageal foreign bodies require follow-up radiographs to show movement into the stomach or evidence of successful passage (by identification in stool).

Foreign bodies that reach the stomach, whether pointed or sharp edged, usually pass completely through the intestinal tract and are evacuated. Cathartics and other efforts to hurry their transit are unnecessary. Whether all GI tract foreign bodies should be followed until evacuation is not clear. Persistent emesis may represent pyloric obstruction.

Occasionally, a long, thin foreign body such as a bobby pin may not be able to traverse the turn where the duodenum joins the jejunum at the ligament of Treitz. If a foreign body is trapped in this area, perforation with local or generalized peritonitis may occur. When entrapment occurs anywhere beyond the pylorus, surgical removal is indicated either to prevent or to treat local perforation. Occasionally, objects such as straight pins, toothpicks, and broom straws become entrapped in the appendix. When this occurs, the appendix should be removed. Special consideration should be given to magnets; when two magnets attract across a loop of bowel, the compressed bowel may necrose. Coins may remain in the child's stomach for considerable time, and if they do not become embedded in the gastric mucosa, they eventually pass, even after several weeks. Objects stuck in the pylorus may cause vomiting and should be removed. With the aid of modern flexible endoscopic equipment, foreign bodies in the stomach can usually be removed with ease. Chapter 123 covers pharyngeal foreign bodies.

CHAPTER 122 ■ DENTAL EMERGENCIES

LINDA P. NELSON, DMD, MSCD, AND STEPHEN SHUSTERMAN, DMD

Nontraumatic orofacial emergencies can appear suddenly and are frightening for children and their families. The major task in evaluating a child with a nontraumatic orofacial emergency is to identify the cause of the problem. In cases of facial swellings, the first step in treatment is determining whether a tooth is the causative agent. In cases of postextraction complications, historical information suggesting a preextraction infection, fractured tooth, or overlying chronic systemic problem may be elicited. Therefore, initial assessments must be performed in the same manner as traumatic orofacial emergencies (see Chapter 109).

POSTEXTRACTION COMPLICATIONS

Hemorrhage

It is expected that any extraction site may ooze for 8 to 12 hours and perhaps longer for a permanent site. However, it is important to check the history for any prior bleeding episodes to rule out a systemic hematologic abnormality. If there is a concern for abnormally prolonged bleeding, a complete blood cell count and coagulation profile would be indicated.

Emergency treatment may include the following steps:

1. Apply pressure, using folded gauze sponges that are placed over the socket with biting pressure applied directly on the site for 30 minutes. If unsuccessful, proceed to step 2.
2. Physically close the socket by suturing. Administer local anesthesia (2% lidocaine with 1:100,000 epinephrine infiltration), and approximate the extraction site with the appropriate sutures. Alternatively, the socket may be packed with Gelfoam®.

A possible home remedy before coming to the emergency department (ED) might include the use of a tea bag. A tea bag is dipped in hot water and allowed to cool, then placed over the socket with pressure. The tannic acid in the tea bag may initiate or accelerate coagulation.

Infection

Postextraction infection is rare in children. If it occurs, it may present as localized swelling or edema surrounded by an erythematous zone. A purulent exudate may be evident from the socket. Emergency treatment includes the application of moist heat, oral saline rinses (if the age is appropriate), and antibiotic therapy. Amoxicillin or Augmentin© (amoxicillin with clavulanate potassium) is the drug of choice. (See the "Dentoalveolar Abscess" section for dose and duration.)

Alveolar Osteitis

Alveolar osteitis, or *dry socket*, is a painful postoperative condition produced by a disintegration of the clot in the tooth socket. This condition usually is seen in adults and only rarely in children younger than 12 years. It generally occurs approximately 72 hours after mandibular extractions and is painful. Emergency dental treatment is variable, but the immediate goal is relief of pain. Under local anesthesia, the socket may be debrided and then packed with ¼-in. iodoform gauze or BIPP (bismuth, iodoform, paraffin) paste. Oral analgesic and antiinflammatory (NSAID) medications should be prescribed for pain. Since it is an osteitis, antibiotics should only be used if there is evidence of infection.

ORAL INFECTIONS

In a retrospective analysis of pediatric dental patients presenting to the ED and dental clinics, toothaches, pain, and facial swellings accounted for 44% of the chief complaints. This is consistent with other studies. It is important to remember that the infant or small child who may be in pain often cannot localize the discomfort. It may be the first opportunity for many children to receive dental care. A complete history from the parents and a thorough oral examination are mandatory. Figure 122.1 shows a diagram of the normal tooth.

Odontalgia—Simple Toothache

The child with a simple toothache often complains of diffuse mouth pain and may not be able to identify a specific tooth. Children often cannot distinguish between tooth pain and soft-tissue pain from a lesion such as an aphthous ulcer. A careful intraoral examination should be preformed to identify the true source of the discomfort. The emergency physician may note a grossly carious tooth or large restoration. Swelling or inflammation in the surrounding soft tissue may be present. The tooth may be sensitive to percussion and may exhibit excessive mobility. A dental consultation is necessary, especially if swelling is noted. In the case of swelling, the tooth may be opened for drainage to relieve the pressure, in a manner similar to the management of any abscess.

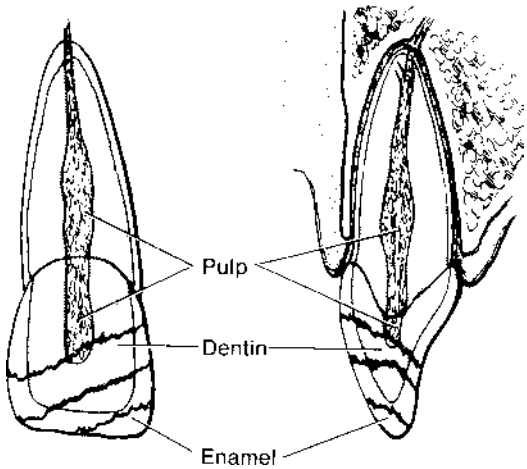

FIGURE 122.1 The anatomy of a tooth that should be considered during a traumatic injury. Enamel fracture, no emergency treatment; dentin fracture, emergency treatment as soon as convenient; and pulpal fracture, emergency treatment as soon as possible.

Dentoalveolar Abscess

Dental abscesses are common in children because of the morphologic characteristic of the primary tooth and immature permanent tooth. In the dentoalveolar abscess, the causative factors are gross or recurrent decay, trauma, or perhaps, chronic irritation from a large restoration. If there is an acute pulpitis, there may be severe pain and swelling, but other symptoms, such as mobility or purulence, may not be present. Establishing drainage through the tooth or soft tissue is key to relief of the symptoms, but antibiotics and/or analgesics may also be necessary. If the infection is long standing, suppuration is usually confined to the bone around the tooth. The swelling can perforate the thin buccal bony plate adjacent to the root of the involved tooth and spread into the subperiosteal area and then to the surrounding soft tissues. In a child, the dentoalveolar abscess usually perforates the buccal plate of bone because of the position of the tooth and the thinness of the overlying bone. If it does not drain intraorally, the infection can spread rapidly through the fascial planes of the face or neck.

The following are clinical manifestations of a dentoalveolar abscess in a child:

- Pain: The tooth may be painful to percussion or may exhibit spontaneous painful episodes.
- Mobility: The tooth may have a more than the normal degree of movement in the socket when palpated.
- Swelling: The soft tissues surrounding the tooth may be edematous and erythematous.
- Temperature elevation: The child may be febrile [temperature higher than 37.5°C (99.5°F)], have general malaise, and have a decrease in appetite.
- Fistulous tracts: These appear clinically as a pustule-like lesion on the gingiva (rarely on the face) when the infection has been present for a long time.
- Extrusion: The tooth may become extruded because of the presence of fluid in the periradicular space.
- Lymphadenopathy: Major lymph node enlargement can occur at any time during the infective process.

The first step in treating a perioral abscess is to determine whether a tooth is the causative agent. This can be accomplished by clinical examination and available radiographs. Corroboration of dental origin can be established by reviewing intraoral radiographs with a dentist. A computed tomography (CT) scan with contrast will enhance the visualization of a dental abscess. If the child is febrile, a blood culture should be obtained, although it may not yield a definitive microorganism. The location and extent of any swelling and/or fistulous tracts, whether intraorally or extraorally, should be noted.

It is important that the treatment of choice for a localized dentoalveolar abscess is local in its focus (e.g., drainage, moist heat). In cases of facial cellulitis with lymphadenopathy caused by acute dentoalveolar abscess, the antibiotic of choice is Augmentin® (amoxicillin with clavulanate potassium), or alternatively clindamycin if there is a known allergy to penicillin derivatives. The initial dose of Augmentin® is 25 mg of amoxicillin/kg/dose orally three times a day, rounding to the nearest 250 mg increment in older children.

Penicillin-sensitive streptococci and anaerobic organisms predominate as the cause of acute dentoalveolar abscesses. If there is facial cellulitis over the maxilla extending toward the inferior border of the orbital rim or if there is mandibular cellulitis, which might be a potential cause of airway compromise, the child may be admitted to the hospital where intravenous antibiotic therapy can be managed. Treatment for facial cellulitis is covered in Chapter 92.

Other factors to consider in determining the need for hospital admission include the child's ability to take fluids and the likelihood of the parent's cooperation for follow-up dental care. Obviously, if the child has signs of sepsis, a hospital admission is indicated. In addition to antibiotics, warm oral saline rinses should be used. Heat should be applied extraorally. There is some concern that extraoral heat will cause the abscess to point extraorally and thus produce an exterior fistula. This has not proven true in our experience. Mild analgesic therapy such as acetaminophen is usually sufficient. Dental consultation should be obtained to vent the offending tooth, to establish drainage, to incise a fluctuant mass, or to remove the tooth.

As with infection elsewhere in the body, the basic surgical principles of treatment must be used to establish drainage and remove the cause. An abscessed primary tooth must be vigorously treated because such infections can affect the developing unerupted permanent tooth bud. A facial cellulitis can have severe systemic consequences, including cavernous sinus thrombosis, airway obstruction, meningitis, orbital cellulitis, and septicemia.

In some cases, there may be a need for additional consultation with infectious disease experts, especially in a situation in which systemic disorders render the child more susceptible to infection.

TABLE 122.1

ERUPTION SCHEDULE FOR SPECIFIC TEETH

	A. Primary teeth			
	Age at eruption (mo)		Age at shedding (yr)	
	Lower	Upper	Lower	Upper
Central incisor	6	7½	6	7½
Lateral incisor	7	9	7	8
Cuspid	16	18	9½	11½
First molar	12	14	10	10½
Second molar	20	24	11	10½
Incisors	Range ±2 mo			
Molars	Range ±4 mo		Range ±6 mo	
	B. Permanent teeth[a]			
	Age (yr)			
	Lower	Upper		
Central incisors	6–7	7–8		
Lateral incisors	7–8	8–9		
Cuspids	9–10	11–12		
First bicuspids	10–12	10–11		
Second bicuspids	11–12	10–12		
First molars	6–7	6–7		
Second molars	11–13	12–13		
Third molars	17–21	17–21		

[a]The lower teeth erupt before the corresponding upper teeth. The teeth usually erupt earlier in girls than in boys.
(Modified with permission from Massler M, Schour I. *Atlas of the mouth and adjacent parts in health and disease*. Chicago, IL: The Bureau of Public Relations Council on Dental Health, American Dental Association, 1946.)

Pericoronitis

Pericoronitis is a localized infection surrounding an erupting tooth. It is usually associated with erupting molars in the adolescent patient, although a mild form may be associated with the eruption of the first permanent molar at age 6 (Table 122.1). Symptoms usually include pain distal to the last erupted tooth in the dental arch, along with erythema and edema localized to the gingiva in the retromolar area. Lymphadenopathy, trismus, and dysphagia may accompany these symptoms. An elevated body temperature is an occasional finding. It is not unusual to see or palpate the cusps of the erupting tooth. The patient may complain of an inability to completely close his or her mouth because of the edematous gingiva. Otalgia is an uncommon complaint.

Emergency treatment includes local curettage, oral rinses, heat, and scrupulous oral hygiene. Amoxicillin or Augmentin® may be necessary (for dose, see "Dentoalveolar Abscess" section) when there are systemic symptoms of infection or facial swelling.

Primary Herpetic Gingivostomatitis or Herpes Simplex Virus Type 1

Primary herpetic gingivostomatitis, or herpes simplex virus type 1, is a communicable childhood disease that is not a true dental emergency but is a common cause of ED visits. The child is usually an infant or toddler who stops eating, drinking, or talking and is extremely irritable. The child usually has had an elevated temperature for 3 to 5 days before any clinical oral findings. A higher incidence of primary herpes has been noted after other viral illnesses. Older children may complain of headaches, malaise, nausea, regional lymphadenopathy, and/or bleeding gums. The physical examination reveals fiery red marginal gingiva with areas of spontaneous hemorrhage. Within 1 or 2 days, yellowish, fluid-filled vesicles develop on the mucosa, palate, lips, or tongue and coalesce. The vesicles may coalesce or rupture spontaneously, leaving extremely painful ulcers, covered by a yellow or gray membrane and surrounded by an erythematous zone. Ulcers, especially on the lips, may become encrusted, as seen in Fig. 122.2.

If necessary, a definitive diagnosis can be made by isolation of the herpes simplex virus in tissue culture (although this is rarely indicated). Emergency treatment includes reassuring the parent and rehydrating the patient. The disease, like recurrent herpes labialis, is self-limiting, with a duration of 7 to 14 days. Dehydration and weight loss are the major concerns; therefore, high-calorie and high-protein shakes, ice cream, and liberal quantities of clear fluids should be encouraged. The young child with extensive lesions may require hospitalization for intravenous hydration.

FIGURE 122.2 A child with typical crusted extraoral lesions of late primary gingivostomatitis.

Viscous lidocaine rinses and "magic mouthwash," Maalox® and Benadryl® with or without lidocaine combinations, may be helpful but may be unrealistic for children in this age range. The unpleasant taste sometimes makes administration difficult, therefore negating any benefit that the child may receive. If using lidocaine do not exceed 3 mg/kg/dose and do not give any more frequently than every 3 hours.

Secondary infection, although rare, is of concern for those children who may be immunosuppressed, and in those cases, antibiotic therapy may be indicated.

Acute Necrotizing Ulcerative Gingivitis, Vincent's Disease, Trench Mouth

Acute necrotizing ulcerative gingivitis (ANUG), Vincent's disease, or trench mouth is characterized by increases in the fusiform bacillus and *Borrelia vincentii,* a spirochete, which usually coexist in a symbiotic relationship with other oral flora. Adolescents complain of soreness and point tenderness at the gingiva and often tell the physician that they feel as if they "cannot remove a piece of food that is painfully stuck between their teeth" (a wedging sensation). They may also complain of a metallic taste in their mouth and bleeding gums. Upon examination, the breath has an obvious fetid odor. The gingivae are hyperemic, and the usually triangular gingiva between the teeth is missing or "punched out" (Fig. 122.3). Intense pain is produced with probing, and a gray, necrotic pseudomembrane may cover some areas of gingiva.

It is extremely rare to find ANUG in a young child, but a mistaken diagnosis is often made by physicians, confusing this disease with primary herpetic gingivostomatitis. Primary herpes is usually seen in infants and toddlers, and ANUG is characteristically seen in adolescents and young adults (ages 15 to 35 years). Emotional stress has been linked to the onset of the disease process, as have malnutrition, severe dehydration, poor oral hygiene, immunodeficiency disorders, especially acquired immunodeficiency syndrome (AIDS), and infectious mononucleosis. The adolescent should be advised to maintain better oral hygiene, rest and reduce stress, and use oral rinses such as Peridex® (0.12% chlorhexidine). Hydrogen peroxide, diluted 1:1 with warm water, may alternatively be used as often as possible throughout the acute phase. Because of the rapidity of tissue destruction and sensitivity of the organisms, as well as risk of secondary infection, penicillin, metronidazole, tetracycline, or erythromycin should be prescribed for the first week, especially in the presence of fever or lymphadenopathy. When the acute phase is over, the patient should be sent to the dentist for a thorough debridement of the area. If the patient is resistant to therapy, a thorough workup of the underlying causes of immunosuppression is indicated, because of the relationship of ANUG and immunosuppression.

ORAL AND PERIORAL PATHOLOGY PRESENTING AS DENTAL EMERGENCIES

Aphthous Stomatitis

Aphthous stomatitis is the most common disease of the oral mucosa and may affect 20% or more of the population. These painful, shallow, circular ulcerations are distinctive because of their size (2 to 4 mm), distribution, and recurrence. Clinically,

FIGURE 122.3 A child with typical "punched out" gingiva—pathognomonic for acute necrotizing ulcerative gingivitis. (Courtesy of Dr. Mark Snyder.)

the floor of the ulceration is yellowish, with a sharply defined red margin. Aphthae affect only nonkeratinized areas of the mouth, such as the tongue, cheek, or vestibule. If the hard palate or gingival margins are affected, it is unlikely to be aphthae. Recurrent aphthae often start in childhood or adolescence. In young children, there is a syndrome of recurring aphthous ulcers and periodic fevers. They peak in early adult life and then seem to spontaneously resolve. Recurrent aphthae usually occur during periods of anxiety, such as during final examinations at school or during domestic disturbances. The ulcerations may appear singly or in clusters. They are usually painful and tender, have a clinical course of 10 to 14 days, and often cause difficulties with eating. Treatment is largely empirical and also usually unsatisfactory. Drugs used in the management of aphthae have included topical local analgesics, such as lidocaine gel or benzocaine oral emollient (Orabase® with benzocaine), which allow the patient to eat in some degree of comfort. Due to the risk of methemoglobinemia secondary to benzocaine toxicity, Orabase® should not be used for more than 2 days in children < 2 years of age. Bland nonacidic diets to avoid further irritation may be the best recommendation.

Erythema Multiforme

Erythema multiforme is primarily a dermatologic disease characterized by macular, papular, vesicular, or bullous lesions on the skin or oral mucosa (Fig. 122.4). The lips may appear crusted, as in primary herpes. Lesions arise from an erythematous area that enlarges and develops a central vesicle or "target lesion." Oral lesions arise at about the same time as skin lesions and are also variable in their clinical appearance, producing painful, bleeding, crusting erosions. These symptoms may occur as an acute drug reaction but can be precipitated by herpes simplex. Stevens–Johnson syndrome is a more disseminated form of erythema multiforme in which conjunctival and genital lesions are seen concomitant with the oral and cutaneous lesions (see Chapter 99). Identifying and eliminating the precipitating drug is the first step in treatment. Immediate care may include caloric and fluid support. Steroids may be of help in severe cases.

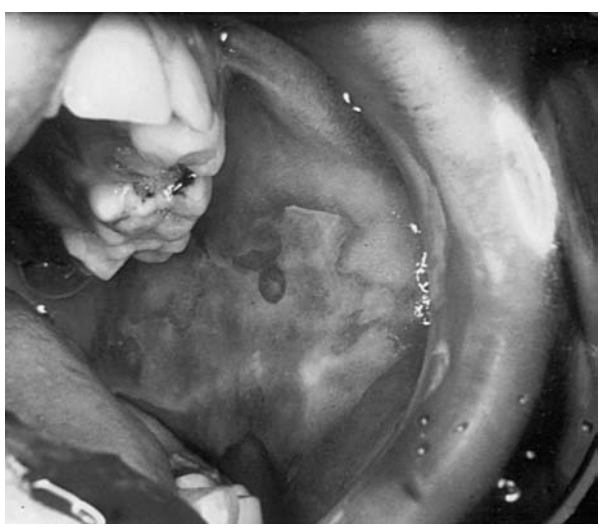

FIGURE 122.4 Intraoral view of erythema multiforme.

Epidermolysis Bullosa

Epidermolysis bullosa is a hereditary vesiculobullous condition affecting the skin, mucous membranes, and teeth. There are several forms of the disease. In the dominant form, oral bullae have been documented. In the recessive dystrophic form, the teeth have hypoplastic enamel, an increased susceptibility to dental caries, and delayed eruption. Oral mucosal involvement appears soon after birth with vesicles from the negative pressure of the sucking reflex. The labial mucosa and lips can appear scarred and taut. Even routine dental management such as toothbrushing may cause the eruption of bullae on the mucosa and lips. Emergency visits may result from pain or bleeding from oral lesions. Treatment should palliate pain and support nutritional requirements.

Pyogenic Granuloma

Pyogenic granulomas develop as granulation tissue in response to an irritant or trauma. Clinically, they are red, elevated, and usually ulcerated. Initial growth is rapid. Pyogenic granulomas are most common on the gingivae and may remain static for a time before becoming fibrotic. Treatment consists of simple excision, but recurrence is common unless the causative agent (calculus or foreign body) is removed.

Neonatal Cysts

Epstein's pearls are keratin-filled cystic lesions located along the midpalatine raphe in the newborn. They appear as round or ovoid, white, raised nodules. Often, only a few can be visualized, but sometimes there are too many to count. They are believed to arise from embryologically trapped epithelium. They are present in about 80% of neonates and should be considered a variation of normal. No treatment is necessary because they disappear within several weeks.

Bohn's nodules are remnants of the dental lamina that appear as cysts on the buccal or lingual aspect of the maxillary and mandibular dental ridges in the newborn. They may appear in the palate but are far removed from the midpalatine raphe. Although similar in shape and color, they are located differently and should not be confused with Epstein's pearls. No treatment is necessary because they, too, are normal and disappear within several weeks.

Dental lamina cysts are multiple, or occasionally solitary, nodules on the alveolar ridge of newborn (Fig. 122.5) or young infants. They represent trapped remnants of the dental lamina. They are soft and spongy, asymptomatic, and tend to disappear with time or with the eruption of teeth.

Eruption Cysts

Eruption cysts arise from the preeruptive dental sac and appear as a swelling of the alveolar ridge. They are associated with the eruption of primary (Fig. 122.6) and permanent teeth. Occasionally, they fill with blood and may be termed *eruption hematomas* (Fig. 122.7). Treatment is unnecessary because the erupting tooth usually emerges within several

FIGURE 122.5 Dental lamina cyst in a neonate.

FIGURE 122.6 An eruption cyst associated with an erupting primary central incisor.

days. If treatment is necessary because of the size of the lesion, excision of the overlying soft tissue to expose the erupting tooth eliminates the problem.

Riga-Fede Disease/Natal or Neonatal Teeth

Riga-Fede disease is a condition observed in infants with natal or neonatal teeth. It is characterized by ulcerations on the ventral surface of the tongue from irritation caused by the incisal edges of lower incisors during nursing or suckling. Treatment should be avoided, but the incisal edge of the erupting teeth can be smoothed off in the dental office if there is bleeding and pain associated with the lesion. In very severe cases, extraction may be necessary if the natal or neonatal teeth interferes with feeding. Natal or neonatal teeth in general should be removed only when they interfere with feeding or represent a danger of aspiration.

Orofacial Neoplasms

Orofacial neoplasms in children are rare. Some benign and malignant neoplasms may result in emergency visits and, therefore, are included. Identification is central to the triage process.

The oral papilloma is a benign epithelial neoplasm that is an exophytic elevation of the surface epithelium with small fingerlike projections from its surface. These lesions, which rarely become malignant, constitute about 8% of all oral neoplasms in children. Slightly more than one-third of the lesions occur on the tongue and (in decreasing order of frequency) palate, buccal mucosa, gingiva, and lip. If spontaneous involution does not occur, the usual treatment is surgical removal.

The fibroma is a common smooth-surfaced lesion with a sessile base. Its consistency varies from soft to firm, and its size ranges from a few millimeters to a centimeter or more in diameter. It may become whitened secondary to the overlying

FIGURE 122.7 Erupting hematoma over erupting maxillary permanent central incisor.

FIGURE 122.8 Mucocele associated with minor salivary gland of the lower lip.

hyperkeratosis caused by trauma. Fibromas occur during the first and second decades of life and are usually found on the palate, tongue, cheek, and lip. Surgical removal is sometimes indicated, and recurrence is rare if the source of the irritation is removed.

The mucocele appears as a soft, raised, fluid-filled, and well-delineated nodule, most commonly on the lower lip or the mucosal lining of the lower lip (Fig. 122.8). Superficial lesions appear translucent and are bluish, whereas deep-seated lesions have a normal color. A mucocele in the floor of the mouth is termed a *ranula* and is seen as a dome-shaped, fluid-filled lesion. Mucoceles are believed to result from severance or obstruction of a salivary gland duct, with pooling of mucin in the lamina propria. Complete excision of the mucocele or marsupialization of the ranula is indicated.

CHAPTER 123 ■ OTOLARYNGOLOGIC EMERGENCIES

LISA M. ELDEN, MD, CM, AND WILLIAM P. POTSIC, MD, MMM

The ear, nose, and throat are common sites for infection and neoplasms and may be the sources of acute pain. Although the diseases prompting the emergency department (ED) visit may be distressing to the patient and cause considerable anxiety for the parents, they are rarely life threatening. This chapter includes discussion of disorders of the ear, nose, nasal sinuses, oral cavity, pharynx, esophagus, larynx, trachea, and neck.

EAR

Methods of Examination

The equipment necessary to properly evaluate the head and neck in an ED should include an otoscope with a pneumatic insufflator, wax loop (curette), illuminated headlight, and otologic forceps.

Examination of the ear begins by inspection of the auricle and surrounding areas. The external meatus should be visualized directly with a bright light after it is fully opened by pulling the pinna posteriorly and superiorly. The tragus may be displaced forward by traction on the skin in front of the ear with the examiner's other hand (Fig. 123.1). The ear canal can then be examined with a pneumatic otoscope, using the largest speculum that will fit in the meatus without discomfort. Wax or debris occluding the ear canal should be removed with a curette or by repeated irrigation with body temperature water (see Procedure 5.3 in Section VII). Irrigation of the canal should not be performed if a ventilating tube is in place or if a perforation of the tympanic membrane (TM) is suspected.

The TM should be evaluated for its appearance, and part of the middle ear contents can usually be seen if the eardrum is translucent (Fig. 123.2). Mobility should be evaluated with the pneumatic otoscope because the accuracy of diagnosing middle ear pathology increases greatly when mobility is assessed by pneumatic otoscopy compared with observation alone. Pneumatic otoscopy is performed by applying positive and negative pressure to the TM, with the pneumatic otoscope fitted snugly into the ear canal. The pressure applied to the ear can be varied by squeezing a rubber bulb (see Procedure 5.1 in Section VII). Middle ear effusion is more likely to be present if the TM fails to move with this technique. The use of tympanometry may be helpful in instances when the clinician cannot assess mobility with a pneumatic otoscope. The test is most useful in excluding the disease because the presence of a normal type A tympanogram (peaked curve at zero pressure) is 90% to 95% sensitive and specific in predicting absence of middle ear effusion. Alternatively, a B type tympanogram (flat tracing), which occurs when there is absence of TM movement, is less accurate in predicting the presence of fluid in the ear with a sensitivity of 81% and specificity of 74%.

The ear of a neonate requires special attention to perform an adequate otologic examination. The ear canal itself is narrow and collapsible. Often, only the otoscopic speculum can be inserted, as positive pressure from the pneumatic bulb is used to distend the canal ahead of the advancing speculum. The canal may be filled with vernix caseosa, which must be removed or irrigated out of the canal to permit visualization of the TM. The neonate's TM lies at a more oblique angle to the ear canal (compared with older children) and may make recognition of the TM and its landmarks more difficult. Amniotic fluid may be present in the middle ear cavity for days to weeks after birth and should not be confused with middle ear infection unless other symptoms such as fever and irritability are present.

In older children, crude hearing acuity can be tested with a ticking watch or a 512-Hz tuning fork. The sound should be heard equally in each ear. However, this does not rule out a symmetric bilateral hearing deficit. If the tuning fork is applied to the forehead, it should be heard equally in both ears. If it is heard only in one ear, it signifies either a conductive loss in the ear that hears the tone or a sensorineural hearing loss (SNHL) in the opposite ear. Audiometry (behavioral) is required for an accurate evaluation of hearing at all frequencies. Auditory brainstem response testing is helpful for a child who cannot cooperate with behavioral testing.

Infections

Acute Otitis Media

Apart from viral infections of the upper respiratory tract, acute otitis media (AOM) is the most common head and neck infection in children and is the second most common diagnosis made in the ED. It may occur as an isolated infection or as a complication of an upper respiratory tract infection. Risk factors that make children more susceptible to recurrent AOM include the presence of otitis media with effusion (OME), which is noninfected fluid in the middle ear (also called serous otitis media or secretory otitis media), day care attendance, exposure to secondhand smoke, and immunodeficiency states.

The more common organisms causing acute otitis at all ages are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*, and less commonly, group A β-hemolytic streptococci and various upper respiratory viruses. Gram-negative organisms may occur in hospitalized patients who are younger than 8 weeks or immunosuppressed.

Clinical Manifestations. Over the last decade, The American Academy of Pediatrics (AAP) and the Joint Committee of

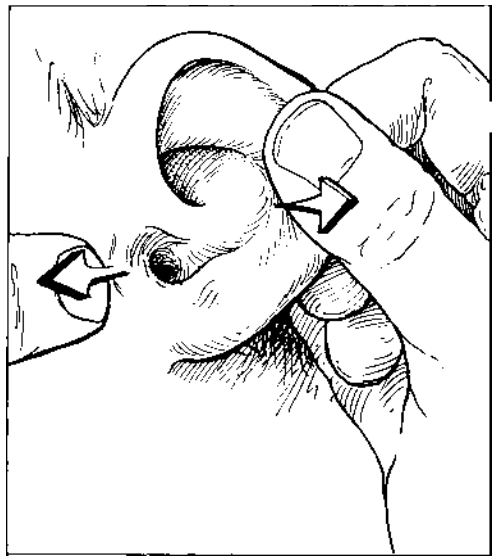

FIGURE 123.1 The external meatus is opened by pulling the auricle in the posterior superior direction and placing traction on the skin immediately in front of the tragus.

American Academy of Family Practitioners (AAFP) have developed guidelines to improve accuracy of diagnosis of AOM. Based on the best available evidence in the literature, three components should be present to diagnose AOM.

1. History of acute onset of symptoms within 48 hours of presentation.
2. Presence of middle ear effusion confirmed by pneumatic otoscopy (or tympanometry).
3. Signs of middle ear inflammation.

AOM should be suspected in any child who is irritable or lethargic, has a low-grade fever, and has localized pain in the ear. The pain develops rapidly and is often severe. Spontaneous perforation of the TM with serosanguineous drainage may occur in less than 1 hour after the onset of pain. On examination, the TM is hyperemic and mobility is decreased. The strongest predictor of AOM is the presence of a bulging TM that obliterates normal landmarks, whereas redness is least helpful in predicting the disease. Infection with *Mycoplasma pneumoniae* and other bacteria may cause blebs on the lateral surface of the drum. The vesicles of bullous myringitis are filled with clear fluid and are painful. The appearance of the TM in AOM secondary to bacterial pathogens does not differ significantly from AOM of viral etiology.

Complications. The following complications of AOM may be encountered in the ED:

1. The purulent exudate that fills the middle ear space causes a conductive hearing loss. The congealed exudate may organize and stimulate hyalinization and calcification, leading to myringosclerosis (white patches within the TM) and sometimes tympanosclerosis (white deposits in the middle ear).
2. Spontaneous perforation of the TM usually produces a small hole that heals rapidly; however, large perforations may occur that do not heal even after the infection has cleared.
3. Ossicular necrosis may also occur in children who have had AOM or OME and can cause a persistent conductive hearing loss. The distal tip of the incus is most susceptible to erosion that can cause eventual disconnection of the incus from the stapes, resulting in conductive hearing loss.
4. As the TM heals after a perforation, skin from the lateral surface of the TM may be trapped in the middle ear to form

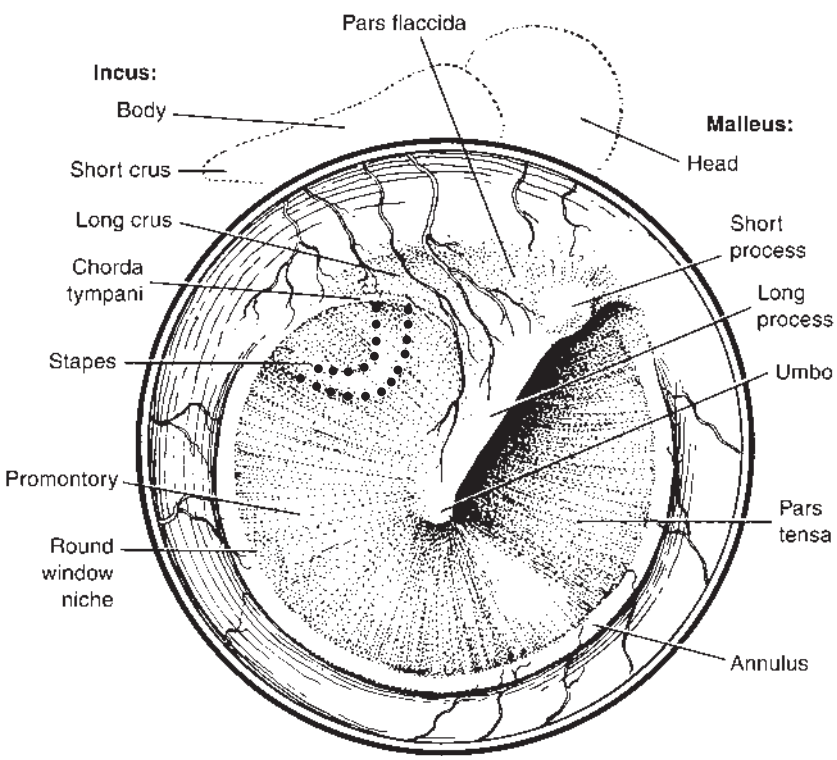

FIGURE 123.2 Right tympanic membrane.

a cyst (cholesteatoma) that can expand and destroy the structures of the middle ear and surrounding bone.

5. Facial nerve paralysis may occur suddenly during AOM. The nerve paralysis may be partial or complete when the child is first examined. The facial nerve usually recovers complete function if appropriate systemic [intravenous (IV) followed by oral] antibiotic therapy is administered and a wide myringotomy with or without tube placement for drainage is carried out as soon as possible.
6. AOM may cause inflammation in the inner ear (serous labyrinthitis). This causes mild to moderate vertigo without a sensorineural hearing loss.
7. Bacterial invasion of the inner ear (suppurative labyrinthitis) causes severe sensorineural hearing loss and severe vertigo that is usually associated with nausea and vomiting. Early treatment with IV antibiotics and wide myringotomy with tube placement may prevent permanent inner ear damage.
8. Suppurative mastoiditis (acute coalescent mastoid osteomyelitis) may develop, causing destruction of the mastoid air cell system. Temporal bone computed tomographic (CT) scans are helpful in differentiating otitis media from mastoiditis. Patients with otitis media or mastoiditis have opacified mastoid air cells when disease is present, but those with mastoiditis also have radiographic evidence of erosion of the mastoid air cells creating larger opacified spaces. As the infection spreads to the postauricular tissues, subperiosteal collection of purulent material displaces the auricle laterally and downward from its normal position. The pus may extend through air cells to the medial portion of the temporal bone, causing sixth cranial nerve paralysis, deep retroorbital pain, and otorrhea (Gradenigo's syndrome). Pus may also break through the mastoid tip and extend into the upper neck (Bezold abscess).
9. The most common intracranial problem associated with AOM is meningitis, which may cause severe sensorineural deafness and irreversible vestibular damage. Less commonly associated problems are cerebritis, epidural abscess, brain abscess, lateral sinus thrombosis, and otitic hydrocephalus. The child with overt or impending intracranial complications should be stabilized, be given IV antibiotics, and have a CT scan with contrast or magnetic resonance imaging (MRI) scan performed.

Children who are younger than 6 years with SNHL who have cochlear implants are 30 times more likely to develop pneumococcal meningitis than are age-matched cohorts without SNHL. This increased risk of meningitis may be caused by the presence of the implant that can act as a pathway for spread of infection into the meninges in children who develop ear infections or because other inner ear malformations coexist in these patients that may allow bacteria to spread to the brain. However, the majority of meningitis in children is a result of bloodborne bacterial seeding of cerebrospinal fluid. The Centers for Disease Control and Prevention recommends that age-appropriate pneumococcal vaccinations be given to all children to prevent the occurrence of meningitis.

Management. Antibiotics prescribed for AOM account for 25% to 50% of all outpatient antibiotics and are partly responsible for the global finding that bacteria, especially *S. pneumoniae*, *H. influenzae*, and *M. catarrhalis*, are becoming increasingly resistant to these medications. As such, expert panels and various medical societies have been forced to examine the benefits and choice of antibiotics used for this disease. The AAP/AAFP guidelines stress the need to improve accuracy of diagnosis to use antibiotics judiciously in treating AOM. Using the best available literature, including randomized clinical trials and cohort studies of patients with suspected AOM treated with antibiotics versus those treated with observation, the AAP/AAFP panel concluded that 80% of children who were not treated with antibiotics had spontaneous resolution of symptoms within a 2- to 7-day onset of symptoms. With this information, the panel suggested that a period of observation might be appropriate for otherwise healthy patients with AOM. However, very young children, those with immune, genetic, or craniofacial anomalies, known or underlying OME, or recent AOM in the previous 30 days should not be considered candidates for this option because they are more likely to suffer adverse consequences from observation alone. The panel also specified that the observation option must be used only if there is a high probability that the parent will be compliant in returning for evaluation if symptoms of AOM persist over the next 72 hours. Specifically, any patient younger than 6 months should be treated with antibiotic even when the diagnosis of AOM is uncertain. The observation option is recommended for children 6 months to 2 years of age whose baseline health is good, who are not seriously ill at presentation, and who have an uncertain diagnosis. The option of observation is available for children older than 2 years, with nonsevere illness at presentation with or without a certain diagnosis (Table 123.1). In prospective studies, 25% of those children did eventually require antibiotic upon follow-up within 48 to 72 hours. With regard to follow-up, the guideline suggests that the observed patients be contacted or seen within 72 hours so that they may be treated if symptoms persist. Other authors have advocated writing a "safety net prescription" to be given to parents of children who are observed at the time of the initial assessment with instructions to fill it if symptoms persist. Children with persistent OME lasting longer than 6 to 8 weeks, complications of middle ear disease, or recurrent bouts of AOM (five episodes in 6 months) should be referred to an otolaryngologist for evaluation for possible surgical treatment (myringotomy and tube placement)

To effectively treat AOM, the most important pathogen to address is *S. pneumoniae* because it is less likely to resolve spontaneously without treatment compared with *H. influenzae* and *M. catarrhalis*. Although a large number of species exist that are resistant to amoxicillin and cephalosporins, evidence from the literature and guidelines suggest that no antibiotic outperforms amoxicillin as the first-line drug to treat AOM in patients who are not allergic to penicillin. Higher dose amoxicillin (80 mg per kg per day) in two divided doses for 5 to 10 days) has been shown to be more effective than standard dosing (40 mg per kg per day) in that it overcomes the minimum inhibitory concentrations of penicillin to kill intermediate and some highly resistant strains of *S. pneumoniae*. Initial therapy in uncomplicated AOM in patients who have type 1 allergy (anaphylaxis or history of hives) to penicillin or cephalosporins should be treated with one of the following antibiotics: azithromycin, clarithromycin, or erythromycin.

In general, if symptoms persist after a child has taken first-line antibiotic for 48 to 72 hours, then the child should be

TABLE 123.1

OPTIONS FOR THE TREATMENT OF ACUTE OTITIS MEDIA (AAP/AAFP) GUIDELINES

Child age	Certain diagnosis	Uncertain diagnosis
Younger than 6 mo	Antibiotics	Antibiotics
6 mo–2 yr	Antibiotics	Antibiotics if severe illness; observe if nonsevere illness[a]
2 yr or older	Antibiotics if severe illness; observe if nonsevere illness[a]	Observe

[a]Nonsevere illness: fever <39°C and/or mild otalgia; severe illness: fever >39°C and/or moderate to severe otalgia

reevaluated by the health care provider (either by phone or in the office). Antibiotics should then be prescribed to cover β-lactam producing organisms. Specifically, amoxicillin-clavulanate (90 mg per kg per day in twice a day dosing) or the modified extra strength version of that antibiotic is appropriate for those who have a history of gastrointestinal intolerance. Other options include oral cefdinir, cefuroxime, cefpodoxime and, less commonly, ceftriaxone in IV or intramuscular dosing.

Pain should be controlled with acetaminophen or ibuprofen. Codeine should be limited for use in those with severe pain. Topical benzocaine (Auralgan or Americaine Otic) provides additional, but brief, relief for some children (30 to 60 minutes) but should not be used in patients who have TM perforations or ear tubes. Antihistamines, decongestants, and corticosteroids have shown only minimal benefit and are not recommended.

External Otitis

External otitis is usually caused by water trapped in the ear canal after swimming and is often called swimmer's ear. Ear canal trauma or foreign bodies may also contribute to the development of external otitis.

Otitis externa (OE) may be localized or diffuse. Localized external otitis is the result of an abscessed hair follicle in the outer two-thirds of the ear canal. These abscesses are most often caused by *Staphylococcus aureus*.

Diffuse external otitis is caused by *Pseudomonas aeruginosa*, staphylococci (including methicillin-resistant staphylococci), fungi, or a mixture of gram-negative and gram-positive organisms. Viral external otitis is usually caused by herpes simplex or herpes zoster virus.

Clinical Manifestations. External otitis usually begins with itching and fullness that progress to severe pain. The pain is worsened by chewing or by touching the ear. The external canal is red, edematous, and narrowed. The diagnosis of external otitis is usually readily made by external inspection and otoscopy. Otoscopy may be painful, and visualization of the eardrum may be impossible because of edema of the canal walls. A foul-smelling, purulent discharge is usually present. Surrounding cellulitis and regional cervical adenitis may also be present. Malignant external otitis occurs rarely in debilitated patients who have diabetes or who are immunosuppressed. It may cause extensive tissue necrosis and can be rapidly fatal if not treated immediately with antibiotics and may require surgical debridement.

Management. If the abscess in localized external otitis is about to drain spontaneously, it should be opened where it is pointing with an 18-gauge needle or a no. 11 scalpel blade. Drainage results in immediate relief of pain. Antibiotic therapy with an antistaphylococcal antibiotic (e.g., erythromycin, dicloxacillin, clindamycin, or cephalosporin) should be administered for 10 days. Clindamycin or trimethoprim-sulfamethoxazole should be considered in regions where methicillin-resistant *S. aureus* (MRSA) is more prevalent. The treatment of diffuse external otitis comprises antibiotic eardrops containing either ciprofloxacin with or without steroids or a combination drop with neomycin, polymyxin, and hydrocortisone (four drops, three times daily) in the affected ear for 10 days. Before the drops are started, the pus and debris should be cleaned from the ear canal with gentle suction, a curette, or cotton-tipped applicators. If the meatus is so swollen that drops cannot enter the external canal, a wick of gauze or Merocel sponge should be gently advanced into the ear canal with a forceps (Fig. 123.3) to facilitate instillation of the topical medicine. The wick should be left in place for 24 to 48 hours, by which time the canal swelling should resolve to permit entrance of the drops. Broad-spectrum systemic antibiotics should be used if cellulitis or regional cervical adenitis is present. No water should be allowed to enter the ear canal during the 10 days of therapy. If OE becomes recurrent or fails to improve after a course of therapy, the discharge should be cultured for fungal and routine bacteria.

Chronic Suppurative Otitis Media

Chronic suppurative otitis media (CSOM) is a persistent perforation of the TM of more than 3 months' duration; the perforation may be acquired (from AOM or trauma) or iatrogenic (by tympanostomy tube) and may or may not be associated with active infection. When infection is present, the causative organism is usually *P. aeruginosa* or *S. aureus,* and it presents with a profuse, foul-smelling discharge. Perforation may be associated with a cholesteatoma (white skin-lined cyst) that can destroy the structures of the ear as it expands.

Clinical Manifestations. COM is usually diagnosed by otoscopy. A perforation of the eardrum is readily seen and the white, pearly, flaky debris from a cholesteatoma may also be present.

Management. Dry perforations require no active treatment. When otorrhea is noted, antibiotic-containing eardrops (four to five drops, three times daily) should be placed in the ear

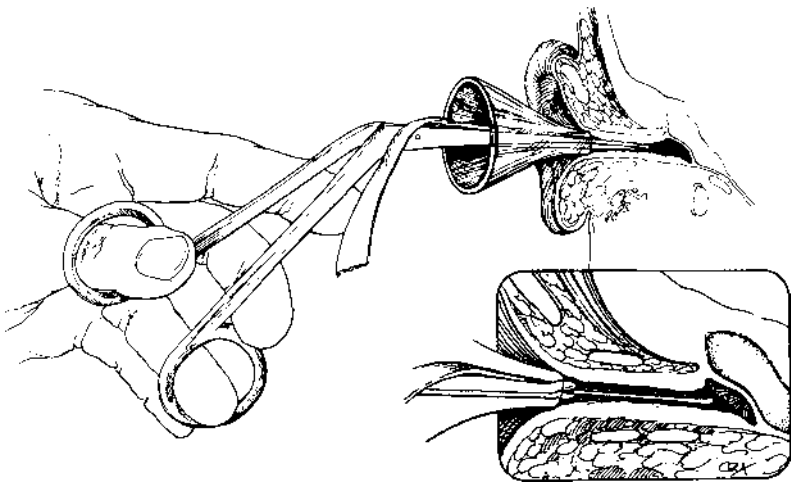

FIGURE 123.3 Gauze wick (¼ × 1½ in) being placed in ear canal to facilitate topical treatment of otitis externa.

canal. Ototoxicity manifested by either SNHL or dizziness has been reported with certain antibiotic drops but is less likely to occur when profuse otorrhea is present. The U.S. Food and Drug Administration has approved flouroquinolones with or without steroids (Ciprodex® and Floxin®, with or without steroids, respectively) in children who have otorrhea and who also have tubes or other openings into the middle ear to lower the risk of ototoxicity. Aerobic, anaerobic, and fungal cultures should be obtained in children who fail a 10-day course of drops. Clotrimazole drops have been shown to be beneficial in clearing fungal infections caused by *Aspergillus* or *Candida* species. Systemic antibiotics are of limited value unless regional cellulitis or cervical adenitis is present but may shorten the course of otorrhea in some instances. In those cases, an antistaphylococcal antibiotic (e.g., erythromycin, dicloxacillin, clindamycin, or cephalosporin) should be administered for 10 days. Cultures are sometimes helpful in recalcitrant cases to identify less common pathogens including fungi (*Aspergillus* or *Candida* species) or MRSA. Chronic perforation and cholesteatoma require surgical correction. All cases should be referred to an otolaryngologist for definitive management.

The complications of COM with infection are the same as those that occur in AOM, including intracranial spread of the infectious process. In addition, with repeated infection, a progressive high-frequency sensorineural hearing loss may develop.

