CHAPTER 90 ■ PEDIATRIC AND ADOLESCENT GYNECOLOGY

JOELI HETTLER, MD

INTRODUCTION

Evaluation of Premenarcheal Girls

Among premenarcheal girls with gynecologic complaints, the most commonly encountered specific entities are vaginal infections, urethral prolapse, trauma, and suspected sexual abuse. Many other patients have nonspecific genital irritation. In assessing any child with a gynecologic complaint, the physician must be alert to the possibility that sexual abuse is the underlying problem.

The premenarcheal girl should not receive a standard pelvic examination, including the use of a speculum and vaginoabdominal palpation, because such an examination is uncomfortable and unnecessary for diagnosis. An exception to this rule is the girl with vaginal bleeding caused by an injury. If an external source for the bleeding cannot be identified, speculum examination of the vaginal vault under procedural sedation or anesthesia is warranted to allow visualization of the injury. Some major vaginal lacerations produce only mild pain or minimal bleeding. For most premenarcheal girls, the history, a general physical examination including inspection of the vulva (Fig. 90.1) and visualization the vagina, and culture of a vaginal discharge, if one is present, will lead to a diagnosis.

Most young children will cooperate readily for initial inspection of the external genitalia either on the examining table or while held on a parent's lap. The child should be placed in the supine position with flexed hips and knees and with heels touching (Fig. 90.2). In most cases, the examiner can obtain a good view of the child's vaginal vestibule by grasping the labia majora firmly and exerting gentle laterocaudal traction. For inspection of the vaginal vault, the knee-chest position is helpful. Most children older than 4 years can cooperate for this maneuver. The child is first asked to "get up on your hands and knees like you are going to crawl." She is then instructed to rest her head on her folded arms, facing her parent. The examiner or an assistant gently presses the child's buttocks and labia upward and outward. If the child relaxes her abdominal muscles and back at this point, her vagina will usually fall open, permitting inspection of the vault, using an otoscope for magnification and illumination (Fig. 90.2). If the child has a vaginal discharge or bleeding, she should then be returned to the supine position so that specimens for culture can be obtained, using either a soft plastic medicine dropper or a cotton-tipped swab moistened with nonbacteriostatic saline solution. A rectal examination should be performed if there is abdominal pain or a lower abdominal mass. Rectoabdominal palpation may be helpful if a hard vaginal foreign body is suspected, but nearly all vaginal foreign bodies are composed of toilet tissue and are therefore not palpable. On rectal examination, a child's cervix is normally felt as a firm, midline button of tissue, but the uterus and ovaries should not be palpable.

Evaluation of Adolescent Girls

The differential diagnosis of gynecologic symptoms and signs in an adolescent girl who has had sexual intercourse includes a number of major entities [e.g., pregnancy, pelvic inflammatory disease (PID), tuboovarian abscess] that do not pertain to the teenager who is not sexually experienced. Therefore, the emergency physician evaluating an adolescent girl must routinely inquire about sexual activity and, if the response is positive, about contraceptive use, prior sexually transmitted infections (STIs), pregnancies, and abortions. A detailed menstrual history—age at menarche, characteristics of the menstrual cycle, date of last menstrual period, presence or absence of dysmenorrhea—should be obtained from every adolescent patient.

Obtaining a candid history of sexual activity from adolescent girls is not always a simple matter, but the