Infection of the Pinna

The pinna may become infected in a fashion similar to skin surfaces anywhere else on the body (see Chapter 92). Preauricular cysts and sinuses may occasionally be infected with *S. aureus* and should be treated with antistaphylococcal penicillin, clindamycin, or cephalosporin for 10 days. If an abscess forms, it should be drained surgically. Infected preauricular sinuses/cysts require surgical excision once the acute infection has been treated. Perichondritis requires immediate antipseudomonal and antistaphylococcal antibiotic treatment.

Sudden Hearing Loss

Sudden hearing loss is not a common complaint in the ED, but it requires prompt attention, especially if the loss is determined to be sensorineural. Sudden conductive losses almost never occur without a known antecedent such as head trauma, ear infection, or wax occlusion of the ear canal. History and otoscopy can usually establish the cause of the conductive hearing loss. However, the cause of sensorineural sudden hearing loss is obscure when the history is unrevealing and otoscopy findings are normal. Tuning fork testing helps confirm the presence of a sensorineural hearing loss.

Sudden sensorineural hearing loss that occurs after an airplane trip, scuba diving, straining, or head trauma is highly suggestive of a perilymph fistula. A perilymph fistula occurs when inner ear fluid leaks out into the middle ear through a rupture in the round window or stapes footplate (oval window). The leaking fluid causes a fluctuating sensorineural loss and vertigo. Urgent surgical exploration of the middle ear is required for repair.

Sudden sensorineural deafness may occur without a history suggestive of a fistula and without otoscopic abnormalities. This is often secondary to concussive middle ear injury or a viral infection of the cochlear labyrinth. Measles, mumps, and cytomegalic viral illnesses are common causes of sudden sensorineural deafness. Other viruses may also injure the cochlea. There may be no systemic symptoms or signs of such a viral infection. These patients may have partial or complete recovery of hearing that usually improves over several weeks. Lyme disease has also been found to be a cause of sensorineural hearing loss.

There is no proven effective treatment of sudden hearing loss. Aspirin has been recommended (in older children) both to decrease platelet aggregation and to maintain patency of the cochlear blood vessels, and corticosteroids have been recommended by some authors who believe that the etiology of some cases is autoimmune. Other treatments have been proposed (e.g., cyclophosphamide, hyperbaric oxygen, inhaled CO_2), but these therapies are of uncertain efficacy. Antivertigo medications may be prescribed for patients experiencing dizziness. All patients with a sudden sensorineural hearing loss should be referred to an otolaryngologist.

Vertigo

Sudden vertigo is a disturbing and sometimes confusing symptom. Vertigo caused by middle ear pathology is often

accompanied by nausea, vomiting, imbalance, and irregular gait. A child may be brought to the ED because the parents think he or she is having a seizure. Vertigo may result from dysfunction of any part of the vestibular system (from the labyrinth to the vestibular cortex). Vertigo may be associated with a number of conditions affecting the middle ear:

1. Serous labyrinthitis may develop in a child with OME, AOM, or COM. Pressure and infection in the middle ear may cause inner ear inflammation and vestibular dysfunction. The conductive hearing loss and the dizziness resolve when the middle ear pressure is normalized or the inflammation subsides.
2. Suppurative labyrinthitis may occur when bacteria invade the inner ear. This condition results in severe vertigo (usually with associated nausea and vomiting) and profound sensorineural hearing loss.
3. When a cholesteatoma arises in association with COM, it may invade the bony wall of the labyrinth. Pneumatic otoscopy may produce the sensation of vertigo by transmitting the pressure directly to the inner ear.
4. A common cause of sudden vertigo is vestibular neuronitis. The origin of this entity is uncertain, and the vertigo resolves spontaneously over several weeks. It may be associated with a minor upper respiratory tract infection.
5. Trauma can be associated with vertigo in several ways. Perilymph fistulae, which occur most often after barotrauma, blunt head trauma, or straining, produce vertigo that fluctuates in severity. However, labyrinthine concussion or hemorrhage (hemorrhagic labyrinthitis) caused by blunt or direct trauma to the head can also result in vertigo. Cerebral injuries involving the temporal lobe (with or without temporal bone fracture) are more likely to cause vertigo. In most instances, the child can compensate for complete vestibular loss in several weeks as long as only one ear is affected and he or she has normal cerebellar and visual functions.
6. Measles and mumps may also infect the inner ear and cause vertigo.
7. Meniere's disease (endolymphatic hydrops) is rare in children. Its origin is unknown. The symptoms are intermittent vertigo, tinnitus, a feeling of fullness in the ear, and fluctuating hearing that lasts several hours and then usually passes.
8. Miscellaneous causes of sudden vertigo in children include benign paroxysmal vertigo of childhood and retrolabyrinthine lesions such as tumors, demyelinating diseases, and temporal lobe seizures. Migraine headaches may also present with episodes of vertigo.

The emergency physician should be reminded that vertigo is only a symptom of an underlying disease. Emergency treatment should consist of searching for the underlying disease, as well as providing symptomatic relief. Vertigo is rarely associated with a life-threatening illness, but CT or MRI scans of the head should be considered in more severe cases to look for intracranial sources of the vertigo. Because sensorineural hearing loss usually accompanies serious causes of vertigo, its absence can provide some level of confidence that no life-threatening disease is present. (See Chapter 20 for further discussion.)

Neoplasms

Neoplasms of the external ear are as varied as the tissue types of the auricle and are not difficult to diagnose because they are usually visible. Neoplasms of the middle and inner ear are rare but bear mentioning because they are often missed until they are far advanced. External canal and middle ear tumors are most often brought to the physician's attention because of painful secondary infection that does not respond to conventional treatment of topical and systemic antibiotics. The examiner may overlook a tumor, assuming it is granulation tissue caused by an infection or related to a ventilating tube. If an ear infection does not respond to appropriate treatment or is associated with any abnormal-appearing tissue, a tumor should be suspected; otolaryngologic consultation should be made to obtain a biopsy of the abnormal tissue.

Inner ear tumors are deceptive in their early stages and are rarely detected until they cause hearing loss, vertigo, or focal neurologic signs. The most common of these tumors are neural sheath tumors of the eighth nerve (acoustic neuromas) that cause progressive sensorineural hearing loss, tinnitus, vertigo, and fifth nerve anesthesia. These tumors are more likely to occur in children who are in their teens or who have neurofibromatosis type 2.

Facial Nerve Paralysis

Facial nerve paralysis is a frightening occurrence in children. Bell's palsy (idiopathic facial paralysis) is the most common cause of facial paralysis. (See Chapter 83 for management of this presumed viral infection.) A child presenting with facial paralysis must have a careful examination to detect any other treatable cause for the nerve dysfunction. Facial paralysis secondary to AOM requires a course of systemic (24 to 48 hours of IV followed by oral) antibiotics and an urgent wide-field myringotomy and tube for drainage. Temporal bone fractures, facial trauma, and neoplasms of the middle ear and parotid area can also present with facial nerve paralysis. A child with a facial nerve paralysis should be referred to an otolaryngologist for a complete evaluation of the head and neck, audiogram, and radiographic imaging.

The most common infectious cause of facial nerve paralysis in children is Lyme disease. It has been reported to be bilateral in 28% of patients. The treatment is doxycycline in adults, but amoxicillin is also effective in children. The majority of cases resolve within 6 months after treatment has been started.

Other less common causes of facial nerve paralysis include herpes zoster virus, herpes simplex virus, Epstein-Barr virus, *M. pneumoniae*, and, less often, cat-scratch disease. Acyclovir has been used with some success in cases of herpes virus infections. Facial nerve paralysis has also been associated with inflammatory disease, including Kawasaki's disease, Wegener's granulomatosis, and Melkersson-Rosenthal syndrome.

NOSE AND PARANASAL SINUSES

Methods of Examination

The external nose and anterior portion of the nasal cavities can be examined by direct visual inspection. A nasal speculum and directed light source are necessary to permit good visualization of the anterior septum and inferior and middle turbinates. In younger children, the examiner's thumb can

elevate the mobile nasal tip to allow adequate inspection of the anterior nasal structures. Vasoconstrictors such as 0.25% phenylephrine or 0.05% oxymetazoline (two or three drops) can be applied to the nose to shrink the mucosa and allow a more complete examination. The posterior nasal structures and nasopharynx can be seen with the aid of a flexible fiberoptic endoscope placed in the nose or the posterior oropharynx (see Procedure 7.5 in Section VII). Patency of the nasal cavities in the neonate can be assessed by the passage of small rubber catheters through the nose and into the pharynx. Palpation is also important in the evaluation of nasal and facial trauma. Tenderness to palpation over the sinuses is a common sign of acute sinusitis.

A careful examination of adjacent areas is important when evaluating a child with sinus disease. Dental pathology may be a possible cause of a bacterial maxillary sinusitis. An examination of the orbit with assessment of visual acuity and ocular mobility should be performed to detect possible orbital complications of sinus disease.

Radiographs are very helpful in evaluating diseases of the nose and sinuses. Plain films (sinus or facial series) can be used as screening devices to evaluate a mass or fluid in a sinus, but CT scans are indicated for more precise and detailed evaluation of sinusitis or tumors of this area. (See the following text.)

Infections

The common cold/upper respiratory tract infection accounts for the majority of infections of the nose and paranasal sinuses. The symptom complex of fever, nasal congestion/rhinorrhea, and headache is most often caused by a viral agent. Physical examination often reveals swollen, erythematous, nasal turbinates. The rhinorrhea can be clear or white. Facial tenderness is usually absent. Viral rhinitis requires a little more than supportive care with hydration, rest, and antipyretics. Topical decongestants should be avoided and their use limited to 3- to 5-day duration because of their tendency to cause rebound congestion as their vasoconstricting effect on the nasal mucosa wears off.

Bacterial infection of the nose and paranasal sinuses is a more serious condition that requires careful examination and prompt treatment. Bacterial rhinosinusitis should be suspected when cough, halitosis, low-grade fever, and purulent rhinorrhea are present. A bacterial infection is more likely to be present when the nasal discharge lasts more than 7 days and the discharge is thick yellow to yellowish green, especially if it is localized in the nasopharynx or middle meatus of the nose. Tenderness over the face may indicate clinical involvement of one or more of the paranasal sinuses, but direct rhinoscopy with an otoscope is more helpful in locating the source of infection. The AAP developed guidelines in 2001 with recommendations that sinus radiographs (plain or CT) should not be used as a routine clinical adjunct to diagnose acute rhinosinusitis in children 6 years or younger because clinical history predicts outcome of imaging studies with 88% accuracy in that age group. They may be considered in older children, but false-positive rates of CT scans are high unless any of the following findings are present: mucosal thickening greater than 4 mm, an air–fluid level, or complete opacification of the sinus. A sinus CT scan should be obtained when the child is severely ill or when complications of disease are suspected in the orbit or brain. Nasal culture should not be obtained unless taken directly from the middle meatus or sinus. Because the most common organisms responsible for bacterial rhinosinusitis are *S. pneumoniae*, nontypeable *H. influenzae*, and *M. catarralis*, amoxicillin (80 mg per kg per day) for 10 days is the treatment of choice. Short courses of saline, humidified air and nasal steroids should be used to help promote drainage.

Complications of acute sinusitis, such as orbital cellulites/abscess, facial cellulitis/abscess, meningitis, or intracranial abscesses require admission to the hospital for appropriate IV antimicrobial therapy and possible operative intervention. Otolaryngologic consultation should be obtained in the evaluation of these patients with complicated acute sinusitis because surgical drainage may be needed. Intracranial complications of sinusitis should be suspected in those who also have sinusitis with changes in mental status, fever, headache, and vomiting. Adolescent boys are more likely to have intracranial complications involving the frontal sinus because the frontal bone and sinuses are developing, and because there is an increase rate of growth of diploic bone at that time. CT of sinuses and brain with contrast are usually necessary to avoid missing complications of frontal sinuses in severely ill children.

The sinus mucocele is a late complication that can flare up, causing a child to present to the ED with acute symptoms. Mucoceles are expansile cystic lesions that occur secondary to a long-standing blockage of a sinus ostium. Although the lesion evolves over several months or even years, the child usually presents with the sudden onset of signs and symptoms usually related to an acute infection of the mucocele. These include pain and swelling secondary to osteomyelitis of the frontal bone, inferior and lateral displacement of the globe with proptosis, limitation of ocular mobility, and chronic nasal/postnasal discharge. Radiographs (plain films and CT) are often needed to determine the presence and extent of a mucocele. The patient should be referred to the otolaryngology service for appropriate IV antimicrobial therapy and surgical drainage.

Underlying conditions should be suspected if rhinosinusitis persists after a prolonged course of antibiotics. The presence of foreign bodies, choanal atresia, neoplasms, septal deviation, dental disease, adenoid hypertrophy, allergic polyps, or immunodeficiency states may all be associated with recurrent or persistent rhinosinusitis.

Chronic Nasal Obstruction

Obstruction to the normal passage of air can occur with various conditions and gives the sensation of a blocked or "stuffy" nose. Temporary partial obstruction of one nasal cavity at a time occurs normally in the nasal respiratory cycle. However, prolonged blockage is not physiologic, and the physician should search for a cause.

Although most instances of nasal obstruction cause only mild feelings of discomfort, some children may present with a history of obstructive apnea (Pickwickian syndrome—see the "Adenotonsillar Hypertrophy" section) and even cor pulmonale. Nasal trauma or a foreign body may be a cause of the obstruction. A careful examination of the nasal cavities and pharynx is necessary to determine the cause of the obstruction. Septal deviation, and turbinate hypertrophy related to allergy and/or infection are common causes.

Adenoid hypertrophy, nasal tumor nasopharyngeal tumor (lymphoma, rhabdomyosarcoma), and choanal atresia (unilateral or bilateral) can all present with nasal obstruction. Flexible fiber-optic examination (see Procedure 7.5 in Section VII) and radiographs (usually CT scan) of the nose and nasopharynx may be useful in the evaluation of the blocked nasal airway. If the source of the obstruction is not apparent after these maneuvers, referral should be made to an otolaryngologist to perform a complete examination of the nose and nasopharynx.

Epistaxis

Epistaxis is relatively common in children, and may cause significant anxiety in both the child and the parent. Although bleeding occasionally occurs secondary to the mucosal maceration caused by upper respiratory tract infections, nose picking accounts for most cases of recurrent epistaxis. (A more complete discussion on the differential diagnosis is presented in Chapter 22.) The usual site of bleeding is the anterior nasal septum, Kiesselbach's or Little's area (Fig. 123.4).

It is important to obtain information regarding the site of bleeding (one or both sides of the nose), frequency, and presence of bleeding from other places, history of trauma, and family history of bleeding in order to properly manage a patient with epistaxis. Figure 123.5 presents an algorithm for the management of epistaxis. A careful examination of the nose should be performed to identify the site and cause of the bleeding. Good lighting, suction, and material for cauterization and packing should be readily available (see Procedure 7.1 in Section VII). Topical vasoconstrictors such as phenylephrine (0.25%), oxymetazoline (0.05%), or epinephrine (1:1,000) on a cotton pledget can be placed in the nose to shrink the nasal mucosa, allowing better visualization of the nasal cavity; vasoconstrictors may slow or even stop the bleeding. Applying pressure for 10 to 20 minutes by squeezing the nostrils together is usually sufficient to stop most epistaxis. Occasionally, a roll of cotton placed under the upper lip will stop bleeding by compression of the labial artery. If pressure is not successful, cauterization with silver nitrate sticks or packing of the nose is performed (see Procedures 7.1

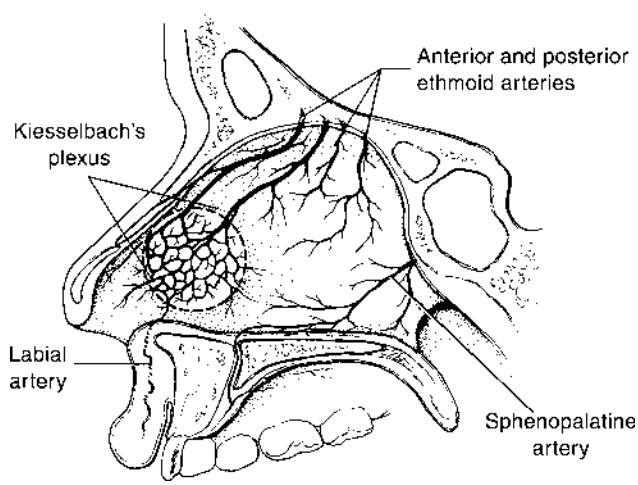

FIGURE 123.4 Vascular supply of nasal septum. Note confluence of vessels that forms Kiesselbach's plexus.

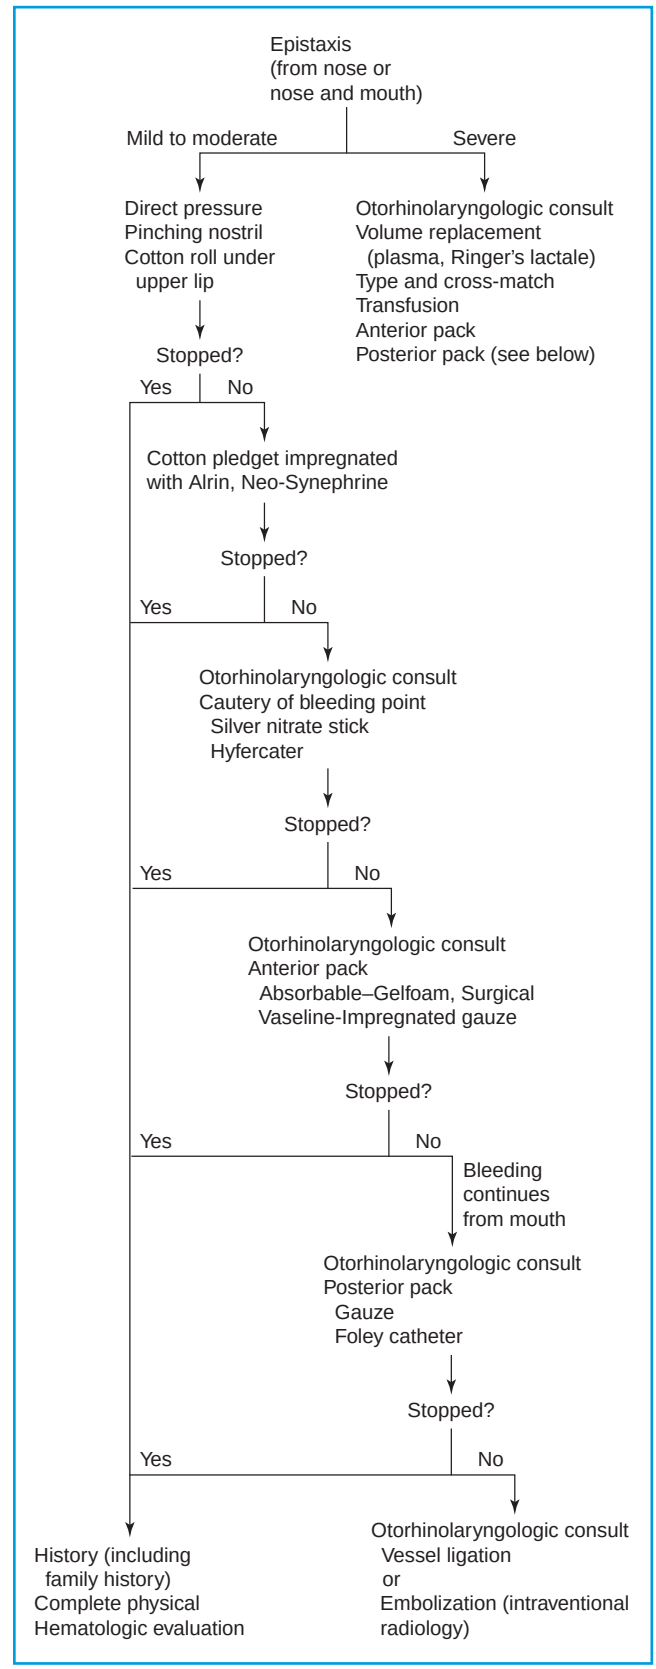

FIGURE 123.5 Algorithm for the management of epistaxis.

and 7.2 in Section VII). Absorbable packing such as oxycellulose (Surgicel®) or gelatin (Gelfoam®) is usually adequate for most epistaxis and is advantageous because it does not need to be removed. Micofibrillar collagen (Avitene©, Davol) is a foam/gel that could be used to prohibit further bleeding but is less helpful when the nose is actively bleeding.

Further treatment should also be directed toward preventing the child from continuing to traumatize his or her nose, which could result in further bleeding. Using a vaporizer to increase the humidity in the child's room and applying petroleum jelly to the anterior septal areas twice daily can aid in healing the irritated nasal mucosa and preventing recurrent epistaxis. Fingernails should be cut short.

Otolaryngologists should be called to assist in diagnosis and management of children who have severe or recurrent episodes of epistaxis. Epistaxis that does not stop with simple pressure or oxycellulose or gelatin packing may require a more substantial anterior nasal pack of petroleum jelly-impregnated gauze. A posterior nasal pack (using gauze or a Foley catheter) may be necessary in managing severe epistaxis that originates in the posterior nasal cavity or nasopharynx (see Procedure 7.2 in Section VII).

If the epistaxis recurs despite these treatments, an otolaryngologist should be consulted to look for other causes for the epistaxis. Nasal septal deviation or perforation, sinusitis, tumor (nasal, nasopharyngeal, or sinus), Rendu-Osler-Weber disease (hereditary hemorrhagic telangiectasia), and nasal foreign body can all present with epistaxis. Blood dyscrasias such as hemophilia, idiopathic thrombocytopenia purpura, von Willebrand's disease, and those hematologic conditions that are associated with leukemia or the administration of chemotherapeutic agents may lead to severe epistaxis. Treatment consists of correcting the underlying hematologic problem in addition to the previously described local measures. Recurrent or severe bleeding may require more extensive cauterization of the vessels on the septum or ligation or embolization of the regional blood vessels, including the maxillary and ethmoid vessels.

Neoplasms

Neoplasms of the nose and sinuses are uncommon in children. They may present as mass lesions or as chronic/recurrent rhinosinusitis. When a neoplasm is suspected, the child should be referred to an otolaryngologist for a complete evaluation of the nose and sinuses and appropriate radiographic imaging, which is a prerequisite to the proper treatment of these lesions.

Hemangiomas are the most common benign neoplasms of the head and neck in children and often occur on the skin near or on the nose. Because hemangiomas often go through a period of rapid growth for the first 12 to 18 months of life before they begin to involute, a period of observation is recommended before corticosteroids or surgical excision is considered. Recurrent bleeding, thrombocytopenia, skin breakdown, obstruction to vision, respiratory distress, and cardiac failure are some indications for early intervention. Papillomas are viral-induced verrucous growths that are the most common neoplasms of the aerodigestive tract. When they appear in the nose, they are most often found on the nasal septum. Simple excision or fulguration is the preferred treatment of these lesions. In addition to these conditions, there are various benign and malignant mass lesions of the nose. Early consultation with an otolaryngologist should be obtained for any tumor of the nose, especially one with recent changes in size or character.

ORAL CAVITY, PHARYNX, AND ESOPHAGUS

Methods of Examination

The oral cavity and oropharynx are directly visible with the aid of a tongue blade. A headlight or brightly lighted flashlight is required for this examination. The tongue should be displaced down and forward with the tongue blade placed on the anterior two-thirds of the tongue to avoid gagging. The examination of the nasopharynx, hypopharynx, and esophagus requires special instrumentation. The nasopharynx and hypopharynx can be examined with a flexible nasopharyngoscope. Nasopharyngoscopy requires special skills and may be best left to the otolaryngology consultant (see Procedure 7.5 in Section VII). Examination of the esophagus requires direct visualization with an esophagoscope under general anesthesia. Palpation of the hypopharynx and nasopharynx should not be performed because it is uncomfortable to the child and potentially dangerous.

Radiography contributes minimally to the examination of the oral cavity and oropharynx because these areas are visible by direct examination. The lateral neck radiograph is useful to evaluate the presence of abnormal tissue or masses in the nasopharynx and hypopharynx because air–tissue interfaces are present. Barium esophagrams may be helpful in diagnosing esophageal strictures or fistulas, and they are helpful in defining areas of external compression caused by extrinsic masses or congenital vascular anomalies.

Infections

Stomatitis

The most common infectious lesion of the oral cavity is the aphthous ulcer. The ulcers are often recurrent, may appear as a single lesion or a confluence of many lesions, and can cause severe stomatitis. The exact cause of aphthous ulcerations is unknown, but it is believed to be infectious.

Herpes simplex virus can cause severe gingivostomatitis, whereas the pharynx is relatively spared. In contrast, coxsackievirus infection (herpangina) causes severe ulcerative lesions of the pharynx but not the anterior mouth. These viral infections cause severe oral pain and inability to eat. They are self-limited and require only symptomatic relief (see Chapters 84 and 124).

Candida albicans oral infection (thrush) usually appears as white patches with surrounding inflammation on the oral mucosa. It often occurs in newborns, immunosuppressed patients, and patients receiving antibiotic therapy. Nystatin is an effective treatment. The dosage is 100,000 to 200,000 units (1 to 2 mL) four times per day for 5 to 10 days.

Acute necrotizing ulcerative gingivitis (trench mouth) causes painful, bleeding gums. Vigorous brushing of the teeth and gums with a soft brush promotes rapid healing. Antibiotics are of limited value.

Pharyngitis/Tonsillitis

Pharyngitis/tonsillitis (pharyngotonsillitis) may be caused by viral or bacterial organisms. Differentiating viral pharyngotonsillitis including mononucleosis from an infection of bacterial origin is difficult on clinical grounds. A child is more likely to have a bacterial pharyngotonsillitis if three of four indicators are present: red tonsils with exudate, cervical lymphadenopathy, fever greater than 101°F, and absence of cough. Rapid strep tests are quick (5 to 10 minutes) and may be helpful in confirming the diagnosis but may miss up to one-third of infections. If this test result is negative and bacterial infection is still suspected, then a routine throat culture may be helpful, but the results are not available for 24 to 48 hours. Bacterial pharyngotonsillitis should be treated with a 10-day course of penicillin or amoxicillin. Patients with repeated debilitating bouts of pharyngotonsillitis (five to seven in a 1-year period or several per year for several years) or complications including peritonsillar abscess should be referred to an otolaryngologist for consideration for tonsillectomy and adenoidectomy.

Pharyngeal infections may spread to the peritonsillar area, causing cellulitis. The affected tonsil bulges forward and medially to touch the uvula. If pus localizes in the peritonsillar space, a peritonsillar abscess is formed. The peritonsillar abscess causes trismus. Suspected abscess formation requires immediate consultation with an otolaryngology specialist. Short-term treatment of peritonsillar abscess requires systemic (24 to 48 hours of IV followed by oral) antibiotics and needle aspiration or incisional drainage (if possible) of the abscess. Occasionally, a "hot" or quinsy tonsillectomy may be required to treat the acute infection. Later, elective tonsillectomy is indicated if there is a previous history of tonsillar or peritonsillar infections.

Retropharyngeal and Parapharyngeal Infections

Retropharyngeal and parapharyngeal lymph nodes may also become infected during an episode of pharyngitis and progress to abscess formation. Retropharyngeal abscess is usually easily seen on the lateral neck radiograph and confirmed by CT of the neck with contrast. Abscess is more likely present when the soft-tissue mass (lymph nodes) has a hypolucent core that has complete rim enhancement (Fig. 123.6). Peritonsillar, retropharyngeal, and parapharyngeal abscesses must be treated with IV antibiotics, and 60% to 80% require surgical drainage. (See also "Infections" under the "Neck and Associated Structures" section.)

Other unusual infections that may occur in the oral cavity include actinomycosis, mucormycosis, and syphilis. Infections due to actinomycosis may cause oral–cervical fistulas, whereas infections due to *Mucor* cause necrosis of the palate. Syphilis is visible in many ways (e.g., ulceration or raised lesion) and has no one characteristic appearance.

Adenotonsillar Hypertrophy

Lymphoid hyperplasia (enlarged tonsils and adenoids) can cause airway obstruction that can range from mild snoring to severe sleep apnea with right-sided heart strain. Young children with obstructive sleep apnea most often weigh in the lower 25th percentile and some have failure to thrive. Alternatively, older children with severe obstructive sleep apnea are often obese and present with daytime somnolence (Pickwickian syndrome). If significant oxygen desaturation with or without bradycardia is present, or signs of right-sided heart strain or daytime somnolence are present, a tonsillectomy and adenoidectomy may be required urgently.

Neoplasms

Benign and malignant neoplasms occur in the oral cavity, pharynx, hypopharynx, and esophagus. Benign neoplasms in the oral cavity may rise from the mucosa or underlying tissues. Minor salivary gland tumors, hemangiomas, lymphangiomas,

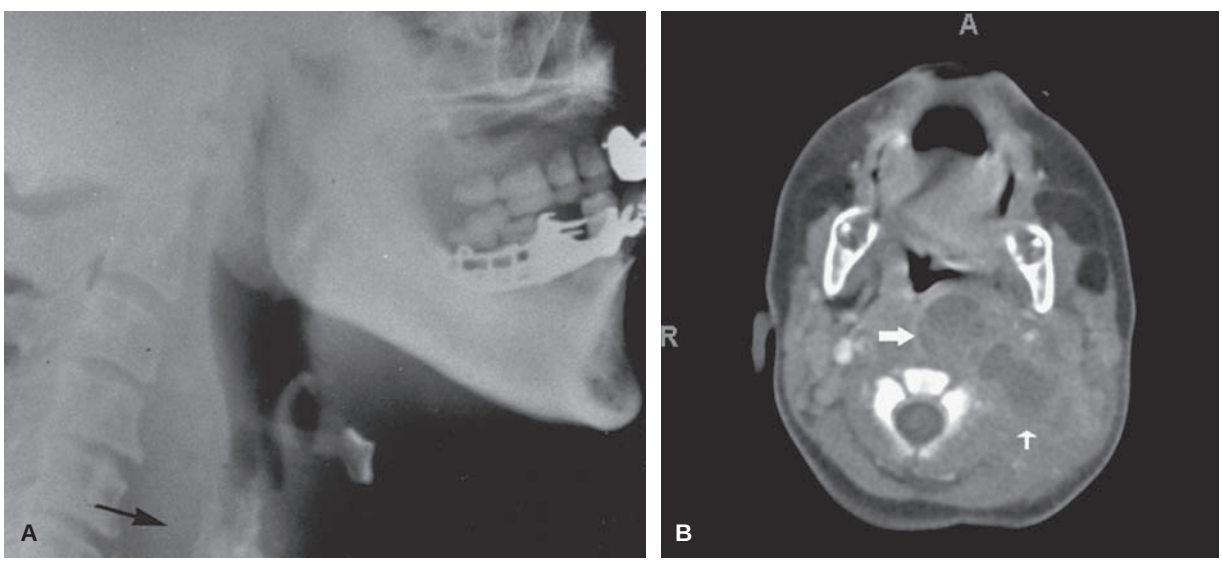

FIGURE 123.6 **A:** A lateral neck radiograph demonstrating retropharyngeal abscess *(arrow)*. **B:** A computed tomographic scan of neck with contrast demonstrating a retropharyngeal abscess *(large arrow)* and smaller, contiguous parapharyngeal abscess *(small arrow)*.

pyogenic granulomas, and neurofibromas are found in the oral cavity, but they rarely require emergency intervention.

Nasopharyngeal angiofibromas occur in pubescent males, and most often present with unilateral bleeding and nasal obstruction. They may appear in the ED with massive epistaxis. Posterior packing is usually required to control the hemorrhage that may be life threatening (see Procedure 7.2 in Section VII).

Malignant neoplasms are rare but can occur throughout the oral cavity, pharynx, and esophagus. Rhabdomyosarcoma, lymphoma, and squamous cell carcinoma (lymphoepithelioma) are the most common lesions and are rarely seen as emergencies unless there is extensive hemorrhage or a compromised airway.

Biopsy of oral, pharyngeal, and esophageal tumors is best done in the operating room, where adequate exposure and control of hemorrhage is most effectively obtained.

LARYNX AND TRACHEA

Methods of Examination

Examination of the larynx is often difficult in young children. Commonly, however, the tip of the epiglottis may be visualized when the tongue is protruded during the examination of the oropharynx. Examination of the larynx can be performed with a flexible fiber-optic endoscope. Vocal cord mobility, the structures of the larynx, and the presence of laryngeal masses can usually be assessed in this manner (see Procedure 7.5 in Section VII). The otolaryngologist may need to be consulted to perform this examination for the child presenting in the ED with symptoms related to the larynx.

Lateral and anteroposterior plain radiographs of the neck can provide significant information about the larynx and upper trachea. Although xeroradiographs offer more precise detail of the airway by virtue of their property of edge enhancement, the extra radiation exposure inherent in this study makes this a less desirable imaging modality. CT and MRI scans are useful in examining the fine detail of laryngeal and tracheal structures, but the sedation may be required to keep the child still for these examinations, restricting their use to specific situations. Fluoroscopic examination of the larynx is another method used to evaluate the movements of the vocal cords during phonation and respiration. Vocal cord paralysis and laryngomalacia can often be identified in this manner. Contrast studies can also be used in the evaluation of laryngeal function. A barium swallow is useful in detecting aspiration associated with vocal cord paralysis, posterior laryngeal cleft, extrinsic masses such as vascular webs, or tracheoesophageal fistula.

Infections

Viral laryngitis usually occurs along with a common upper respiratory tract infection, resulting in vocal cord edema manifested by a hoarse, raspy voice. Airway obstruction is rare in viral laryngitis. Symptomatic treatment with humidification, antipyretics, analgesics, throat gargles, and voice rest is recommended while the disease runs its natural course. When the viral infection involves the subglottic space, a more serious clinical problem appears. Laryngotracheobronchitis (croup) is a common and potentially life-threatening infection occurring in early childhood. The diagnosis and management of croup is discussed in Chapters 72 and 92.

Bacterial laryngotracheobronchitis does occur but is not nearly as common as its viral counterpart. Children aged 3 to 6 years are more commonly affected by bacterial tracheitis than by the infection of viral origin that usually appears in children younger than 3 years. It may be difficult to distinguish bacterial laryngitis on clinical grounds from a similar infection of viral origin. Etiologic agents responsible for bacterial laryngitis include staphylococci, streptococcus, and *H. influenzae*. Severe airway obstruction is a common symptom of bacterial laryngotracheobronchitis. This is caused by thick, inspissated secretions that fill the trachea and are difficult for the child to clear. In addition to the treatment measures recommended for viral laryngitis, patients should be prescribed antimicrobial agents and may require observation in the hospital if airway symptoms are severe. The otolaryngologist is usually required to perform a direct laryngoscopy and bronchoscopy to confirm the diagnosis and to aspirate the thick secretions for therapeutic and diagnostic purposes.

Diphtheria may involve the larynx, as well as other areas of the upper aerodigestive tract. The diagnosis is suspected by the presence of a membrane covering the pharynx and larynx that leaves a raw, bleeding surface when it is removed. The diphtheria membrane can obstruct the laryngeal airway to cause respiratory distress. Endoscopic removal of the membrane and/or tracheostomy may be required, in addition to antimicrobial therapy.

Bacterial infection of the supraglottic larynx can cause a symptom complex with potentially life-threatening airway obstruction. Epiglottitis (more appropriately called supraglottitis) is an infection of the supraglottic larynx that is caused most often by *H. influenzae* type b. Although the *H. influenzae* type b vaccine is generally effective (with reported overall efficacy of 98%), vaccine failures do occur. Up to 27% of reported cases of epiglottitis occur in children who have been vaccinated. Other bacteria that can cause epiglottis include *S. pneumoniae* and group A, B, or C streptococci. The diagnosis and management of epiglottitis are discussed in Chapters 72 and 92.

Neoplasms

Neoplasms of the larynx and trachea are uncommon in children. The otolaryngologist should be consulted to assist the emergency physician in the management of these patients.

The most common neoplasm of the larynx in children is the laryngeal papilloma. This is believed to be a viral-induced neoplasm (human papillomavirus, HPV) that has a predilection for the upper aerodigestive tract and the larynx in particular. The disease is most often transmitted from the mother to the infant at birth, but symptoms do not usually become apparent until the child is between 2 and 5 years of age. The child presents with persistent or worsening hoarseness and, occasionally, airway obstruction. Vaccination with HPV vaccine Gardasil® has been recommended for use in teenage women and has been shown to prevent cervical HPV infections that can later be transmitted to their offspring during pregnancy or childbirth.

If papillomas are suspected as the source of hoarseness in a child, the otolaryngologist should be consulted to perform the

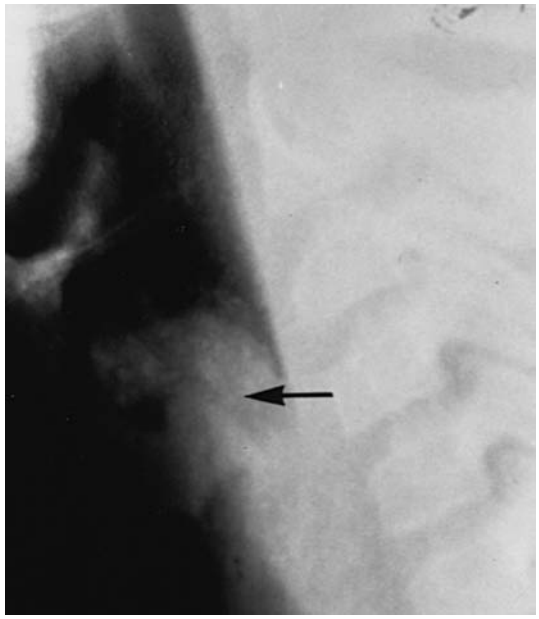

FIGURE 123.7 Lateral neck radiograph demonstrating soft-tissue density *(arrow)* at the level of larynx. Direct laryngoscopy revealed this to be papilloma.

indirect or direct laryngoscopy required to confirm the diagnosis. A lateral neck radiograph may demonstrate a soft-tissue mass in the area of the larynx (Fig. 123.7). The course of the disease is characterized by multiple cycles of growth and regression until a spontaneous remission occurs, usually around puberty. The otolaryngologist's goal in managing these patients is to maintain an adequate voice and unobstructed airway by frequent repeated excision (with cup forceps, carbon dioxide laser, or microdissectors) of the papillomas. A tracheostomy may be required in cases of severe airway obstruction. Hemangiomas may occur in the larynx, primarily in the subglottic area. As with most juvenile hemangiomas, these lesions present in the second to sixth months of life and can enlarge over several months to cause significant airway obstruction. Episodes of stridor may be precipitated by an upper respiratory tract infection. Of children with subglottic hemangiomas, 50% have other cutaneous lesions. The presence of cutaneous hemangiomas in an infant with stridor should suggest to the emergency physician the possibility of a subglottic hemangioma; however, only 1% of patients with cutaneous hemangiomas have airway lesions. Hemangiomas may appear as posterior subglottic masses on lateral neck radiographs, but the diagnosis must be confirmed by laryngoscopy performed by an otolaryngologist. Because most hemangiomas of infancy tend to involute after an initial period of rapid growth during the first 1 to 2 years of life, close observation is the only treatment required for those lesions that are causing minimal symptoms. If there is severe, persistent, or recurrent respiratory distress, intervention is indicated. Systemic corticosteroids, direct surgical excision, and tracheostomy are some of the modes of treatment presently being advocated. The carbon dioxide laser has been used as another method to vaporize hemangiomas but is used less frequently because it has been associated with increased scarring leading to subglottic stenosis.

Malignant neoplasms of the larynx are uncommon. They include rhabdomyosarcoma, chondrosarcoma, and lymphoma. These tumors are seen with varying degrees of hoarseness and respiratory obstruction. If a laryngeal malignancy is suspected, the otolaryngologist should be asked to perform indirect or direct laryngoscopy to confirm the laryngeal problem and obtain tissue for histologic identification of the tumor.

Stridor

The differential diagnosis and emergency management of a child presenting with stridor is discussed in detail in Chapter 72.

NECK AND ASSOCIATED STRUCTURES

Methods of Examination

Visual inspection and palpation provide the basis for examination of the neck and its enclosed structures. The head should be erect during the examination, with the normal prominence of the sternocleidomastoid muscle on each side. Anterior projection of the thyroid cartilage or "Adam's apple" is seen in postpubescent males. Palpation of the neck is performed to assess the normal structures in the neck and to detect the presence and nature of any cervical masses. Examination of the two sides is done simultaneously so that they can be compared with one another. The examiner should be able to grasp the thyroid cartilage and move it gently from side to side without any discomfort to the patient. Immobility or significant pain may indicate the presence of laryngeal pathology. Crepitance of the neck indicates free air in the tissue planes of the neck from perforation of a hollow viscous. Passive and active range of motion of the neck should be complete in all directions. Restriction in movement may be caused by tender cervical adenopathy, cervical spine disease, spasm or fibrosis of the sternocleidomastoid muscle, or meningeal irritation (Brudzinski's sign). Arterial pulses of equal strength should be palpable in the carotid artery on each side of the neck. The carotids can also be auscultated for evidence of bruits.

Radiographs are often invaluable in the examination of the neck. Plain anteroposterior and lateral views provide significant information in the evaluation of cervical problems. The presence of masses projecting into and compromising the airway can be detected. Air between the muscle planes of the neck indicates a perforation of a hollow viscus such as the pharynx, esophagus, larynx, trachea, or pulmonary alveolus. CTs and MRIs of the neck obtained with contrast are often helpful in determining the cause of a neck mass.

Infections

Cervical adenitis is the most common cause of a neck mass in a child. The lymphatic system of the neck drains the internal cavities of the head and neck (ear, nose, mouth, pharynx, sinuses, and larynx), as well as the skin and associated adnexal structures of the face and scalp. Regional cervical lymph nodes respond when there is a primary infection in any area of the head and neck. Because certain groups of nodes drain into specific sites in the head and neck, the location of the swollen and infected

lymph node can often help the practitioner to identify the area of the primary infection. Infraauricular nodes most often drain during ear infections, jugulodigastric nodes usually swell during pharyngeal infections (e.g., tonsillitis), and posterior neck nodes swell during nasopharyngeal infections (e.g., adenoiditis).

Cervical adenitis does not usually occur following a brief, uncomplicated viral infection of the upper respiratory tract. Instead, these tender and enlarged nodes occur more often as a result of bacterial infection of the head and neck. Infections of the ear and throat are the most common source. Because *Streptococcus* species are the causative agents in the majority of bacterial infections of the head and neck, the infected lymph nodes usually contain the same organisms. Treatment with amoxicillin or penicillin usually clears the primary infection and causes regression of the enlarged lymph nodes. Culture of the nasopharynx, throat, or aspirate of the cervical node can assist the physician in the choice of antimicrobial agents.

Although most children respond to oral antibiotics, a small group of children develop nodes that progress to suppurative cervical adenitis that usually requires hospitalization. A recent study of children hospitalized with cervical adenitis has shown a predominance of *S. aureus* as the causative agent (63% of positive cultures were *S. aureus* and 22% were group A streptococci, respectively). Of the staphylococcal infections, 27% were MRSA and all of these were sensitive to clindamycin and trimethoprim-sulfamethoxazole, 63% were sensitive to ciprofloxacin, and 25% to erythromycin. Of the methicillin-sensitive *S. aureus* isolates, 100%, 86%, and 82% were sensitive to trimethoprim-sulfamethoxazole, clindamycin, and ciprofloxacin, respectively. The high incidence of staphylococci in these hospitalized patients may occur because they have not responded to oral antimicrobials effective against the more commonly occurring *Streptococcus* species. Therefore, if cervical adenitis has not responded to the primary antimicrobial treatment, agents should be added that are effective against *S. aureus* (as well as other *Streptococcus* species).

A child who has demonstrated rapid enlargement of cervical nodes, poor response to oral antimicrobials, cellulitis of the overlying skin, abscess formation, or signs of toxicity (high fever, malaise, dehydration) should be admitted to the hospital for treatment with IV fluids and antimicrobials. Surgical consultation should be obtained in the management of these complicated cases in which needle aspiration, incision and drainage, or biopsy (for possible neoplasm) may be required.

Retropharyngeal or parapharyngeal nodes are commonly involved with inflammatory processes that originate in the pharynx. Sore throat, dysphagia, and stiff neck are some of the symptoms that can significantly accompany enlarged pharyngeal nodes. Retropharyngeal nodes can sometimes be seen overlying the cervical spine during examination of the oropharynx. They also can cause widening of the retropharyngeal soft tissues on lateral neck radiographs. Parapharyngeal nodes are seldom detected clinically unless they enlarge sufficiently to deviate the tonsil and pharyngeal wall medially. Treatment of enlarged pharyngeal nodes consists of IV antimicrobials (usually β-lactamase–resistant penicillin) and observation of the child's airway. Biopsy of the mass is indicated if resolution does not occur with treatment or if a malignancy is suspected.

A collection of purulent material within the tissues of the neck, a neck abscess, requires prompt and specific treatment. The most common cause of a neck abscess is breakdown or necrosis of an infected lymph node. Purulent material may be located within a single node or may accumulate between several adjacent nodes. Once the process of cervical adenitis has progressed to the point of abscess formation, treatment involves evacuation of the infected material and the prevention of further spread of the infection. The child is hospitalized, and IV antimicrobials are administered that are effective against *S. aureus* and *Streptococcus* species (with antistaphylococcal and β-lactamase–resistant activity). Otolaryngologic consultation is obtained to perform a needle aspiration or incision and drainage to evacuate and culture the infected material. Less common causes of cervical adenitis include cat-scratch fever, atypical *Mycobacterium* tuberculosis, and tuberculosis.

Deep neck abscesses are uncommon in children but can be dangerous when they occur. Parapharyngeal abscess occurs when purulent material collects in the parapharyngeal space lateral to the pharyngeal constrictors and medial to the vascular compartment of the neck. Necrosis of parapharyngeal lymph nodes and lateral extension of a peritonsillar abscess are the two main sources of this infection in children. The child with a parapharyngeal abscess presents with a stiff neck, high fever, malaise, dehydration, and other signs of toxicity. The child usually has dysphagia and may not be able to swallow his or her own saliva. Physical examination reveals diffuse swelling and tenderness of one side of the neck, but fluctuance is seldom appreciated. Intraoral examination may demonstrate medial displacement of the lateral pharyngeal wall and tonsil. Lateral neck radiographs are usually not helpful in evaluating this disease process. CT or MRI scans with contrast provide the best evaluation of suspected deep neck abscesses (Fig. 123.8). If left to progress, the parapharyngeal abscess can involve the adjacent vascular structures in the neck, descend

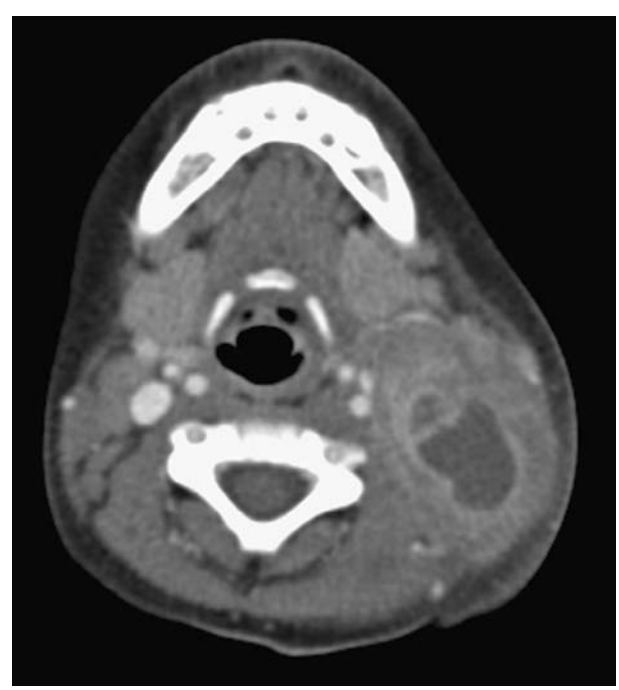

Figure 123.8 Computed tomographic scan with contrast demonstrating left lateral neck abscess/necrotic lymph nodes from cervical adenitis.

into the mediastinum, or spontaneously rupture into the pharynx, causing aspiration of purulent material.

Otolaryngologic consultation should be obtained to assist the emergency physician in the evaluation of a patient with a parapharyngeal abscess. Appropriate treatment consists of hospitalization, IV fluids, antimicrobials effective against *S. aureus* and *Streptococcus* species (antistaphylococcal and β-lactamase–resistant penicillins, clindamycin, cephalosporins), and external drainage of the abscess. Occasionally, infections may be polymicrobial in nature and include anaerobic bacteria from the oral cavity and, less often, gram-negative organisms.

Retropharyngeal abscess occurs as a result of the necrosis of retropharyngeal lymph nodes or secondary to perforation of the pharynx or esophagus. Purulent material collects between the retropharyngeal and prevertebral layers of the cervical fascia, also called the danger space. This potential space extends from the base of the skull to the mediastinum, thus allowing extensive spread of the infection. A child presents with symptoms similar to those associated with parapharyngeal abscess. Lateral neck radiographs demonstrate widening and bulging of the retropharyngeal space, but these radiographs have a high false-positive rate and are best used as screening tests (Fig. 123.6). CT scanning with IV contrast is most useful to diagnose the presence of a retropharyngeal infection but is less helpful in differentiating a drainable abscess from cellulitis. Treatment consists of hospitalization, IV fluids, and antimicrobials effective against *S. aureus* and *Streptococcus* species. Drainage of the abscess (either intraoral or through the external neck) is necessary in 60% to 70% of cases and should be done if the child has signs of airway compromise, has findings of a large hypolucent mass with thick enhancing capsule on CT radiographs, or has failed to respond to IV antibiotic therapy after 48 to 72 hours.

Nontubercular mycobacterial (NTM) infection is a common cause of chronic cervical adenitis in children. Also called atypical mycobacteria, the ubiquitous agent is believed to gain access to the cervical lymph nodes through oral mucosal or skin breaks (e.g., teething, minor trauma). Most cultures grow *Mycobacterium avium intracellulare* (MAI). These organisms are commonly found in the environment in dirt, dust, and water. They can also be transmitted through food. The usual presentation of NTM cervical adenitis is that of a nontender, slightly fluctuant cervical mass with overlying skin that has a characteristic violaceous hue. By history, the mass may have been present for weeks, so it is important to rule out other causes of persistent lymphadenopathy such as lymphoma or other malignancies. Chest radiographs are usually normal and purified protein derivative test results are most often reported as negative or intermediate in their response. Fine needle aspiration to collect specimens for cytology or culture/smears for acid-fast bacteria are more likely to confirm the diagnosis. NTM infections do not respond to antitubercular antibiotics. Long courses (months) of some macrolides (clarithromycin) with or without rifabutin are sometimes effective, especially when surgical treatment has not been thoroughly effective. In general, the child should be referred to an otolaryngologist to consider surgical biopsy and excision or curettage to cure this condition. Incision and drainage are discouraged because these can lead to a chronic draining sinus.

Salivary gland infections should be considered in the differential diagnosis of a cervical mass suspected to be infectious in origin. Both viral and bacterial agents can be responsible for the infection, with the former being more common. Mumps (endemic parotitis) is the most common salivary infection in children. Although the parotid gland is involved in more than 85% of the cases, the submandibular gland may also be involved with the viral infection. The infection appears with acute painful swelling of the involved gland or glands. There is erythema around the intraoral orifice of the salivary duct, and the saliva expressed is generally clear. Treatment is supportive, with clear fluids, antipyretics, and analgesics as necessary.

Bacterial infections of the salivary glands are seen with signs and symptoms similar to those associated with cervical lymphadenitis. Neonatal parotitis and, less commonly, submandibular sialadenitis usually occur in a 3- to 4-week-old child after a systemic illness has caused dehydration. The affected gland is swollen and abscess formation may occur. Purulent material may be expressed from either Stenson's or Wharton's duct by massage of the affected salivary gland. Otolaryngologic consultation should be obtained. The child is hospitalized for treatment with IV antimicrobials effective against *S. aureus* (antistaphylococcal penicillin) and surgical drainage of any collection of purulent material. Recurrent or chronic infections of the salivary glands are usually related to some predisposing factors such as stones, ductal stenosis, or secretory immunodeficiency. Management should include the detection and correction of these conditions.

Neoplasms

Neoplasms of the neck, both primary and metastatic, occur in children. If a cervical neoplasm is suspected, an otolaryngologist should be consulted to perform a complete examination of the head and neck, including endoscopy of the nasopharynx, larynx, and hypopharynx.

The hemangioma is the most common neoplasm of the head and neck in children. Although they are more common on the skin of the face and scalp, lesions can occur on the skin of the neck and involve deeper structures such as the parotid gland. The diagnosis of cutaneous hemangiomas of the cervical skin is usually obvious on physical inspection; the lesions are red to reddish purple, flat or raised, blanch with pressure, and increase in size with crying or straining. Deep-seated lesions without cutaneous manifestations may require special diagnostic aids such as CT or MRI scans and, rarely, biopsy to confirm the diagnosis.

These juvenile hemangiomas demonstrate a cycle of rapid growth for the first 12 to 18 months of life. Slow regression and even total disappearance occurs over the next year or two. Because of this natural history, once the diagnosis of hemangioma is made, the preferred treatment is close observation. Lesions that grow rapidly to produce complications such as airway obstruction, skin necrosis, hemorrhage, high-output cardiac failure, or thrombocytopenia require more active intervention. The child should be admitted and otolaryngologic consultation obtained. Treatment modalities presently advocated include systemic corticosteroids, cryotherapy, CO_2 laser excision, interferon, sclerosing agents, and surgical excision.

Lymphangiomas are uncommon benign lesions of the neck. Cystic hygroma is the most common type of lymphangioma found in the neck. These lesions consist of multiple cystic

spaces filled with lymph and, occasionally, blood. They appear most commonly as large lateral neck masses in neonates. The diagnosis is often obvious on physical examination of a large cystic lesion that transilluminates. The natural history of these lesions is usually one of progressive growth and enlargement. Lymphangiomas can fluctuate in size secondary to a concurrent infection of the head and neck or hemorrhage into a cyst. Small, stable, asymptomatic lesions can be managed by close observation. Surgical excision has been the treatment of choice for large symptomatic lesions, with several staged procedures often being required. Aspiration of a large cyst (or cysts) can temporarily decompress a lesion, and use of sclerosing agents introduced by needle under radiographic guidance has been useful in controlling symptoms in those who have disease that is difficult to excise. Large cystic hygromas may cause feeding difficulties or respiratory distress in the newborn and may necessitate early surgical intervention, which can include tracheostomy and gastrostomy.

Less common benign neoplasms of the neck in children include teratomas, paragangliomas (carotid body tumors, glomus tumors), neural sheath tumors (neurofibromas, neurolemmomas), and thyroid and salivary gland neoplasms.

The sternocleidomastoid "tumor" of infancy is an unusual lesion that appears as a discrete mass within the substance of the sternocleidomastoid muscle in a child 4 to 8 weeks old. The cause of this localized area of fibrosis is unknown. The lesion usually resolves with range-of-motion exercises. Surgical intervention is indicated in those cases in which the fibrosis progresses to cause persistent torticollis (see the "Neck Stiffness" section in Chapter 46), or if there is suspicion of a malignancy.

The most common malignant neoplasm of the neck in children is lymphoma, being almost equally divided into Hodgkin's and non-Hodgkin's types. The disease may be localized in the neck or be a part of a more generalized disorder. Physical examination often reveals multiple firm, rubbery, unilateral, or bilateral nodes. If the diagnosis of lymphoma is suspected, otolaryngologic consultation should be obtained for a careful examination of the oral cavity, pharynx, and paranasal sinuses to look for a primary or associated lesion. This not only aids in the evaluation of the extent of the lymphoma but may also locate a site from which a biopsy can be obtained without the morbidity of a neck exploration.

Cervical lymph nodes may appear as neoplasm metastatic from a nonlymphogenous primary tumor. Thyroid carcinoma, squamous carcinoma (lymphoepithelioma) of the nasopharynx, and malignant melanoma may all be seen first with enlarged cervical lymph nodes. These nodes tend to be hard, singular, and may be fixed to underlying structures. Otolaryngologic consultation should be obtained for a complete examination of the head and neck to search for a primary lesion. Biopsy of the node is usually required for diagnosis.

Rhabdomyosarcoma is the most common soft-tissue sarcoma of the head and neck in children, and its frequency of occurrence in the neck is second only to that in the orbit. The child usually presents with a history of rapid enlargement of a painless neck mass. The mass itself is hard, often diffuse, and poorly mobile. Although the diagnosis of rhabdomyosarcoma may be suspected from the history and physical examination, biopsy is always required for confirmation.

Many other malignant neoplasms can also occur in the neck. These include soft-tissue sarcomas other than rhabdomyosarcoma, malignant fibrous histiocytoma, and neuroblastoma.

Neck Mass

The differential diagnosis and ED management of the child with a neck mass are presented in detail in Chapter 44.

Torticollis (Wryneck)

The differential diagnosis and ED management of the child with torticollis or stiff neck are presented in detail in Chapter 45. For further details, see Chapters 111 and 110.

CHAPTER 124 ■ UROLOGIC EMERGENCIES

HOWARD M. SNYDER III, MD

Early in their lives, children become familiar with the act of voiding and the appearance of their genitals. Disturbances of either are a great source of concern to them and their parents. This may result in an anxious trip to the emergency department (ED), requiring the emergency physician to be familiar with the problems discussed in the chapter on scrotal pain (see also Chapter 57). This chapter discusses (i) penile problems, (ii) testicular problems, and (iii) urinary tract infections (UTIs). Renal trauma is covered in Chapters 100 and 112.

PENILE PROBLEMS

Penile Care in the Uncircumcised Male Infant

Although the data of Wiswell and Roscelli suggest that the presence of the foreskin may make ascending urinary infection an increased risk in newborn males, the overall low incidence of problems associated with the foreskin and the lack of benefits from its removal led us to continue to discourage routine circumcision. This view is common and increasing numbers of uncircumcised children are seen in EDs. Surprisingly, few physicians know how to care for uncircumcised boys. It is important to realize that, in male infants, adhesions between the glans and the foreskin are normal (Fig. 124.1). The foreskin is not normally retractable in this age group. No effort should be made to strip the foreskin back in infants because that not only produces undue pain for the child but also may result in a raw surface with consequent inflammation and scarring. Between ages 2 and 4, lysis of the adhesions is spontaneous in 90% of children. It is rare for the male infant to have any adverse hygienic consequence from leaving the foreskin in place until spontaneous lysis of the adhesions takes place. The small, whitish lumps that may be seen and felt beneath the foreskin represent only desquamated epithelium and need not be removed. When toilet training has occurred, it is wise to teach a boy to retract the foreskin enough to expose the meatus when he voids. Not only does this facilitate better aiming, but it also avoids leaving the inner foreskin wet with urine. Ammoniacal irritation can lead to inflammatory adhesions and may create a portal of entry for a bacterial balanoposthitis. When a boy is able to retract his foreskin, usually between 4 and 6 years of age but sometimes later, he may be taught to withdraw the foreskin and perform normal hygiene as part of bathing.

Phimosis and Paraphimosis

Phimosis exists when tightness of the distal foreskin precludes its being withdrawn to expose the glans. Although inflammation of the foreskin from severe chronic ammoniacal rash or infection may lead to scarring and a true phimosis, this is uncommon in children. More often, normal penile adhesions are confused with phimosis.

In the uncircumcised male infant, if the foreskin is retracted behind the glans and left in that position, venous congestion and edema of the foreskin results, making it difficult to reduce the foreskin to a normal position. This condition of a swollen, retracted foreskin is called *paraphimosis* (Fig. 124.2). The application of ice and steady local manual compression usually reduces the edema and permits manual reduction of the paraphimosis. Topical anesthetic cream or a local anesthetic penile block of the dorsal nerve of the penis at the base of the shaft will reduce the discomfort experienced by the child during compression of the edematous foreskin. Once a portion of the edema has been reduced, pressure on glans (like turning a sock inside out) usually permits reduction of the foreskin back to its normal position (Fig. 124.3). If manual reduction fails, a surgical division of the foreskin to permit reduction is indicated (Fig. 124.4). This may usually be accomplished with sedation and local anesthetic. If surgical reduction of the foreskin is required, it should be followed a few weeks later by a circumcision. Education in the care of the uncircumcised boy will reduce the incidence of this condition.

Balanoposthitis

Balanoposthitis is an infection of the foreskin that may extend onto the glans (Fig. 124.5A). It is a form of cellulitis and has its origin from a break in the penile skin, commonly associated with ammoniacal dermatitis. It may be the result of local trauma or may, in the older boy, be associated with poor penile hygiene. Scarring after the inflammatory reaction may lead to true phimosis. The acute infection is dealt adequately by warm soaks and the administration of an appropriate antibiotic, usually ampicillin (50 to 100 mg per kg every 24 hours in four divided doses) (Fig. 124.5B). It is unusual for a child to be unable to void as a result of this condition, although he may be more comfortable voiding while in a tub of warm water. After resolution of the acute infection, the youngster should be examined again, and, if true phimosis is present, a circumcision is advisable. One episode of balanoposthitis with a normal retractable foreskin does not indicate a need for a circumcision. However, if a child has recurrent infections, a circumcision is in order.

Penile Swelling

Although most penile swellings are painful and the result of either infection, as described previously, or trauma, to be

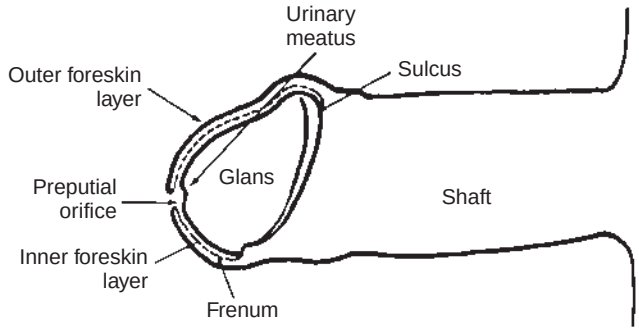

FIGURE 124.1 Anatomy of normal uncircumcised male. Adhesions between inner foreskin layer and glans are normal in newborns and prevent retraction of the foreskin. (From Wallerstein E. *Circumcision: an American health fallacy*. New York: Springer, 1980:201. Reprinted with permission.)

FIGURE 124.2 Paraphimosis—a foreskin that is left in a retracted position leads to venous congestion and edema of the foreskin.

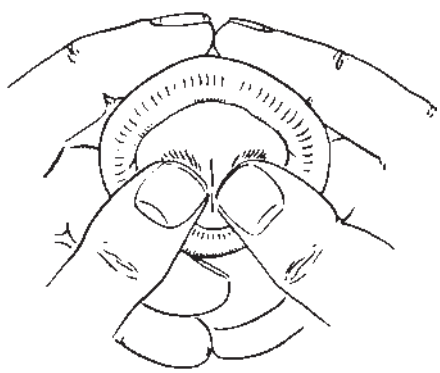

FIGURE 124.3 Manual reduction of paraphimosis. After a local anesthetic block of the dorsal nerve of the penis, the foreskin is manually compressed to reduce edema. The foreskin can be reduced by pressure on glans—like turning a sock inside out. (From Klauber GT, Sant GR. Disorders of the male external genitalia. In: Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, 2nd ed. Philadelphia, PA: WB Saunders, 1985:287. Reprinted with permission.)

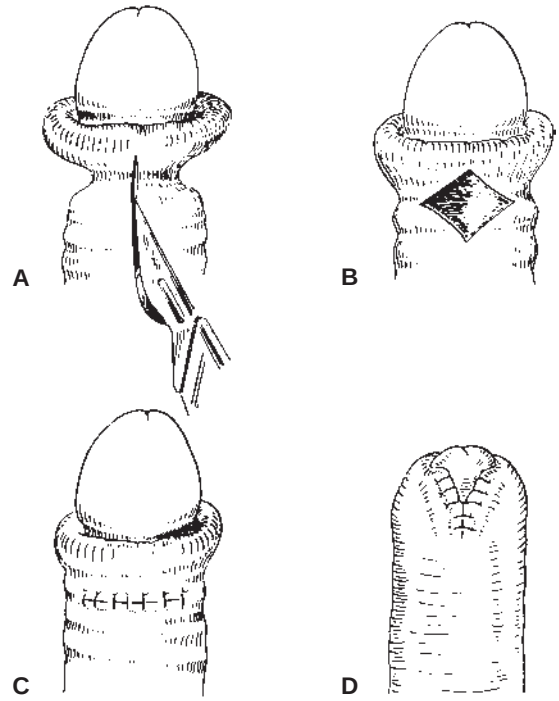

FIGURE 124.4 Surgical correction of phimosis. **A:** Constricting foreskin is incised vertically on dorsum. **B:** The incision opens laterally, relieving constriction. **C:** Incision is closed transversely with chromic catgut sutures. **D:** Foreskin can now be reduced. (From Klauber GT, Sant GR. Disorders of the male external genitalia. In: Kelalis PP, King LR, Belman AB, eds. *Clinical pediatric urology*, 2nd ed. Philadelphia, PA: WB Saunders, 1985:827. Reprinted with permission.)

described later, occasionally a child has isolated penile edema that is either nontender or minimally tender. This may result from an insect bite, with local edema secondary to histamine release. A history of a bite or the finding of a small punctate lesion may give the clue to diagnosis. Painless penile edema may be present with a generalized allergic reaction or as part of the manifestation of a general edematous state secondary to renal, cardiac, or hepatic problems. Here, the diagnosis is suggested by evidence of dysfunction in these organ systems on general examination. It is also important to remember that penile swelling may be caused by a strangulation injury (see "Strangulation" section).

Priapism

Prolonged, painful penile erection unaccompanied by sexual stimulation is called *priapism*. In the pediatric age group, this entity may be caused by trauma or leukemic infiltration, but it is most often seen in African American male persons with sickle cell disease. A sickling crisis that involves the corporal bodies does not necessarily need to be related to symptomatic sickling elsewhere in the body. Sickling of the erythrocytes produces sludging and stasis in the erectile tissue of the corporal bodies. This stasis leads to further hypoxia, acidosis, and more sickling. The thick, dark sludge that is formed prevents detumescence of the erectile tissue and thus causes priapism.

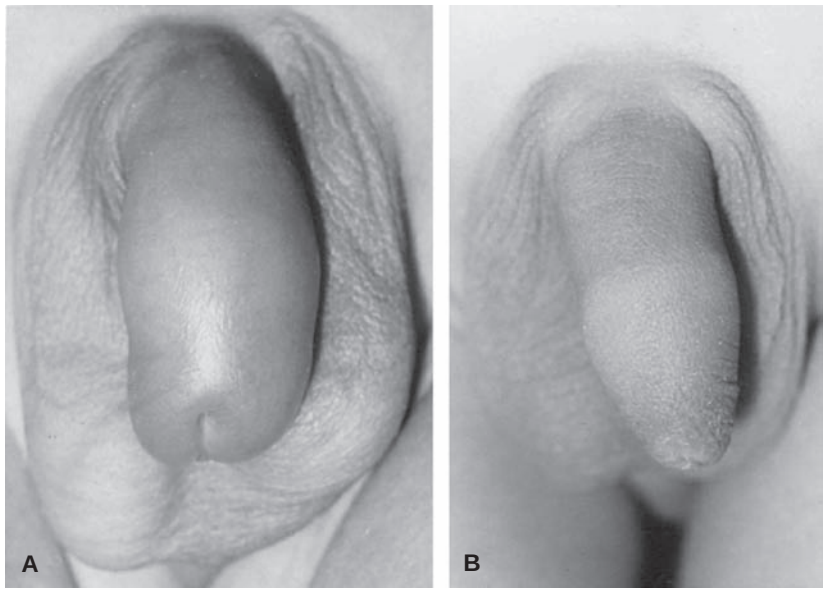

FIGURE 124.5 **A:** Balanoposthitis—cellulitis of normal foreskin with erythema, edema, and tenderness. **B:** Normal foreskin after treatment of balanoposthitis with antibiotics and warm soaks.

Pain results from ischemia. It is speculated that an inflammatory reaction to this material may lead to fibrosis of the erectile tissue. Impotence may result.

Although recommendations for treating priapism have ranged from ice or hot packs, estrogens, and spinal anesthesia to radiation therapy, the best treatment for priapism associated with sickle cell diseases now appears to be hydration and irrigation of the corporal bodies with saline in combination with vasoactive substances. This is best performed with urologic consultation. Although priapism has been documented to lead to impotence in some cases, impotence is rare in priapism related to sickle cell disease, unless the patient has been subjected to a surgical procedure. It may be that the more difficult cases are the ones most likely to come to surgical treatment, and impotence thus may reflect more the basic disease, rather than the type of treatment.

Meatal Stenosis

Meatal stenosis is a problem almost exclusively of circumcised male persons and follows an inflammatory reaction around the meatus, usually the result of the lower edge of the meatus rubbing against a wet diaper, with inflammation of the meatus resulting from mechanical and ammoniacal chemical dermatitis. Meatal stenosis is rare in the boy who has a circumcision after becoming continent. Appearances are often deceiving. The meatus may appear to be stenotic but may be functioning adequately. Significant meatal stenosis causes spraying of the urinary stream or, more commonly, dorsal deflection of the stream. Surgical treatment of the meatus is warranted only if these symptoms are present. Meatal stenosis is not a cause of frequency, enuresis, or UTI. When it is indicated, we perform a meatotomy in our office after application of topical penile anesthesia with EMLA Cream. A general anesthetic is usually neither necessary nor indicated.

Penile Trauma

Direct Injury

The most common cause of direct injury to the penis comes from a toilet seat's falling on the penis of a little boy who is learning to stand at the toilet to void. Although the resulting penile edema may be notable, significant injury to the corporal bodies or urethra is rare. Although parents may be concerned that the child will be unable to void, this generally is not a problem, but the child may be more comfortable voiding in a tub of warm water. The only treatment required is warm soaks and expectant observation.

After blunt or sharp trauma, if blood is seen at the urethral meatus, urethral injury must be considered and a retrograde urethrogram performed. Pediatric urologic consultation is appropriate, as is follow-up for possible stricture formation (see Chapter 112).

If a child is seen for a laceration of the shaft of the penis, it is important to be certain that the corporal bodies and urethra have not been injured concurrently. When a question exists, pediatric urologic consultation, retrograde urethrogram, and exploration under anesthetic may be needed. For simple lacerations of the penile skin, repair with chromic catgut suffices. It should be recalled that a child who has any form of a genital injury might be a victim of sexual abuse (see Chapter 132).

Zipper Injury

Boys often seem to be in a hurry and sometimes fail to get their penis or foreskin completely back in their pants before they pull up the zipper. This results in the entrapment of penile skin or foreskin in the teeth of the zipper. The teeth may be so engaged that it is impossible to simply unzip the zipper. Often, the problem may be dealt with simply, as shown in Fig. 124.6. The median bar of the zipper may be cut with a pair of wire cutters, which will permit the two halves of the zipper to fall

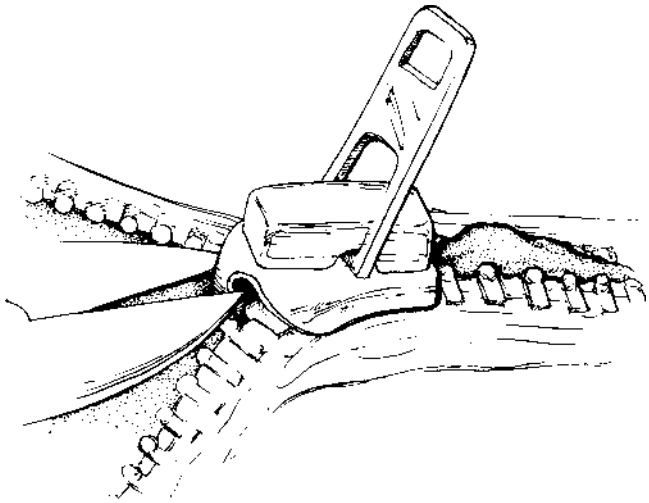

FIGURE 124.6 Penile zipper injury. A wire cutter may be used to cut the median bar of the zipper, releasing the two sides of the zipper and freeing the penis.

apart, releasing the entrapped skin. Mineral oil has also been used quite effectively to allow the tissue to slide free of the metal zipper. Local infiltration of lidocaine (Xylocaine®) or application of anesthetic cream makes this procedure less traumatic to the child. Only rarely is a general anesthetic required. After the zipper is removed, the penis may become edematous, but generally nothing more than warm soaks is required for further treatment.

Strangulation

The penis may be encircled by a constricting ring formed by a hair, fiber, or thread, just as occurs with digits. Many times, the cause of the problem is not immediately evident because local edema may hide the ring of hair. The edema is produced by venous engorgement, which takes place early, after the development of this type of constriction around the penis. Once the source of the problem has been identified, therapy requires the division of the hair and the release of the constriction. This may require a general anesthetic. Pediatric urologic consultation is advisable. A urethrocutaneous fistula, or even loss of the penis, has been reported but is rare. How the hair comes to encircle the penis is generally unknown, but it should be remembered that such constriction occasionally has been reported as a form of sexual abuse.

TESTICULAR PROBLEMS

Background

Primordial germ cells have their origin in the entoderm of the yolk sac. By the fifth week of intrauterine life, they have reached the ventromedial portion of the urogenital ridge, the portion destined to form the testes. A mesodermal cord, the gubernaculum, becomes attached to the bottom of the testis at the epididymis and runs to the bottom of the scrotum. With rapid growth of the trunk, the testes lie adjacent to the internal ring by the third month of gestation. The testes remain at this location until the seventh month when, preceded by a fold of peritoneum (the processus vaginalis), the testes move down the inguinal canal and reach their final scrotal position shortly before birth. This fact accounts for the higher incidence of undescended testis in premature boys.

The gubernaculum appears to have an important role in testicular descent, although the exact nature of that role remains incompletely understood. Acute conditions involving the testes are discussed in Chapter 57.

Retractile Testis

In the physical examination of the child in the ED, an empty scrotum on one or both sides is a common finding. Although the testis may be found to be truly undescended, more often it is merely a retractile testis. In a boy with a retractile testis, the active cremaster muscle attached to the small prepubertal gonad is able to draw the testis up into a position near the pubic tubercle. There is no evidence that this causes any harm to the gonad. When the testis enlarges at puberty, it will assume a scrotal position permanently because the cremaster is no longer able to draw it out of its more normal position. The diagnosis of a retractile testis is made when one is easily able to milk the testis down into a position in a dependent portion of the scrotum where the testis stays, at least briefly, after overstretch of the cremaster muscle. In an obese youngster, it may be difficult to grasp the testis to pull it down. It is worthwhile putting a youngster in a "catcher's position," in which the testis is pushed down to where it can be grasped and drawn into the scrotum. If the testis can be pulled into the scrotum but, regardless of how much the cremaster is overstretched, the testis "pops up" when released, this is a low form of a true undescended testis and not a retractile testis. This is a common diagnostic difficulty, and pediatric urologic consultation should be sought if the situation is questionable.

Undescended Testis

True undescended testes are seen in 4% of newborn males. That instance decreases to 1.6% by 1 year of age, indicating that some undescended testes do descend after birth. Spontaneous descent rarely occurs after 6 months of age. Although it may be appropriate to continue for a few months to observe an infant who has an undescended testis, the child older than 6 months should have urologic consultation.

Testicular malignancy and infertility are increased in the male infant with an uncorrected undescended testis. By electron microscopy, it is possible to demonstrate degenerative changes in the undescended testis by 1 year of age. Early referral to a urologist for orchiopexy (before age 2 and preferably near age 1) appears advisable because data are now accumulating that indicate early surgery may decrease the incidence of both testicular malignancy and infertility.

Usually, an undescended testis is asymptomatic. However, in a position against the abdominal wall, it may be more subject to trauma than when freely mobile in the scrotum. The undescended testis is also malfixed and may undergo torsion

more easily than a normally descended one. The boy who presents with an acutely tender groin mass with an ipsilateral empty scrotum may have torsion of his undescended testis. The physician must consider the differential diagnosis of an incarcerated inguinal hernia or acute hydrocele of the cord. Prompt surgical treatment is required.

Varicocele

Varicoceles are abnormal dilations of the cremasteric and pampiniform venous plexuses surrounding the spermatic cord (Fig. 124.7). They generally present as an asymptomatic scrotal swelling about the time of puberty and are rare in the prepubertal boy. Almost all are of congenital origin and affect the left testis. The anatomic problem is a defect in the valves of the left spermatic vein that, on the left, drains directly into the left renal vein. A higher left renal vein pressure may also play a role. Why varicoceles are often not noted until boys approach puberty is unclear, but they are common in that age group, affecting about 15% of adolescent boys. If the varicocele does not disappear when the child lies down, it suggests a varicocele secondary to obstruction of the left renal vein, and a renal and bladder ultrasound is appropriate. Varicoceles are rarely symptomatic; a heavy or tugging sensation is occasionally reported.

Approximately 15% of these boys with a varicocele will have an adult problem with infertility, although the exact mechanism of injury to the spermatogenic elements remains to be defined. Thus, periodic examination of these boys as they progress through pubertal change is recommended. As in the postpubertal testis, more than 80% of testis volume is a result of the spermatogenic elements; testis size is generally accepted as an indication of the effect of the varicocele on testis function. Although testicular asymmetry is common during pubertal change, a progressively smaller ipsilateral testis over 2 years or more of follow-up is an appropriate indication for surgical or radiographic treatment of the varicocele. "Catch-up" enlargement may occur after treatment of the varicocele. In our experience, any form of treatment is needed in only a small minority of cases. However, controversy exists on this point and long-term follow-up of adolescent boys with a varicocele is insufficient to permit firm conclusions.

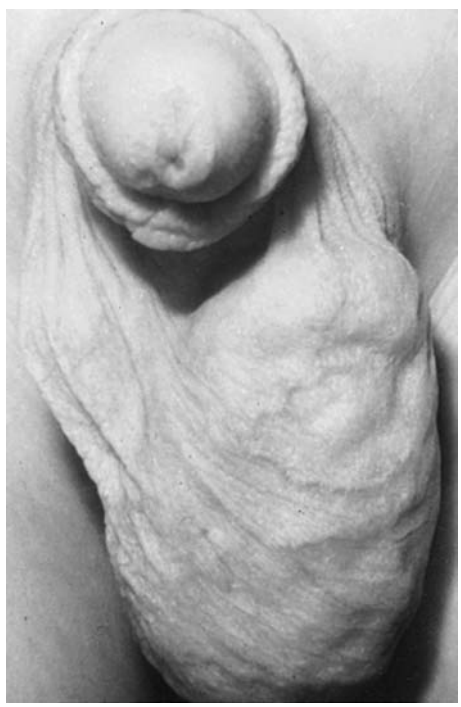

FIGURE 124.7 Varicocele—abnormal dilation of cremasteric and pampiniform venous plexuses surrounding the spermatic cord, giving the scrotum the appearance of a "bag of worms."

URINARY TRACT INFECTIONS

Background

UTI ranks behind upper respiratory tract problems as the second most common form of bacterial infection in children. Between 1% and 2% of infants and children have bacteriuria at any given time, and 5% of all girls have UTI during their school years. Most UTIs result from fecal bacteria on the perineal skin ascending the urethra. The short female urethra, with resultant ease of bacterial contamination of the bladder, accounts for the higher incidence of UTIs in girls. The uncircumcised male infant younger than 6 months also appears to be at increased risk of ascending urinary infection because foreskin bacterial colonization may lead to increased meatal contamination. However, because the absolute risk of UTI in male infants is in the order of 1%, it is questionable to suggest the risk of UTI is an indication for routine circumcision.

It is now recognized that the major risk factor in the development of UTI is the physical nature of the uroepithelium lining the urethra and bladder. In some children and adults, adherence factors in the mucosa lead to recurrent episodes of symptomatic infection. In addition, some bacteria (piliated ones) have increased adherence characteristics that add to the risk of invasive infection. Because voiding dysfunction may also contribute to recurrent infection, this is another reason to consider pediatric urologic consultations, especially in the older child who persists with wetting after appropriate treatment of infection.

A UTI may be defined as the multiplication of bacteria in the urinary tract. Normally, urine from the bladder and upper urinary tract should be sterile. The concept of "significant bacteriuria" (10^5 or more organisms per milliliter of one colony type) in a cleanly voided midstream specimen is based on the statistical likelihood that this colony count is associated with the actual presence of bacteria in the bladder. A colony count of 10^5 or more organisms per milliliter of a single type suggests infected urine, with an 80% confidence level. Reliability can be increased to 95% if a second culture confirms the presence of the same bacteria type with identical antibiotic sensitivity; 10^4 to 10^5 bacteria per milliliter is an equivocal result and requires repeat culture. Less than 10^4 organisms per milliliter or the presence of several different organisms suggests no infection or contamination of the specimen (see Chapter 84).

Clinical Manifestations

Particularly in the infant, UTIs may produce nonspecific findings. The urine may be cloudy or have a foul odor. There may be a history of unexplained fevers, general irritability, or failure to thrive and gain weight normally. Gastrointestinal (GI) symptoms are common, and many times, the youngster with a UTI is believed to have gastroenteritis or a food allergy. A high index of suspicion is required. If a urine culture is not obtained, the source of the child's problem will be missed.

In the older child, symptoms may point more directly at the urinary tract. Frequency, urgency, and dysuria are produced by inflammation of the bladder and urethra. A previously toilet-trained child may begin to have "accidents." Particularly in girls, hematuria may be seen. Although symptoms do not provide a completely reliable way of differentiating cystitis from pyelonephritis, the presence of systemic findings such as a high fever and malaise or abdominal/flank pain suggests renal involvement. A UTI, especially when chronic, may also have few or no symptoms. It is important to emphasize that in children, anything that irritates the urethral meatus may produce dysuria and, occasionally, urgency and frequency (see Chapter 53). The source of the irritation may be a tight or moist bathing suit, underwear, or an ammoniacal rash. Bubble bath or other soap in contact with the urethral meatus may not only produce these symptoms but also, by producing inflammation, contribute to the ascent of bacteria up the urethra and to the development of true infection. To avoid being confused by a noninfectious cause of symptoms, it is important that UTIs be proven by urine culture and not diagnosed by history and urinalysis alone.

Escherichia coli is the most commonly isolated organism responsible for UTI in children, constituting 80% to 90% of the total. This is because of the prevalence of the organism in GI tract flora, as well as its short mean generation time, which enables it to multiply rapidly once it has entered the bladder. The other organisms commonly found can be seen in Table 124.1.

Management

The first step in management is to make an accurate diagnosis. The presence of pyuria does not provide an accurate criterion for the diagnosis of UTI. At least 20% of children with pyuria do not demonstrate significant bacteriuria. In any febrile illness, mobilization of the peripheral leukocyte pool may be adequate to produce the presence of white blood cells in the urine. Conversely, a child with bacteriuria occasionally does not demonstrate pyuria. Bacteria demonstrated by Gram stain of an unspun urine specimen are more reliably indicative of a UTI. However, it is difficult to determine whether one type of bacteria or several different contaminants are present. Thus, culture of the urine must continue to be the benchmark for the diagnosis of a UTI in children. Obtaining an adequate urine specimen for bacterial culture is the most critical step in diagnosing UTI. A cleanly voided specimen obtained as a midstream catch after washing of the periurethral area is the preferred technique in the toilet-trained child. Simple soap and water washing of the periurethral area is preferred because antimicrobial soaps or solutions may become mixed with a voided specimen and lead to a false-negative result.

In the infant, obtaining an adequate urine specimen is more difficult. Specimens collected in a plastic bag (U-bag) attached to the perineum are rapidly contaminated by perineal bacterial skin flora. If a culture from a bag is sterile, it is acceptable. However, the demonstration of bacterial growth must be confirmed by some other means before a bona fide UTI can be presumed to be present. The most reliable way to obtain a confirming specimen of urine is by urethral catheterization or suprapubic aspiration of urine from the bladder, a procedure that is not dangerous and that has a reliability approaching 100%. The procedure for performing suprapubic aspiration is covered in Section VII. If it is essential that the first specimen be the definitive one for diagnosis of UTI, as in the infant undergoing septic workup, the primary use of these techniques is justified. When symptoms strongly suggest the possibility of a UTI, beginning antibiotic therapy as soon as an adequate urine specimen for culture has been obtained is recommended. The matter of just 1 or 2 days before the institution of antibiotics may make a difference in the degree of eventual pyelonephritic scarring. If the urine culture turns out to be negative for UTI, the antibiotics may be stopped. Table 124.2 lists the most commonly used outpatient antibiotics for UTIs.

Although any of these antibiotic choices is acceptable in the initial therapy of a UTI, sulfamethoxazole–trimethoprim has become most commonly used in recent years because of its acceptance by children and its high efficacy. Nitrofurantoin, although effective, can produce GI upset (lessened by taking with meals) and is less well-tolerated by most children. Also poor serum levels make it a poor choice in the treatment of pyelonephritis. Methenamine mandelate is not useful unless there is urinary stasis and acid urine and accordingly has little role in most childhood UTIs. Tetracycline is not recommended for the child younger than 10 years because of its potential for discoloration of the teeth. When the organism causing UTI is sensitive to the antibiotic selected, the urine is usually sterilized rapidly. It is advisable to repeat a culture 48 hours after starting an antibiotic. The continued presence of infection suggests inaccuracy of the sensitivity, noncompliance, or obstruction.

If a child is sufficiently toxic to warrant hospitalization, the intravenous administration of antibiotics is appropriate. The drug of choice while cultures are pending is ampicillin or cephalosporin, usually combined with an aminoglycoside.

More recently, the duration of therapy has been a subject of debate. For uncomplicated cystitis, 1 to 3 days of therapy is usually adequate. For children with a febrile UTI or who have not been radiographically evaluated or for any child with a congenital anomaly, a 10-day course of antibiotics continues to be recommended.

TABLE 124.1

BACTERIA COMMONLY CAUSING URINARY TRACT INFECTIONS

Escherichia coli	*Proteus* species
Klebsiella pneumoniae	*Pseudomonas aeruginosa*
Streptococcus faecalis (enterococcus)	*Staphylococcus epidermidis*

TABLE 124.2

ANTIBIOTIC AGENTS FOR URINARY TRACT INFECTIONS

Drug	Oral dosage	Number of doses
Sulfamethoxazole–trimethoprim	1 mL suspension/kg/day	2
Sulfisoxazole	120 mg/kg/day	4
Nitrofurantoin	5–7 mg/kg/day	4
Amoxicillin	50–100 mg/kg/day	3
Cephalexin	50–100 mg/kg/day	4

Other factors in the treatment of UTI involve high fluid intake with regular and frequent voidings to promote bladder washout of bacteria. If the child has a history of wetting, infrequent voiding, or frequent urge episodes, the possibility of dysfunctional voiding, which can contribute to recurrent infections, should be considered and appropriate consultation obtained. Avoiding constipation helps ensure better bladder emptying. Constipation is being recognized increasingly as a factor that contributes to UTI. Good perineal hygiene, including wiping from front to back after a bowel movement, is important. Eliminating pinworms prevents a source of inflammation, excoriation, and secondary increase in perineal skin flora. Bubble bath, by producing inflammation at the meatus, may promote the ascent of bacteria and should be avoided. Acidification of the urine with oral vitamin C or juices high in citric acid content may be useful to produce an acid urine in which bacteria multiply less rapidly.

Urologic Follow-up and Radiographic Investigation

A suppressive dose of antibiotics should be begun after the acute phase of full-dose treatment. It is customary to use one-third to one-half the dose of antibiotic used for acute treatment, usually administered in a once-per-day evening dose. Suppressive antibiotics reduce the likelihood of recurrent infection, pending urologic consultation and radiographic investigation.

The routine radiographic evaluation of a UTI is by means of a voiding cystourethrogram (VCUG), followed by an ultrasound examination of the kidneys and bladder. These studies are usually performed about 2 to 4 weeks after the acute treatment of a UTI; however, failure of a child to respond promptly to appropriate antibiotic therapy should lead to the urgent performance of an ultrasound examination to rule out urinary obstruction. The cystogram must include a voiding phase or else significant pathology may be missed, particularly vesicoureteral reflux, which may be evident only on voiding films. In the usual child with a UTI, cystoscopy contributes little to the initial investigation; therefore, it is not recommended.

Any child with a history of a febrile UTI and all boys should be investigated after their first UTI. In girls without a febrile UTI, the usual recommendations have been to wait until a second infection before recommending urographic investigation. However, Kunin's data demonstrate that after one UTI there is an 80% likelihood of a second episode of bacteriuria and that half of these children will be asymptomatic. Thus, it appears justified to perform radiographic studies after a first documented infection in girls, as well as boys, or at the least to follow girls who have recovered from a first UTI, with repeat cultures at regular intervals.

In approximately 50% of infants and 30% of older children, an anatomic abnormality is found in association with a UTI. The most common finding is vesicoureteral reflux. Reflux permits infected urine to ascend to the kidney, where pyelonephritic damage may occur. With linear growth of the child, many milder cases of reflux may spontaneously resolve, leaving surgical management primarily for the more severe cases. These decisions are best made in consultation with a pediatric urologist.

As for the child who has no abnormality demonstrated by ultrasound and VCUG, the parents can be reassured that although the child may have a symptomatic problem from cystitis, there is little likelihood of renal damage. Occasionally, if a child has frequent episodes of symptomatic cystitis, suppressive antibiotics are justified to reduce the morbidity of these infections. The primary factor responsible for the development of urinary infection appears to be an adherent uroepithelium, which leads bacteria that ascend the urethra to stick to the bladder lining and become invasive. Like adults, children who have such bladder lining may experience several UTIs per year. Surgical manipulation, such as urethral dilation, does nothing to change the basic bladder problem and is no longer performed. When infections recur in rapid sequence, this may indicate the colonization of the GI bacterial flora by organisms with increased adherence characteristics. Fortunately, during 3 to 6 months of suppressive antibiotic therapy, these organisms tend to modulate to less adherent bacteria. It should also be borne in mind that children with dysfunctional voiding patterns also tend to be troubled with frequent UTIs. Thus, if a child has an abnormal voiding pattern when uninfected (wetting, infrequent voiding), a pediatric urologic assessment is in order.

ACUTE URINARY RETENTION

A patient with acute urinary retention is unable to empty the bladder even though it is full. In children, as in adults, the cause may be a urethral obstruction. Congenital lesions, such as urethral valves, or acquired lesions, such as posttraumatic strictures, may lead to urinary retention. In such cases, a careful history often elicits symptoms of a weak stream or difficulty initiating the stream. Children who have any form of

urethral irritation and dysuria may voluntarily retain urine. That is a different situation and needs to be separated carefully from organic obstruction causing retention. For the child with voluntary retention, gentle massage of the lower abdomen, combined with a soak in a warm tub, usually leads to spontaneous evacuation of the bladder. Rarely does a child's bladder become so distended, as after an outpatient surgical general anesthetic, that the child is unable to void. A simple one-time emptying of the bladder by catheterization with a feeding tube usually corrects the problem. It should be remembered that a child is able to hold urine voluntarily for longer periods than would be suspected; up to 12 hours is not unusual. Unless the child has a history suggestive of an organic obstruction or has a palpably enlarged bladder that cannot be emptied by massage and warm tub soaks, instrumenting the child's urethra should not be considered. Urologic consultation would be advisable before undertaking such maneuvers.

CHAPTER 125 ■ ORTHOPEDIC EMERGENCIES

MARK D. JOFFE, MD, AND JOHN M. LOISELLE, MD

ORTHOPEDIC CONDITIONS

Orthopedic emergencies usually result from trauma (see Chapter 114). Nontraumatic orthopedic problems are often a clinical challenge because they may present as suspected injuries. Physicians must not be misled by the virtually ubiquitous history of injury in active young children. The nontraumatic orthopedic conditions described in this chapter are especially important to consider when a reported injury mechanism is minor or onset of symptoms is delayed. Evaluation of children with complaints such as limp (see Chapter 42), joint pain (see Chapter 56), and back pain (see Chapter 50), to name a few, requires consideration of both traumatic and nontraumatic causes. Children involved in competitive athletics train more intensively and at younger ages than in previous years, resulting in overuse syndromes. With knowledge and appropriate suspicion, physicians caring for children can identify nontraumatic orthopedic problems, begin treatment, and make intelligent recommendations about referral.

Osteomyelitis

Background

Osteomyelitis is an inflammation of the bone and bone marrow, most commonly of infectious origin. Infection is confirmed by the presence of two of the following: pus on an aspirate of the bone, clinical findings consistent with the diagnosis, positive blood or bone aspirate cultures, and consistent findings on medical imaging. Osteomyelitis is more common in boys with the highest incidence found among infants and preschool age children. Age and underlying disorders are associated with an increased risk for contracting osteomyelitis, as well as for the particular pathogens involved.

Pathophysiology

Infection occurs by one of three routes: hematogenous, direct spread, or inoculation through a penetrating wound. Hematogenous spread is the most common route of infection in children. A transient bacteremia is believed to be the initiating event in the infection. Bacteria enter the bone at the level of the metaphysis where the predominant vascular supply is located. The sluggish blood flow within the microvasculature of the marrow predisposes to infection. Local trauma has been suggested as a possible cause of microthrombotic events further predisposing bone to infection. This is supported by an association of trauma with the occurrence of osteomyelitis and the preponderance of infections occurring within the long bones, especially those of the lower extremities. In sickle cell patients, microinfarcts within the more tenuously supplied area of the diaphysis may explain the increased occurrence in this region of the bone. As infection progresses, pressure increases and organisms penetrate up through the cortex to the subperiosteal space. If left untreated, the infection may spread along this space or rupture through the periosteum into the surrounding soft tissue.

Differences in the underlying bony structure in the neonate and young infant predispose them to a higher incidence of multifocal osteomyelitis and concomitant septic arthritis. The thin cortex allows easier penetration to the subperiosteal space. The periosteum is less adherent in these ages and less effective in limiting the spread of infection. Transphyseal vessels, which are present through the first 18 months of life, allow bacteria to gain access to the adjoining epiphysis and joint space.

A less common source of osteomyelitis in children is penetration of the periosteum by adjacent infections. Inoculation of the bone from stepping on a nail, surgical instrumentation, or intraosseous needle placement provides a third means for infection to gain entrance to the bone.

Inadequately treated infections can progress to a chronic osteomyelitis and may result in potentially deleterious effects on growth. There have also been reported cases of chronic recurrent multifocal osteomyelitis (CRMO), which is an autoinflammatory disorder characterized by bone pain and fever. Its course is one of exacerbations and remissions. The etiology of this condition is still unknown. Cultures of bone are sterile and radiographs may show lytic lesions. The presentation may mimic acute bacterial osteomyelitis, which must be ruled out and CRMO is a diagnosis of exclusion.

Clinical Findings

Physical signs of osteomyelitis are age dependent. The older child is more likely to have localized infection and is more capable of expressing or identifying a site of localized pain and point tenderness. The neonate or young infant may present with a pseudoparalysis of the affected limb. Another common, although nonspecific, finding in this age group is paradoxical irritability in which the infant exhibits pain or distress upon handling and is more comfortable when left alone.

Fever and pain are highly sensitive findings but are not universally present. Fever is described in up to 90% of children with osteomyelitis upon presentation and may be quite elevated. Pain is expressed through limp, refusal to bear weight, or a decreased range of motion when a limb is involved. Erythema and swelling are less frequent but can also be observed at the site, and usually suggest more advanced periosteal involvement.

Diagnosis

The diagnosis of osteomyelitis in the child can be challenging and misdiagnoses are common. Several injuries and illnesses with overlapping clinical, laboratory, and radiologic findings can mimic osteomyelitis. In addition to clinical findings, the diagnosis of osteomyelitis depends on culture results. Blood cultures and bone aspirates should be obtained in suspected cases of osteomyelitis before the initiation of antibiotics. Isolation of the causative organism is important not only in diagnosis, but also in antibiotic selection and the possibility of eventual outpatient therapy. Reports of positive blood cultures in the setting of osteomyelitis range from 30% to 57%. An organism is recovered from a bone aspirate in 51% to 90% of cases. The combination will identify a pathogen in 75% to 80% of cases. Bone aspirates may remain positive for several days after antibiotic use, whereas blood cultures are often sterile within 24 hours of the initiation of antibiotics.

Laboratory tests vary in sensitivity. The white blood cell (WBC) count rises in only one-third of the cases of osteomyelitis, whereas both the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are elevated in more than 90% of the cases. The latter tests are useful in diagnosis and in monitoring the response to therapy. The CRP peaks at 2 days and returns to normal following 7 to 10 days of appropriate therapy. The ESR may remain elevated for several weeks despite adequate treatment.

The plain radiograph is the initial imaging study of choice. It is useful both in detecting early signs of osteomyelitis and excluding other diagnostic possibilities. The earliest radiograph changes suggestive of osteomyelitis include deep soft-tissue swelling with elevation of the muscle planes from the adjacent bone (Fig. 125.1). These may be seen as early as 3 to 4 days after the onset of symptoms. Lytic bone changes are not detectable until 10 to 14 days. Periosteal elevation, when present, is not generally visible until 10 to 21 days after infection (Fig. 125.1). A negative radiograph in the first 10 days of illness does not rule out osteomyelitis. When suspicion remains high in the setting of a negative radiograph, further imaging studies should be obtained. The triple-phase technetium bone scan has a reported sensitivity and specificity of more than 90%, and will detect osteomyelitis within 24 to 48 hours of symptom onset. The bone scan can localize the site of infection and differentiate soft-tissue infection from bony involvement. It is the test of choice when osteomyelitis is suspected but a specific site of concern can not be identified by physical examination or when multiple foci of infection are possible. Magnetic resonance imaging (MRI) is also highly sensitive in detecting osteomyelitis and does not expose the child to ionizing radiation. In addition, MRI provides a higher degree of detail than the bone scan (Fig. 125.2). This is useful in detecting suspected complications of osteomyelitis such as a subperiosteal abscess or bone sequestrum. Many orthopedic surgeons prefer this high degree of resolution to guide a bone aspirate or biopsy. Both imaging studies commonly require sedation of the young child, but the bone scan is not as affected by small movements. A bone aspirate preceding a bone scan or MRI will not alter the results and should not be delayed because of this concern.

FIGURE 125.1 Periosteal activity in distal fibula in child with *Staphylococcus aureus* osteomyelitis; day 20 of illness.

Microbiology

Organisms responsible for osteomyelitis differ according to the age of the patient, the route of infection, and any underlying medical problems. *Staphylococcus aureus* is the most common pathogen across all age groups accounting for 70% to 90% of cases. The incidence of community-acquired methicillin-resistant *S. aureus* (CA-MRSA) has increased dramatically in most areas of the United States. Some studies have found over 50% of cases due to MRSA. Osteomyelitis due to MRSA has been associated with longer duration of fever, extended hospitalization and increased frequency of complications. This may be a result of the high prevalence of certain genes encoding for virulence factors such as Panton-Valentine leukocidin (PVL). Group A β-hemolytic streptococcus is the second most common organism isolated in childhood osteomyelitis and accounts for 10% of cases outside of the neonatal period. A high prevalence is found in association with recent varicella infections. *Kingella kingae* has been sporadically reported in the toddler and preschool age group. It is a gram negative organism and therefore resistant to vancomycin and clindamycin, but sensitive to cephalosporins and β-lactam antibiotics. Bacterial isolates from neonates younger than 2 months include *S. aureus*, group B streptococcus, and *Escherichia coli*, and antibiotic coverage should reflect this.

Certain groups are at risk for particular organisms. Patients with sickle cell disease have a high incidence of osteomyelitis caused by salmonella. *Pseudomonas aeruginosa* is a common organism found in osteomyelitis of the foot, often resulting from a nail penetrating a sneaker.

Management

Initial therapy for osteomyelitis includes intravenous antibiotics. Empiric antibiotic coverage should be based on the predominant

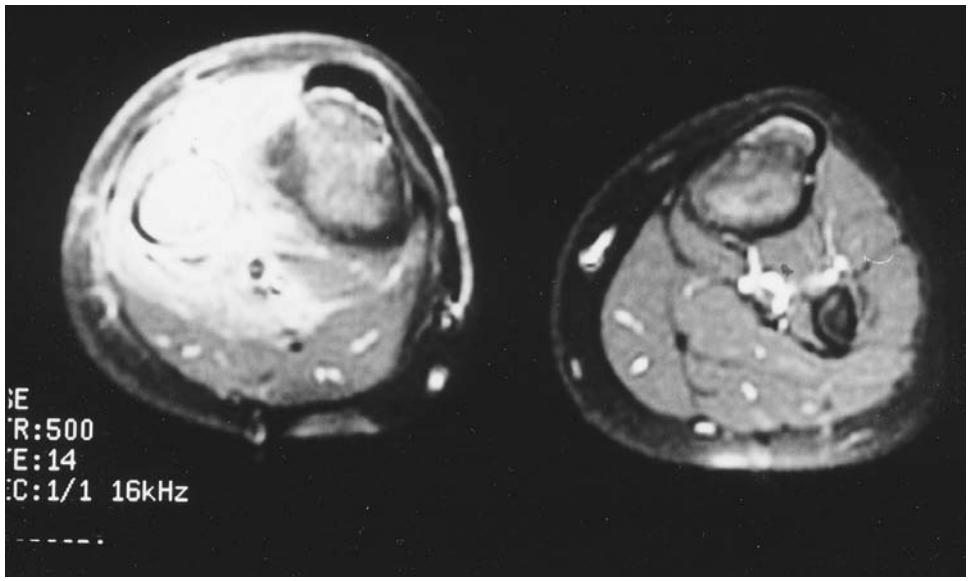

FIGURE 125.2 Magnetic resonance imaging of osteomyelitis of the proximal right fibula.

organisms in each age group, local sensitivity patterns, the mechanism of infection, and Gram stain results. Clindamycin is the treatment of choice for osteomyelitis outside of the neonatal age range when MRSA is suspected. Vancomycin may be indicated for empiric treatment when the incidence of clindamycin resistance in the community is high. Definitive treatment is ultimately based on the identification and sensitivity of recovered isolates. A third-generation cephalosporin or the addition of an aminoglycoside is indicated in the neonatal age group.

Suggested agents are listed in Table 125.1. Early aggressive antibiotic therapy frequently prevents the need for surgical intervention.

Septic Arthritis

Background

The presence of bacterial pathogens within the articular capsule presents a true surgical emergency. Delay in the identification and treatment of an infected joint in a child can result in severe and permanent sequelae. The urgency associated with this diagnosis has given rise to the maxim, "The sun should never rise or set on a septic hip." In many cases, the pediatric emergency physician will be the initial point of contact, and must maintain a high index of suspicion to recognize and appropriately treat these patients at the time of the first visit.

Pathophysiology

Bacteria gain entry to the joint space through one of three means. The highly vascular synovium is most commonly infected through hematogenous seeding. The role of local injury in predisposing joints to infection by this means is unclear. Organisms from adjacent areas of infection may invade the joint, or direct inoculation can occur through penetrating injuries. Infection secondary to penetrating objects may be delayed from the actual time of injury. External wounds may be small or healed at the time of presentation. Undetected penetration of the knee joint by a sewing needle in a crawling infant may give rise to a septic knee. A metatarsal joint infection may be the result of a nail puncture wound to the foot that occurred several weeks earlier.

TABLE 125.1

INITIAL ANTIBIOTIC THERAPY: OSTEOMYELITIS[a]

Age	Pathogens	Antibiotics
Neonate <2 mo	*Staphylococcus aureus*, group B streptococcus, gram-negative bacilli	Vancomycin and cefotaxime
>2 mo–5 yr	*S. aureus*, group A streptococcus, *Streptococcus pneumoniae*, *Kingella kingae*	Clindamycin[b,c]
>5 yr	*S. aureus*, group A streptococcus, *S. pneumoniae*	Clindamycin[c]
Special Cases		
Sickle cell disease	Salmonella, *S. aureus*	Clindamycin and ceftriaxone
Foot puncture wound	*Pseudomonas aeruginosa*, *S. aureus*	Cefepime or piperacillin/tazobactam

[a]Coverage modified on the basis of culture results and sensitivities.
[b]Add ceftriaxone for Gram stain negative for gram-positive cocci or culture positive for *Kingella kingae*.
[c]Vancomycin if high incidence of clindamycin resistance in community.

Eighty to 90% of septic joints occur in the lower extremities. The knee and hip are most commonly afflicted. The same distribution is found in the preambulatory child. Infections involve only a single joint in greater than 90% of cases. Multifocal infections are more common in neonates.

Once established within the joint, bacteria release endotoxins that stimulate the production of proteolytic enzymes by neutrophils and synovial cells. These enzymes directly damage the intraarticular cartilage. Pressure elevation within the minimally distensible joint capsule can compromise vascular flow, resulting in ischemic injury to the bone. This is a particular concern in the hip, where avascular necrosis of the femoral head is a well-described complication of septic arthritis. Prognosis is worse in children younger than 1 year, with involvement of the hip joint, with delay to the initiation of therapy, and with infection by *S. aureus*.

Clinical Findings

Pain is the most common presenting complaint in the child with a septic joint. The child may express this in many ways. The older child is better able to localize the area of discomfort. Because of the predominance of septic arthritis in the lower extremities, the younger child often presents with a limp, abnormal gait, or inability to bear weight. Referred pain from the hip may manifest as groin, thigh or knee pain.

Range of motion around the affected joint is dramatically reduced. Any degree of movement causes great distress and is vigorously resisted. Many clinicians rely on this aspect of the evaluation more than any other in differentiating infection from alternative causes of joint pain.

Clinical signs are more subtle in the neonate or young infant with a septic joint. Nonspecific findings such as septic appearance, irritability, and pseudoparalysis of a limb are common presenting findings in these ages. Parents may note excessive irritability associated with diaper changes in the infant with a septic hip. The child with a septic hip will typically hold the lower extremity in abduction and external rotation in order to decrease intracapsular pressure by maximizing the volume of joint space (Fig. 125.3). A high degree of suspicion, close observation, and isolated manipulation of each extremity will help locate the particular area of involvement.

FIGURE 125.3 Five-month-old infant with septic arthritis of the right hip. Hip joint is held in flexion, abduction, and external rotation.

The skin surface should be closely evaluated for local signs of injury. Most involved joints will have obvious erythema, warmth, and swelling. The exception is the hip joint because of its deep-seated location. Swelling may be less obvious in the pudgy infant. Fever is a commonly associated sign but is absent in up to one-third of patients.

Diagnosis

The diagnosis of septic arthritis is confirmed by the identification of purulent fluid within the joint space. Arthrocentesis is a mandatory procedure in all suspected causes of septic arthritis. The decision to perform this procedure is based on the degree of clinical suspicion in combination with results of laboratory tests and imaging studies. None of these in isolation are 100% sensitive in detecting or excluding septic arthritis from other conditions. A sample of synovial fluid is often the only means of discriminating septic arthritis from less serious inflammatory processes.

The mean peripheral WBC count is elevated in children with septic arthritis, however, more than half of the patients will have a WBC count less than 15,000 per mm^3. The ESR and CRP are more sensitive markers and are elevated in 90% to 95% of patients.

Plain radiographs may demonstrate signs of an effusion ranging from subtle blurring or displacement of fascial planes to complete dislocation of the joint. The main role of the radiograph in the evaluation is to exclude fractures or other bony abnormalities that may mimic septic arthritis. Ultrasound is most useful in evaluating the hip. It is much more sensitive than the radiograph in detecting a joint effusion. Some have suggested that the absence of an effusion on an ultrasound scan effectively excludes the diagnosis of septic arthritis. The ultrasound cannot, however, distinguish between infected and sterile inflammatory effusions. Ultrasound guidance is useful in performance of a needle aspiration of the hip joint.

The bone scan localizes areas of inflammation and is unaffected by prior arthrocentesis. It cannot differentiate infection from other causes of inflammation. A bone scan may be helpful in excluding osteomyelitis. Inflammation is found symmetrically across a joint in septic arthritis, whereas in osteomyelitis it is limited to one side. The reliability of a bone scan in differentiating joint from bone involvement decreases in the neonatal age group.

The isolation of a bacterial pathogen is important in diagnosis and in directing subsequent management. Cultures of joint fluid and blood should be performed on all patients with a possible septic joint. The yield of organisms can be increased by directly inoculating joint fluid into a blood culture bottle. When indicated, cultures from additional sites should be obtained to increase the potential isolation of a pathogen. Cultures of the joint fluid demonstrate the highest yield and are positive in 50% to 80% of cases. Blood cultures identify an organism in 15% to 46% of patients with septic arthritis and are positive in many cases in which the organism is not isolated from the joint fluid. Cervical or urethral cultures in sexually active adolescents with septic arthritis may identify *Neisseria gonorrhoeae* as the responsible organism. In 20% of cases, a causative organism is not recovered. Improvement in polymerase chain reaction (PCR) techniques may increase the ability to identify pathogens.

A Gram stain should be performed on joint fluid, and it occasionally provides additional assistance in identifying both the presence of an infection and the infecting organism. Although elevation of the WBC count more than 100,000 per mm^3 in the synovial fluid is considered strong evidence of infection, the actual counts are often much lower. Presence of purulent fluid, a positive Gram stain, and a highly elevated WBC count with a left shift in the synovial fluid are often used as indications for operative intervention when there is a concern of a septic hip.

Microbiology

With a few exceptions, bacteria found in septic arthritis are the same as those in osteomyelitis. *S. aureus* is the most common reported isolate in all age groups. Prior to the introduction of the Hib vaccine, *Haemophilus influenzae* type b was the leading cause of septic arthritis in the 6-month-old to 5-year-old age group. Through immunization, this organism has now been essentially eliminated and surpassed in frequency by group A streptococcus and Streptococcus pneumoniae. *S. aureus* is also the predominant pathogen in neonatal patients. Gram-negative coliforms and Group B β-hemolytic streptococcus are also found in this age group. *N. gonorrhoeae* is found in the neonatal ages and is a frequent pathogen in sexually active teenagers. *K. kingae* is a fastidious gram-negative rod, susceptible to beta lactam antimicrobials, which has recently been isolated as a pathogen in numerous childhood bone and joint infections. It is found most commonly in children younger than 36 months. *Neisseria meningitidis* is a rare but reported cause of septic arthritis in children.

Management

The management of septic arthritis consists of parenteral administration of antibiotics (Table 125.2) and joint immobilization. Joint irrigation should be performed in selected cases. Empiric antibiotic therapy is dictated by the common organisms in the age group, local sensitivities and by results of the synovial fluid Gram stain. Vancomycin or clindamycin is indicated depending on the incidence of clindamycin-resistant MRSA in the community. Gram-negative coverage should be added in neonates and adolescents. A third-generation cephalosporin should be added in patients with sickle cell disease because of susceptibility to salmonella infection.

Surgical intervention for joint irrigation is generally indicated for all cases involving the hip joint; infections in which large amounts of fibrin, debris, or loculations are found within the joint space; or when the patient fails to improve following several days of intravenous antibiotic therapy. Expeditious and aggressive management limits but does not eliminate potential sequelae of septic arthritis.

Lyme Arthritis

Lyme disease is a common cause of infectious arthritis in certain geographic locations within the United States. The infection is caused by the spirochete *Borrelia burgdorferi*. Arthritis is a manifestation of late disease and can occur 1 to 12 months following inoculation. Lyme arthritis is most often a monoarticular infection of the knee. If left untreated, symptoms can be episodic, lasting several days followed by several weeks to months without symptoms. Clinical and laboratory findings are similar to those for septic arthritis. Joint swelling is marked and out of proportion to the degree of pain. Fever is often absent and is generally low grade when present. Pain and limitation of movement of the affected joint is less than in septic arthritis, and patients are often able to ambulate despite the swelling. Infection can occur without a preceding history of a tick bite or the classic skin manifestations of erythema migrans. Extraarticular manifestations such as facial palsy or meningitis are rare but are helpful in the diagnosis when present. The ESR and CRP are elevated. The mean leukocyte count in synovial fluid is usually 10,000 to 25,000 cells per mm^3 but can exceed 50,000 cells per mm^3 with a neutrophil predominance. Routine cultures of synovial fluid are negative. Diagnostic testing for Lyme arthritis is indicated in endemic areas and should include serum enzyme-linked immunosorbent assay. Positive results should be confirmed by a Western immunoblot for IgG antibodies to *B. burgdorferi*. An IgM immunoblot assay is not necessary in late disease and may result in false-positive results. Negative serum IgG serology virtually excludes Lyme as the cause of arthritis. Treatment for Lyme arthritis consists of a 4-week course of oral antibiotics. Doxycycline in a dose of 4 mg per kg per day divided twice daily with a maximum of 100 mg per dose is effective for children older than 8 years, whereas amoxicillin (50 mg per kg per

TABLE 125.2

INITIAL ANTIBIOTIC THERAPY: SEPTIC ARTHRITIS[a]

Age	Pathogens	Antibiotics
Neonate <2 mo	*Staphylococcus aureus*, group B streptococcus, gram-negative bacilli	Vancomycin and cefotaxime
>2 mo–5 yr	*S. aureus*, group A streptococcus, *Streptococcus pneumoniae*, *Kingella kingae*	Clindamycin[b,c]
>5 yr	*S. aureus*, group A streptococcus	Clindamycin[c]
Adolescent	*S. aureus*, group A streptococcus, *Neisseria gonorrhoeae*	Clindamycin and ceftriaxone[d]

[a]Common pathogens and empiric antibiotic coverage by age.

[c]Vancomycin, if high incidence of clindamycin resistance in community.
[d]Empiric treatment in sexually active adolescent.

day in three divided doses with a maximum of 1.5 g per day) is sufficient in younger children. Serum antibody titers remain elevated even after adequate antibiotic treatment and should not be used as a measure of success of treatment. Persistent or recurrent joint swelling may occur two months beyond the initiation of treatment. Although this may represent a local autoimmune response, experts recommend retreatment with a second 4-week course of oral antibiotics or a 2- to 4-week course of parenteral ceftriaxone.

Transient Synovitis

Background

Transient or toxic synovitis is a benign, self-limiting inflammatory condition of the hip. It afflicts males more frequently than females and is the most common cause of acute hip pain in children 3 to 10 years of age. The underlying cause is unknown, although a postinfectious inflammatory response has been suggested. Its presentation can mimic that of septic arthritis of the hip (Fig. 125.4), a distinction that is as crucial in management as it is difficult in diagnosis.

Clinical Findings

The onset of symptoms is abrupt with unilateral hip pain and limp. Fever is rare, occurring in less than 10% of cases, and when present, is usually low grade. Although patients complain of discomfort with movement of the limb, it is generally possible to gently maneuver the hip through a full range of motion. This contrasts with the septic hip in which pain and spasm are more extreme, and patients resist a full range of motion. Additional signs of systemic illness are absent and, despite the title, the child is nontoxic appearing.

Laboratory

Laboratory tests are generally useful only in attempting to distinguish transient synovitis from more serious conditions. The WBC count, ESR, and CRP are generally normal or only slightly elevated. The mean WBC count, ESR, and CRP are significantly lower than in septic arthritis; however, sufficient overlap exists between values in transient synovitis and septic arthritis such that they do not reliably distinguish between the two conditions in individual patients.

Radiographs may demonstrate an effusion but principally serve to exclude pathologic osseous conditions. Ultrasound is more sensitive than plain films at detecting joint effusions, although accuracy declines in patients younger than 1 year of age. Reports of an effusion of the hip by ultrasound in transient synovitis vary from 50% to 95%. The clinician must use a combination of clinical, laboratory, and radiographic findings to determine which patients require further evaluation with needle aspiration of the hip. Although patients often report relief of pain following aspiration, the procedure is unnecessary except to exclude the presence of a bacterial infection. Synovial fluid, when obtained, is sterile. The synovial fluid WBC count is typically less than 50,000 cells per mm^3.

FIGURE 125.4 Seven-year-old child with transient synovitis of the left hip. Hip joint is held in same position of comfort as in septic arthritis.

Management and Prognosis

Treatment occurs on an outpatient basis, and emphasizes rest and analgesics. Traction is of unproven benefit and is potentially harmful. Nonsteroidal antiinflammatory medications are the first-line therapy for pain. Pain duration is typically 3 to 4 days but may last as long as 2 weeks. Exacerbations can occur if activity is resumed too early.

There is no evidence of serious sequelae resulting from transient synovitis. The relationship between transient synovitis and the subsequent development of Legg-Calvé-Perthes disease (LCPD) is unclear. Studies have been unable to demonstrate cause and effect. Some suggest that these patients are at increased risk for developing LCPD, whereas others believe only that the clinical presentations are similar. Recurrences of transient synovitis can occur up to several years later and are not associated with worse outcomes.

Penetrating Intraarticular Wounds

Penetrating intraarticular wounds are not specific to children, but they are injuries that the pediatric emergency physician must recognize and treat on an urgent basis in order to prevent serious and potentially permanent sequelae. Knees are the most commonly injured joints. Motor vehicle accidents are the cause in the overwhelming number of cases. A penetrating joint injury commonly missed in the emergency department is the closed fist injury in which the patient strikes an opponent in the mouth. A tooth can disrupt the capsule of the metacarpophalangeal joint and introduce oral bacteria. Failure to recognize this injury can result in septic arthritis, osteomyelitis, and permanent joint damage.

An open joint may be detectable on direct visualization or by palpation through a periarticular laceration. Injuries that extend below the skin surface adjacent to a joint effusion should raise a high level of suspicion that the joint space has been violated. The presence of air in the joint on radiograph is diagnostic for joint penetration (Fig. 125.5). In less obvious cases, disruption of the joint capsule can be demonstrated by the saline load test. Arthrocentesis is performed through an uninjured site on the skin surface, and saline is injected. Extravasation of saline from the joint into the wound is diagnostic for penetrating injury. A volume of 60 mL of saline is generally adequate to evaluate knee joint integrity, 20 mL for

FIGURE 125.5 Intraarticular air in knee joint following penetrating injury sustained from fall on edge of stone.

elbow or ankle joints, and 1 to 2 mL for finger joints. The addition of a small amount (<0.1mL) of methylene blue to the saline may improve visualization of extravasated fluid. Voit et al. found that clinical evaluation had poor sensitivity in identifying penetrating wounds compared with saline injection. Other studies have shown that the saline load test may also miss a significant number of joint disruptions. If a question still remains regarding the integrity of the joint after such testing, then further imaging studies or surgical exploration is necessary.

The treatment of an open joint wound is similar to that of an open fracture. Open wounds of the joint are considered contaminated and broad-spectrum antibiotics should be administered. Surgical intervention consists of vigorous irrigation and debridement, often in the operating room. Attention should be given to appropriate tetanus prophylaxis, splinting, wound dressing, and pain control while the patient remains in the emergency department.

The prognosis of penetrating intraarticular wounds is dependent on the degree of overlying soft-tissue injury and the extent of intraarticular damage. Infectious complications are the most common. Septic arthritis with a variety of both gram-positive and gram-negative organisms is an early and common outcome of inadequate early intervention. Delayed synovitis, often necessitating synovectomy, has been described after unidentified penetration of small foreign bodies.

Annular Ligament Displacement (Radial Head Subluxation)

"Nursemaid's elbow" is the most common joint injury in pediatric patients, usually occurring in children between 6 months and 5 years of age. The term annular ligament displacement (ALD) is replacing radial head subluxation for this entity because it is more anatomically correct. Displacement of the annular ligament occurs as a result of traction on a pronated hand or wrist, causing the ligament to slide overtop of the radial head and become interposed between the radius and capitellum. Except for a very slight increase in the distance between the radial head and capitellum that can be seen on ultrasound, the relationship between radial head and capitellum remains essentially unchanged, and radiographs are normal in patients with ALD. The radial head is not abnormal and the annular ligament does not always tear when this injury occurs. The left elbow is more often affected because adult caregivers tend to hold the child's left hand with their dominant right hand.

In up to half of the cases, a history of traction on the arm is not obtained, which may suggest another mechanism for this injury or perhaps caregivers who are reluctant to volunteer self-incriminating information. Astute clinicians should suspect this injury even in the absence of the typical history.

ALD can be strongly suspected from across the examining room. The child generally holds the arm slightly flexed and against his or her body. When left alone, the child does not appear to be in significant pain. Parents may report a problem with the wrist or shoulder because, in their attempts to assess these joints, inadvertent movement of the elbow causes pain. Physicians can be similarly fooled, especially when a classic history is not obtained.

Evaluation and Management

The young child must be approached in a slow and nonthreatening manner. Examination that does not move the elbow joint at all is necessary to exclude point tenderness of the clavicle, humerus, radius, and ulna that may suggest a fracture. True tenderness and swelling at the elbow are usually absent. When disuse of the elbow is present without significant pain or bony tenderness, the clinician should perform the reduction maneuver to confirm the diagnosis of radial head subluxation. Radiographs of the elbow are unnecessary unless the physician suspects another injury. Swelling and localized tenderness of the distal humerus are usually apparent with supracondylar fractures, the next most common elbow injury in this age group.

Reduction of a displaced annular ligament is one of the most gratifying procedures for physicians and parents alike. Nonmedical caregivers have been instructed by telephone to reduce recurrent ALDs. Several effective reduction maneuvers have been described. In performing the traditional supination–flexion maneuver, the clinician holds the elbow with his or her thumb over the radial head (Fig. 125.6). In the majority of patients, full supination of the affected arm rotates the flared aspect of the radial head, snapping the annular ligament back to its original position with a telltale click. Flexion or extension of the elbow after supination may add to the success rate. If no click is felt, a second attempt can be made, perhaps exerting mild traction to disengage the annular ligament from between the radial head and capitellum. Forced pronation or pronation–flexion is an alternative method for reduction that appears to be more effective and less painful than the supination–flexion maneuver. Pronation–flexion sometimes succeeds after the initial attempt at reduction with supination–flexion has failed. After an attempt at reduction that does not result in a perceptible click, the child should be observed and tested for return of arm function because some successful reductions occur without a detectable click. Excessive failed attempts at reduction should be avoided. Radiographs may be useful for patients who fail reduction maneuvers.

Return of function after successful reduction is usually prompt, but not immediate. Toys, bottles, or interesting objects can be used to encourage the child to use the affected

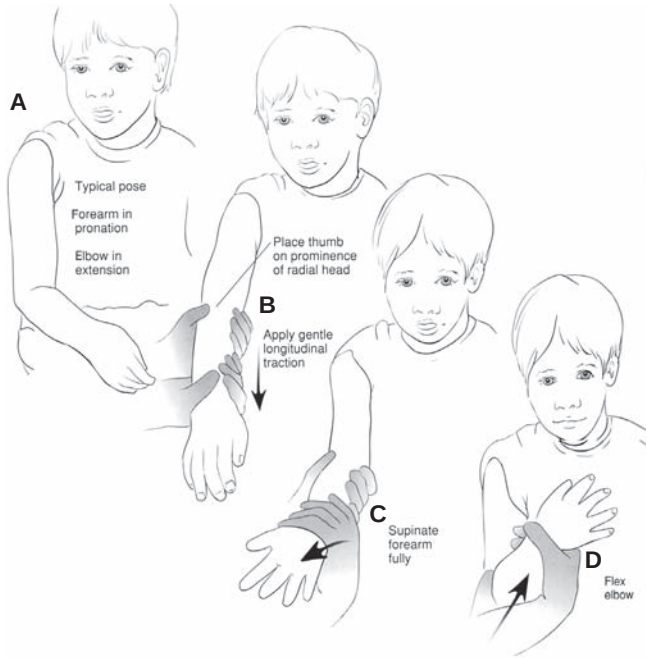

FIGURE 125.6 **A–D:** Supination–flexion maneuver for reduction of radial head subluxation (nursemaid's elbow).

arm. Voluntary use of the arm will return in less than 15 minutes in almost 90% of patients. Younger children generally take longer to begin reusing the arm. Longer duration of subluxation does not appear to be associated with delayed return of function. Many clinicians relate experiences with "failed" reductions in children whose arms are better the following morning. If disuse of the arm persists and radiographs are normal, a sling should be placed and the child should be seen in follow-up by an orthopedist.

Recurrent ALDs are common, occurring in a quarter to one-third of cases. Caregivers should be counseled to lift the child from the axillae, avoiding traction on the distal extremities.

Shoulder (Glenohumeral) Subluxation/Dislocation

Shoulder dislocation is extremely uncommon in young children. Shoulder dystocia at delivery can lead to displaced Salter I fractures that look like dislocations because the unossified proximal humeral epiphysis remaining in the glenoid fossa is not visible radiographically. True dislocations become more common in adolescence, and their management is described in Chapter 135. Intraarticular lidocaine injection is an alternative to intravenous narcotic/benzodiazepine as analgesia for reduction of shoulder dislocations that has a lower complication rate and requires less time in the emergency department.

Glenohumeral subluxation/dislocation will be recurrent in about half of all the cases managed nonoperatively, especially if the anterior glenoid rim is avulsed (Bankhart lesion). Patients may report functional impairments from a shoulder that "pops out" and reduces spontaneously. Some disturbed individuals intentionally dislocate their shoulder. Arthroscopic surgery can stabilize the shoulder, reducing the likelihood of recurrent dislocation. Data are insufficient and opinion is divided on whether surgical intervention is indicated after the first shoulder dislocation or better reserved for cases that are recurrent.

Slipped Capital Femoral Epiphysis

Background

Slipped capital femoral epiphysis (SCFE) is the most common hip disorder in adolescent patients and should be familiar to all who care for children in this age group. It is twice as common in males as females, and more common in African–American patients. Over 80% of patients with SCFE have body mass index above the 95th percentile, but clinicians must also consider SCFE in patients who are not obese to avoid delayed diagnosis. As expected, increasing rates of childhood obesity have been associated with increase in the incidences of SCFE. Cases of SCFE are usually sporadic, but some familial tendency has been noted. Most children with SCFE are early adolescents in their growth spurt. Boys are most commonly affected between 13 and 15 years of age, and girls between 11 and 13 years of age because of their earlier pubertal development. SCFE onset after menarche is extremely rare.

Slippage of capital femoral epiphysis is almost always posterior and inferior relative to the proximal femoral metaphysis, however, displacement anteriorly or superiorly has been reported. The epiphysis maintains a normal relationship with the acetabulum. The left hip is affected more often than the right. Although symptoms are usually unilateral, plain radiographs document bilateral slippage in about 25% of cases, computed tomographic (CT) scans and MRI in up to 50%.

Pathophysiology

The pathogenesis and biomechanics of SCFE have been the subject of some research and much reasoned speculation. The perichondrium is primarily responsible for the strength of the proximal femoral physis. SCFE differs from a displaced Salter I fracture in that the perichondrium remains intact in most cases of SCFE and is disrupted with acute Salter I fractures. Collagenous bridges that traverse the physeal cartilage and the undulating convexity of the physis toward the epiphysis contribute to the shear strength of the physis. Children with more vertically inclined physeal angles have greater shear stress across their proximal femoral physes and therefore are at greater risk for SCFE. Although it takes an enormous shearing force to produce acute slippage of an initially normal hip joint, the viscoelasticity of the physeal cartilage allows for gradual slippage. Most children with acute presentations will have radiographic evidence of chronic slippage. A so-called "preslip" may be diagnosed in a symptomatic child with normal radiographs. MRI will usually document physeal widening posteromedially on T1-weighted images.

Most patients with SCFE do not have identifiable endocrinologic problems. However, several hormonal abnormalities have been associated with increased risk. Elevated growth hormone and somatomedin, hypogonadism, hypothyroidism, and secondary hyperparathyroidism from renal failure (renal osteodystrophy) have been associated with SCFE. Short children receiving exogenous growth hormone therapy and tall, thin, rapidly growing children with high

levels of endogenous growth hormone are both at increased risk. Children outside the usual age range for SCFE, and those with other signs and symptoms that suggest possible endocrine abnormalities, should be referred for endocrine evaluation.

Clinical Presentation

Pain and/or limp are the most common chief complaints in patients with SCFE. Physicians may be misled when the pain is referred to the thigh, knee, or groin. It is often dull, vague, intermittent, and chronic in nature. The average duration of symptoms prior to diagnosis of SCFE is 2 months and slip severity is correlated with delay in diagnosis. A history of trivial injury is sometimes obtained, perhaps causing the additional slippage that precipitates a medical evaluation. Acute onset of severe symptoms suggests acute or acute-on-chronic slippage, sometimes referred to as "unstable" SCFE. These patients are often unable to bear weight and may be in significant pain. Major trauma can cause SCFE, but these presentations are rare.

Examination findings in patients with SCFE include a resting position with hip flexion and some external rotation. Range of motion of the hip, especially full flexion, medial rotation, and abduction, is decreased and painful. Hip flexion will often be associated with obligate external rotation. Patients with significant displacement may have evidence of limb shortening. Occasionally, there is tenderness of the hip anteriorly. Patients with more acute presentations should not be forced to walk as part of the evaluation. Testing for full range of motion is unnecessary once a decision to obtain radiographs has already been reached.

Diagnosis

It is important for emergency physicians to have skill in interpreting plain radiographs for SCFE. Radiographs of the hip should include two views because SCFE is inapparent in one-third of cases in which a single anteroposterior (AP) view is obtained (Fig. 125.7). On the AP view, widening of the physis is usually seen, even if the displacement is inapparent. A line drawn along the lateral aspect of the femoral neck on the AP view (Klein's line) should intersect a small portion of the femoral epiphysis in a normal hip, but will not in cases of SCFE. The epiphysis in SCFE is almost always displaced posteriorly. The externally rotated frog-leg view turns the posterior aspect medially and facilitates visualization of the offset between the epiphysis and the metaphysis in cases of SCFE. New bone formation is often visible, suggesting a chronic slip. When radiographic findings are equivocal, comparison with the contralateral, asymptomatic hip should be done with caution, given the frequency of bilateral slippage with unilateral symptoms. Two radiographic views of the hip are 80% sensitive for SCFE. Those with suspicious clinical presentations but normal radiographs may have early SCFE or a "preslip" that may be detected by MRI. Ultrasonography may be very sensitive for SCFE, but clinicians should be cautious in relying on this operator-dependent modality before expertise is established.

FIGURE 125.7 Slipped capital femoral epiphysis of right hip. Epiphysis is displaced medially on the frog view.

SCFE is classified by symptom duration, stability, and degree of displacement. Patients with acute SCFE have symptoms for less than 3 weeks; with chronic SCFE, symptoms are present for more than 3 weeks. Acute-on-chronic SCFE describes patients with symptoms for more than 3 weeks with a recent exacerbation. An acute slip with severe symptoms is unstable. Acute or chronic slips with mild symptoms are stable and have a more favorable prognosis. The degree of slippage is expressed with a grading system: grade I or preslip with possible widening of the physis but no displacement, grade II with displacement less than one-third of the width of the metaphysis, grade III with displacement of one-third to half of the metaphyseal width, and grade IV with displacement of greater than half the metaphyseal width.

Management

Children with SCFE who present with severe symptoms and/or acute onset should be admitted and promptly evaluated by an orthopedic surgeon. Those with milder symptoms may be sent home on crutches, assuming timely orthopedic follow-up has been arranged. Treatment of SCFE is primarily surgical. Screws are usually placed through the femoral neck into the epiphysis. Reduction of the displacement is not performed because there is some evidence that it may increase the likelihood of avascular necrosis of the femoral head and chondrolysis. Chondrolysis is the most common complication of SCFE, occurring in about 8% of patients. Pain and persistent decreased range of motion after pinning are the usual presenting symptoms. If the pins extend into the joint space, the risk of chondrolysis is increased. Two-thirds of patients with chondrolysis have a progressive course. Ankylosis may ensue, leading to long-term disability. Some pediatric orthopedists advocate prophylactic pinning of the contralateral hip after unilateral SCFE if the risk for subsequent slippage is high. Younger chronological age (girls younger than 10 years, boys younger than 12 years) is a very significant predictor for development of a contralateral slip.

Legg-Calvé-Perthes Disease

LCPD is a hip disorder that affects about 1 in 1,200 children and generally has onset between the ages of 4 and 9 years. Males outnumber females by a ratio of 4:1. Most children

with LCPD are short, with average or above-average weight, and often have delayed skeletal maturation.

LCPD, or osteonecrosis of the capital femoral epiphysis, is the result of ischemia. LCPD can be simulated in experimental animals by embolizing the blood supply to the femoral head. The theory that LCPD is the result of a variety of clotting abnormalities has gained support in recent years. Thrombotic venous occlusion in the proximal femur may increase intramedullary pressure and lead to ischemia. Patients may remain asymptomatic despite varying degrees of necrosis and resorption of the femoral head. Some children recover completely without developing symptoms. Symptoms usually begin when routine trauma causes stress fracture of the abnormal subchondral bone. Rarefaction of the femoral head with subluxation and deformity may ensue. The process of reossification and remodeling takes 2 to 4 years.

The onset of symptoms in LCPD is usually insidious. Presentation as an acute emergency is rare. Mild hip pain and limp have usually been present for weeks to months before diagnosis. Pain is often referred in the distribution of the obturator nerve to the knee, anteromedial thigh, or groin. Physical findings include decreased hip abduction and internal rotation. Thigh muscle atrophy, and in advanced cases, limb shortening may also be noted.

The sequence of radiographic changes in LCPD has been described in detail (Fig. 125.8). Gadolinium subtraction MRI may offer radiographic evidence of disease during the first 3 to 6 months of symptoms when plain radiographs are normal. At diagnosis, most patients have widening of the articular cartilage with a small, dense proximal femoral epiphysis. Subchondral fracture may be visible. Irregularity and flattening of the epiphysis develops over time. The differential diagnosis includes various bone tumors and skeletal dysplasias. As the disease progresses, anterolateral subluxation may be quantitated radiographically.

Management of LCPD requires a pediatric orthopedist who will follow and treat the child through the various stages of the disease. Prompt referral may influence long-term prognosis. Older children, obese children, girls, and those with more severe disturbance of the epiphysis on radiographs have a poorer prognosis.

FIGURE 125.8 Legg-Calvé-Perthes disease of left hip. Epiphysis is narrowed and radiodense. A subchondral fracture is also visible.

Discitis (Diskitis)

Background

Discitis is an uncommon and poorly understood inflammatory condition involving the intervertebral disc space. Vertebral osteomyelitis with involvement of the disc space is a distinct diagnostic entity with different epidemiology and pathophysiology from discitis. The mean age of patients with discitis is less than children with vertebral osteomyelitis. No gender or racial predilection has been noted. The involved disc space is usually lumbar or lower thoracic. Most authorities believe discitis results from infection. A history of trauma is obtained in some patients with discitis, but whether the injury plays a role or is a "red herring" is unclear. The vascular anatomy of the disc space supports the notion that organisms reach the disc space via the hematogenous route. In children, the blood supply of the disc space comes from adjacent vertebral body end plates. These vascular connections are absent in older adolescents and adults, and may be the reason discitis is so rare in this age group. Discitis can also be a complication of lumbar puncture.

Bacteria are cultured from a minority of children with discitis. *S. aureus* is the predominant isolate from disc space aspirates and occasionally blood, but other organisms including anaerobes have also been recovered.

Diagnosis

Children with discitis are a diagnostic challenge for clinicians. The condition is uncommon and symptoms are often nonspecific and vague, especially in the younger child. They usually have been present for more than 1 week at the time of diagnosis. Back pain is not always described. Limp, refusal to walk, leg pain, hip pain, and abdominal pain are common presenting complaints. Unlike vertebral osteomyelitis, which is usually associated with fever, only about a quarter of patients with discitis are febrile. Irritability may also be reported.

Physical findings suggesting discitis will be missed if this entity is not considered because careful examination of the spine is not performed routinely by most clinicians. Many children assume a recumbent position of comfort from which they do not want to be moved. Decreased range of motion of the spine and paravertebral muscle spasm are usually present. There is often a change in the lumbar lordosis, which may be decreased or increased. Tenderness to palpation of the disc space can usually be demonstrated. Range of motion of the hips is essentially normal, but inadvertent movement of the lumbar spine during hip examination may cause pain that is misinterpreted to suggest hip pathology. Straight leg raise may be limited by muscle spasm in the hamstrings. Neurologic assessment of the lower extremities is generally normal, but there are reports of discitis with neurologic involvement. Abnormalities in strength, sensation, and/or deep tendon reflexes suggest a spinal cord lesion, tumor, epidural abscess, or herniation of the disc (rare). Signs of discitis may vary, depending on the location of the inflamed disc. Patients with lesions of the upper spine may have meningismus. Imaging studies can be useful in the diagnosis of discitis. Plain radiographs may be normal initially, but intervertebral disc space narrowing develops

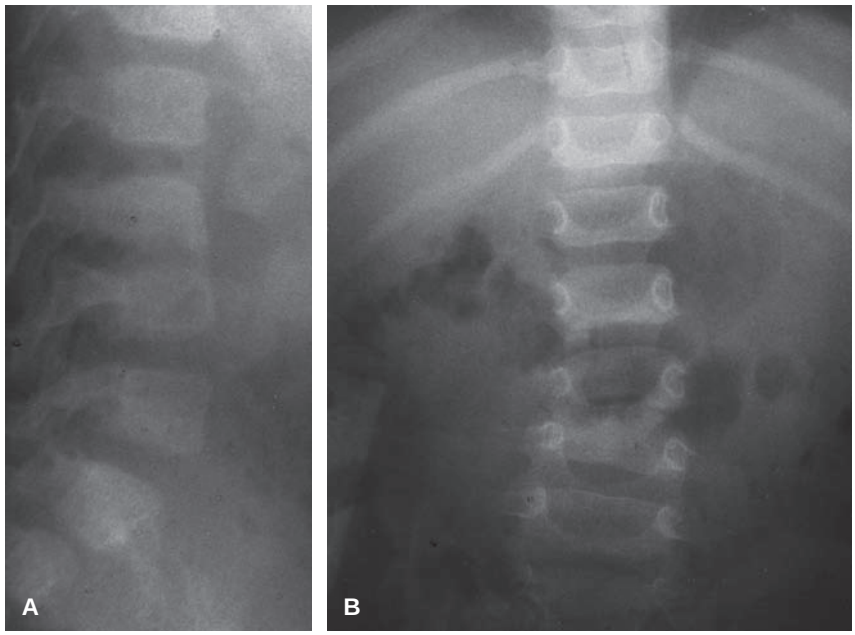

FIGURE 125.9 Discitis. L3–L4 intervertebral disc space is narrowed. Anteroposterior (**A**) and lateral (**B**) views.

after 2 to 3 weeks of illness (Fig. 125.9). At the time of diagnosis, 76% of children with discitis will have abnormal radiographs. MRI is 90% sensitive for discitis, and bone scan is perhaps the most sensitive imaging modality, especially early in the course of this disease. Increased uptake at the level of the involved disc can confirm the diagnosis. CT scanning can demonstrate the degree of bony erosion of the vertebral end plates and paravertebral soft-tissue involvement.

Laboratory testing plays a minor role. Elevation of the WBC count is sometimes noted at the time of diagnosis. ESRs of 40 to 60 mm per hour are usually noted in patients presenting with discitis and decrease with resolution of the disease. Skin testing for tuberculosis, as well as serologic testing for brucellosis and salmonellosis, are often performed but not routinely recommended. Discitis can usually be diagnosed and treated without biopsy or aspiration of the involved disc space. If the presentation is atypical, signs and symptoms severe, or response to therapy unsatisfactory, obtaining a guided-needle aspiration can be helpful.

Management

Discitis is a self-limited disease and need not be treated aggressively. Virtually all children in reported series return to normal function in a few months. Resting the spine usually results in improved symptoms in days to weeks. Immobilization with plaster has not been shown to improve outcome over bed rest alone, but therapeutic decisions should be individualized with input from an orthopedist.

Although there are no data to suggest that they speed recovery or improve outcome, antistaphylococcal antibiotics seem prudent, given the frequency of documented staphylococcal infection. When cultures demonstrate particular organisms with known antimicrobial susceptibilities, antibiotic therapy can be individualized.

SPONDYLOLYSIS AND SPONDYLOLISTHESIS

Spondylolysis, with or without spondylolisthesis, occurs in 2% to 5% of children, but the majority are asymptomatic. Most children presenting with low back pain will not receive a definitive diagnosis, but of those that do, spondylolysis is the most common condition identified. Adolescents involved in sports are at highest risk.

Spondylolysis is a defect in the pars interarticularis of the vertebral body. Spondylolisthesis is displacement of the vertebral bodies, usually involving L5 slipping anteriorly on S1. Spondylolisthesis may result from structural abnormalities of the vertebral bodies (dysplastic type) or acquired defects of the pars interarticularis (isthmic type) that allow slippage. There is a genetic predisposition to spondylolysis and spondylolisthesis. Parents of children with spondylolisthesis are found to have this condition in 28% of cases.

The cause of the defect of the pars interarticularis in spondylolysis is not fully understood. Repeated stress, such as occurs in gymnasts with frequent hyperextension of the spine, causes stress fracture. One side of the pars interarticularis fractures overtly, which adds to the stress on the contralateral side. Fracture becomes bilateral. Displacement may or may not occur. Children who play sports that stress the spine, such as gymnastics, football, rowing, diving, weight lifting, and high jumping, are at particular risk.

Patients who develop symptoms generally present during the adolescent growth spurt. Back pain usually has an insidious onset and worsens with activity, improves with rest. Over time, there may be pain in the buttocks and posterior thighs. Symptoms radiating down the legs suggest significant nerve root irritation. Parents may describe an increase in the lumbar lordosis or a change in the child's gait.

FIGURE 125.10 Spondylolisthesis with slippage of L5 anteriorly on S1.

Physical examination in the prone position shows tenderness with hyperextension of the lumbar spine and with deep palpation. The hamstrings are usually tight, with decreased range of motion on straight leg raise and flexion of the trunk. Children seldom have motor (10%), sensory (15%), or reflex (10%) deficits in the legs.

Plain radiographs should include AP, lateral, and oblique views. The "scotty dog" of the oblique view will have a collar on the neck if spondylolysis is present. Spondylolisthesis can be diagnosed on the lateral view, and the degree of displacement can be quantitated relative to the width of the vertebral body (Fig. 125.10). A bone scan or MRI in children with chronic back pain and normal plain radiographs can identify spondylolysis in its early stages, when conservative therapy can result in bony union.

Treatment varies, depending on symptoms and degree of displacement, if any. Most cases of asymptomatic spondylolysis and spondylolisthesis with mild displacement will not progress. Children with displacement greater than 25% should avoid rough sports. Symptomatic children with displacement may benefit from immobilization. Decisions about treatment should be made in consultation with an orthopedic surgeon.

OVERUSE SYNDROMES

Overuse syndromes is a general term that encompasses various injuries that result from excessive and repetitive forces on susceptible structures. Children are at unique risk for such injuries, which are particularly common in adolescent athletes. There is an increased susceptibility during the growth spurt when skeletal growth exceeds the growth of the muscle—tendon unit. This results in increased stress at the apophysis, the musculotendinous origin, or insertion. In children, cartilage is interposed between the tendon and bone, and is most prone to injury from repetitive forces. Repetitive tensile forces at these sites result in chronic irritation and microfractures or avulsions of the apophysis. If allowed to progress, there is evidence that the repetitive microtrauma may weaken the bone and predispose to major avulsion fractures. Underlying anatomic variations, poor quality sporting equipment and unforgiving playing surfaces may predispose young athletes to overuse injuries. Traction apophysitis is unique to the growing child. By adulthood, the tendon has fused to the bone. Repetitive forces then cause tendinitis rather than apophysitis. The late childhood and early teenage years coincide with increased participation in organized sporting activities. There is a tendency in high-intensity programs to overtrain young athletes, and at times, to encourage them to work through or ignore the early warning signs of pain.

General therapy for these injuries must emphasize several points. Rest is crucial for the specific area involved until pain has completely resolved. The athlete should be actively encouraged to use alternative activities to maintain conditioning during this time. The role of inflammation in overuse injuries is controversial, but the application of ice and use of antiinflammatory agents is generally recommended. Directed stretching exercises reduce tension on affected areas. Biomechanics should be assessed and corrected when necessary. When returning to full activity, an appropriate training regimen should emphasize a slow gradual buildup in intensity and duration and should include explicit limits. The sudden increase in intensity and duration of training that occurs with a change of sporting seasons is a major culprit in overuse injuries.

Numerous overuse syndromes have acquired popular eponyms. Among the most common overuse syndromes in children are Osgood-Schlatter disease, Little Leaguer's elbow, and Sever's disease.

Osgood-Schlatter Disease

Osgood-Schlatter disease is an apophysitis of the tibial tubercle. Repetitive stress imposed by the patellar tendon on its site of insertion results in a series of microavulsions of the secondary ossification center and underlying cartilage. The condition is most common in running and jumping athletes between the ages of 11 and 15 years, and has been associated with tibial torsion. Boys are most commonly affected, but the rising incidence among girls may be because of increased participation in previously male-dominated sports. Cases are bilateral in a quarter of cases, although symptoms are commonly asymmetric.

The physical examination is notable for localized tenderness at the tibial tubercle. Any action that applies tension to the patellar tendon elicits pain. Placing the patient prone and flexing the knee so the heel contacts the buttocks will typically trigger pain at the tibial tubercle. Additional maneuvers likely to cause pain include forced extension of the knee, jumping, squatting, or direct pressure as when kneeling. In advanced cases, callus formation occurs, resulting in further prominence of the tubercle. Some experts have suggested a relationship

FIGURE 125.11 Acute tibial tubercle avulsion fracture in child with history of Osgood-Schlatter disease.

FIGURE 125.12 Avulsion of the inferior pole of the patella in a 10-year-old child with Sinding-Larsen-Johansson disease.

between Osgood-Schlatter disease and acute avulsion fractures of the tibial tubercle (Fig. 125.11). The diagnosis is based on the clinical features. Radiographs are not necessary in typical cases, although some orthopedic surgeons recommend imaging in unilateral cases to rule out bony disorders that may mimic Osgood-Schlatter disease. In the early stages of the disease, radiographs are normal. Fragmentation of the tibial tubercle can be a normal finding in the adolescent and must be correlated with clinical findings. In advanced stages of the disease, avulsions from the secondary site of ossification may form ossicles that are visible on a lateral radiograph of the knee.

Management consists first and foremost of avoiding activities that place stress on the tibial tubercle. This is perhaps the most difficult instruction to enforce in young athletes. A brief period of immobilization or non–weight bearing is recommended by some as a means of ensuring compliance. Application of ice will reduce pain and swelling. Nonsteroidal antiinflammatory medications are commonly recommended. Activity may be resumed when the patient is free of pain. Flexibility exercises concentrate on stretching the quadriceps and hamstrings to alleviate stress on the tubercle and avoid recurrences. A neoprene sleeve on the knee will reduce patellar mobility and reduce forces on the tubercle. Over 90% of cases resolve within 12 to24 months with conservative treatment.

Sinding-Larsen-Johansson Disease

The tension in the infrapatellar tendon that causes Osgood-Schlatter disease is also transmitted proximally to the inferior pole of the patella. A traction apophysitis at this site results in pain and localized tenderness, and is known as Sinding-Larsen-Johansson disease. The predisposing factors for this injury are the same as those for Osgood-Schlatter disease, and include running and jumping acitvities. Sinding-Larsen-Johansson disease and Osgood-Schlatter disease can occur simultaneously. Provocative maneuvers that produce discomfort in Osgood-Schlatter disease produce pain at the distal patella. Radiographs are nonspecific but may show fragmentation or a small avulsion at the distal pole of the patella (Fig. 125.12), which must be differentiated from an acute sleeve fracture of the patella or a bipartite patella. Treatment emphasizes rest, application of ice, stretching exercises and oral anti-nflammatory agents. Resolution occurs over a period of 12 to 18 months.

Little Leaguer's Elbow

Little Leaguer's elbow refers to a group of disorders resulting from repetitive valgus stress applied to the skeletally underdeveloped elbow. The cause of these injuries is multifactorial and includes the number of pitches thrown per outing, the number of outings, type of pitches thrown, throwing technique, and degree of skeletal maturity. Valgus force places tension on the medial collateral ligaments, which is translated to the medial epicondyle. A medial epicondylitis or apophysitis is the most commonly resulting lesion. An avulsion fracture of the medial epicondyle may result from an acute valgus force once the site has become weakened from repetitive microtrauma. As expected, Little Leaguer's elbow occurs most commonly in boys aged 9 to 12 years.

Patients complain primarily of elbow pain that is exacerbated by throwing. Athletes report progressive drop off in throwing distance. Tenderness is localized over the medial elbow. Applying a valgus stress to the partially flexed elbow will reproduce the pain. Flexion of the wrist or fingers against resistance will also elicit pain. In advanced cases, extension of the elbow becomes limited.

Radiographs may reveal nonspecific changes such as an irregular or widened medial epicondylar physis, but in general an apophysitis is not visible. An avulsion fracture may appear as a bony fragment separated from the medial epicondyle. Comparison views of the nonthrowing elbow may confirm asymmetric changes.

Treatment emphasizes rest for a period of at least 1 month, application of ice, and return to activity only after all pain is gone. Once activity is resumed, the athlete must concentrate on limiting the total amount of pitching, as well as minimizing stress on the medial epicondyle by employing an overhand rather than sidearm pitching motion. Routine stretching and range of motion exercises will reduce the risk of recurrence. Displacement of an avulsion fragment may require surgical repair to restore full elbow function.

Sever's Disease

Sever's disease is a calcaneal apophysitis occurring at the insertion of the Achilles' tendon at the posterior aspect of the calcaneus. It afflicts predominantly runners, jumpers, and soccer players. Sever's disease is often bilateral, is more common in males, and has its peak incidence between 10 and 12 years of age.

Localized tenderness occurs at the insertion of the Achilles' tendon on the calcaneus. A maneuver such as hanging the heels over the edge of a step, climbing steps, or hopping applies tension to the Achilles' tendon and exacerbates the pain. Patients are often found to have a tight gastrocnemius-soleus muscle complex and limited dorsiflexion of the foot. Radiographs of the site are usually normal and are unhelpful, except to exclude bony injuries such as stress fractures.

Management includes rest, ice, and antiinflammatory medications. Heel padding or lifts may be helpful in relieving tension in the area. Flexibility exercises should concentrate on both the hamstrings and the calf muscles. When therapy is initiated early in the disease, most patients are able to return to normal activity by 2 months.

Bursitis

Bursa sacs are both the shock absorbers and the ball bearings of the musculoskeletal system. They disperse forces from blows on bony prominences and reduce friction where tendons or ligaments are in frequent motion.

Trauma, either in a single blow or by repetitive forces, can inflame the bursa, which responds with increased production of synovial fluid. The bursa sac subsequently swells and a cycle of swelling, irritation, and inflammation ensues. Bursitis is most commonly an overuse syndrome seen in adults and adolescents, and is less common in young children.

Injury or cellulitis of the skin overlying a bursa sac can predispose to infection. Aspiration and culture are necessary for definitive diagnosis. The organisms found in septic bursitis are the same as those in septic arthritis, with *S. aureus* accounting for more than 90% of cases. There is no consensus on the need for parenteral versus oral antibiotics. The prepatella bursa and olecranon bursa are most commonly infected.

Bursae are located throughout the body, but bursitis occurs only in a few. Prepatella bursitis, commonly called "housemaid's knee" results from frequent or prolonged kneeling. Pes anserinus bursitis occurs on the lateral aspect of the knee where the tendons of the hamstring muscles overlie the tibia. Retrocalcaneal bursitis occurs between the calcaneus and Achilles' tendon, and is often caused by direct pressure from ill-fitting footwear or high-heeled shoes. Olecranon bursitis most often results from a single direct blow to the elbow. Shoulder or subacromial bursitis is often associated with calcifications and produces severe pain with abduction. Other commonly affected bursae include the inferior calcaneal bursa and the trochanteric bursa.

An unusual form of bursitis is known as a popliteal or Baker's cyst. This occurs in the bursa that cushions the tendons of the gastrocnemius and semimembranous muscles from the distal femur. The presence of this condition in adults is highly suggestive of intraarticular knee damage. In children with a Baker's cyst, there is frequently a congenitally wide opening joining the bursa sac with the knee joint itself. One-way flow of synovial fluid into the bursa produces swelling just below the popliteal fossa on the medial side. Patients with chronic inflammatory conditions of the knee, such as juvenile rheumatoid arthritis, are at increased risk of developing popliteal cysts. The swelling limits full flexion of the knee and produces the sensation of tension with extension. An arthrogram or bursagram may outline the cyst, document the articular connection, and detect ruptures of the cyst. Ultrasound is a useful noninvasive diagnostic modality. MRI is more accurate than ultrasound but not as essential in children, given the lower incidence of accompanying intraarticular injury.

Bursa inflammation produces swelling and localized pain with direct palpation. Any movement of the tendons overlying the site will reproduce the pain.

Conservative therapy consisting of restricted activity, frequent application of ice, and regular use of nonsteroidal antiinflammatory medications is successful in most cases. Resistant cases respond well to aspiration of synovial fluid and injection of corticosteroids. Frequently recurring cases may require surgical removal of the bursa sac. A new bursa will be generated.

Osteochondritis Dissecans

Background

Osteochondritis dissecans is an acquired lesion involving separation of an osteochondral fragment from underlying healthy bone. Various articular lesions are often lumped together under this term, including acute osteochondral fractures and epiphyseal dysplasias. This results in confounding descriptions of the natural course and outcome of the true condition. Adults are often diagnosed with osteochondritis dissecans; however, it remains primarily a condition of the adolescent age group, with the highest incidence occurring among male athletes between 12 and 16 years of age. The term "juvenile osteochondritis dissecans" (JOCD) refers to lesions that occur prior to the closure

of the growth plates, whereas "adult osteochondritis dissecans" presents after the closure of the growth plate. This distinction has important implications for prognosis and treatment because the likelihood of spontaneous healing is significantly greater in JOCD. The primary sites of osteochondritis dissecans include the medial femoral condyle in the knee, the posteromedial aspect of the talus in the ankle, and the capitellum in the elbow. It is less frequently reported in the hip, foot, and wrist. Involvement of multiple sites is rare, although some series report bilateral knee lesions in up to 30% of cases.

Pathophysiology

The underlying cause of osteochondritis dissecans remains controversial and may differ based on the anatomic location of the lesion. Trauma, vascular insult, genetic predisposition, and abnormalities of ossification have all been proposed as possible etiologies. The greatest evidence supports repetitive trauma as the sole or major contributory cause of the pathology. Overuse injury is most clearly associated with osteochondritis dissecans of the capitellum, where the majority of cases occur in Little League pitchers. Higher incidences of osteochondritis dissecans of the knee and ankle are seen in participants of activities that place increased stress on these areas, such as distance running, ballet, and basketball. Focal necrosis is suspected to follow the initial insult. Spontaneous resolution may occur at this point, or the lesion may progress with the subchondral bone undergoing various degrees of separation from the underlying epiphysis. In advanced stages, complete separation of the osteochondral fragment results in a free-floating body within the joint, which can disrupt normal mechanical function.

When the disease occurs in the second decade of life, long-term outcome is generally good. Progression to osteoarthritis or other degenerative joint diseases is rare. A worse prognosis is associated with a diagnosis after skeletal maturity, a larger lesion, and complete separation of the fragment.

Clinical Findings

Symptoms develop gradually over several months. Joint pain and stiffness typically occur following strenuous exercise and improve over several hours with rest. Swelling may occasionally be present with activity.

When a free body is present, patients describe intermittent, abrupt locking of the joint. Locking in the knee or elbow prevents full extension of the extremity. This is in contradistinction to buckling, stiffness, or pain with extended range of motion.

The physical examination of the joint is frequently normal. Occasionally, a small effusion may be detectable. Lesions in the medial femoral condyle may be directly palpated and pain elicited when the knee is held in 90 degrees of flexion. The typical location of a lesion in the talus is not accessible on examination. Osteochondritis dissecans in the femoral condyle may give rise to an abnormal gait with external rotation of the affected limb.

Wilson described a clinical test for osteochondritis dissecans of the knee. Wilson's sign is elicited by flexing the affected knee to 90 degrees. The tibia is held in internal rotation while the leg is slowly extended. In a positive test, pain occurs at approximately 30 degrees of flexion as the tibial spine contacts the classic location of osteochondritis dissecans in the femur. External rotation of the tibia relieves the pain. Wilson's sign has demonstrated low sensitivity in validation studies but, when present, is considered specific for a medial femoral condyle lesion. Conversion from a positive sign to a negative sign over time correlates with clinical healing.

FIGURE 125.13 Osteochondritis dissecans of the medial femoral condyle. Crescentic lesion with radiolucent margin in a 14-year-old girl.

Diagnosis

Plain films of the joint should be obtained, and are often diagnostic when osteochondritis dissecans is suspected (Fig. 125.13). Radiographs reveal a crescentic-shaped defect within the subchondral bone. The avascular segment of subchondral bone may have increased density. A radiolucent line may demarcate the separation from the remainder of the epiphysis. A free body often includes a portion of dead subchondral bone, which appears as a radiodense object within the joint space. In addition to the standard AP and lateral views of the knee, tunnel and sunrise views are useful in detecting lesions within the femoral condyle. Lateral, AP, and mortis views of the ankle are adequate when a lesion of the talus is suspected, and AP and lateral views of the elbow are indicated for lesions in the capitellum.

Early lesions may not be detected on plain films, and alternate imaging modalities may improve overall sensitivity. When correlated with arthroscopic or surgical findings, MRI has been shown to have excellent ability to detect osteochondritis dissecans and accurately define the extent and stage of the lesion. Osteochondritis dissecans lesions are staged according to the degree of separation from the underlying bone. Stage three or four lesions by MRI have significant separation and are considered unstable. Most orthopedic surgeons consider MRI useful in distinguishing JOCD from other pathologic conditions, guiding therapy and monitoring healing.

Management

The management of osteochondritis dissecans depends on the age and skeletal maturity of the patient, the location of the lesion, and the stage of the lesion. Conservative therapy consisting of restricted activity and relief of stress on the involved joint

is the first line of treatment in children who have not reached skeletal maturity and for those diagnosed at an early stage of the disease. Immobilization in a cast or non–weight bearing for lower-extremity lesions is unnecessary but occasionally employed to enforce rest. Early return to sports may increase the risk of arthritis or further joint disease. Patients should be followed closely by an orthopedic surgeon both for resolution of clinical symptoms and evidence of healing on serial radiographs or MRIs. Most stable lesions occurring in patients prior to physeal closure go on to heal; however, a few will progress to separation. Lesions occurring in adults generally do not heal without surgery. Surgical intervention is generally recommended when lesions fail to improve clinically or radiographically after 6 months of rest. The presence of an unstable or free-floating fragment is also considered an indication for surgery. Most corrective surgical procedures can now be performed arthroscopically. Fine transarticular or retroarticular drilling through the subchondral fragment into healthy bone appears to stimulate revascularization and promote healing. Fragments are replaced whenever possible. Loose fragments and larger free bodies may be reduced and fixed in place with the use of screws or Kirschner wires. When free bodies must be removed from the joint space, the resulting defects may be repaired with the use of a bone graft or through stimulation of fibrocartilage or scar tissue formation to restore congruity to the articular surface.

Chondromalacia Patellae

Chondromalacia patellae is a pathologic diagnosis referring to damage of the articular cartilage of the patella. Specific changes include softening, fissures, and erosions. Patellofemoral pain syndrome, a term often used interchangeably with chondromalacia patellae, more accurately describes a constellation of symptoms, principally anterior knee pain arising from the patellofemoral joint. Whether the two conditions are actually related is the subject of debate. They share a number of symptoms and precipitating factors. Patellofemoral pain syndrome may represent the early end of the spectrum of injury, which ultimately may or may not progress to true pathologic changes within the cartilage.

Patellofemoral pain syndrome and chondromalacia patellae are first seen in early adolescents. The rise in incidence tends to parallel the growth spurt. A number of underlying causes or associated factors have been identified. Malalignment of the patella and an abnormal tracking of the patella over the femoral condyles appear to be the major contributors to patellofemoral disorders. The quadriceps or Q angle is the angle between a line from the center of the tibial tubercle to the center of the patella and a second line from the center of the patella to the anterior superior iliac spine. A Q angle greater than 20 degrees has been found in a significant number of affected individuals and results in disproportionate lateral traction applied to the patella during extension. The wider pelvic bones in females result in a generally wider Q angle, which may account for the higher proportion of patellofemoral problems in females. Another contributing anatomic factor is a relative strength imbalance of the four muscles composing the quadriceps. A shallow femoral intracondylar sulcus has also been associated with the disorder.

Chondromalacia patellae and patellofemoral pain syndrome are often classified as overuse syndromes because individuals exposed to repetitive trauma are at higher risk for these disorders. Runners are particularly predisposed to develop these conditions. Poor training regimens, rapid increases in duration or intensity of training, hard or uneven running surfaces, and inadequate shoes have been blamed.

Symptoms consist mainly of anterior knee pain often described as arising from beneath or on the sides of the patella. Pain is usually of gradual onset and is exacerbated by exercise. Activities that involve loading of the knee when it is in flexion, such as climbing steps, are particularly painful.

The physical examination is notable for tenderness along the patellar margins or the posterior surface, which is accessible when the patella is manually displaced medially or laterally. Pain, and occasionally crepitus, are elicited with flexion and extension of the knee, or tightening the quadriceps while compressing the patella against the femoral condyles. Range of motion is not limited, and swelling is rare. The presence of an effusion is suggestive of significant cartilaginous damage. Provocative tests that reproduce the pain include climbing steps, squatting, or knee extension against resistance.

Radiographs are generally insensitive but may show changes to the patella in advanced cases. Radiographs may also be obtained to more accurately measure the intracondylar sulcus or Q angle, or to rule out alternative diagnoses. MRI, with sensitivity greater than 80%, is considered the best noninvasive diagnostic modality for chondromalacia patellae. True confirmation of lesions requires arthroscopy.

Treatment is conservative. More than 90% of cases of patellofemoral pain syndrome resolve after instituting a program of rest, antiinflammatory medications, and ice followed by physical therapy. Exercises that begin once the initial pain has resolved emphasize strengthening of the quadriceps muscles. Recommended exercise regimens include isometric contractions of the quadriceps with the knee in extension, straight leg raises, and knee extensions, first without and then with weights. Training routines for athletes may need modification and should emphasize soft, even running surfaces; proper biomechanics; and shoes with appropriate cushioning and support. Surgery is recommended only as a last resort in the most recalcitrant cases because results have been generally less than satisfactory. Surgery is directed at either correcting unequal tension applied to the patella or removing loose or nonviable cartilage from the posterior patellar surface.

COMPARTMENT SYNDROME

Compartment syndrome refers to vascular insufficiency caused by elevated tissue pressures that usually occurs after an injury involving hemorrhage or edema within an enclosed fascial compartment. Tight circumferential bandages or casts can also limit expansion of swollen tissues and result in elevation of tissue pressures. Fluid extravasation from intravenous or intraosseous lines, especially pressure-driven extravasation, may significantly elevate compartment pressures. Direct injury to an artery is less common as the cause of vascular insufficiency after injury but is also considered as compartment syndrome.

Abdominal compartment syndrome is a life-threatening condition in which intraabdominal pressure elevation compromises blood flow to the intestine and kidneys, impairs ventilation, and reduces cardiac output by compressing the inferior vena cava thereby reducing venous return to the heart. The

most frequent causes of abdominal compartment syndrome are trauma, burns, pancreatitis and intestinal obstruction.

When compartment pressures approach the perfusion pressure of muscle, which is approximately 30 mm Hg, arterial inflow is reduced and veins and capillaries are collapsed. Ischemia of muscle leads to further swelling, and a positive feedback loop of ischemia—edema can further elevate tissue pressures and lead to complete cessation of perfusion. Muscle necrosis is irreversible after 6 to 8 hours of tissue anoxia. Fibrosis develops and ischemic contracture results in permanent disability. The emergency physician must identify patients at risk for compartment syndromes, and consult with an orthopedist who can monitor tissue pressures and treat compartment syndromes before irreversible injury occurs.

Knowledge of the common pediatric injuries that are associated with compartment syndromes can raise the clinician's index of suspicion appropriately. Displaced supracondylar fractures may injure the anterior interosseous artery and the flexor compartment of the forearm causing a compartment syndrome that leads to the classic Volkmann's contracture. Though controversial, some have suggested that delayed reduction is a risk factor for compartment syndrome after supracondylar fracture. Forearm fractures may also cause compartment syndromes, affecting either the flexor or extensor musculature. Fractures of the tibia and/or fibula can lead to compartment syndrome of the lower leg. Fractures that are open are at greater risk for the development of a compartment syndrome, perhaps because they result from higher-energy mechanisms. Compartment syndromes may occur from crush injuries and other soft-tissue trauma that does not necessarily involve a fracture. Poisonous snakebites, especially pit vipers, and deep tissue infections such as myositis or fasciitis may also lead to dangerous elevations of compartment pressures.

The "five Ps" of compartment syndrome is a mnemonic that can be misleading. One "P," pain, is often the only early symptom or sign of vascular insufficiency. The astute clinician will have consulted an orthopedic surgeon and suspected compartment syndrome before paresthesia, pallor, paralysis, and pulselessness are present.

Pain, the hallmark of compartment syndromes, is a symptom in almost all significant injuries. Distinguishing the pain from the injury itself from that related to the vascular insufficiency is difficult. Pain that increases over time or seems out of proportion to the injury itself suggests muscle ischemia. Full extension of the fingers or toes stretches ischemic muscles and exacerbates the pain in compartment syndromes, making this part of the examination especially important in patients at risk for compartment syndromes.

Paresthesia may be noted in the distribution of the nerves that traverse the ischemic compartment. When the flexor compartment of the forearm is involved, the median nerve is usually affected. Over time, paresthesias may progress to complete anesthesia, and pain may decrease.

Pallor from decreased perfusion may be noted distally. Sluggish circulation may cause cyanosis. Paralysis is a late finding and is probably the least sensitive marker for compartment syndrome. Pulselessness is a useful finding if present, but some physicians are falsely reassured when distal pulses are palpable. Collateral circulation can preserve pulses in larger vessels but the ischemia in compartment syndromes results from vascular occlusion of small vessels.

Treatment of a compartment syndrome should begin from the moment it is suspected. All circumferential bandages should be removed. If symptoms persist, measurement of compartment pressures should be obtained. Reduction of displaced fractures can improve blood flow to affected compartments. Fasciotomy in the operating room is indicated if compartment pressures remain high.

COMPLEX REGIONAL PAIN SYNDROME TYPE 1 (REFLEX SYMPATHETIC DYSTROPHY)

Complex regional pain syndrome type 1 (CRPS1), formerly known as reflex sympathetic dystrophy (RSD) or reflex neurovascular dystrophy (RND), is a poorly understood disorder characterized by pain, abnormal sensation, and circulatory irregularities. Over time, atrophic changes of the extremity may develop. Initially thought to be primarily an adult disease, CRPS1 is increasingly being recognized in children. There are often delays in diagnosing children with CRPS1. Emergency physicians can play a valuable role by considering CRPS1 in children with pain and making appropriate referrals for a prompt, definitive diagnosis. In many patients symptoms of CRPS1 will eventually resolve, but early treatment may prevent prolonged disability.

Children with CRPS1 as young as 3 years have been described. The average age of children with CRPS1 is approximately 12 years, girls outnumbering boys by as much as 6:1. Most cases in children involve the lower extremity. CRPS1 usually follows minor trauma, but some cases develop without an identified precipitant.

The pathophysiology of CRPS1 is not well-understood. Early theories suggested abnormal synapses develop between sensory afferent nerves and sympathetic afferents after an injury. "Sympathetic" dystrophy is probably a misnomer, and nomenclature has changed because local epinephrine and norepinephrine levels are lower, not higher, than normal, and vasodilation, not sympathetic vasoconstriction, may predominate. Current theories include regional sensitization of the central and perhaps peripheral nervous system from an initial injury. Experimental evidence suggests involvement of glutamate and NMDA (*N*-methyl-D-aspartic acid) receptors in this process. The role of cytokines in the development and maintenance of sensitization is also under investigation. Patients with other dysautonomic conditions, including gastrointestinal dysmotility, migraine, cyclic vomiting and chronic fatigue, may also have CRPS1. Most of these patients meet criteria for maternally inherited mitochondrial disease, the significance of which has yet to be elucidated.

Pain is usually the presenting complaint with CRPS1. The pain is continuous, often burning in quality, with exacerbations but no complete remissions. Abnormal sensitivity is distinctive, with severe pain provoked by normally nontender touching (allodynia). The extremity is usually swollen and cool to the touch, although warmth has also been reported (Fig. 125.14). Dusky discoloration of the skin with hyperhidrosis or anhydrosis may be present. The arm or leg is not used, and atrophic muscle, skin, and bony changes develop in some patients over time. There is some evidence that demineralization of bone occurs more rapidly than would be expected from disuse alone.

FIGURE 125.14 Reflex sympathetic dystrophy in a 10-year-old girl after a minor wrist injury.

Psychiatric and personality problems have been suspected in many patients with CRPS1, but controlled prospective studies are lacking. Factitious illness or conversion reactions are often considered because symptoms are out of proportion to the inciting injury.

The characteristic history and physical examination, including pain, loss of function, and evidence of autonomic dysfunction, allow for a clinical diagnosis of CRPS1 in most cases. Radiographs in children may not demonstrate the osteoporosis described in adults, especially early after the onset of symptoms. Radionuclide bone scans generally show increased blood flow and periarticular uptake in adults, but in children with CRPS1 the blood flow and osseous uptake is more often reduced. Thermography may document decreased temperature in the affected extremity. Treatment of CRPS1 focuses on early mobilization of the extremity through physical therapy to avoid atrophic changes. Physiotherapy may initially exacerbate symptoms, but experienced clinicians believe it both prevents atrophy and decreases the duration of pain. The knee-jerk response to splint for comfort may be counterproductive with CRPS1. Referral to a pediatric pain program is advisable if symptoms persist. Sympathetic block with local anesthetic is commonly performed in patients with CRPS1 but evidence of its effectiveness is lacking. There are case reports of successful treatment of CRPS1 with intravenous regional block using guanethidine, transcutaneous nerve stimulation, and sympathectomy.

CHAPTER 126 ■ NEUROSURGICAL EMERGENCIES, NONTRAUMATIC

DANIEL S. TSZE, MD, MPH, AND DALE W. STEELE, MD

Patients with nontraumatic neurosurgical emergencies present to the emergency department (ED) with a variety of signs and symptoms, including headache, vomiting, seizures, changes in mental status, weakness, and coma. Although headache and vomiting are commonly associated with many benign self-limiting conditions, a high index of suspicion for more serious pathology is required. Because the most urgent problems are related to the onset of increased intracranial pressure (ICP), this chapter opens with a general discussion of ICP, followed by descriptions of the common congenital, infectious, vascular, and neoplastic conditions that may present as neurosurgical emergencies.

INCREASED INTRACRANIAL PRESSURE

Pathophysiology

The functions of the buffering systems that maintain ICP at normal levels have been detailed in Chapter 116. The cranium contains three components: brain tissue predominantly, cerebrospinal fluid (CSF), and blood. An abnormal increase in volume of any of these components (by means of edema or mass lesion, increased production or diminished absorption of CSF, or increased blood flow) may result in elevated ICP. This closed space has limited capacity to compensate for increased volume. ICP levels normally rise and fall over the course of the day. ICP is at its peak during sleep because the horizontal posture and the relative hypoventilation that increases arterial P_{CO_2} result in increased cerebral blood flow. This is especially true during rapid eye movement sleep, which usually occurs just before awakening. Headaches that awaken a child during the night or that occur on awakening may be caused by ICP waves elevated beyond the normal nighttime peaks. With the improved ventilation and the assumption of upright posture on arising, P_{CO_2} is lowered and cerebral vasodilation is lessened. If vomiting occurs, the accompanying hyperventilation also decreases cerebral blood flow. As a result, the severity of the headache may then lessen significantly in the awakened child.

Clinical Manifestations

A careful history must be taken with respect to the timing and severity of headaches, vomiting, changes in behavior, visual changes, and episodic decreases in level of consciousness (Table 126.1). Nighttime and morning headaches that improve on arising are always ominous, as is recurrent vomiting without fever, abdominal pain, or diarrhea. Most children presenting to the ED with headache will have common diagnoses, including viral infections, migraine, and sinusitis, and do not require routine neuroimaging. The need for further evaluation will depend on the age of the child and the clinical examination. For example, children younger than 7 years of age do not have frontal sinuses, thus ruling out the possibility of frontal headache caused by sinusitis. Conversely, frontal sinusitis in adolescent boys has a significant rate of intracranial complications, especially subdural and epidural abscesses.

The clinical examination can help confirm the presence of intracranial hypertension, but a normal examination cannot reliably exclude it. Fundoscopy will identify papilledema but it is possible to have ICP without papilledema. Visual fields and visual acuity should be checked. Cranial sutures may split in infants and young children with chronic elevation of ICP, resulting in a hyperresonant note when the skull is percussed, a "cracked pot" sound known as Macewen sign. Cranial nerve palsy may occur, usually affecting the third and sixth nerves, resulting in dilated pupil, diplopia, and strabismus. When the fourth nerve is affected, the child may exhibit a "cock robin" head tilt. Cerebellar herniation may also cause head tilt; if bilateral, the neck may be held in an extended position.

The possibility of cerebral herniation should be considered and aggressively treated in the presence of an evolving pattern of diminishing level of consciousness, unexplained bradycardia, pupillary changes, or abnormal or asymmetric posturing with stimuli. Spontaneous posturing should not be confused with seizure activity. Cushing's triad (hypertension, bradycardia, and irregular respirations) is a near terminal event, with bradycardia usually the first and most sensitive indicator.

Management

The emergency treatment of increased ICP depends on the patient's clinical state and the cause of the intracranial hypertension (Table 126.2). The first priority in all patients is to follow the ABCs (airway, breathing, and circulation) of resuscitation and to prevent hypoxemia, hypercarbia, and systemic hypotension with oxygenation, ventilation, and appropriate fluid therapy. Seizures should be treated aggressively and, if possible, prevented because ICP spikes during seizures will aggravate intracranial hypertension.

Sedative agents given without controlled ventilation may result in hypercarbia, causing an increase in cerebral blood volume and, consequently, in ICP. Therefore, it is often prudent to

TABLE 126.1

SIGNS AND SYMPTOMS OF ELEVATED INTRACRANIAL PRESSURE

Symptoms	Signs
Headache	Papilledema/retinal hemorrhage
Nocturnal, episodic severe	Cranial nerve palsies/ sunset sign
Vomiting	Meningismus
Stiff neck	Head tilt
Double vision	Bulging fontanel/prominent scalp veins
Transient visual loss	Macewen (cracked pot) sign
Gait difficulties	Decorticate/decerebrate posturing
Behavioral changes	Coma
Irritability/screaming episodes	Progressive hemiparesis
	Bradycardia

Modified from Bruce DA. Neurosurgical emergencies. In: Fleisher GR, Ludwig S, eds. *Textbook of pediatric emergency medicine*, 3rd ed. Baltimore: Williams & Wilkins, 1993:1410.

perform tracheal intubation using an rapid sequence intubation (RSI) technique to blunt increases in ICP (see Chapter 5) before CT scan or interfacility transport.

Hyperventilation is only recommended for acute herniation. The effects of hyperventilation are transient and not recommended for prophylactic treatment of increased ICP. Hyperventilation decreases cerebral blood flow leading to cerebral ischemia, depletion of brain tissue interstitial bicarbonate buffering capacity leading to a loss of local vasoconstrictor effects, and a possible rebound phase of increased ICP as the CSF pH equilibrates. Mild hyperventilation (P_{CO_2} 30 to 35 mm Hg) may be implemented to allow time for more definitive treatments. More extreme reductions in P_{CO_2} and routine chronic hyperventilation (to P_{CO_2} of 20 to 25 mm Hg) will result in brain hypoperfusion and have a detrimental effect on outcome. Continuous, portable capnometry may be useful to avoid excessive hyperventilation during transport or diagnostic imaging.

TABLE 126.2

TREATMENT OF INCREASED INTRACRANIAL PRESSURE

- Prevent hypoxia and hypercarbia
  - Tracheal intubation/controlled ventilation
  - Seizure treatment and prophylaxis
- Maintain adequate cerebral perfusion pressure and cerebral perfusion
  - Treatment of shock
  - Limitation of excessive hyperventilation
- Decrease cerebral blood volume
  - Acute hyperventilation
- Decrease brain tissue volume
  - Mannitol/hypertonic saline
  - Dexamethasone for vasogenic edema
- Decrease cerebrospinal fluid (CSF) volume
  - CSF drainage
  - Acetazolamide
- Removal of mass lesion
  - Surgical removal/decompression

The head of the bed should be elevated to 30 degrees to promote displacement of CSF from the intracranial compartment to the spinal compartment, and the head maintained in a neutral position to minimize venous outflow resistance. A ventriculostomy catheter may be used to measure ICP, direct medical therapy, and allow drainage of CSF. CSF volume may also be reduced by drainage from a shunt reservoir or by a ventricular tap via an open fontanel, a split suture, or a burr hole. Hyperosmolar therapy is used to acutely decrease ICP in the deteriorating patient. Mannitol is most commonly used, lowering ICP in 1 to 5 minutes with a peak effect in 20 to 60 minutes. Mannitol is relatively contraindicated in hypovolemic patients because of its diuretic effects. Hypertonic saline reduces ICP while augmenting intravascular volume and thus has a clear advantage over mannitol in hypovolemic or hypotensive patients. Dexamethasone is useful in treating vasogenic brain edema associated with tumor and abscess, but onset of this effect is slow, with ICP decreasing over the course of 2 to 5 days. Steroids have been shown to have no benefit or a detrimental effect in other neurosurgical disorders, such as traumatic brain injury and spontaneous intracerebral hemorrhage.

HYDROCEPHALUS

Hydrocephalus is characterized by dilated cerebral ventricles that contain an excessive amount of CSF, resulting from imbalance between production and absorption. Production occurs in the choroid plexus, almost always remains stable, and is only rarely excessive. In noncommunicating hydrocephalus, CSF in the ventricular system is blocked from communicating with CSF in the subarachnoid spaces and basal cisterns by a congenital or acquired defect. In communicating hydrocephalus, the block in absorption is on the meningeal surfaces, outside the ventricular system. Congenital hydrocephalus may result from aqueductal stenosis or in association with Dandy-Walker or Arnold-Chiari malformations. Acquired hydrocephalus may follow bacterial meningitis, obstruction by tumor, or result from the inflammatory response to subarachnoid or intracranial hemorrhage.

Previously Undiagnosed Hydrocephalus

Children with undiagnosed hydrocephalus rarely present first to the ED, but hydrocephalus must be considered in infants with increasing head circumference, bulging fontanel, dilated scalp veins, lower extremity spasticity, and other signs and symptoms of increased ICP (Table 126.1).

Management

Noncontrast head CT demonstrates enlarged ventricles. The urgency of ventricular drainage depends on the child's condition. Ventricular puncture through an open fontanel or coronal suture may be lifesaving in a child with evidence of herniation. Endoscopic third ventriculostomy and other endoscopic

techniques have been increasingly utilized for treating selected patients with hydrocephalus, avoiding the need for an indwelling shunt.

Previously Shunted Hydrocephalus

CSF shunts allow diversion of CSF into another area of the body outside the brain. Unfortunately, placement of shunts may be accompanied by numerous complications.

Pathophysiology

Many different types of shunts are in use; therefore, emergency physicians must become familiar with those commonly used in their area. All shunts share three common features: a radiopaque ventricular catheter; a one-way valve; and distal tubing that is palpable subcutaneously and most commonly enters the peritoneal cavity, or rarely into the right atrium or pleural cavity. Many shunts also include a pumping mechanism and a reservoir, which enables percutaneous sampling of CSF without damage to the shunt. Some shunts are programmable, allowing noninvasive adjustments in valve pressure to treat both under- and overdrainage.

Shunt-related problems include obstruction, infection, mechanical failure, overdrainage, loculation of the ventricles, and abdominal complications. The risk for shunt failure is greatest in the first months after placement. Up to 40% of shunts fail during the first year after placement, and 80% require revision by 10 years. Approximately 80% of obstructions occur at the proximal (ventricular) end of the shunt tip as a result of occlusion by tissue or migration of the shunt tip into the brain parenchyma. Shunt infections are most common in the early postoperative period. Mechanical failures include fracture of the distal tubing, disconnection of shunt components, or migration or misplacement of either the ventricular or the distal end of the catheter. Overdrainage implies a properly functioning shunt that removes more fluid than necessary. Rarely, overdrainage can acutely cause extra-axial fluid accumulation or subdural hematoma. Noncommunicating loculations may form so that a single shunt does not drain the entire ventricular system. The most common abdominal complication is pseudocyst formation around the catheter. Pseudocysts are often associated with low-grade shunt infection and can be seen on abdominal ultrasound or CT. Severe constipation may cause reversible ventriculoperitoneal shunt failure due to increased intra-abdominal pressure. Other intra-abdominal complications include ascites and bowel or bladder perforation.

Shunt Malfunction

Clinical Manifestations

Patients with shunt malfunction commonly present with manifestations of increased ICP (Table 126.1), and presentation may differ by age. Uncommon, but relatively specific signs are nonlocalizing sixth nerve palsy, intermittent downward gaze (sunset sign), and swelling from CSF tracking along the shunt tract. The fontanel may be full and tense, even when the infant is upright. Papilledema is uncommon in acute shunt malfunction. Although seizures are common in patients with shunts, one series found that only 2.9% of ED visits by patients with shunts for isolated seizures culminated in shunt revision. A history of onset or worsening of symptoms with upright posture suggests overdrainage. Parents, particularly those who have witnessed prior episodes of shunt malfunction, are perceptive to the subtle and often intermittent symptoms that herald shunt malfunction.

Shunts should not be routinely pumped as this test lacks sensitivity, and because the negative pressure generated in a small ventricle may occasionally result in obstruction. However, if the ventricular catheter is shown on CT scan to be in the center of a dilated ventricle and the shunt umbilicates on depression with slow refill, shunt obstruction is likely.

Management

If the history or physical examination suggests shunt malfunction, early neurosurgical consultation is strongly recommended. A plain radiographic "shunt series" should be done, consisting of anteroposterior and lateral views of the skull, neck, thorax, and abdomen. These radiographs allow the type, location, connections, and intactness of the system to be evaluated.

A noncontrast head CT should also be done and compared, if possible, with previous scans taken when the shunt was functioning. In some patients, ventriculomegaly may persist despite a functioning shunt. Conversely, some patients have increased ICP despite small or unchanged ventricles. Rapid-sequence (quick-brain) MRI avoids radiation exposure and may be used to visualize ventricular catheters and ventricular size. Although CT and shunt series are useful, a normal result for either should still be scrutinized. Several series have shown that as many as 8.4% of patients with shunt malfunction were identified by an abnormal shunt series, while having a normal CT scan. Another series demonstrated that out of 267 patients with both normal head CT and shunt series, 14 (5.2%) patients were subsequently diagnosed with shunt malfunction. If there is persistent concern for shunt malfunction, a radionucleotide shuntogram may be done to further assess the patency of both the proximal and distal shunt catheters, as well as the integrity of the valve mechanism.

Shunt tap, performed selectively by the neurosurgical consultant, may be useful in patients in whom shunt function is questionable. Assuming the ventricular end is patent, the pressure in the system can be estimated by the level to which CSF rises when the butterfly tubing is held erect. Poor flow of CSF on shunt tap is highly predictive of proximal catheter obstruction, but both distal and proximal obstruction may still be present despite good CSF return. In patients with distal shunt obstruction, the need for emergency shunt revision is less because the ICP can be controlled by withdrawing CSF until a pressure of approximately 10 cm of water is reached.

The urgency of shunt revision depends on the patient's status. Patients with proximal obstructions may worsen quickly, and if the child suddenly deteriorates, CSF cannot be quickly withdrawn from the shunt reservoir to relieve pressure. In this instance, the ventricle must be tapped through the fontanel if open, through the sutures if they are split, or through the shunt burr hole. This latter maneuver usually damages the shunt and is only a temporizing measure to lower the ICP before definitive shunt revision. Acetazolamide is sometimes used to reduce CSF production in the chronic medical management of hydrocephalus. However, acetazolamide may

cause transient, paradoxical increases in ICP and should be avoided in patients with rapidly progressive hydrocephalus and signs of increased ICP.

Shunt Infection

Pathophysiology

The incidence of shunt infection is greatest in the first 8 weeks after surgery, with 90% of infections occurring in the first 6 months. *Staphylococcus aureus* infections are most common in the early postoperative period and gram-negative infections are more common after 6 months. However, approximately 75% of infections are caused by low virulence *Staphylococcus epidermidis*. These organisms secrete an extracellular polysaccharide "slime" substance that coats the shunt, making the enclosed colonies of organisms highly resistant to phagocytosis and systemic antibiotics.

Clinical Manifestations

In the immediate postoperative period, erythema and warmth along the course of the shunt are highly predictive of early wound infection. Infections are associated with fever in only 42% of patients which, if present, may be low grade and intermittent. Signs of obstruction may be present, but infection can and often does occur in the setting of a functioning shunt. When present, abdominal pain, peritoneal signs, and meningeal signs are strongly associated with infection. A rare presentation of shunt infection is glomerulonephritis, most commonly seen in association with ventriculoatrial shunts.

Management

The diagnosis of shunt infection requires CSF obtained from the shunt. However, there is some, albeit small, risk that tapping the shunt may cause an infection. Thus, shunt tap is not indicated in all children with a shunt who present with fever. A diligent search for alternative explanations of fever should be undertaken. Urinary tract infections are a particularly common cause of fever in children with myelomeningocele. Debilitated patients with severe developmental delay are at risk for pneumonia. Fever without localizing signs in patients whose current shunt was placed or revised years ago, and who lack signs and symptoms of shunt malfunction, may be appropriately managed with close follow-up or observation without shunt tap.

In patients with noncommunicating hydrocephalus, if the shunt tap is negative but a CNS infection is clinically suspected, a lumbar puncture is required because ventriculitis may not accompany meningitis. A false-negative shunt tap may also occur when children are on chronic antibiotics (e.g., child with myelomeningocele on antibiotics for urinary tract infection prophylaxis) or if the focus of infection is distal and below a one-way valve. In the latter case, identifying the infection may require exteriorizing of the shunt so that the intra-abdominal portion may be cultured.

CSF obtained from the shunt tap is sent for Gram stain, cell count, glucose, protein, and culture. If the CSF contains more than 100 cells per mm^3, cultures are positive in about 90% of patients. However, most infected shunts have only modest pleocytosis (less than 200 white blood cells per mm^3), slight decrease in glucose, and modest protein elevation. Blood cultures are infrequently positive.

If shunt infection is presumed, empiric treatment with broad-spectrum antibiotics is begun until specific organisms are identified and sensitivities are available. Patients may require either externalization of the abdominal catheter or complete removal of the shunt and a period of external drainage followed by placement of a new shunt into a different anatomic location.

STROKE

Stroke denotes a sudden onset of a persistent focal neurologic deficit, resulting from interruption of blood flow to a localized area of the brain. Pediatric stroke has a wide range of causes and risk factors distinct from those in adults, thus limiting comparison to stroke in adults. Strokes can be categorized into hemorrhagic or ischemic. Unlike the adult population, in which ischemic episodes account for 80% to 85% of strokes, approximately 55% of strokes in children are ischemic. Stroke is often undiagnosed or diagnosed late in its course. The ED physician must have a high index of suspicion for this condition.

Pathophysiology

Hemorrhagic strokes refer to spontaneous intraparenchymal hemorrhage and nontraumatic subarachnoid hemorrhage (causes of hemorrhagic stroke are listed in Table 126.3). Intraparenchymal hemorrhages are the result of bleeding from a ruptured blood vessel within the brain parenchyma and can result in progressive surrounding edema and focal mass effect. They are most often the result of anteriovenous malformation (up to 50%), followed by hematologic abnormality and hemorrhage into brain tumors. Congenital or acquired disorders, such as sickle cell disease, severe factor VIII deficiency, or severe thrombocytopenia, have been reported to be the major risk factor in 10% to 30% of hemorrhagic stroke in most series and may result in spontaneous intracranial bleeding with minimal or no preceding head trauma.

TABLE 126.3

CAUSES OF HEMORRHAGIC STROKE

Secondary hemorrhage into ischemic brain
Arteriovenous malformations
Vascular malformations
Sickle cell disease
Saccular (berry) aneurysms
Hemorrhage into intracranial tumor
Coagulopathy
Hemorrhagic disease of the newborn (vitamin K deficiency)
Clotting factor deficiency (VIII, IX, XI)
Thrombocytopenia
Arterial hypertension
Renal vascular or parenchymal disease
Coarctation of the aorta
Pheochromocytoma
Illicit drugs with sympathomimetic effect
Amphetamines, cocaine

TABLE 126.4

CAUSES OF ISCHEMIC STROKE

Moyamoya
Migraine
Thrombotic (arterial and sinovenous)
Hypercoagulable state, congenital or acquired protein C, S, antithrombin III deficiencies, factor V Leiden, prothrombin 20 210A mutation, oral contraceptives, anticardiolipin antibodies
Hyperviscosity (polycythemia, dehydration)
Genetic/metabolic

Nontraumatic subarachnoid hemorrhages are most often because of intracranial aneurysms. Ruptured aneurysms account for 10% of intracranial hemorrhage in children. About 5% of children with intracranial aneurysms will have more than one aneurysm. Congenital ruptured aneurysms may rarely occur as early as the first week of life. Bleeding occurs from an aneurysm located at branching points of the major arteries coursing through the subarachnoid space at the base of the brain. The incidence of aneurysm is increased in various congenital and hereditary conditions, including coarctation of the aorta, autosomal-dominant polycystic kidney disease, fibromuscular dysplasia, Ehlers-Danlos type IV, neurofibromatosis type 1, and Marfan syndrome.

Ischemic strokes include both arterial ischemic strokes (AIS) and cerebral venous sinus thrombosis (CVST). Ischemic injury to the brain occurs as a result of embolism from the heart or proximal circulation or from thrombosis in the arterial or sinovenous system. Almost half of all children with an ischemic stroke have a known risk factor. The most common risk factor (in about 25% of patients) is congenital heart disease. At least two-thirds of children will have one or more risk factors identified after an extensive workup (Table 126.4).

Clinical Manifestations

The diagnosis of stroke in children is often delayed by the failure to consider it, as signs and symptoms can be subtle and nonspecific. There are some generalizations that can be made as to how strokes present in children. Ischemic strokes most often present as a focal neurologic deficit. Hemiplegia is the most common focal manifestation, occurring in up to 94% of cases. Hemorrhagic strokes, on the other hand, most commonly present with headache or altered level of consciousness and are more likely to cause vomiting than ischemic strokes. Seizures are common, occurring in up to 50% of children with strokes.

There are significant differences in clinical presentation based on the age of the child: the younger the child, the more nonspecific his or her symptoms may be. Perinatal strokes may present with focal seizures or lethargy. Similarly, infants in the first year of life may present with apnea or hypotonia. In arterial dissection, patients may complain of sudden ipsilateral pain in the head, neck, or eye. There may be an associated Horner syndrome if the cervical sympathetic chain is involved. A bruit may be heard over the involved carotid. A posterior circulation stroke may result in vertebrobasilar insufficiency and cranial neuropathy, difficulties with balance and coordination, and tremor. After a subarachnoid hemorrhage (SAH), neck stiffness may be followed by lower back pain and radicular leg pain which may subsequently predominate as CSF circulates.

Management

The management of stroke in children is understudied and largely extrapolated from the adult literature and can be categorized into general supportive measures applicable to all types of strokes, diagnostic modalities, and stroke-specific treatment. It is prudent to have a stroke protocol in place.

General supportive measures include correction of hypoxemia, control of fever, normalization of serum glucose, and treatment of increased ICP. Judicious control of severe systemic hypertension is recommended. However, rapid reduction of blood pressure has been associated with worse neurological outcomes and larger infarcts in adults. There is no evidence to support prophylactic anticonvulsants in the absence of clinical or subclinical seizures in children with AIS, but they should be considered in children with hemorrhagic stroke and CVST.

The next priority is to exclude an acute intraparenchymal bleed or SAH. Non-contrast head CT is readily obtained, quickly completed, and sensitive for acute hemorrhage although the adult literature suggests that a lumbar puncture is still needed to exclude SAH not seen on CT. MRI is as good as CT for identifying hyperacute hemorrhage (less than 6 hours).

In ischemic stroke, CT may reveal low-density lesions within vascular territories in AIS and evidence of CVST. However, CT is usually normal within the first 12 hours after the onset of symptoms. CT angiography (CTA) may be used to identify arterial dissection. However, CTA requires larger radiation doses than standard CT. The contrast required may also limit the volume of contrast that can be safely administered for subsequent, more definitive delineation by catheter angiography (CA).

MRI should be performed if a hemorrhagic stroke is not found on CT. MRI is sensitive for ischemic stroke, even within a few hours of symptom onset. Magnetic resonance angiography (MRA) will yield further information about blood flow and vessel patency, and magnetic resonance venography (MRV) will more reliably identify CVST.

CA yields the most precise detail of vascular anatomy and affords the option of endovascular therapy. It will also identify specific signs of vasculitis or dissection and abnormalities in medium or smaller arteries, which MRA may miss. However, CA is an invasive procedure, less commonly performed in children, and has a similar diagnostic yield as MRI when combined with MRV and MRA. Other investigations to consider include ultrasound of the extracranial carotid circulation and echocardiography.

Once the type of stroke is identified, specific treatment is tailored to the etiology. In hemorrhagic stroke, coagulation defects should be corrected (see Chapter 91). Emergent splenectomy is indicated for intraparenchymal bleeding associated with idiopathic thrombocytopenic purpura. Recombinant factor VIIa is a promising therapy which promotes hemostasis and may stabilize intracerebral hematoma and reduce hemorrhage volume and improve clinical outcome.

Surgical management of hemorrhagic strokes is controversial. However, evacuation of a rapidly expanding hematoma causing cerebral herniation may be of benefit.

The goal of medical management of ischemic stroke is to preserve neurologic function and prevent recurrent stroke. Treatment may include short-term anticoagulation with low–molecular-weight heparin (LMWH) or unfractionated heparin. Although LMWH has reproducible pharmacokinetics and requires fewer monitoring tests, its effects cannot be completely reversed within minutes as it could be in someone who received unfractionated heparin. The loading dose of heparin is 75 units per kg intravenously over 10 minutes, followed by 20 units per kg for children older than 1 year of age, or 28 units per kg for children younger than 1 year of age titrated to a target partial thromboplastin time of 60 to 85 seconds. Alternatively, LMWH (enoxaparin 1 mg per kg subcutaneously for children more than 2 months of age, or 1.5 mg per kg for infants less than 2 months of age) may be given. It is prudent to start anticoagulation in children because the likelihood of a child having an underlying condition that would benefit from anticoagulation is high. Anticoagulation is also often used in children with arterial dissection, dural sinus thrombosis, or hypercoagulable disorders; in those at high risk of embolism; or in response to progressive deterioration during the initial evaluation of a new cerebral infarction.

The decision to use thrombolytic therapy in children with ischemic strokes must be made in a guarded and judicious manner. Although there have been anecdotal reports of successful endovascular thrombolysis in children, there are also reports of a high complication rate in children with systemic thromboses who receive tissue-type plasminogen activator (tPA) despite successful lysis of said thromboses. Published guidelines suggest that tPA may be considered in a select group of children with CVST, and that it would be most prudent to consider the same guidelines used in adults: administration of intravenous tPA within 3 hours of stroke onset and intra-arterial tPA within 6 hours of stroke onset for anterior circulation strokes. Delayed administration may lead to an unacceptable rate of intracerebral hemorrhage in children, as has been demonstrated in adults. Whether adult guidelines can be readily applied to older adolescents nearing adulthood is unclear, but there is as of yet little evidence to support the use of tPA in children outside of a clinical trial.

Rates of stroke in children with sickle cell disease (SSD) are much higher than in the rest of the pediatric population, and the management in this context requires specific considerations. In addition to supportive measures, ischemic strokes should be treated with hydration and simple or partial exchange transfusion to achieve a hemoglobin SS fraction of less than 30% and a hemoglobin level below 10 g per dL to avoid hyperviscosity. Evaluation for a structural vascular lesion in children with sickle cell disease and a hemorrhagic stroke is reasonable. Aneurysm is often present in adolescents with SCD and an SAH, and there is potential for rebleeding in these individuals. Evaluation with CA should be deferred until after reduction of the percentage of sickle hemoglobin because of concerns that CA might facilitate sickling.

CENTRAL NERVOUS SYSTEM INFECTIONS

Infection of the CNS, including subdural empyema, brain abscess, bacterial and viral meningitis, and viral encephalitis, are often associated with some degree of increased ICP. Acute hydrocephalus may complicate tuberculous, fungal, amebic, and rarely bacterial meningitis. Subdural empyema and epidural abscess may occur as a complication of parameningeal infections (e.g., sinusitis, orbital cellulitis, or mastoiditis) and are true neurosurgical emergencies, often progressing to death if not recognized early. Children with CNS infectious processes may present with fever, evidence of meningeal irritation, seizures, increased ICP, focal neurologic findings, and herniation.

Management

Supportive care and antibiotics are the first priority in treatment of suspected meningitis. Lumbar puncture should be deferred in patients with cardiorespiratory instability, signs of impending herniation, papilledema, or focal neurologic deficits. A CT may identify acute brain edema or other signs of increased ICP, but a normal CT scan does not eliminate the possibility that ICP is increased. Normal CT scans have been seen in patients with fatal herniation. MRI may be more sensitive than CT for identifying potential complications of meningitis, such as infarction, ventriculitis, and venous sinus thrombosis. If a subdural empyema or brain abscess is suspected, a contrast-enhanced CT may be helpful. However, MRI is more sensitive for identifying this intracranial complication, particularly the early cerebritis phase of brain abscess and those located in the brain stem or posterior fossa.

Subdural empyema requires immediate surgical drainage. For brain abscess, closed-needle drainage with stereotactic CT guidance permits precise targeting of small lesions. This technique allows rapid relief of mass effect by removing purulent material and provides a specimen for culture and sensitivity testing to guide subsequent antibiotic therapy. The use of corticosteroids for treatment of brain abscess is controversial because of concerns related to decreasing antibiotic penetration and inhibition of leukocyte migration and host defense mechanisms. However, steroids may be selectively used to control life-threatening intracranial hypertension due to mass effect and edema.

BRAIN TUMORS

Brain tumors account for nearly 20% of all cancers in children, second only to leukemia. Early signs and symptoms are often attributed to benign causes resulting in delayed diagnosis.

Pathophysiology

The most common pediatric brain tumors are gliomas, primarily astrocytomas. The majority are infratentorial and arise in the posterior fossa. The clinical features can be either generalized, resulting from elevated ICP due to mass effect, edema, or obstructive hydrocephalus; or focal, resulting from mass effect on specialized brain regions.

Clinical Manifestation

Early signs and symptoms are often nonspecific, and neurologic abnormalities may be subtle. Behavioral symptoms account for up to one-fifth of initial symptoms in children. Isolated persisting vomiting and vomiting on awaking, due to position change, is ominous. Headaches associated with intracranial mass lesions may be nonspecific but are usually of recent onset. Other predictors of surgical space-occupying lesions include absence of a family history of migraine; sleep-related headache (headache either wakes child from sleep or is present immediately on awakening); confusion; and an abnormal neurologic examination.

Physical examination should include fundoscopy to look for papilledema, cranial nerve examination for palsy, and search for focal motor deficits and ataxia. Acute symptoms may result from seizure, acute intracranial hypertension with pressure waves, or acute obstructive hydrocephalus or hemorrhage into tumor.

Management

Most children who require emergent management for tumor-related obstructive hydrocephalus, mass effect, and hemorrhage are recognized using noncontrast CT. In the stable patient who does not require sedation, when local resources permit, one may consider obtaining an MRI as the first-line imaging study. MRI is more sensitive than CT in identifying small brain tumors, particularly in the posterior fossa and is useful for identifying other potential pathologies that may be responsible for the presenting symptoms, including hyperacute hemorrhages. MRI will eventually be necessary for definitive management. Dexamethasone may be useful in treating increased ICP before surgery.

SPINAL CORD COMPRESSION

Nontraumatic acute spinal cord compression is relatively uncommon but will result in devastating sequelae if not considered early and diagnosed promptly. In children, it occurs most frequently with paravertebral neoplasms. Back pain in a child with known cancer should raise concern for cord compression until proven otherwise.

Pathophysiology

Spinal cord compression may be caused by paravertebral neoplasms or vertebral metastases; spinal epidural or, rarely, subdural, abscesses; epidural hematoma; central disc herniation; or congenital tethered cord. Spinal epidural abscesses (SEA) occur most frequently in children younger than 2 or older than 12 years of age. SEA is most frequently caused by seeding in the epidural space following hematogenous spread from a distant infectious focus including cellulitis, tonsillitis, and pneumonia, or in association with IV drug abuse.

Clinical Manifestations

Back pain in children commonly signals an important diagnosis. A history of localized or radicular back pain or refusal to walk mandates a careful evaluation. Radicular pain may misdirect the clinician depending on the nerves involved, manifesting instead as hip, extremity, or abdominal pain. The back pain of SEA in older children may be excruciating, causing them to lie absolutely still. Younger children may present with a nonspecific reluctance to lie prone. A history of change in gait or difficulty with bowel or bladder control should be sought. The level of maximal spinal tenderness is usually the site of pathology. Deep tendon reflexes, Babinski reflex, motor strength, sensation, and anal sphincter tone should be assessed.

Management

Blood cultures may help guide antibiotic therapy during hospitalization. If SEA is suspected, a lumbar puncture should not be performed, as it does not significantly contribute to the diagnosis and may spread bacteria into the subdural or subarachnoid space. Plain radiographs of the spine may show evidence of osteomyelitis or vertebral abnormalities but will miss significant pathology. Therefore, emergent MRI should be carried out to identify the cause and degree of spinal compression. The entire spine should be imaged as metastases or abscesses may be seen in multiple places.

Tumor-related cord compression with neurologic deficits mandates immediate treatment. Prompt initiation of high-dose corticosteroid therapy is indicated. Additional treatment options include decompressive surgery, radiation therapy, and chemotherapy. Abscess formation, subdural or epidural hemorrhage, and symptoms related to cord tethering are usually indications for surgical intervention.

CHAPTER 127 ■ OPHTHALMIC EMERGENCIES

ALEX V. LEVIN, MD, MHSC, FRCSC

Many ocular disorders in children may be seen first by the pediatric emergency physician. Although ophthalmology consultation is necessary in some cases, some problems can and should be treated by the emergency physician. This chapter provides the emergency physician with a basic foundation for the diagnosis and treatment of common pediatric eye emergencies.

EXAMINATION

Many children regard eye examinations and eye drops with the same fear that they harbor for injections. Therefore, it is important to gather as much information as possible before touching the patient or instilling eye drops. This can be accomplished by turning the initial parts of the eye examination into a game, using toys and distracting stimuli, and exploiting the full potential of the direct ophthalmoscope, the main instrument for ophthalmic examination available to the pediatric emergency physician.

A detailed history can be a valuable tool in focusing the examination and making a diagnosis. Questions regarding unilaterality/bilaterality, acute/chronic onset of symptoms, and prior ophthalmic care are particularly helpful. Perhaps the child is known to have an eye with poor vision. Even if the parent does not know that this is the case, a history of having one eye patched for a visual problem suggests that the unpatched eye had amblyopia. If a child has previously passed his or her visual screening examination at school, this does not necessarily imply that the vision was normal because false-negative tests are well known to occur. The child may also be unaware of having poor vision in one eye because the pediatric brain is able to suppress recognition of the blurred image and focus solely on the clear image, allowing the child to proceed with normal activity unaware of the unilateral visual deficit.

The examiner starts the evaluation either by testing visual acuity in children who are readily verbal and interactive, or by using other techniques in children who need to be "warmed up." In the latter case, it is often useful to start with assessment of the extraocular muscle movements. This procedure is discussed in Chapter 23. By using a toy or another interesting hand-held object, the physician can distract the child to look in the direction in which the object is placed. Both eyes should move equally, quantitatively and qualitatively, in all directions. The examiner should test up, down, left, and right gaze.

The examiner can use the direct ophthalmoscope as a tool to accomplish several tasks without touching the child. The direct ophthalmoscope light may be useful as a fixation target in testing eye movements. It can also be used to assess whether the eyes are aligned (Hirschberg light reflex test, see Chapter 23) and to test for a red reflex (see Chapter 117). In addition, the ophthalmoscope can be used as a simple hand-held magnifier by viewing through the ophthalmoscope and dialing the focusing wheel in the direction of the black or green numbers. This allows the eyeball to come into focus regardless of the distance between the examiner and the patient. The closer one gets, the higher the black or green number needed on the focusing wheel, and the greater the magnification. The examiner can perform this maneuver with or without his/her own glasses on.

Visual acuity testing is usually performed at a distance of 20 ft or 10 ft. Most standard wall charts are calibrated to be read at 20 ft. If space does not permit this distance to be used, the patient can be placed 10 ft from the chart and the results interpreted with an adjustment for this distance. For example, the line marked 20/60 on the chart (a line that a person with normal sight can see at 60 ft, but a person with that visual acuity would need to stand at 20 ft to see) becomes a 20/30 line at a distance of 10 ft. In some centers or with some vision charts, the metric system is used with 20 ft being equivalent to 6 m. As examples, vision of 20/20 is written as 6/6, 20/30 as 6/9, and 20/200 as 6/60.

Chart selection is important when trying to obtain an accurate visual acuity. Letter charts should be used only for patients who can clearly recognize the alphabet. If there is any question by parental report, a number or picture chart (Fig. 127.1) should be used. The patient may be asked to walk right up to the chart to identify the letters, numbers, or pictures. If the patient can perform this task, the chart may then be used for distance testing. Some children give remarkably unique interpretations of the pictures (e.g., calling the birthday cake a bag of French fries). When using picture charts that have colored figures, the examiner should avoid using those figures that are yellow because the bright illumination of the emergency department (ED) lessens the contrast between these figures and the white chart background, thus making recognition more difficult. The "tumbling E" chart is not recommended in young children as it may be too complex for their developmental level and requires some sense of handedness, which is not developed until an age when they should easily be able to perform the other tests. This chart is more useful for older non–English-speaking children and illiterate adults. It is sometimes referred to as the "illiterate E" test.

A useful option for children who are not "in the mood" to verbalize their responses or are very shy is the use of matching acuity chart systems. The two most common are the Sheridan Gardiner (Keeler Instruments, Inc., Broomal, PA) and HOTV (Precision Vision, La Salle, IL). In both situations, the child is holding a card that has all of the letters that are on the posted or hand-held chart 10- or 20-ft away. The child need not know letters but can identify them as shapes. For example, the H can be called a little ladder and the O a circle. Instead of verbally

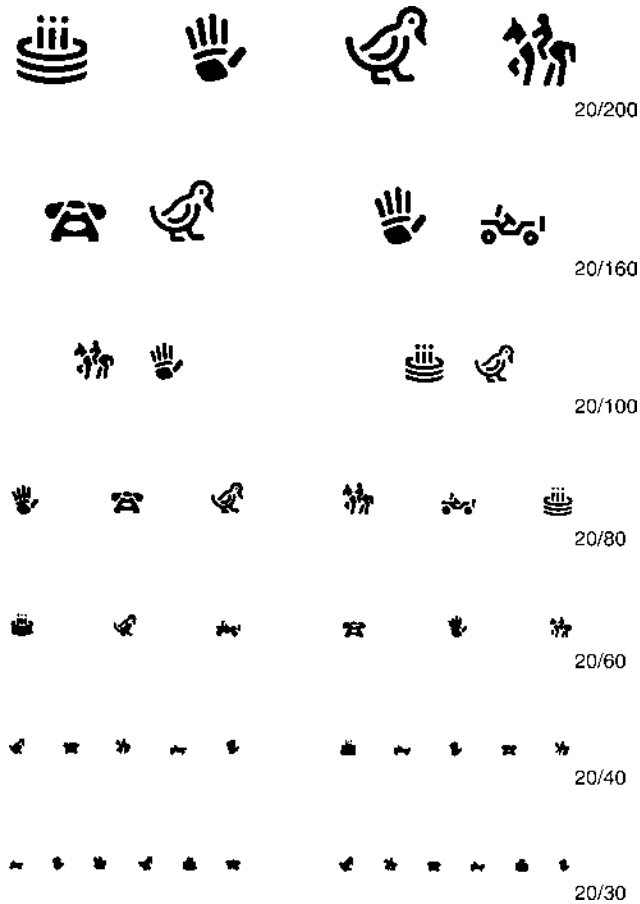

FIGURE 127.1 Picture visual acuity chart.

responding, the child points to the matching shape (letter) on the card he/she or his/her parent is holding. EDs can even make their own hand-held card to match whatever wall chart they have posted to accommodate to children in this younger age range where matching is more easily accomplished than verbal response.

When using any visual acuity chart, it is not necessary to start with the largest symbol and have the patient read every symbol on every line thereafter. Doing so risks losing the child's attention. Rather, one can start with the 20/20 line and then go to larger lines if the child is having trouble. The child needs to recognize only a few letters on each line. Minor errors such as the substitution of the letter F for the letter P, or the letter C for the letter O, may be tolerated.

It is almost an instinct for young children to use their better eye and suppress the vision in their lesser eye. Therefore, if the good eye is covered inadequately, the patient will naturally try to read the chart with what the examiner thought was the covered eye. Children should never be allowed to cover their eye with their own hand because the small cracks between the fingers can actually allow vision out of the "covered" eye and even improve that vision by the pinhole effect (see Chapter 117). Children may also look around commercially available occluders for the same reasons. Perhaps the best way to obstruct the vision in the eye not being tested is to use a broad piece of tape, ensuring the tape also covers the depression at the bridge of the nose (Fig. 127.2). To help ensure the patient

FIGURE 127.2 A broad piece of tape can be used to obstruct the vision of the eye not being tested. If the tape is not adherent to the bridge of the nose, the child can peek out by turning the face to the side (**right frame**).

is not "cheating," the examiner should stand by the chart indicating the letters or pictures while looking back at the child.

Any child who shows a reduced visual acuity should be offered the pinhole test. If the patient is unable to identify any object or picture on the chart, the examiner should at least try to determine whether vision is present. After external examination and visual acuity are completed, the examiner can then proceed with other procedures as indicated, such as upper lid eversion and dilating the pupil. These techniques, along with the proper methods of examining the retina and optic nerve using the direct ophthalmoscope, are discussed in Chapter 117.

One circumstance that may present an obstacle to proper examination of the eye is the situation in which the eyelids are swollen or the patient refuses to voluntarily open the eyelids. The techniques described in Chapter 117 for opening the traumatized eye may be useful. Commercially available speculums, when used in association with a topical anesthetic, are a painless and efficient way of opening the eyelids (see Chapter 117, Fig. 117.5). If these are not available, either a Desmarres retractor (see Chapter 117, Fig. 117.6) can be used or a similar device can be fashioned out of paper clips (Fig. 127.3). These types of single-blade retractors are most helpful when used on the upper eyelid (see Chapter 117, Fig. 117.6). A retractor can also can be applied simultaneously to the lower eyelids, although this often requires an extra assistant if there is a problem holding the child still while the eyelids are retracted. When paper clips are used, it is important to inspect the paper clip after bending. Some paper clips have a coating that may become fragmented, potentially causing particles that could be dispersed to the conjunctiva or cornea as tiny foreign bodies. Eyelid speculums and retractors should be sterilized between patients. Paper clip speculums are designed for single usage and may be prepared by cleansing with an alcohol swab.

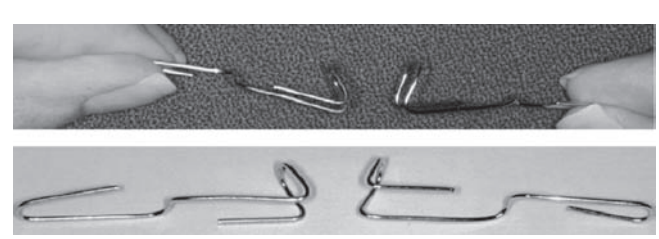

FIGURE 127.3 Paper clips can be bent into a retractor to open the eyelids.

In infants, the eyelids may be separated by using cotton swabs. The swabs should be placed at the midbody of the upper and lower eyelids. As they are separated, pressure should be applied down against the eyelid and the swab should be rotated inward toward the eyelashes. This will keep the eyelids in place so they do not spontaneously evert and further obstruct the examiner's view. When long cotton swabs are used, the stick should be grasped close to the patient to prevent breakage when pressure is applied. The cotton swab technique should not be used in patients being evaluated for eye trauma because pressure on the eyeball from this technique could cause further injury (see Chapter 117).

COMMON EYE EMERGENCIES

The pediatric emergency physician is called on to care for a number of eye problems. The reader is referred to other sections of this book for discussions of eye injuries (see Chapter 117), red eye (see Chapter 23), disorders of the eye muscle movement and strabismus (see Chapter 24), iritis (see Chapters 23 and 117), and unequal pupils (see Chapter 25).

Periorbital and Orbital Cellulitis

Clinical Manifestations

The primary concern when making the diagnosis of periorbital cellulitis (preseptal cellulitis) is to rule out the possibility of orbital cellulitis. The cardinal signs of orbital cellulitis include decreased eye movement, proptosis, decreased vision, and papilledema (or other signs of optic nerve involvement such as decreased color vision, visual field defects, or Marcus Gunn pupil). Both orbital and periorbital infection may be associated with fever, pain, swollen eyelids, and red eye. If orbital cellulitis is suspected, computed tomography (CT) scanning of the orbit is indicated, keeping in mind that a CT scan taken in the first 24 to 48 hours of infection can appear normal. Clinical examination is therefore very important. Ophthalmology consultation is indicated in all cases of suspected or proven orbital cellulitis. Surgical intervention may be required. Otorhinolaryngology consultation should also be considered when orbital cellulitis is secondary to contiguous sinus infection.

Historical and clinical information can also be helpful in establishing the probable bacterial etiology of the infection. Infection secondary to a bug bite or other skin wound that may have served as a route of entry for local bacteria is more often caused by staphylococci or streptococci. The bluish hue of the periorbital skin that is sometimes attributed to *Haemophilus influenzae* is not a specific or sensitive indicator. In fact, since the introduction of the *H. influenzae* type b vaccine in 1985, the incidence of this pathogen as a cause for periorbital or orbital cellulitis has dropped substantially. It is now an uncommon cause.

One must rule out other conditions that can mimic a periorbital cellulitis. Insect bites and allergic reactions can cause dramatic acute periorbital swelling. These conditions are not usually associated with fever. Often, close inspection of the skin with magnification (using the direct ophthalmoscope) can localize the site of an insect bite. Allergic swelling is often bilateral, whereas periorbital cellulitis is rarely bilateral. Underlying sinusitis can also cause periorbital swelling. Some authors have argued that CT scan evaluation of the sinuses is indicated in all cases of presumed periorbital cellulitis but this is not common practice in many centers. Severe conjunctivitis, especially adenoviral infection and neonatal gonorrhea conjunctivitis, can also result in significant lid swelling. The presence of conjunctival discharge is helpful in making these diagnoses. Contiguous spread of conjunctival infections to the periorbital tissues can occur, and one must be careful about falsely eliminating the diagnosis of periorbital infection based on the presence of conjunctivitis.

Management

There is some controversy about the appropriate route of antibiotic administration in periorbital cellulitis. When *H. influenzae* was more common with the risk of hematogenous spread, it seemed prudent to use intravenous (IV) antibiotics. Clinicians have generally become more liberal with oral antibiotic treatment now that the risk of *H. influenzae* has declined. In otherwise well children who are beyond infancy and have mild periorbital cellulitis and no systemic signs or symptoms, particularly when the cause of the cellulitis is believed to be a skin wound, intramuscular and/or oral antibiotics may be tried. The patient should be seen again (or with telephone follow-up) within 24 to 48 hours, at which time improvement should be documented. If no improvement occurs, the patient could then be admitted for IV antibiotics. Clinical scales are available for assessing the patient's status and response to treatment. Periorbital cellulitis is a potentially fatal disease because complications such as meningitis may develop if inadequately treated. All cases of orbital cellulitis must be treated with IV antibiotics.

The choice of antibiotics should reflect the probable causative organism. Antibiotic coverage that would be used for presumed sepsis in an immunocompetent host with an unknown organism is usually appropriate. Before starting IV antibiotics, blood culture should be obtained. Other systemic cultures (e.g., cerebrospinal fluid, urine) may be indicated if signs of systemic toxicity are present. Percutaneous aspiration from the area of cellulitis is not recommended. Conjunctival cultures do not necessarily identify the causative agent of the cellulitis, but it may be reasonable to treat a predominant organism, particularly if purulent conjunctivitis is present. The patient should be monitored daily for signs of orbital cellulitis if there is no improvement.

Chalazions and Styes

Clinical Manifestations

Chalazion (internal hordeolum) and stye (external hordeolum) represent blocked glands within the eyelids. Both may present acutely with localized lid swelling, erythema, and tenderness. Styes are associated with swelling and purulent drainage at or near the lid margin (Fig. 127.4, see also color plate). More than one lesion may occur simultaneously, and more than one lid may be involved. Acute chalazion causes swelling and redness in the body of the eyelid and may be associated with drainage on the conjunctival surface of the eyelid with or without a red eye. They may also point and drain via the skin (Fig. 127.5, see also color plate). A chalazion may enter a chronic phase in which there is a nontender, noninflamed, mobile pea-size nodule within the body of the eyelid (Fig. 127.6). History

FIGURE 127.4 Acute sty (external hordeolum).

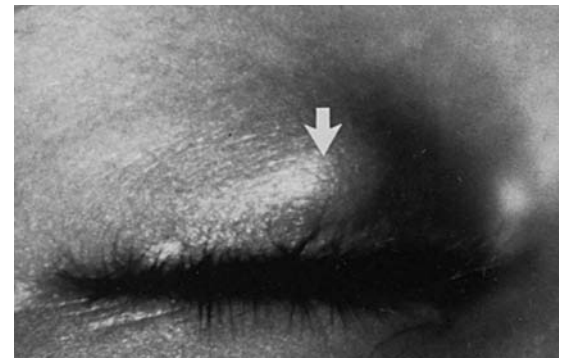

FIGURE 127.6 Chronic chalazion *(arrow)* within upper lid.

can be helpful in establishing these diagnoses because patients often have had recurrent lesions in the same or other eyelids.

Management

The treatment for both chalazion and stye is essentially the same. Eyelash scrubs with baby shampoo once or twice daily are helpful in mechanically establishing drainage. Baby shampoo is applied to a washcloth and then used to gently scrub the base of the eyelashes while the eyelids are shut. Some authors prefer cotton swabs for this procedure but this raises the risk of a swab injuring the eye if the swab slips between the lids. Warm compresses over closed eyelids are also sometimes recommended, but rarely tolerated well by younger children. Optimally, warm compresses should be applied four times daily for 10 to 20 minutes at each sitting. This is very difficult to accomplish. Antibiotics probably play a minimal role in the treatment of stye and chalazion. If desired, a topical antibiotic ointment with coverage for coagulase-negative staphylococcal species (Table 127.1) can be given twice daily following eyelash scrubs. If medical treatment has failed to cause adequate resolution after at least 4 weeks, surgery can be offered either for cosmesis or for uncomfortable lesions. In severe recurrent cases, particularly when associated with red eye or facial rosacea, oral erythromycin or tetracycline (only for patients older than 8 years) may be tried, although at this stage ophthalmic consultation should be obtained.

FIGURE 127.5 Chalazion draining spontaneously via skin.

Chemical Injury

Clinical Manifestations

When the child has a clear history of a noxious substance coming in contact with the ocular surface, it is important to determine whether this substance is an acid or an alkali. Alkali injuries tend to be much more severe as they can cause aggressive tissue necrosis. It is also important to determine whether particulate matter may have been deposited on the ocular surface. Smoke can also cause chemical conjunctivitis, particularly in house fires when chemicals are liberated into the air from the burning of

TABLE 127.1

PEDIATRIC EMERGENCY DEPARTMENT OPHTHALMIC DRUG GUIDELINES

Use	Avoid
Dilating drops	
Phenylephrine 2.5%	Scopolamine
Tropicamide 1%	Atropine
Cyclopentolate 1%	Homatropine
	Cyclopentolate 2%
Antibiotics	
Bacitracin ointment	Neomycin
Erythromycin ointment	Sulfacetamide
Polysporin drops or ointment	Aminoglycosides (except neonate)
Polytrim (trimethoprim/polymyxin B) drops	Quinolones
Lubricants	
Artificial tear drops or ointment	
Vasoconstrictors/antihistamines (e.g., naphazoline/antazoline)	
Diagnostic agents	
Topical fluorescein	
Anesthetic agents	
Proparacaine, tetracaine (DO NOT PRESCRIBE)	Cocaine
AVOID ALL ANTIVIRALS, MIOTICS (see Chapter 26), STEROIDS,[a] and ANTIGLAUCOMA AGENTS.	

[a]Including steroid-containing preparations, such as combination antibiotic-steroids.

plastics and other substances. Foreign bodies due to ashes and other particulate matter in the smoke are not uncommon.

The examiner must also assess the degree of exposure. If a child has no symptoms (pain, photophobia) or signs (red eye, epiphora, conjunctival swelling) and a weak history of actually getting the chemical into the eye, it may be acceptable to avoid lavage.

Management

Chemical injury to the eyeball is a true ocular emergency. Immediate intervention by ED personnel is essential to improving the patient's prognosis. Any patient with sufficient history should be immediately placed in the supine position, even if some level of restraint is needed, so ocular lavage may be started. Ocular lavage can often be frightening to a child. If sedation can be administered promptly, it may be helpful. The physician should never wait for the effects of sedation before proceeding with lavage. Although a drop of topical anesthetic can make this procedure more comfortable, the physician should not wait for this to become available if it is not immediately handy. Usually, the irrigating solution itself will induce cold anesthesia. If a speculum, Desmarres retractor, or paper clip is readily available (see above), this may be used to help obtain optimal exposure of the ocular surface. Commercially available irrigation lenses achieve similar results but often at greater monetary cost. Again, the physician should not wait for these to become available.

Virtually any IV solution can be used for ocular lavage, although normal saline solution or Ringer's lactate is perhaps preferable (although there is some controversy). A standard IV bag and tubing set is used without a needle on the end. Rather, the solution is allowed to flow, with the system at its maximum flow rate, across the surface of the open eye from medial to lateral. If both eyes have been exposed, they should both be lavaged simultaneously with two separate setups. Lavage should be continued until the involved eye(s) has received either 2 L of fluid or until approximately 20 minutes has elapsed. Lid eversion should be performed (see Chapter 117, Fig. 117.12), and lavage should be continued with the lid in this position so that the conjunctiva under the upper lid may also be cleansed. Mechanical debridement should be limited to the removal of visible particles from the ocular surface.

It is useful to have a strip of standard litmus paper available in the ED. The litmus paper is touched against the surface of each conjunctiva before beginning lavage. The pH is noted and the lavage is continued if, after the required minimum time/volume, the pH has not become normal (6.5 to 7.5) and equal between the two eyes. The end point of equality should only be used if one eye has not been exposed to chemical injuries. The conjunctiva under the upper lid may also be tested separately because noxious material can be harbored in the recess above the eye under the lid.

Ophthalmology consultation is usually indicated in cases of significant chemical injury. The consultant should be notified while lavage is ongoing. Do not delay lavage while awaiting the arrival of the ophthalmologist. In cases of minor exposure to substances that are clearly not alkaline or strongly acidic, and when the eye is not injected, an ophthalmology consultation may be deferred or may not be necessary, but emergency physicians must be cautious about the absence of conjunctival injection because alkali burns can cause blanching of the conjunctiva, which is a poor prognostic sign.

Conjunctivitis

Clinical Manifestations

Chapter 23 provides an approach for eliminating other causes of red eyes from the differential diagnosis. Table 127.2 is designed to give some additional help in differentiating causes

TABLE 127.2

DIFFERENTIAL DIAGNOSIS OF CONJUNCTIVITIS

of conjunctivitis. The patient's age is often useful in determining a diagnosis. Neonates presenting in the first 3 days of life can have a chemical conjunctivitis caused by silver nitrate used for ocular prophylaxis perinatally. Almost all hospitals should have now discontinued this practice, and instead should be using erythromycin ointment or dilute betadine solutions. No prophylaxis is completely effective in eliminating subsequent gonorrheal or chlamydial conjunctivitis in the neonatal period. These two forms of conjunctivitis, as well as bacterial conjunctivitis often secondary to enteric organisms, can be difficult to distinguish clinically. Each can present as either a mild purulent form or more severe acute purulent conjunctivitis. A dramatically hyperacute conjunctivitis with significant lid swelling and copious purulent ocular discharge is more characteristic of gonorrhea (Fig. 127.7, see also color plate). In view of the risk of spontaneous corneal perforation associated with gonorrhea conjunctivitis, infants should be presumed to have this infection until proven otherwise. Immediate Gram stain should be performed looking for gram-negative diplococci. If present, treatment for gonorrheal conjunctivitis should be started emergently while awaiting culture results.

In this age group, chlamydia studies may also be useful. Conjunctival scrapings are useful to look for inclusion bodies of chlamydial conjunctivitis. However, the sensitivity of this test depends on sampling, and the techniques may not be readily available or properly performed. Other methods to detect chlamydia must always be used. Although rapid slide methods are approved for conjunctival samples, chlamydia cultures are preferred because they increase diagnostic sensitivity. Even if chlamydia is detected by Giemsa staining, this does not rule out the presence of concomitant gonorrheal infection.

In children beyond the neonatal period, a wide range of organisms, both viral and bacterial, as well as chlamydia, can cause conjunctivitis. Clinically, these entities may be indistinguishable. In general, purulence is more characteristic of bacterial infections, whereas clear serous discharge is more characteristic of viral infection. Although both viral and bacterial conjunctivitis may be unilateral or bilateral, a history of multiple infected contacts argues in favor of a viral etiology. Likewise, dramatic lid swelling associated with preauricular adenopathy, mucoid or serous discharge, and perhaps an uncomfortable, sandy, foreign-body sensation is strongly suggestive of epidemic keratoconjunctivitis secondary to adenovirus. This fulminant viral infection is usually easy to recognize (Fig. 127.8, see also color plate). Rapid tests for adenovirus are now available. Infectious conjunctivitis may present as a unilateral or bilateral disease, but consecutive involvement of one eye and then the other is particularly suggestive. Viral culturing is rarely necessary. Bacterial cultures should be considered in cases of purulent conjunctivitis, particularly when antibiotic treatment is going to be instituted.

Non seasonal acute allergic conjunctivitis is usually a hyperacute conjunctival injection associated with tearing and a blister-like swelling of the conjunctiva (chemosis) (Fig. 127.9). Itching is often a prominent symptom, although this may also be a symptom of blepharitis (see Chapter 23). Conjunctival smears stained with Gram or Wright methods may reveal abundant eosinophils.

FIGURE 127.8 Patient with right epidemic keratoconjunctivitis infection. Note the lid swelling, red eye, and absence of purulent discharge. Patient also has right preauricular adenopathy (not visible). Note the early injection of left eye, representing sequential involvement.

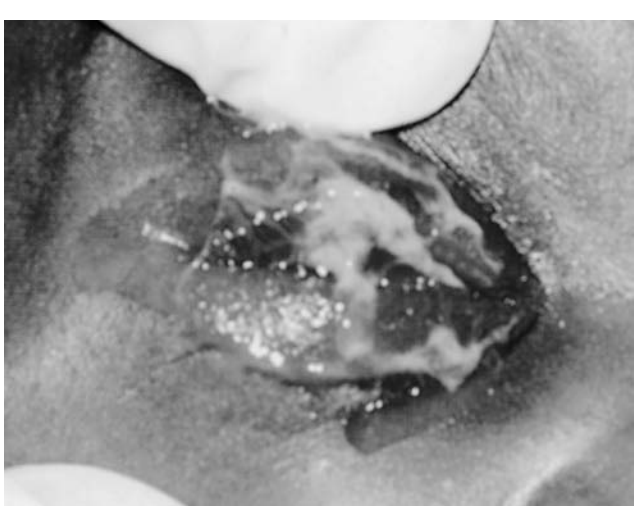

FIGURE 127.7 Neonatal gonorrheal conjunctivitis. Note the dramatic lid swelling and severe purulent discharge.

FIGURE 127.9 Non seasonal acute allergic conjunctivitis. Acutely swollen conjunctiva (chemosis) is indicated *(arrow)*.

FIGURE 127.10 Left nasolacrimal duct obstruction. Note discharge on medial lower lid and wet lower lid lashes. The conjunctiva is noninflamed (no "red eye") indicating that the child does not have conjunctivitis.

Nasolacrimal duct obstruction is often confused with conjunctivitis because discharge may be present, but the conjunctiva is rarely inflamed (i.e., no "red eye"), indicating the absence of true conjunctivitis (Fig. 127.10, see also color plate). The discharge is mostly mucus that has precipitated out of the tear film because of stagnation of tear flow. Patients are usually younger than 1 year, with a history of symptoms dating back to the first weeks of life. The discharge is usually worse on waking. Crusts may form on the lashes (Fig. 127.10). Chronic skin changes of the lower lid will develop over time. Tearing may become more prominent after the first few months of life. Older children often have epiphora without discharge. The diagnosis can be confirmed by placing pressure on the lacrimal sac, which lies under the skin against the lacrimal bone between the medial canthus and bridge of the nose. This maneuver may cause an increase in the amount of discharge as it is forced out of the sac back onto the surface of the eye via the medial upper and lower lid margin puncta.

Management

Until proven otherwise, and in the presence of gram-negative diplococci, neonatal purulent conjunctivitis should be treated as gonorrheal conjunctivitis, pending the results of cultures. The patient should be admitted for parenteral antibiotic therapy with cephalosporin (ceftriaxone 25 to 50 mg per kg, maximum 125 mg, intramuscularly or intravenously as single dose, or cefotaxime 100 mg per kg intramuscularly or intravenously as single dose), particularly in areas where penicillinase-producing strains are common. Ophthalmology consultation is indicated. Saline ocular lavage on an hourly basis may be helpful in decreasing the amount of organisms having access to the cornea. Topical erythromycin ointment is helpful because it will also treat chlamydia, but topical treatment alone is insufficient for either organism. If chlamydia is laboratory proven, then the child must also receive a 14- to 21-day course of oral erythromycin. This is necessary to eradicate carriage of chlamydia in the nasopharynx, which can subsequently lead to pneumonitis. The mother and father should also be tested for any sexually transmitted disease found in the child. The child should be tested for other sexually transmitted diseases. Consideration of possible covert sexual abuse should be given for postneonatal, prepubertal children with gonorrhea or chlamydia conjunctivitis, although there is evidence that nonsexual transmission to these sites may occur (unlike infection of the vagina, urethra, anus, or throat).

Any of the topical antibiotics suggested in Table 127.1 would be appropriate for empiric coverage in treating a presumed bacterial conjunctivitis other than gonorrhea while awaiting culture results. Gram stain can be helpful when narrowing down the possible causes, particularly when sheets of one predominant type of organism are seen. In the first 3 months of life, topical aminoglycosides might be a reasonable choice because gram-negative and enteric organisms are more common. In older children, without strong evidence to suspect such organisms, aminoglycosides should be avoided because they may be toxic to the corneal epithelium and may select for resistant organisms.

If the patient clearly has a viral conjunctivitis, antibiotic treatment is probably not needed. Some physicians use antibiotics to "prevent secondary infection." This is not a clinically significant problem in immunocompetent children. Rather, these patients are best soothed with cool compresses and over-the-counter artificial tear preparations. Depending on the virus, symptoms may last for up to 2 to 3 weeks. Patients with symptoms that appear to be getting worse or persisting for longer than 1 week may benefit from ophthalmology consultation.

Allergic conjunctivitis is soothed by topical lubricants and cool compresses. The combination vasoconstrictor/antihistamine preparations listed in Table 127.1 may also be prescribed. Patients with recurrent allergic conjunctivitis, atopy, or asthma may benefit from long-term or seasonal topical mast cell stabilizers. A host of antiallergy eye drops are now available, the review of which is well beyond the scope of this chapter. Ophthalmology consultation may be useful, especially when symptom relief is not obtained or pain and red eye are present. Steroids should not be used without ophthalmology consultation.

Any patient with a history of herpetic ocular infection, should be referred immediately for ophthalmology consultation. Herpetic corneal infection is usually painful. Patients may or may not have a history of skin lesions. Characteristic fluorescein dendritic staining patterns can be seen on the cornea or conjunctiva (Fig. 127.11, see also color plate). Even if there is no staining

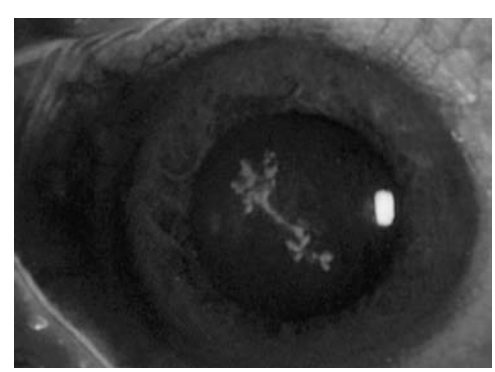

FIGURE 127.11 Fluorescein staining pattern of herpes simplex virus corneal infection. Eye is illuminated with blue light to demonstrate yellow/green branching fluorescein staining pattern of herpetic dendrite.

but a history of herpetic (varicella-zoster or simplex) corneal infection, urgent ophthalmology consultation is essential. Skin lesions on the lids without any conjunctival injection do not require ophthalmology consultation.

Any patient who wears contact lenses and has conjunctivitis, should be referred immediately for ophthalmology consultation.

DRUGS

Table 127.1 is designed to give emergency physicians some guidelines regarding the prescription and use of ophthalmic medications. Those drugs that should be avoided are listed because of problems with ocular toxicity, systemic toxicity, undesirable selection of resistant organisms, or the need for ophthalmology consultation and management regarding the problem that those drugs are designed to treat. In addition, emergency physicians are advised to follow these guidelines:

1. No topical drugs should be prescribed to patients who wear contact lenses without the supervision and consultation of an ophthalmologist.
2. Topical anesthetics must never be prescribed for outpatient use. These are strictly diagnostic agents. Prolonged use of topical anesthetics may result in corneal ulceration.
3. Steroids should never be prescribed by the emergency physician. Inappropriate use of steroids may lead to glaucoma, cataract, increased severity of corneal viral infection, or rebound symptoms when the drug is discontinued.

Instillation of eye drops can sometimes be difficult because of swollen eyelids or noncompliance from the patient. Some of the drop is often expelled upon blinking after drop instillation. This is not an indication for repeat instillation because only approximately 20% of an eye drop is actually absorbed for use. Ophthalmic solutions are designed for a one-drop dose. Drops are most efficiently delivered by pulling down the lower eyelid and placing the drop in the inferior fornix. In patients who are extremely resistant, forced eyelid opening is needed to expose just a small strip of palpebral conjunctiva. The eyeball itself does not need to be visualized. The same techniques described previously and in Chapter 117 for opening the eyelids may be used for the administration of eye drops in the ED. An alternative technique involves placing the eye drop in the sulcus between the medial canthus and the side of the bridge of the nose while the patient is in the supine position. Every child must eventually open his or her eyes and when this happens the eye drop will naturally flow onto the conjunctiva.

Topical anesthetics do sting for approximately 10 to 20 seconds before taking effect. This may still be more desirable than the severe sting associated with dilating drops. In addition, the placement of a topical anesthetic before instillation of dilating eye drops increases the effectiveness of the latter by loosening gap junctions between the corneal epithelial cells.

When an eye drop and ointment are to be used simultaneously, the solution should always be instilled before the ointment. Solutions which are suspensions, must always be shaken very well before instillation. Ophthalmic ointments are applied by placing a strip of ointment along the conjunctiva of the lower lid without touching the tip of the applicator to the eye. When treating stye or chalazion located within the eyelid, ointment can be placed on the lashes or conjunctiva. Some parents find ointments harder to instill. Blepharitis, styes, and chalazion are more effectively treated by ointment as the site of action is the lid margin. Ointment antibiotic doses are usually twice daily whereas drops are usually four times daily. Ointments last longer and can give coverage while the child is sleeping. The choice of ointment versus drops may be come a matter of parental preference.

CHAPTER 128 ■ THORACIC EMERGENCIES

JOY L. COLLINS, MD, FAAP, AND MICHAEL L. NANCE, MD

INTRODUCTION

Thoracic emergencies in children often result in life-threatening alterations in cardiorespiratory physiology. A rapid, yet organized, approach to the child with a thoracic emergency is essential. The purpose of this chapter is to describe nontraumatic surgical diseases of the thorax and guide the evaluating health care provider in the diagnosis and treatment of these conditions. Congenital abnormalities that are usually diagnosed at birth are not included. Thoracic trauma is discussed in Chapter 118.

This chapter reviews the pathophysiology and clinical manifestations of thoracic emergencies, as well as the general principles of physical and laboratory assessment. Subsequent sections cover specific entities within the following categories: (i) airway obstruction, (ii) violations of the pleural space, (iii) circulatory impairment, (iv) intrinsic pulmonary lesions, (v) mediastinal tumors, (vi) diaphragmatic defects, and (vii) chest wall tumors.

Pathophysiology

Thoracic conditions of surgical significance frequently present as a result of a mechanical or infectious complication of an anatomic abnormality. These anatomic distinctions may be grouped into conditions resulting in airway compromise, violations of the pleural space, intrinsic lesions of the lung, mediastinal masses, and diaphragmatic defects.

Within each category, it is particularly useful to consider *fluid pressure* changes and that fluids, including air, move in the body down pressure gradients. During inspiration, the pressure within the thoracic cavity is negative with respect to atmospheric pressure, thereby allowing air to be drawn through the oropharynx, the trachea, and into the lungs and alveoli. Any barriers to this pressure gradient, such as accumulation of air or fluid around the lungs in the pleural space, need to be corrected if limiting lung expansion. Obstructions to flow caused by masses compressing the airway or esophagus also impact the necessary pressure gradient.

Infectious problems requiring surgical care usually evolve in the setting of an underlying *anatomic abnormality*. Examples include congenital lung lesions such as infected bronchogenic cyst or pulmonary sequestration, or an H-type tracheoesophageal fistula producing aspiration pneumonia. An exception to this rule is empyema, the accumulation of infected pleural fluid, often a complication of severe pneumonia in childhood. The pathophysiology of this condition and its predilection for younger children remain poorly understood.

In patients with thoracic masses in which there is no compressive effect, or in those in which the anatomically urgent issue has been addressed, it is important to remember that some of these entities will require further evaluation or biopsy. Appropriate referral of such patients is imperative.

The emergency physician evaluating the child with a thoracic problem must attempt to determine whether the patient has evidence of airway compromise, circulatory compromise, or components of both.

Airway Compromise

Airway compromise can occur anywhere in the respiratory tract from the nose to the alveolus. Obstructive emergencies relating to the oropharynx, larynx, and proximal trachea are discussed in Chapters 110 and 123.

Compromise of the more distal tracheobronchial tree may be caused by lesions in the lumen, in the wall, or extremities to the bronchus. Intrinsic bronchial obstructions may result from compression by a tumor within the bronchial lumen (e.g., carcinoid tumor), foreign body, or a mucous plug. Obstruction from lesions in the wall of the bronchus includes collapse from tracheomalacia and stenosis after tracheostomy. Extrinsic lesions (e.g., bronchogenic cyst or inflamed lymph nodes) may be symptomatic by producing impingement on a bronchus. Table 128.1 lists intraluminal, mural, and extrinsic conditions that produce airway obstruction.

The anatomic level of the obstruction correlates with its effects: an obstruction of the distal tracheobronchial tree may lead to segmental lung overdistension or segmental infection. An obstruction of the proximal trachea affects both lungs, with a much greater likelihood of catastrophe for the patient. Similarly, greater degrees of obstruction, as a rule, lead to greater effects on gas exchange and severity. Infection commonly follows obstruction of bronchial drainage because the clearance of bacteria or inhaled foreign materials by the mucociliary elevator is prevented.

Circulatory Impairment

Hemorrhage has somewhat different effects on the circulation in children than in adults. The ability of the child to support blood pressure in the face of significant blood loss has particular implications in the chest. Significant blood loss may go unrecognized in the large volume of the chest. It is important to recognize the early signs of shock (monitor pulse/pressure, increased pulse, cool extremities, prolonged capillary refill) before significant decreases in blood pressure occur because this may represent a loss of 30% to 40 % or more of the blood

TABLE 128.1

TRACHEOBRONCHIAL CONDITIONS ASSOCIATED WITH AIRWAY COMPROMISE

Intraluminal
Foreign bodies

volume. Fortunately, nontraumatic causes of intrathoracic major blood loss are rare in children.

Collections of fluid in the pleural space and mediastinum, whether the result of bleeding or other causes, may produce obstruction of the venous return by *tension physiology*: a child's mediastinum is mobile, and kinking of the great veins [e.g., inferior vena cava (IVC) and superior vena cava (SVC)] occurs much more easily than in adults. In a patient who requires positive-pressure ventilation, the positive inspiratory pressure inside the chest may be greater than the venous pressure returning blood to the heart. Thus, major intrathoracic bleeding may produce more than one difficulty: the central venous pressure and systolic arterial pressure are decreased because of loss of blood volume, and in addition, the pressure inside the chest of a ventilated patient may collapse the veins, returning blood to the heart. Both problems require rapid administration of volume to the patient.

Rarely, the heart itself can be obstructed by primary tumors such as rhabdomyosarcoma or metastatic Wilms' tumor. Tamponade of the heart can be caused by pericardial effusion, hemopericardium, or, more rarely, by pneumopericardium or pneumomediastinum. These topics are addressed in Chapter 84.

Clinical Manifestations

Physical Examination

Evaluation of the child with a thoracic emergency requires a calm, orderly assessment of airway, breathing, and circulation (ABCs). In assessing the airway, the physician must evaluate the adequacy of air movement and gas exchange. Pulse oximetry should be performed upon the patient's arrival. Anxiety or confusion in a patient with a thoracic emergency may be evidence of hypoxemia. Increased work of breathing may indicate partial airway obstruction and can be evaluated by assessing the use of intercostal, subcostal, and supraclavicular accessory muscles. Prolonged use of these accessory muscles may result in the most common cause of cardiac arrest in children—respiratory arrest.

Breathing is best evaluated by palpation and auscultation of the chest. The trachea should be palpated to ensure it is midline. Any lateralization of the trachea is suggestive of either unilateral volume loss or a lateral space-occupying process, such as a pneumothorax, pleural effusion, or mass. The neck and chest should be palpated for signs of subcutaneous emphysema, suggestive of a pneumothorax or airway injury with an air leak. Finally, breath sounds should be assessed via auscultation for symmetry and adequacy of inspiratory and expiratory airflow.

Evaluation of the cardiovascular system should include an assessment of the patient's pulse for quality, rate, and regularity. The peripheral skin should be assessed for color, temperature, and capillary refill. Signs of poor perfusion often precede that of pressure instability. The neck should be assessed for signs of jugular venous distension. Finally, the heart should be examined for signs of displacement of the point of maximal impulse; shift or alteration in the heart tones; or new murmurs, gallops, or friction rubs.

Laboratory Studies

The most important study when evaluating any patient with a thoracic emergency is a good quality chest radiograph. The radiographs of the chest in the posteroanterior (PA) and lateral views should be performed in an upright position (unless contraindicated by the patient's condition). The width of the mediastinum and the degree of mediastinal shift are much better seen in the upright chest radiograph. Moreover, abnormalities in the lung, pleural cavity, and diaphragm are also best appreciated in this view. When a pulmonary effusion exists, lateral decubitus anteroposterior views of the chest can be obtained to determine whether the effusion layers freely or is loculated.

In interpreting the chest radiograph, the physician should distinguish between a diffuse pulmonary problem and a focal lesion. Hyperaeration of one portion of the lung suggests air trapping in the involved lobe. Hyperaeration of the entire lung field on one side is usually the result of compensatory enlargement of the lung because of atelectasis and loss of lung volume on the opposite side.

Other studies that should be considered in a patient with a thoracic emergency include a complete blood cell (CBC) count, blood urea nitrogen, serum glucose, electrolytes, CO_2 concentration, and arterial blood gas or measurement of oxygen saturation. Depending on the patient's specific problem, a cross-match, blood cultures, and an assessment of any sputum by Gram stain and bacteriologic culture may be helpful. Clinical evidence of a bleeding problem, but not need for operation alone, mandates evaluation of platelet count, prothrombin time, and partial thromboplastin time. Other diagnostic studies, such as pulmonary function tests, barium contrast studies, echocardiography, computed tomographic (CT) scans, and magnetic resonance imaging (MRI), can be used as indicated.

AIRWAY OBSTRUCTION

Tracheal Obstruction

Tracheal obstruction may be produced by stenosis or lesions within the lumen of the trachea (Fig. 128.1), in the wall of the trachea, or by extrinsic compression. One of the most common

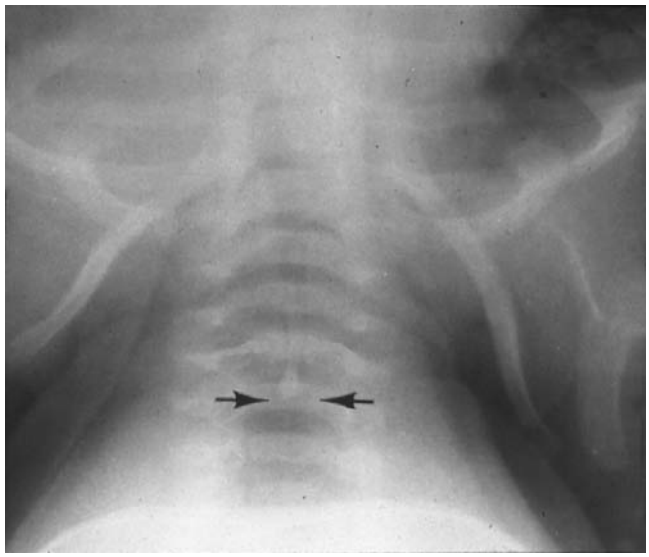

FIGURE 128.1 Foreign body (glass) oriented in an anteroposterior (AP) position in the trachea as evidenced on AP radiograph.

causes of intrinsic obstruction in children is an aspirated foreign body. Other causes include congenital anomalies such as subglottic stenosis, laryngomalacia, and vocal cord paralysis; acquired subglottic stenosis after tracheostomy or prolonged intubation; viral or bacterial tracheitis or any process that causes significant mucosal edema, particularly in an infant with small baseline airway diameter; or more rarely, a space-occupying lesion such as a hemangioma. Tracheomalacia, sometimes complicating lung disease of prematurity, is characterized by a floppy trachea that collapses during expiration when the intrathoracic trachea is compressed by the positive intrathoracic pressure. Laryngomalacia, or tracheomalacia outside the thoracic inlet, may produce obstruction during inspiration when the negative intraluminal pressure transmitted from the chest causes the floppy wall to collapse. Tracheomalacia often occurs in infants born with tracheoesophageal fistula. Extrinsic compression may occur both from mass lesions (Table 128.1) and as a result of anomalous arteries.

Clinical Findings

Tracheal compromise produces symptoms that vary from mild to severe, depending on the degree of obstruction present. When symptoms are mild, the underlying cause may not be evident. Occasional episodes of respiratory infection that are believed to result from croup or bronchitis may be the only symptom. Stridor, wheezing, or cough occurs in patients with more significant obstruction, and a history of previous hospitalizations for treatment with mist tent, antibiotics, and chest percussion may be obtained.

Severe tracheal compromise is usually manifested by a history of stridor at rest. Progressive cyanosis and apneic episodes may occur. On examination, a child with obstruction caused by extrinsic compression often has wheezing or stridor throughout the respiratory cycle. In contrast, a patient with the floppy trachea of tracheomalacia often wheezes only during expiration.

Radiographic evaluation of the stable patient should begin with PA and lateral chest radiographs, ideally obtained at full

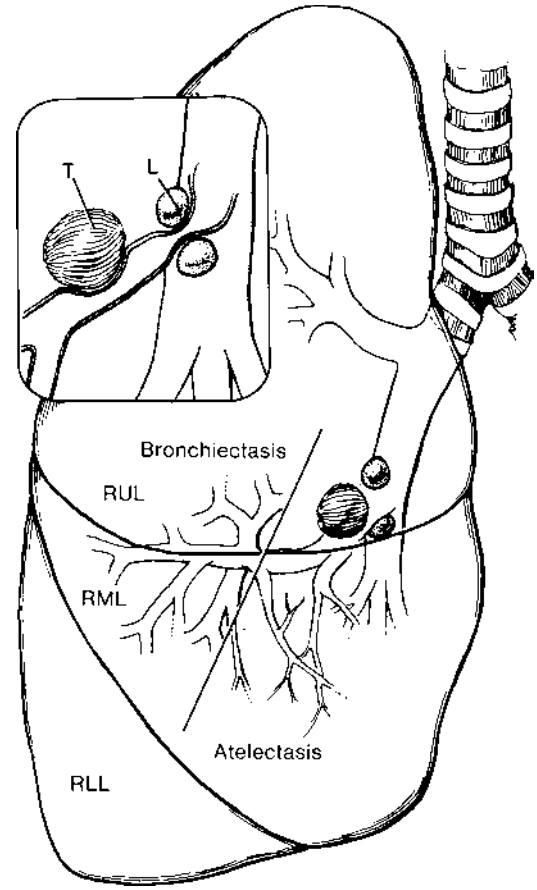

FIGURE 128.2 Acute and chronic obstruction of a bronchus owing to tumor or cyst (T) or lymph nodes (L). When the obstruction is acute, there may be bronchiectasis caused by recurrent pneumonia. The right middle lobe as shown here is particularly prone to bronchial obstruction caused by pressure from encircling lymph nodes. RUL, right upper lobe, RML, right middle lobe, RLL, right lower lobe.

inspiration and again at full expiration. Lateral radiographs of the neck may be useful in showing an edematous epiglottis in patients with suspected epiglottitis. Mass lesions will require cross-section imaging (e.g., CT) for evaluation. Bronchoscopy is often indicated to evaluate obstructive lesions, whether in the lumen, the wall, or extrinsic to the wall of the trachea (Fig. 128.2).

Management

If the patient has a life-threatening airway obstruction, he or she should receive airway management as outlined in Chapters 1 and 5. A coordinated effort between the emergency department (ED) physician, the surgeon, and the anesthesiologist or critical care physician may be necessary to establish an airway by endotracheal intubation, bronchoscopy, or tracheostomy. Intubation of the airway to within a short distance of the carina supports most patients with lesions extrinsic to the trachea or in the tracheal wall with a critical obstruction. Such a patient requires admission to an intensive care or other unit with ventilator capability. Lesions within the lumen will likely require endoscopic management in an operating room, and early involvement of an experienced surgeon is recommended.

Many inflammatory processes are controlled with antibiotics and respiratory care without airway manipulation or surgical intervention. Treatment in these cases includes the administration of humidified oxygen and inhaled racemic epinephrine, combined in some cases with the administration of oral, intramuscular, or intravascular dexamethasone. Endotracheal intubation is well tolerated in the patient with epiglottitis, since the inflammation is supraglottic, and may be necessary for some patients with significant inflammation and upper airway compromise. Rarely is intubation necessary for more than 24 to 48 hours in these patients, after which antibiotics have begun to reduce the swelling associated with infection. In a patient with viral or bacterial tracheitis, however, intubation for more than 24 to 48 hours may produce tracheal injury and ulceration.

Vascular Rings

Vascular rings are developmental anomalies of the aorta and great vessels. They may produce obstruction of the esophagus, trachea, or both. These rings are a result of failure of the normal involution of the appropriate segments of the six embryologic aortic arches. The number of possible variants is at least 36; 16 or more have been seen in humans. The level of obstruction is usually the trachea, but compression of a bronchus by the ductus arteriosus, or by a pulmonary artery sling, may produce compression more distally. The reader is referred to standard texts of pediatric or thoracic surgery for further details.

Clinical Findings

Vascular rings may be asymptomatic in infancy but lead to significant airway obstruction in childhood. The wide variety of anomalies produces varying degrees of symptoms. Vascular rings should be suspected in infants with stridor, dysphagia, failure to thrive associated with difficult feeding, or recurrent pneumonia. Esophageal obstruction can produce difficulty swallowing, coined *dysphagia lusoria* by Bayford in 1794. A patient with esophageal compression may also have respiratory symptoms from compression on the trachea from a distended esophageal pouch. This may lead to reflex apnea during feeding, and eventually tracheomalacia in a more chronic setting. Often, diagnosis is delayed by failure to consider these anatomic obstructions. In a patient presenting with an acute airway obstruction or other medical problems requiring intubation and nasogastric tube placement, detection of a vascular ring can be more difficult because of the presence of these tubes. Chest radiographs may be supplemented by various diagnostic tests: contrast esophagography, angiography, echocardiography, MRI, and digital subtraction angiography are needed in some combination to define the anatomy.

Management

Although some patients with constricting anomalies improve as they grow, most will require surgical correction. Surgical treatment is usually indicated to relieve the obstruction, with predictable and immediate resolution of symptoms. This is accomplished by dividing the vascular ring and preserving the blood supply to the aortic branches. This is usually accomplished by a left thoracotomy.

BRONCHIAL LESIONS

Bronchial Atresia

Congenital bronchial atresia is a rare anomaly characterized by a bronchocele caused by a mucus-filled, blindly terminating segmental or lobar bronchus, with resulting hyperinflation of the distal obstructed segment of lung. Hyperaeration is believed to result from communication with the normally aerated lung via the pores of Kohn and the channels of Lambert.

Clinical Findings

Neonates and infants with the lesion are usually seen for respiratory distress. In older patients, a history of episodic upper respiratory infection and wheezing may be elicited. Some older patients may complain of dyspnea on exertion or unilateral chest pain. Physical findings seldom suggest the diagnosis, but unilaterally decreased breath sounds may be evident.

Management

Often, the diagnosis is suggested by chest radiograph, but chest CT scan may be necessary to help more closely define the anatomy. Bronchoscopy is the most efficient way to identify the atretic opening to the involved bronchus. Bronchography has been used in the past, but high-resolution CT scan can often provide the same anatomic information noninvasively. Complete atresia of a main stem or lobar bronchus may lead to infectious complications or compression symptoms from overdistention of the affected lobe. This may require surgical management, such as lobectomy.

Right Middle Lobe Syndrome

Right middle lobe syndrome is the recurrence or persistence of atelectasis or pneumonitis of the right middle lobe, sometimes associated with bronchiectasis. It has been described in all age groups, in both the right middle and lower lobes concomitantly, and has also been observed in the lingula segment. This process can be caused by extraluminal or intraluminal obstruction, or by nonobstructive causes. The right middle lobe is anatomically predisposed to compression of its bronchus by the lymph nodes in the vicinity that encircle it. Previously, especially in the era before antituberculous chemotherapy, this resulted in compression of the right middle lobe bronchus alone, eventually leading to bronchiectasis. Because the right middle and lower lobes are favored sites for aspirated material (Fig. 128.3), recurrent inflammation caused by pneumonia can lead to chronic atelectasis and adenopathy. A similar situation can be seen with intraluminal tumors and other space-occupying lesions. Nonobstructive causes such as asthma can result in prolonged atelectasis, which promotes recurrent infection and eventual bronchiectasis.

Clinical Presentation

Middle lobe syndrome may present as symptomatic or asymptomatic atelectasis of the right middle lobe on chest radiograph and may be recurrent or persistent. It may also present as bronchiectasis or pneumonitis of the affected area. Recurrent episodes of pneumonia and associated atelectasis in

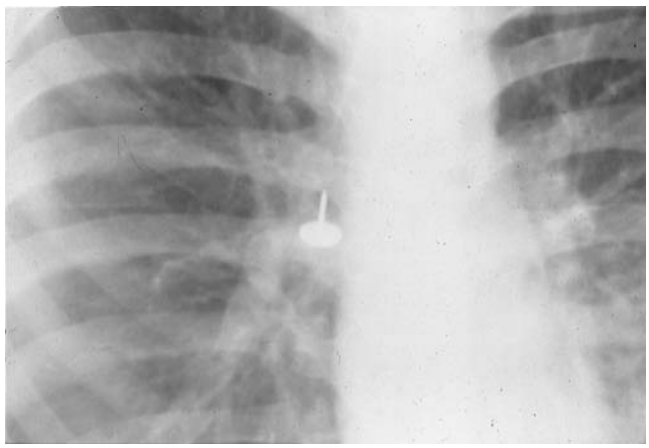

FIGURE 128.3 Foreign body (thumb tack) in the right main stem bronchus.

the lingula or right middle (and often lower) lobes occur in these patients and are not responsive to chest percussion, postural drainage, or antibiotic treatment. Radiographic findings reveal right middle lobe collapse or atelectasis. The mechanical compression of the bronchus leads to a sequestered infection that may require resection of the right middle or right middle and lower lobes for resolution.

Management

Although the need for resection is far less common than in the past, acute pneumonia in these anatomic locations should prompt a discussion of previous pneumonias and treatment. There are some data suggesting a beneficial role for fiber-optic bronchoscopy and bronchoalveolar lavage in some patients, which may restore patency of the bronchus and allow better postural drainage and enhance antibiotic effectiveness. Those patients with obstructing lesions, bronchiectasis, bronchial stenosis, or failure to respond to medical management should be considered candidates for lobectomy.

ESOPHAGUS-RELATED CAUSES OF AIRWAY DIFFICULTIES

Tracheoesophageal Fistula

Tracheoesophageal fistula (TEF) occurs in children both as a congenital lesion and, rarely, as an acquired problem after suppuration of mediastinal nodes. The congenital fistula is accompanied by atresia of the esophagus in more than 85% of patients and generally presents in the immediate perinatal period with feeding intolerance and inability to handle secretions. These patients with esophageal atresia undergo repair shortly after diagnosis, typically via a right thoracotomy. More recently, surgeons who are adept at minimally invasive techniques will perform thoracoscopic repair in select patients. Approximately 3% of all patients with TEF have "H-type" fistula, in which both the trachea and the esophagus are intact and patent but are connected by a fistula that is frequently in the cervical region or high in the thorax (Fig. 128.4). Because there is no accompanying esophageal atresia, these patients are more likely to present

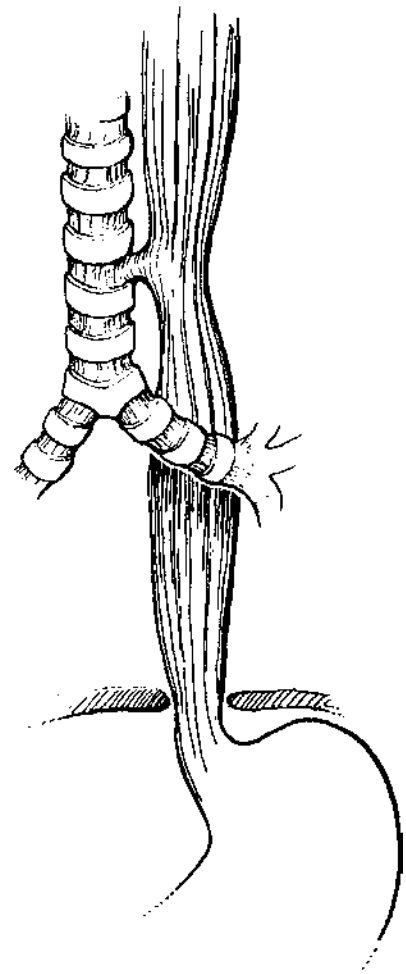

FIGURE 128.4 H-type tracheoesophageal fistula.

to the ED later in infancy or childhood for symptoms of recurrent respiratory distress or pulmonary aspiration.

It is this "H-type" fistula that is most likely to be seen in patients presenting to the ED and is therefore the type that we will discuss primarily in this chapter. The acquired form is usually in the distal trachea or proximal bronchial tree and is extremely uncommon.

Clinical Findings

H-type fistulae are notoriously difficult to diagnose. Children generally develop recurrent pulmonary infections with no obvious source. The characteristic history of choking or gagging when swallowing that accompanies esophageal atresia with TEF may not be present, but parents may describe excessive secretions or noisy breathing after feeds.

Mention should be made of the fact that children in whom the more common esophageal atresia with repaired distal TEF may present to the ED with wheezing, stridor, and other respiratory symptoms because of potential tracheomalacia and an increased susceptibility to respiratory compromise with viral illnesses. These children are also at high risk for esophageal food bolus obstruction or esophageal foreign bodies, with the site of retention being a stricture or relative narrowing at the site of anastomosis.

Management

Contrast esophagram may identify an H-type TEF. Most of these fistulae are small in diameter (less than 1 cm) and short (also less than 1 cm), making radiographic identification difficult. Even when contrast appears in the tracheobronchial tree, it may be difficult to know whether primary aspiration of orally administered contrast is responsible. Placing a feeding tube in the esophagus and injecting contrast while pulling the tube back up from the lower esophagus under fluoroscopic observation may be helpful. This study is most accurate when performed with the patient is in the prone position. High-resolution CT scanning may identify the anatomy. Bronchoscopy and esophagoscopy may both be diagnostic and may aid the repair if a small catheter can be passed across the fistula to aid its identification by enabling palpation at operation. Most such fistulae are cervical and can be repaired without a thoracotomy.

Gastroesophageal Reflux

The mucosal lining of the trachea and bronchial tree tolerates periodic soilage relatively well; even witnessed aspiration of gastric contents does not reliably produce infection or pneumonia. Ongoing irritation by gastric acid, bile, or contaminated secretions will eventually overcome the mucociliary elevator and the other barriers to infection of the tracheobronchial mucosa, and bronchitis or pneumonia will result. Common causes of repetitive soilage of the tracheobronchial tree include primary aspiration of oropharyngeal secretions, often in children with impaired swallowing mechanisms, and gastroesophageal reflux (GER). GER is universal in babies and is usually outgrown without the need for intervention. In patients with neurological impairment or in patients with significant cardiac or pulmonary disease, however, GER may require medical or surgical treatment.

Clinical Presentation

GER often presents with symptoms of spitting up or vomiting after eating. Aspiration may lead to presentation with recurrent pneumonia. Complications that follow prolonged GER include failure to thrive because of inadequate nutrition, esophagitis, esophageal ulceration, and esophageal stricture (Fig. 128.5). Some patients present with an acute life-threatening event (ALTE) in which laryngospasm or bronchospasm precipitated by aspiration of gastric contents produces profound hypoxia and even respiratory or cardiac arrest. GER is common in patients with an anatomic abnormality or a history of surgery around or near the esophagus or gastroesophageal junction, as in patients who have undergone TEF repair or repair of congenital diaphragmatic hernia (CDH).

Management

Management of GER begins with establishing the diagnosis. If this is evident clinically and the child responds to medical management, no further evaluation may be needed. Recalcitrant GER may be an indication for an upper gastrointestinal contrast study (UGI series) to establish that there is no anatomic obstruction to gastric emptying such as pyloric stenosis, malrotation, a duodenal web or annular pancreas. Recording the esophageal pH over a 12- to 24-hour period with a pH probe will help quantify the severity of the problem. Scintigraphy for the evaluation of GER may also be useful, as it identifies GER and aspiration of gastric contents into the tracheobronchial tree and quantifies the efficacy of gastric emptying.

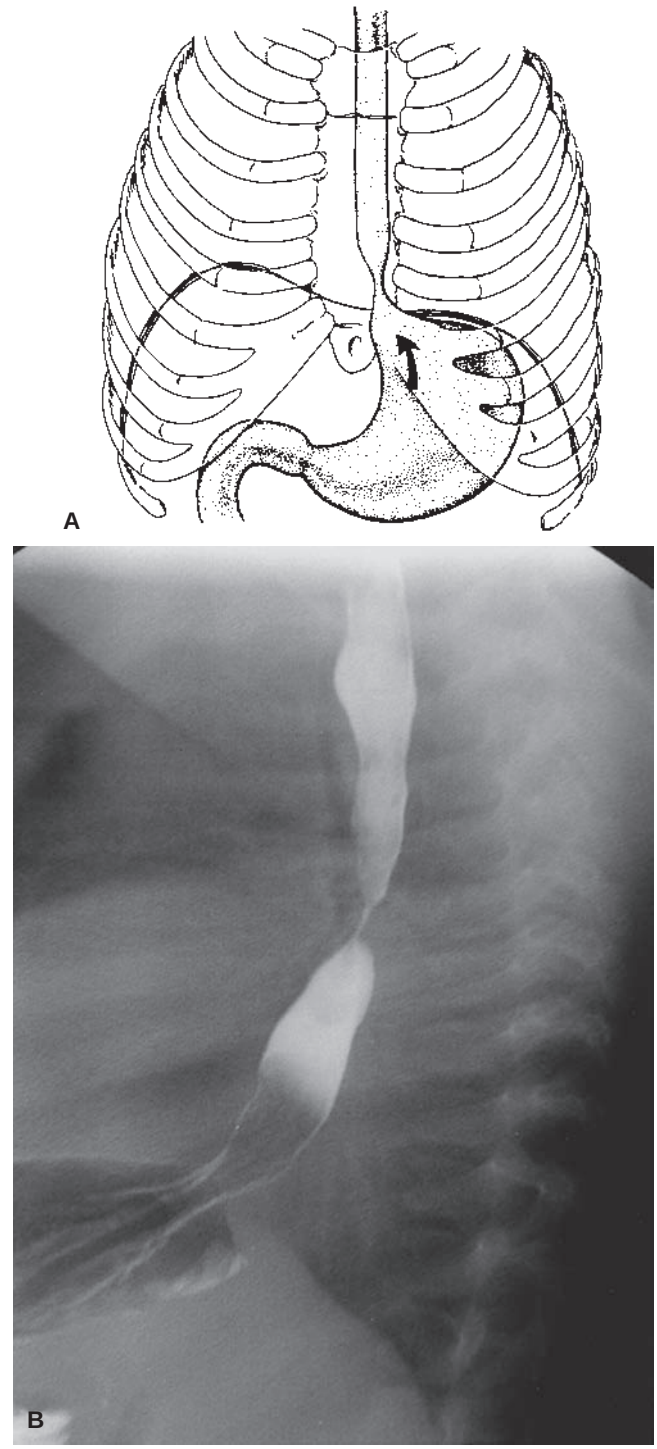

FIGURE 128.5 **A:** Distal esophageal stricture caused by prolonged reflux esophagitis. Note the loss of the normal angle between the esophagus and the stomach. **B:** Esophageal stricture. Lateral barium esophagram shows narrowing of midesophagus in an infant with gastroesophageal reflux.

GER is managed by a three-tiered approach. Initially, elevating the head of the bed, thickening the feeds, and decreasing the volume of individual feeds are useful to allow gravity and mechanical effects to help. If these measures are ineffective, medical management of this problem includes efforts to decrease gastric acidity and to improve motility. The most common agents to neutralize or decrease acid production include antacids, H_2-receptor antagonists such as ranitidine, and proton pump inhibiting drugs (e.g., omeprazole, lansoprazole). Many clinicians add prokinetic medications such as metoclopramide to improve the gastric motility, however, reports of irreversible tardive dyskinesia and movement disorders are decreasing the use of metoclopramide in favor of low dose erythromycin. Concerns regarding the association between the prokinetic drug, cisapride, and drug interactions leading to ventricular tachycardia have led to virtual cessation of its use. Indications for surgical management of GER include failure of medical management or the occurrence of complications, such as esophageal stricture or repeated ALTEs without other evident cause. Also, patients who have an anatomic reason for reflux, such as a hiatal hernia or a neurologic or other condition that severely impedes the ability to protect their airway, should be considered for surgical treatment of significant GER. Presently, the favored operative treatment in North America is fundoplication: wrapping the fundus of the stomach either partially (a Thal operation if anterior to the esophagus or Toupet operation if posterior) or completely (the Nissen operation) around the esophagus just above the gastroesophageal junction. All of these procedures may be performed laparoscopically in appropriate patients.

Esophageal Web

Rarely, a patient presents with reflux that is caused by an esophageal web (Fig. 128.6). The membranous, congenital narrowing of unclear origin can usually allow liquids to pass, and symptoms often do not arise until the child begins to eat solid food. Recurrent aspiration pneumonia may also develop. Rarely, it can present with associated anemia, in the form of Plummer-Vinson syndrome. An esophagram is usually diagnostic. Often, a thin, membranous web may be split by esophageal dilators, cautery, or a hydraulic balloon placed endoscopically across the stenosis. If this approach is unsuccessful because the lumen is too small to transmit the dilator or the tissue is unyielding, segmental esophageal resection may be necessary via thoracotomy.

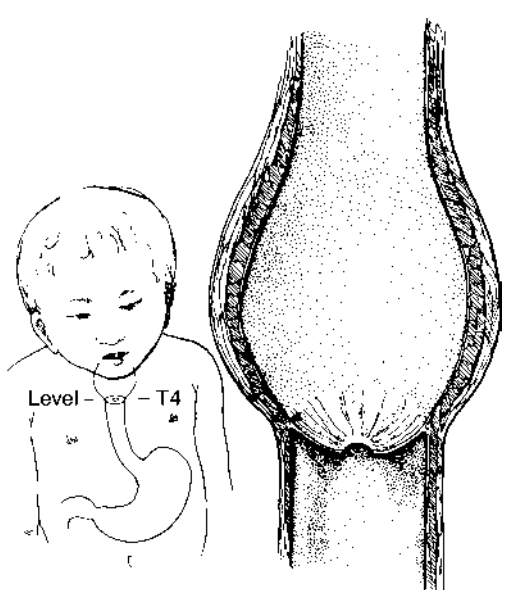

FIGURE 128.6 A child with chronic partial obstruction of the esophagus caused by a congenital web. Similar bulbous enlargement of the proximal esophagus can occur with any type of stricture and results in pressure on the trachea and recurrent regurgitation with aspiration. T4, 4th thoracic vertebrae.

CIRCULATORY IMPAIRMENT

Thoracic emergencies leading to shock are often due to a decrease in cardiac preload or filling pressure. Preload may be reduced by tension pneumothorax causing kinking of the great veins returning blood to the heart in the child's mobile mediastinum; by massive intraabdominal hemorrhage compressing the IVC; by a cardiac tumor obstructing one of the atria; or by tamponade of the heart from mediastinal pressure caused by blood, pericardial fluid, or air. The causes, presentation, and management of cardiogenic shock are reviewed in detail in Chapter 3. Shock as a result of trauma is reviewed in Chapters 3, 104, and 118.

Clinical Findings

Findings are dependent on the type of shock and the primary lesion. Whether caused by tension pneumothorax, intracardiac tumor, or tamponade, hypovolemic (or decreased preload) shock is accompanied by tachycardia. Usually blood pressure is maintained until upwards of 30% to 40% of the blood volume is lost; predicting the onset of hypotension with tension pneumothorax or a compressive phenomena is difficult. Characteristically, the extremities are cold and poorly perfused as peripheral vasoconstriction compensates for the loss of central venous pressure. Tamponade is accompanied by muffled heart tones, often difficult to recognize in a noisy ED, especially in the setting of trauma. Distended neck veins are often present. Once tamponade has reached a critical compression pressure, it often does not respond to intravenous (IV) fluid. Pulsus paradoxus may not accompany acute tamponade.

Clinical findings suggestive of cardiogenic shock are discussed in Chapter 3. Septic and neurogenic shocks are "warm shock" in which the extremities are well perfused because of loss of vascular tone; tachycardia is commonly typically present. Fever in septic shock, as well as flaccid extremities with loss of bladder control and rectal tone in neurogenic shock, may aid the different ED diagnosis.

Management

IV support with two large-gauge peripheral catheters, electrocardiogram monitoring, pulse oximetry, and oxygen supplementation are indicated for any type of circulatory collapse. Stable patients should undergo a chest radiograph immediately. Afterward, management is directed to relieving the condition suspected of causing the shock.

If acute cardiac tamponade is suspected, emergency pericardiocentesis is indicated (see Section VII, Procedures). If the patient is not improved by pericardiocentesis, the pericardium may be filled with clotted blood not amenable to drainage. In this circumstance, pericardial drainage will require a larger

opening in the pericardium. In a patient with shock and incipient cardiac arrest, a vertical subxiphoid incision should be made in the ED (i.e., pericardial window). After opening the linea alba, the pericardium can be opened widely enough to digitally extract hematoma from the pericardium.

PLEURAL DISEASES

The lung is covered by the densely adherent visceral pleura, which moves smoothly over the parietal pleura of the chest wall because of a thin film, and the friction created by apposition of the pleural layers (like two plates of glass held together by a film of water) contributes to the full expansion of the lung mechanically. When air, excess fluid, or purulent material comes between the two layers of the pleura, the lung may collapse or become significantly compressed and consideration needs to be given to drainage of the pleural space.

Pneumothorax

A pneumothorax is a collection of air in the pleural space. It can occur for short- or long-term duration and can be static or accumulate progressively. Because atmospheric pressure is greater than intrapleural pressure, any mechanism that allows even momentary communication between the atmosphere outside the chest wall or within the tracheobronchial tree can result in a rapid shift of air into the pleural space. A pneumothorax may occur spontaneously, or it may be the result of trauma or a therapeutic intervention. Spontaneous pneumothorax can occur in children with no known underlying condition or as a result of a congenital bleb, pneumatocele, congenital cystic adenomatoid malformation, or other such structural abnormality. Such a process can lead to a small pneumothorax or complete collapse of the involved lung (Fig. 128.7). In patients with cystic fibrosis, spontaneous pneumothorax is the second most common pulmonary complication and usually occurs in teenage or young adult patients with far advanced, diffuse disease. Another group of children with a high incidence of spontaneous pneumothorax are those with pulmonary metastases, such as patients with osteogenic sarcoma. Children with staphylococcal pneumonia are especially prone to develop unilateral or bilateral pneumothorax. Iatrogenic causes of pneumothorax include thoracentesis or central venous catheter insertion, bronchoscopy, aggressive mechanical ventilation ("barotrauma"), or cardiopulmonary resuscitation. Penetrating and blunt trauma to the chest may cause injuries to the lung, pleura, esophagus, trachea, and bronchi, all of which can result in pneumothorax. A more detailed discussion of trauma-related causes of pneumothorax can be found in Chapter 107.

Two special forms of pneumothorax require emphasis because these conditions may result in the death of the patient if not recognized early and attended to rapidly. The first is a tension pneumothorax, which results not only in a complete collapse of the ipsilateral lung but also in progressive pressure across the mediastinum (Fig. 128.8). This pressure impedes ventilation of the contralateral lung resulting in further compromise. Tension pneumothorax results for air accumulating in the pleural space with each inspiration. Whether the entry site of air into the pleural space is through the chest wall, a torn bronchus, or an injured lung, the physiologic result is that of a one-way valve, whereby air continues to accumulate in the pleural cavity with inspiration but cannot be expelled on expiration. This phenomenon continues until the intrathoracic pressure on the involved side is so high that no further air can enter the pleural space. This is often the point at which venous return from below the diaphragm is also impeded and circulatory failure ensues.

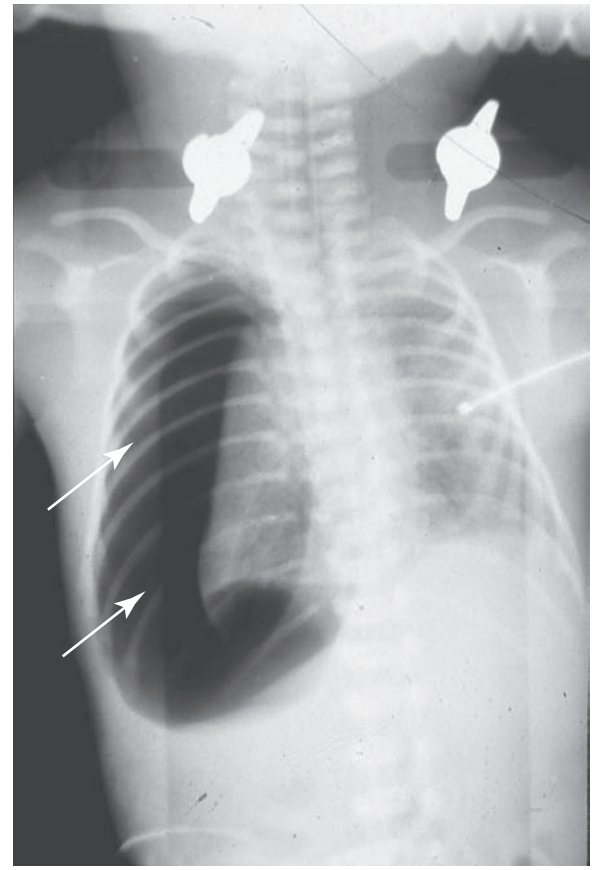

FIGURE 128.7 Large pneumothorax involving the entire thorax. Atelectatic lung border is marked by *arrows*.

The second life-threatening form of abnormal collection of air in the thorax is massive pneumomediastinum with or without an associated pneumothorax. In extreme cases, the tension produced in the mediastinum can be great enough to impair both circulation and ventilation. This phenomenon is particularly likely to occur in a patient who is receiving positive-pressure ventilation, which enhances escape of air from the bronchial tree into the mediastinum (Fig. 128.9).

Clinical Findings

The symptoms and signs of pneumothorax depend on the size of the pneumothorax and how rapidly it occurs. The most common presenting symptoms are unilateral chest pain and dyspnea. For example, it is common for a patient with spontaneous rupture of an emphysematous bleb to complain of sudden acute pain on the involved side of the chest followed by tachypnea, pain at the tip of the ipsilateral shoulder, and a sense of shortness of breath. Such patients usually have a small to moderate pneumothorax (less than 20% of the lung volume), often with no accompanying hypoxia. Decreased breath

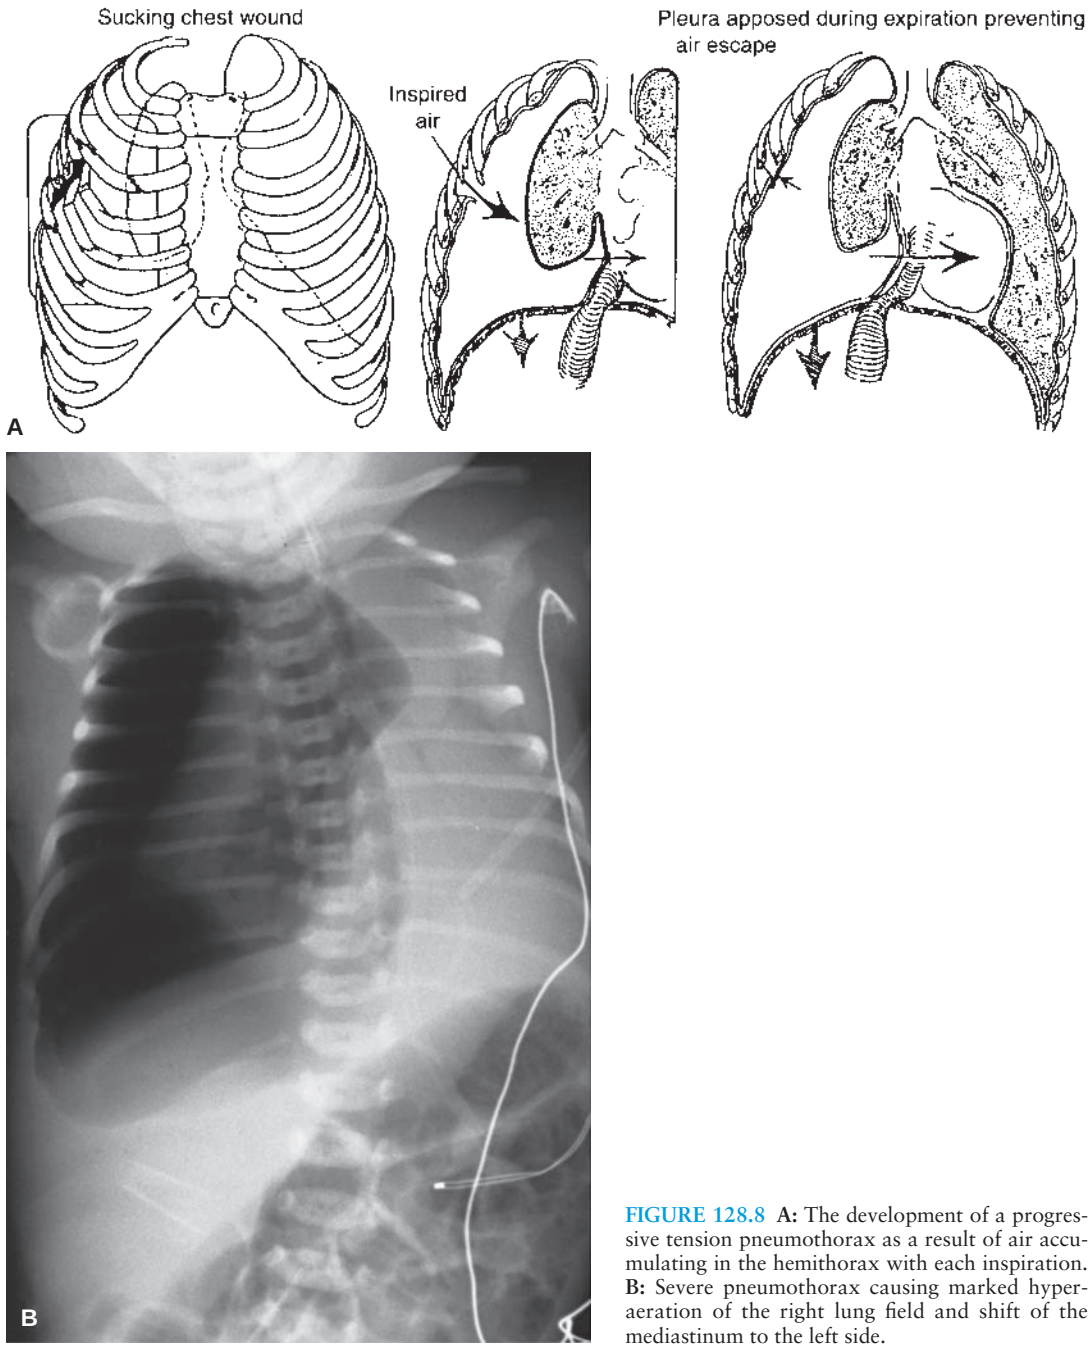

FIGURE 128.8 **A:** The development of a progressive tension pneumothorax as a result of air accumulating in the hemithorax with each inspiration. **B:** Severe pneumothorax causing marked hyperaeration of the right lung field and shift of the mediastinum to the left side.

sounds may be heard on the ipsilateral side, and a chest radiograph will usually demonstrate the pneumothorax, particularly if taken at end expiration.

In general, a patient with a pneumothorax of 50% or more of the lung volume will to exhibit signs and symptoms of ventilatory impairment: dyspnea, tachypnea, pain, splinting on the involved side, agitation, increased pulse rate, diminished breath sounds, and increased resonance to percussion on the involved side and, possibly, displacement of the trachea and heart away from the involved side. Severe dyspnea should alert the physician to the possibility of a very large or possible tension pneumothorax. A child with existing underlying lung disease may display more severe symptoms and hypoxemia with a small or moderate pneumothorax.

Management

The essential components of management involve confirmation that a pneumothorax exists and reexpansion of the lung. If the patient's condition is not severe, an immediate upright PA and a lateral chest radiograph should be taken. These radiographs are important to determine not only the site and extent of the pneumothorax but also any complicating features such as tumor, fluid within the pleural space, or abnormalities of the lungs, diaphragm, or mediastinum.

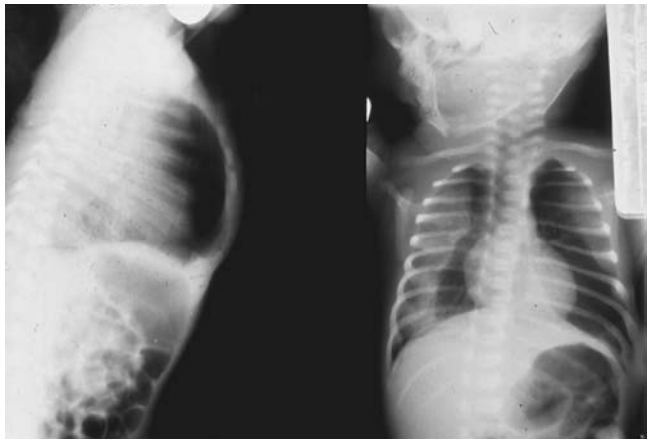

FIGURE 128.9 Pneumomediastinum with accentuation of the cardiac silhouette.

Management depends on the extent of the pneumothorax, the severity of symptoms, ongoing expansion, presence of tension, physiology, and the suspected underlying etiology or clinical condition. Small pneumothoraces (e.g., less than 15% to 20% of lung volume) that are asymptomatic can typically be followed by observation alone. Larger pneumothoraces or those with evidence of ongoing leak from the lung surface usually require intervention. Options include thoracentesis, placement of a small "pigtail" catheter, or placement of a standard chest tube (see Section VII, Procedures). In the ED, the percutaneous, guidewire "pigtail" catheters are ideal for pneumothorax not associated with blood in the chest or empyema. In a patient in whom continuous accumulation of air takes place in the pleural space despite the presence of a pigtail catheter, a standard-sized chest tube should be placed.

If the child's condition is so severe that there is no time for a chest radiograph and if a pneumothorax is suspected, immediate therapy includes (i) tamponading and obliterating any sucking or open chest wound and (ii) inserting a large-bore (14-gauge) angiocatheter into the second intercostal space anteriorly to evacuate the air and relieve the tension. The insertion of the needle and catheter will immediately result in release of the tension on the mediastinum and diaphragm. This maneuver should be followed by the controlled placement of an appropriate-sized chest tube. Depending on the suspected etiology, further studies may be needed.

Many infants can be effectively managed in this way if the amount of air present in the pleural space is small. However, these temporary catheter devices are small gauge and thus tend to easily develop fibrin plugs. Therefore, in any infant or older child who requires a tube within the pleura for more than 24 hours, it is best to proceed with a standard chest tube insertion. Patients with a pneumothorax should be admitted to the hospital, even if no chest tube is believed necessary, to monitor for signs of clinical deterioration (e.g., hypoxia) and to repeat a chest radiograph to ensure no progression of the process.

A surgical consultation is generally warranted for any patient with a pneumothorax, particularly if there is evidence of a continuing air leak or the mechanism was traumatic, or due to an underlying anatomic abnormality.

Pleural Effusion

Pleural fluid in excess amount is not a disease per se, but it indicates the presence of pulmonary or systemic illness. The classification of the fluid into *transudate*, which accumulates when the normal pressure relationships between the capillary pressure in the lung, the pleural pressure, and the lymphatic drainage pressure are disturbed, or *exudate*, an inflammatory collection, has less utility today than in previous years because of other diagnostic tools presently available. Nevertheless, an awareness that an increased pulmonary capillary pressure (as in congestive heart failure), a decreased colloid osmotic pressure (as in renal disease), increased intrapleural negative pressure (as in atelectasis), or impaired lymphatic drainage of the pleural space (e.g., from surgical trauma to the thoracic duct) may result in transudative effusion is important. In children, the inflammatory cause of effusion is most commonly a result of pneumonia, with accumulation of infected fluid in the pleural space, or empyema. The accumulation of blood in the pleural space because of trauma is discussed in Chapter 107. Hemothorax may also result from nontraumatic conditions. Necrotizing pulmonary infections, tuberculosis, pulmonary arteriovenous (AV) malformation, torn pleural adhesions with spontaneous pneumothorax, hemophilia, thrombocytopenia, and systemic anticoagulation, and pleural tumors have all been reported to cause hemothorax. Chylothorax, or the accumulation of lymphatic fluid in the pleural space, has increased in frequency as thoracic, especially complex cardiac, surgical operations have become more common in children.

Clinical Findings

Small, sterile collections, as well as large, chronic collections, may be asymptomatic. Acute collections produce symptoms by compressive effects on the lung, with resultant atelectasis, and right-to-left shunting, with resultant hypoxia and hypercapnia. Respiratory distress may follow, marked by dyspnea, tachypnea, increased use of accessory muscles of respiration, and even cyanosis. Small to moderate effusions may not be evident on physical examination, with most effusions detected by chest radiograph. Bilateral decubitus chest radiographs help define the presence of pleural fluid in patients in whom it is difficult to see because of the concurrent parenchymal disease. This examination also demonstrates whether the fluid is free to move about in the chest.

Management

If the presence of a significant effusion is evident by examination and radiograph, no further radiographic studies may be needed. A CT scan or an ultrasound examination of the chest helps determine whether opacity seen on a chest radiograph is due to parenchymal disease or due to pleural fluid. All patients should have a CBC count with differential and blood culture. Analysis of the pleural fluid itself (including cultures) may be a useful diagnostic test. The technique for thoracentesis is given in Section VII.

Aspirated fluid should be sent for cell count, differential, Gram stain, acid-fast bacillus (AFB) stain, total protein, lactate dehydrogenase (LDH), protein, specific gravity, and a complete set of cultures (aerobic, anaerobic, AFB, and

fungal). The normal protein concentration is 1.5 g per dL. Classically, an exudate was said to have a total protein of more than 3.0 g per dL and a specific gravity of more than 1.016. An accuracy rate of more than 99% in classification of the fluid as an exudate if any one of the following criteria are present: (i) pleural fluid protein divided by serum protein is more than 0.5; (ii) pleural fluid LDH divided by serum LDH is more than 0.6; or (iii) pleural fluid LDH more than two-thirds of the upper limit of normal for serum LDH. The studies ordered should clearly be tailored to the clinical setting: in patients with hemothorax with an evident cause, little is to be learned by studies of the pleural fluid. Suspected chylothorax may be identified by the measurement of triglycerides, cholesterol, or lymphocyte count; a fat stain such as Sudan black or oil red "O" may be done on the fluid. Empyema can appear similar to chylothorax. Centrifuging the specimen can differentiate the two because the supernatant of empyema is clear.

Draining the pleural fluid must then be considered. Thin fluid may sometimes be managed by intermittent thoracentesis. The effusion may resolve as the underlying condition is treated. If not, a small-diameter tube, such as an 8F pigtail percutaneous tube, can be placed in the anterior or midaxillary line. Thick fluid, such as blood, pus, and sometimes chyle, requires the placement of a larger diameter tube. Either tube must be attached to a pleural drainage system. When the drainage decreases significantly, to approximately 1 mL per pound of body weight per day, the drain may be removed. The drain should not be removed in the presence of an accompanying "air leak" caused by a bronchopleural connection.

Empyema

An empyema is the presence of infected fluid within the pleural cavity and is typically associated with an underlying pneumonia. The predominant organisms are *Streptococcus pneumoniae*, *Staphylococcus aureus*, group A streptococci, and *Haemophilus influenzae*. When empyema follows accidental trauma or surgery, other bacterial organisms may be involved.

Clinical Findings

Empyema is most common in children 2 to 9 years of age. Presentation with a pneumonia that does not respond to antibiotic treatment should lead to the consideration of decubitus chest radiographs or a CT scan for diagnosis. CT scan can identify and distinguish parenchymal consolidation from lung abscess and empyema. High fever is common, as are the symptoms of pneumonia: cough, pleuritic chest pain, and lassitude. Children may also demonstrate tachypnea, respiratory distress, and hypoxia.

Management

Empyema in healthy children may respond to prolonged IV antibiotic therapy and chest tube drainage, if the fluid is thin and not loculated. If a patient fails to respond to this management, loculation of thick purulent material should be suspected. CT scan findings of a loculated fluid collection with a thickened border and "scalloped" edges are suggestive of an empyema with a surrounding fibrinous peel that may be treated most effectively with surgical drainage. Recovery may be hastened in many cases by thoracoscopic debridement of the pleural space of this infected fibrinous peel that encases the lung and prevents its full expansion. Under a general anesthetic, a fiber-optic, high-resolution camera placed within the pleural space via a short (1-cm) incision between the ribs allows the removal of the purulent material and the fibrinous peel that often encases the lung, restricting its expansion. The peel may be removed under direct visualization with the aid of thoracoscopic instruments placed through additional thoracoscopic incisions. A chest tube is then placed to drain the pleural cavity and left in place for a period of days. Because sedation approaching the depth of general anesthesia is needed for the placement of a chest tube, many surgeons and infectious disease consultants recommend thoracoscopy as the initial approach to a child with empyema. Seldom is open thoracotomy now necessary to resolve empyema.

Solid Lung and Pleural Lesions

A number of solitary lesions are benign, with the most common being inflammatory pseudotumor and hamartoma, both of which may become quite large and cause symptoms of respiratory distress, cough, airway obstruction, or mediastinal compression. Solid lesions in the pleural space occur uncommonly in children. A localized, pleural-based mass should suggest neoplasm, which may be primary or metastatic. The most common primary lung tumors are bronchial adenomas, and the most common metastatic lesions are Wilms' tumor and osteogenic sarcoma. They may encase the lung and produce restrictive lung disease.

Clinical Presentation/Management

It is impossible to generalize on the mode of presentation of such rare processes. Focal lesions may be expected to be found in the investigation of symptoms caused by local compression or erosion; because of the large functional pulmonary reserve of children, restrictive lung disease caused by a diffuse process is distinctly uncommon, or by serendipity. A full radiographic evaluation, including a CT scan, should be obtained, admission to the hospital strongly considered, and appropriate consultation sought. Focal lesions should be considered malignant until proven otherwise; thus, operation for biopsy or excision will likely be required.

LUNG LESIONS

The lung is often affected in childhood illness. Asthma, pneumonia, and other conditions that do not require surgical management are addressed elsewhere in this text. Mass lesions and cystic lesions of the lung include congenital cystic adenomatoid malformation, congenital lobar emphysema, bronchogenic cyst, congenital pulmonary AV fistula, and bronchopulmonary foregut malformations. Acquired conditions of the lung that require surgical management are distinctly uncommon because of the control of tuberculosis in North America. Bronchiectasis—the chronic dilation of the bronchi resulting from the chronic infection of the lung in cystic fibrosis, tuberculosis, or

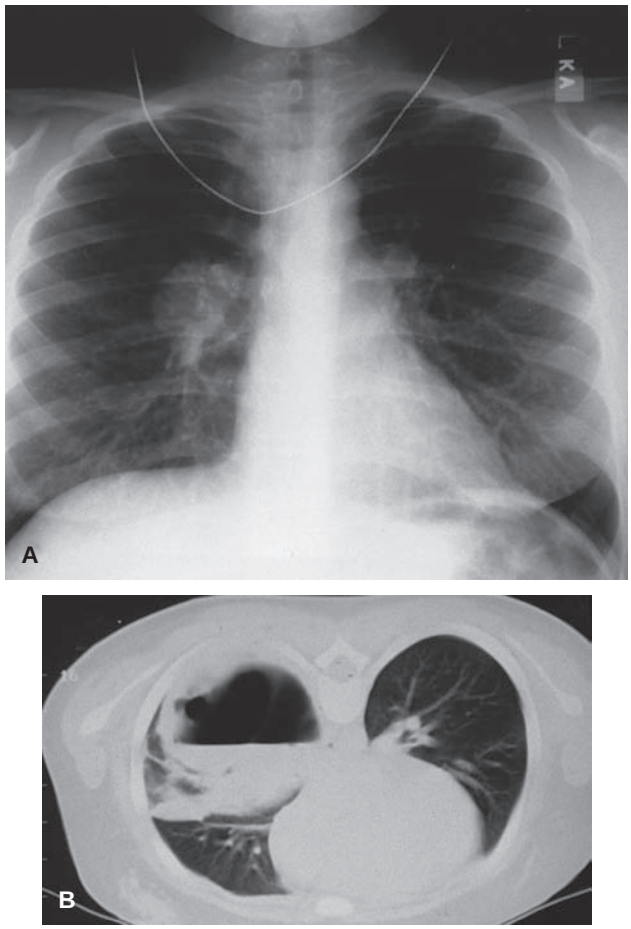

FIGURE 128.10 **A:** Plain film of a patient with a bronchogenic cyst arising from the right main stem bronchus. **B:** Computed tomographic scan of a similar lesion reveals large fluid-filled cyst compressing adjacent lung tissue.

other chronic pneumonic infection—may require pulmonary resection.

Bronchogenic Cyst

Bronchogenic cysts are believed to result from aberrant budding from the primitive foregut or tracheobronchial tree. They arise from the trachea or a bronchus and may be found anywhere along the tracheobroncheal tree, in the lung substance, adjacent to the esophagus, or in other ectopic locations (Fig. 128.10).

Clinical Presentation

In children, centrally located cysts may present with symptoms caused by compression of an airway. Wheezing, persistent cough, fever, and recurrent pneumonia may result in such children. In infants and smaller children, airway compression can lead to significant and life-threatening air trapping and congenital lobar emphysema. In contrast, patients with peripherally located cysts are more likely to be asymptomatic or present with milder, nonspecific symptoms such as cough, dyspnea, tachypnea, or wheezing. Physical examination is often unrevealing, but in patients with large, centrally located lesions, tracheal deviation may be present.

Management

Detection of bronchogenic cysts almost always occurs by radiographs. A chest radiograph may demonstrate findings of a smooth paratracheal or hilar mass, airway displacement and/or air trapping, a structure containing an air–fluid level, or may be normal. CT scan and MRI are helpful in identifying and delineating the anatomic relations of these lesions to surrounding structures. Cysts with turbid, mucoid fluid may appear solid on a CT scan.

The standard treatment of bronchogenic cysts is surgical resection, even if asymptomatic. Active infection should be brought under control. Asymptomatic cysts should be removed to establish the diagnosis and to prevent the complications of secondary bronchial communication, bleeding, or perforation into the pleural cavity. Carcinomas and fibrosarcomas have been reported to arise in benign appearing bronchogenic cysts. Preservation of adjacent normal lung parenchyma is ideal, but some lesions require concomitant wedge, segmental, or lobar lung resection. Thoracoscopy may be used for some lesions, depending on the location and size of the mass.

Congenital Cystic Disease of the Lung (Congenital Cystic Adenomatoid Malformation and Bronchopulmonary Sequestration)

Grouping the several pathologic entities included in congenital cystic disease of the lung makes particular sense for the emergency physician. From a single, giant, unilocular cyst to a mixed lesion composed of multiple cysts and solid tissue, or a lesion composed predominantly of solid tissue with only an occasional small cyst, these lesions are all congenital processes that present with pulmonary infection, an abnormal chest radiograph finding, or possibly, a mass or tension effect. Congenital cystic adenomatoid malformations (CCAMs) are the result of an overgrowth of bronchioles (Fig. 128.11) and an increase in terminal respiratory structures and mucous cells lining the cyst walls. These lesions can lead to air trapping and recalcitrant pulmonary infections. Rarely, neoplasms have been identified within congenital adenomatoid malformations. Bronchopulmonary sequestrations (BPS) arise from an accessory bronchopulmonary bud of the foregut. Histologically, they are portions of pulmonary tissue; however, they are not connected with the normal bronchial tree bronchi or pulmonary vessels and hence the pulmonary tissue is "sequestered." Occasionally, sequestrations have a connection with the esophagus or stomach because of the foregut derivation. Usually, there is a systemic rather than pulmonary blood supply. Sequestration can be intralobar (like cystic adenomatoid malformation) or extralobar. Sequelae of bronchopulmonary sequestration can be either respiratory, in the form or pneumonia or respiratory distress, or circulatory, in which substantial AV shunting can occur within the sequestered lobe, leading to high-output cardiac failure. Case reports of associations between bronchopulmonary sequestration and diaphragmatic abnormalities have been described.

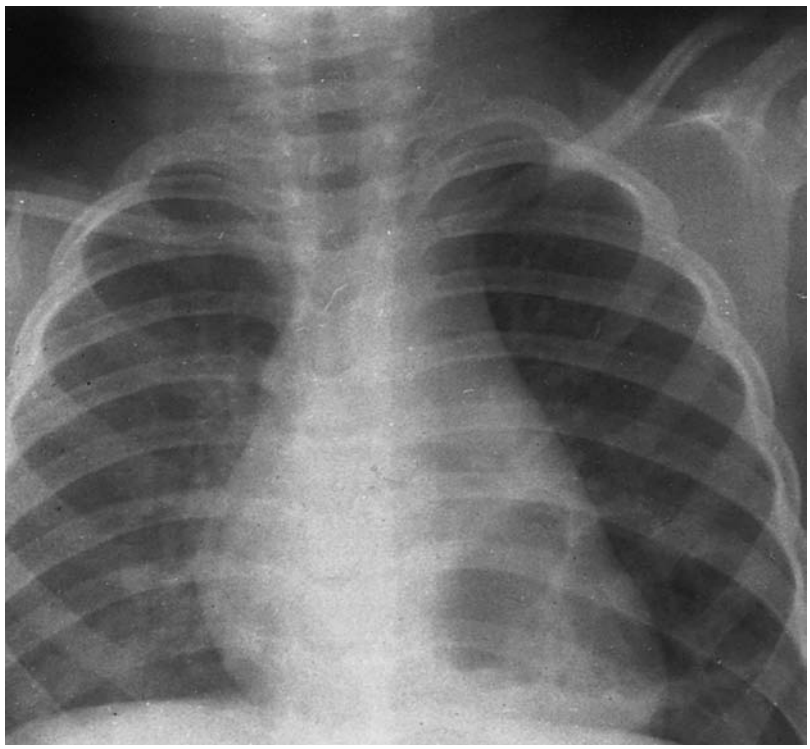

FIGURE 128.11 Cystic adenomatoid malformation in a 12-month-old girl with recurrent episodes of left-sided pneumonia of the lower lobe.

Clinical Findings

Recurrent respiratory infections often lead to the chest radiograph, which confirms the condition. These lesions can appear as hyperaerated segments of lung or lung containing air–fluid levels in the instance of CCAM, or as solid masses in BPS. Clinical findings may be identical to those of a lobar pneumonia, with respiratory symptoms and feeding difficulties. Occasionally, a lesion is discovered after an empyema fails to recover by chest tube placement.

Management

Chest radiographs in the PA, lateral, and bilateral decubitus positions should be obtained to evaluate any areas with air–fluid levels. When a CCAM or BPS is suspected, a CT scan with IV contrast should be obtained to identify any possible systemic blood supply. Because the blood supply may arise from below the diaphragm, the scan should include both the chest and the abdomen. Arteriography is seldom necessary with currently available imaging techniques. The CT scan will likely exclude other conditions that may be misdiagnosed, such as a diaphragmatic hernia, postpneumonic pneumatoceles, or esophageal duplication. Any pathogens identified in the sputum should be treated with appropriate antibiotics (see Chapter 92). After control of superimposed infection, the lesion should be resected to prevent recurrent infection. Attempted aspiration of the cystic lesions or placement of a chest tube is to be avoided because it may lead to spread of infection into the pleural space. Resection can be accomplished with low morbidity and mortality; thoracoscopic resection is feasible for some lesions, with the remainder approached via traditional thoracotomy.

Congenital Lobar Emphysema

Congenital lobar emphysema, also known as infantile lobar emphysema or congenital segmental bronchomalacia, is caused by overexpansion of the air spaces of a segment or lobe of the lung (Fig. 128.12). Operative findings can reveal large blebs protruding from the lung parenchyma (Fig. 128.13), but

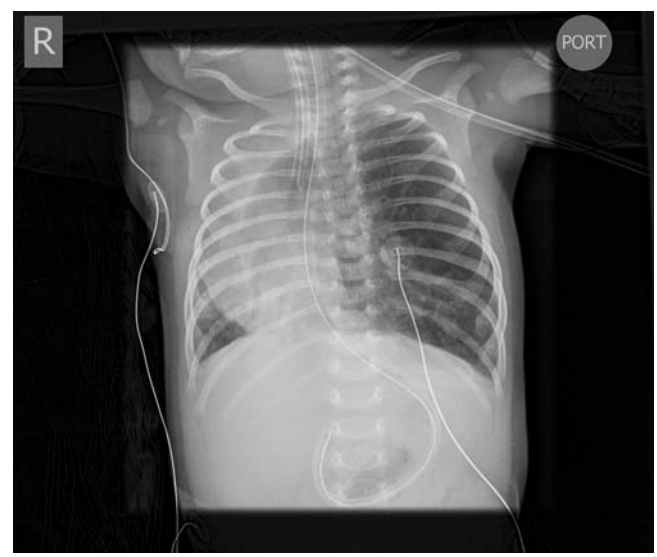

FIGURE 128.12 Congenital lobar emphysema of the left upper lobe in a 3-month-old girl who presented with decreased breath sounds and rales in this area. Note the left-sided secondary compression atelectasis of the lower lobe.

FIGURE 128.13 Operative findings in a child with congenital lobar emphysema.

often the lobe is anatomically normal in appearance, with the exception of massive overdistention. Compression of adjacent normal lung and mediastinal structures frequently occurs, with impairment of gas exchange and life-threatening circulatory collapse a possibility. This process is caused by air trapping from either a developmental deficiency of supporting cartilage in the bronchus of a particular lobe or partially obstructing bronchial lesion, either from endobronchial compression or from external compression.

Clinical Findings

Infants with congenital lobar emphysema are often normal in appearance at birth, but develop tachypnea, cough, wheezing, dyspnea, and/or cyanosis within a few days. The onset of symptoms may be more gradual; nevertheless, 80% of patients are symptomatic by 6 months of age. The upper lobes are involved in about two-thirds of patients, and in less than 1%, the lower lobes are involved. Chest radiographs show striking radiolucency in the involved lobe, with mediastinal shift to the opposite side. The diaphragm is usually flattened on the affected side. It can be difficult to tell whether pulmonary markings are present in the involved lobe, and pneumothorax may be suspected. The compressed normal lung may be erroneously believed to be atelectatic with the emphysematous lobe compensatory.

Management

Initially, the clinical presentation and physiologic derangements may be similar to those of tension pneumothorax, and the two entities should be distinguished. Physical examination may reveal an asymmetric thorax, unilateral hyperresonance and decreased breath sounds on the affected side, and evidence of mediastinal shift. Typical findings on a chest radiograph include lobar overinflation, contralateral shift of the mediastinum, and collapse of lung tissue on the contralateral side, with flattening of the ipsilateral hemidiaphragm.

If a patient is asymptomatic, bronchoscopy may be helpful in identifying and relieving a reversible cause of bronchial obstruction, such as a mucous plug or granulation tissue. However, pulmonary lobectomy is most commonly required and may be needed in the short term if symptoms are progressive. The diseased lobe is evident at thoracotomy because of its overdistended state, often billowing out of the chest. Lobectomy is curative if the cause of the obstruction is also relieved.

Congenital Pulmonary Arteriovenous Fistula

Congenital pulmonary AV fistula is a congenitally occurring communication between a major pulmonary artery and a vein within the lung, usually with an aneurysmal sac. Fistulae vary in size, from a few millimeters to several centimeters, and can be multiple. At times, a systemic artery may also be involved. Direct right-to-left shunting leads to hypoxemia, and the size of the fistula correlates with the degree of desaturation.

Clinical Findings

As the initial presentation of this disorder is frequently that of wheezing and desaturation, the child may be misdiagnosed as having asthma. Clubbing and cyanosis may demonstrate the hypoxemia. Examination of the chest may recall a palpable thrill or murmurs. If there are symptoms of hemoptysis and epistaxis, one may find telangiectasias or hemangiomas of the skin and mucous membranes. Evaluation of the family may also reveal the presence of hereditary hemorrhagic telangiectasis (Rendu-Osler-Weber disease), which is present in more than half the patients with congenital pulmonary AV fistula.

Management

Children who are symptomatic from this condition are best evaluated by CT scan, contrast echocardiography, perfusion scintigraphy, and arteriograms of the pulmonary artery and aorta. Chest radiographs may demonstrate the aneurysmal areas as rounded or lobulated discrete lesions in the parenchyma. Often, tortuous vessels trace from these rounded areas to the hilum. Resection of the fistula, often involving lobectomy, is indicated if the lesion is localized. Unfortunately, some patients have such diffuse disease that resection is impossible.

Rare Lesions

There are various rare lesions of the lungs, including tumors and uncommon infections. Rare tumors, often identified incidentally on radiographs, include primary sarcoma, pulmonary blastoma, hamartomas, and teratomas. Fungal infections, including actinomycosis, histoplasmosis, mucormycosis, and coccidioidomycosis, may look like tumors on chest radiographs. Atresias of the bronchus or pulmonary artery are rare and produce differences in the density of the two lungs. The reader is referred to texts of pulmonary medicine or thoracic surgery for further discussion.

MEDIASTINAL TUMORS

Mediastinal Mass

At least one-third of all mediastinal masses occur in children younger than 15 years. Half of these masses are symptomatic and half of the symptomatic masses are malignant tumors,

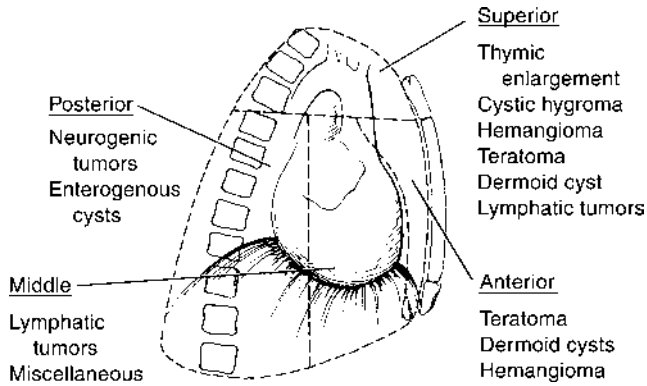

FIGURE 128.14 Mediastinal tumors in children. Differential diagnosis is based on anatomic location within the mediastinum.

with the likelihood of malignancy increasing with age of the patient. More than 90% of the asymptomatic masses are benign. The mediastinum is commonly divided into anterior, superior, middle, and posterior compartments (Fig. 128.14). The superior mediastinal compartment contains germ cell tumors of the thymus, thymomas, and lymphangiomas. The anterior compartment contains thymic tumors, lymphangiomas, as well as lymphomas and teratomas. Bronchogenic cysts in the area of the hilum are located in the middle mediastinum. Most neurogenic tumors, such as neuroblastomas and ganglioneuromas, as well as esophageal cysts, are found in the posterior compartment. Neurogenic tumors are the most common cause of mediastinal masses, with lymphomas and germ cell tumors being second and third in frequency. Infection is an uncommon cause of mediastinal node enlargement but, when present, is largely caused by histoplasmosis. Thymic enlargement may mimic an anterior mediastinal mass.

Clinical Presentation

Mediastinal masses usually present with chest pain or respiratory symptoms as a result of airway obstruction or erosion. Patients may present with cough, wheezing, recurrent respiratory infections, bronchitis, atelectasis, and hemoptysis. Dysphagia and hematemesis may occur with compression of the esophagus. SVC syndrome is a rare complication, usually in association with a rapidly growing tumor. If the recurrent laryngeal nerve is compressed as a result of the mass, hoarseness and inspiratory stridor may result. Spinal cord compression and vertebral erosion can be seen with a posterior mediastinal tumor.

Management

Children with tumors of the anterior or superior mediastinum should be admitted to a hospital to undergo urgent evaluation because these tumors may pose an immediate threat to life. CT scan or MRI of the chest is generally needed to supplement plain radiographs in order to further define the location and extent of the mass, as well as potentially provide details that may help establish the diagnosis.

When biopsy of a large mediastinal mass is necessary, the logistics of biopsy require careful, thoughtful evaluation, ideally involving the pediatrician, surgeon, oncologist, and anesthesiologist. Airway compression by large mediastinal masses may be critical. Endotracheal intubation and delivery of general anesthesia may decrease negative intrathoracic pressure leading to occlusion of the thoracic trachea by the tumor. This situation can be challenging to manage; passage of a rigid bronchoscope may be necessary to stent the trachea open to allow gas exchange. CT scan should be used to evaluate large mediastinal masses in order to assess the likelihood of tracheal compression. MRI may be a better diagnostic modality for posterior mediastinal masses because many of them are neurogenic in origin and may have extension into the spinal canal. If tracheal compression is present, consideration should be given to the feasibility of biopsy under local anesthesia. An echocardiogram should be obtained prior to surgery in order to assess the extent of mediastinal shift and the degree of atrial or ventricular compression by the mass. The anesthesiologist should be apprised of the nature of the tumor, and a bronchoscope should be at hand if a general anesthetic is needed. Tissue may be obtained in numerous ways, with the location of the tumor dictating the approach: (i) with a mediastinoscope, inserted via an incision above the sternal notch and passed behind the sternum; (ii) a video-assisted thoracic surgery (thoracoscopy); (iii) a thoracotomy, usually limited, or (iv) through a high, anterior interspace approach (Chamberlain procedure). In some cases, mediastinal masses can be accurately diagnosed by biopsy of supraclavicular or other extrathoracic adenopathy.

DIAPHRAGMATIC PROBLEMS

Congenital Diaphragmatic Hernia

CDH is the presence of intestinal viscera in the chest through a defect in the diaphragm not caused by trauma. Nearly 90% of CDHs occur on the left side through the foramen of Bochdalek. Herniation may also occur through the foramen of Morgagni, which lies just posterior to the sternum comprising 2% or 3% of all diaphragmatic hernias. CDH may be associated with a variety of genetic conditions, including Cornelia de Lange, Fryns, and Beckwith-Wiedemann syndromes. Traumatic diaphragmatic rupture may occur through any portion of the diaphragm and may present in a delayed time frame. Information in this chapter focuses on diaphragmatic hernias diagnosed in stable older babies and children who are more likely to present to the ED than those in whom the diagnosis is made in the perinatal period.

Pathophysiology

Most babies with CDH become symptomatic as newborns when profound respiratory compromise leads to diagnosis. Until recent years, it was believed that the respiratory difficulties of babies with CDH were caused by mechanical compression of the lung by the intestinal viscera extruded through the diaphragmatic opening into the chest. It has become clear that the situation is more complex. Pulmonary hypertension, surfactant deficiency, and a vicious cycle of hypoxia, acidosis, and intrapulmonary shunting lead to the death of a significant number of newborns with this diagnosis. CDH may also be identified after the neonatal period. Older infants and children are less likely to present with this form of respiratory distress but may present with features of bowel obstruction, visceral

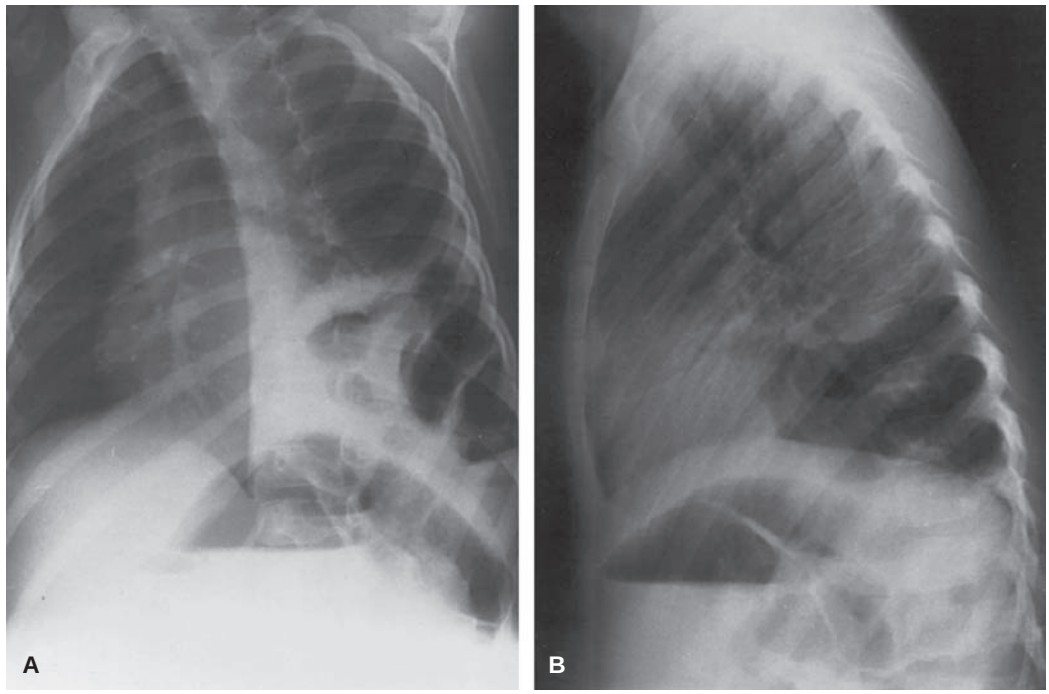

FIGURE 128.15 A 4-year-old boy admitted with 1-day history of recurrent severe upper abdominal colicky pain with dyspnea and decreased breath sounds in the left base. Posteroanterior (**A**) and lateral (**B**) chest films demonstrate multiple bowel loops in the lower, posterior, left side of chest, indicative of a foramen of Bochdalek hernia that was subsequently repaired without difficulty.

ischemia, or pleural inflammation arising from sudden shift of abdominal viscera into the chest.

Clinical Presentation

When found in older babies and children, identification is usually by a chest radiograph obtained for nonspecific symptoms such as fever, cough, chest or abdominal pain, or vomiting. The presence of loops of intestine above the diaphragm may be seen on the chest radiograph, and the stomach may be confirmed to be in the chest by the passage of a nasogastric tube that demonstrates its tip in the thorax. Loops of intrathoracic intestine on the chest radiograph may suggest pneumonia with pneumatocele formation (Fig. 128.15). A gastrointestinal contrast study or preferably a chest and abdominal CT scan may provide clarity if the diagnosis is uncertain. Potential intestinal or visceral ischemia caused by obstruction and strangulation is one of the reasons operative repair is undertaken.

Management

In the stable patient, surgical repair should be undertaken soon after the diagnosis is made but may be elective in the asymptomatic patient. Because diagnosis may be made incidentally during evaluation for a condition such as pneumonia, which would increase the risk of elective operation, the timing of surgery must be tailored to the individual situation. Certainly, the pediatric surgeon should be consulted as soon as the diagnosis is suspected. If a patient is symptomatic from an acute ischemia of the herniated viscera, an urgent operation may be required. Usually, a transverse or subcostal abdominal incision is used because it permits reduction or resection of compromised intestine or other abdominal viscera and allows for correction of the malrotation that usually accompanies this condition. In selected patients, thoracoscopic repair has been performed safely and effectively.

Foramen of Morgagni Hernias

Frequently asymptomatic or presenting with vague symptoms of abdominal discomfort, a Morgagni diaphragmatic hernia results from a defect in the anterior diaphragm just behind the sternum. Substernal or epigastric pain and bowel obstruction resulting from the narrow neck of the sac may occur spontaneously or be precipitated by any condition that increases intraabdominal pressure (Fig. 128.16).

Clinical Findings/Management

A lateral chest radiograph should clarify the abnormality as anterior and demonstrate that the herniation is not through the esophageal hiatus. A contrast enema or a CT scan in stable patients should be considered if doubt persists. Surgical repair, indicated to prevent incarceration of bowel even in asymptomatic patients, may be performed laparoscopically or through an upper abdominal incision.

Diaphragmatic Eventration

Eventration is an abnormal elevation of the diaphragm and may present to the emergency physician as an unexpected finding on a chest radiograph obtained for another reason. Eventration may be congenital or acquired. Acquired diaphragmatic even-

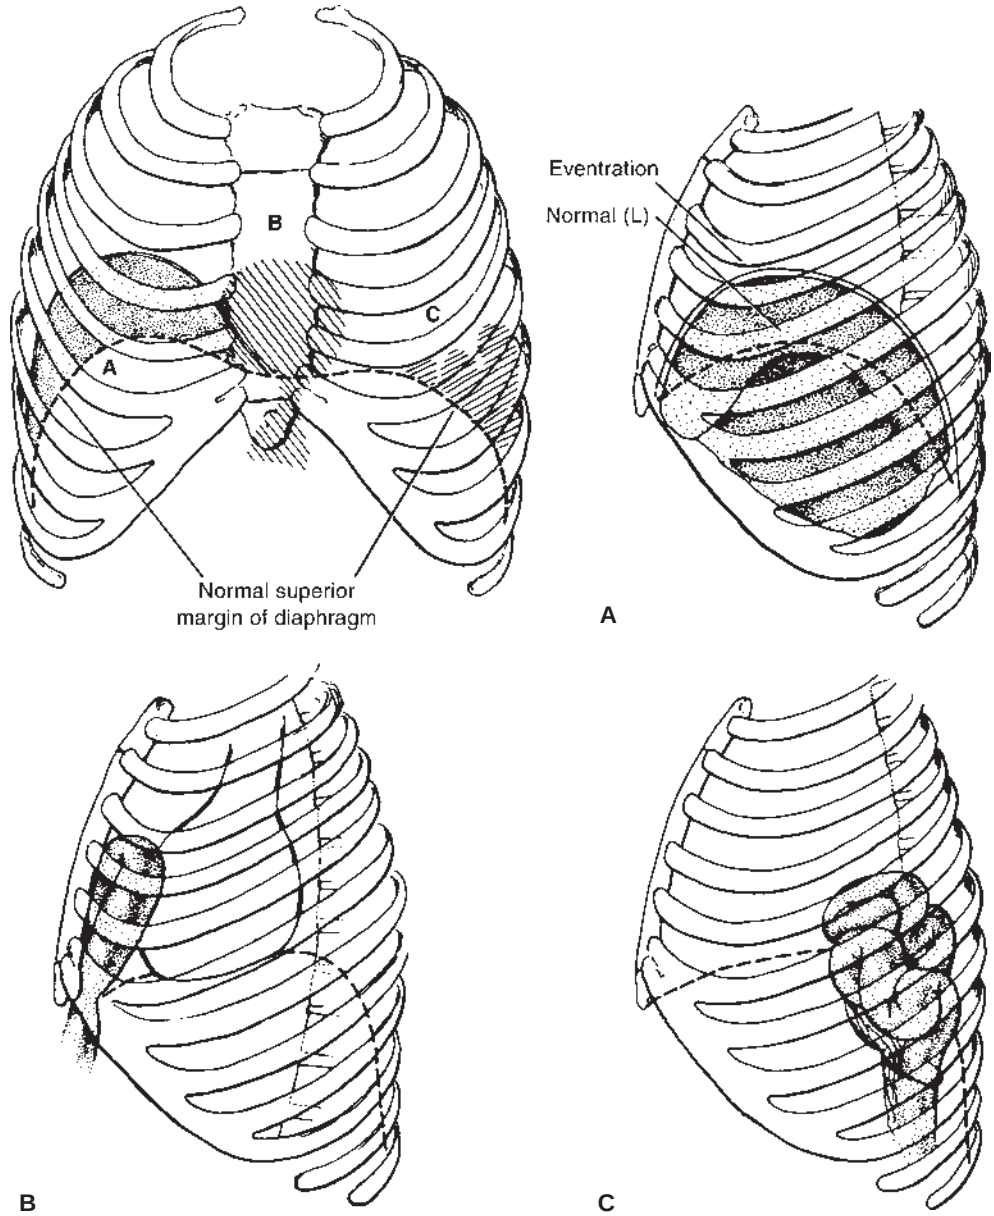

FIGURE 128.16 Diaphragmatic defects in infants and children. The nature of these defects are often better appreciated on a lateral view of the chest. Eventration of the diaphragm (**A**); foramen of Morgagni hernia (**B**); and left foramen of Bochdalek hernia (**C**).

tration is commonly the result of a phrenic nerve paralysis, which may be caused by birth, operative, or other trauma. Neoplastic or inflammatory processes near the phrenic nerve can also lead to eventration.

Diaphragmatic eventration occurs most commonly on the left side but may be bilateral. The affected hemidiaphragm moves paradoxically during inspiration and expiration, with compromise of pulmonary mechanics and function. A large enough congenital eventration may affect prenatal and postnatal lung development, potentially resulting in pulmonary hypoplasia.

Clinical Findings

Patients with eventration may be asymptomatic but potentially will exhibit respiratory distress as a result of alveolar hypoventilation and paradoxical diaphragmatic movement. This frequently manifests as tachypnea, pallor, and feeding difficulties. Physical examination findings of nonaerated lung, including absent breath sounds and dullness to percussion, should be investigated by chest radiograph. Chest radiographs usually confirm the presence of an elevated hemidiaphragm (Fig. 128.17). This study may be confirmed by fluoroscopy or ultrasonography, which will demonstrate paradoxical motion of the hemidiaphragm and mediastinal shift with inspiration and expiration.

Management

Small degrees of eventrations that are incidentally identified and asymptomatic may be observed. The need for repair is based on the severity of the eventration and the degree of

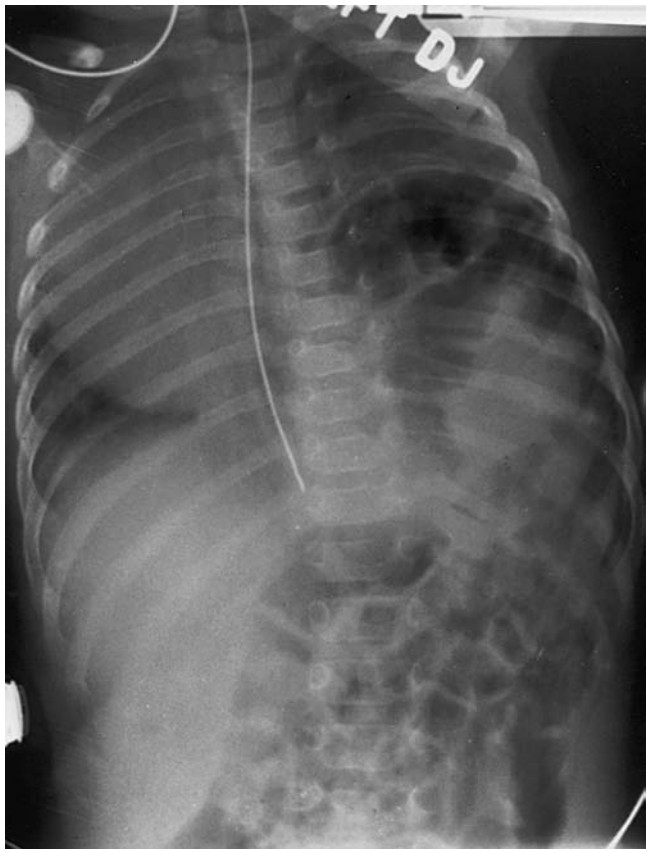

FIGURE 128.17 This 2-month-old girl was well until 4 days before admission. She developed congestion and an apparent upper respiratory tract infection. She slowly developed increasing dyspnea and was admitted in acute respiratory distress. A chest radiograph revealed a high left diaphragmatic eventration with a significant mediastinal shift to the right.

pulmonary dysfunction. Repair consists of plication of the attenuated portion of diaphragm and can be performed thoracoscopically or via open thoracotomy. In selected cases of acquired diaphragmatic dysfunction due to phrenic nerve paralysis, an implanted pacemaker can be used to stimulate the phrenic nerve and produce diaphragmatic motion.

Paraesophageal Hernia

A paraesophageal hernia is a form of hiatal hernia in which the stomach and potentially other intraabdominal organs protrude through the esophageal hiatus. It is uncommon in children and may be congenital and/or associated with other anomalies. A paraesophageal hernia typically presents with symptoms of respiratory distress, vomiting, and failure to thrive. Symptoms of upper abdominal pain, tachypnea, and tachycardia may accompany the condition, as the herniated stomach distends with swallowed air inside the chest. Such symptoms may also be indicative of gastric volvulus, strangulation, and necrosis, although these findings are uncommon in children with paraesophageal hernia.

Clinical Findings/Management
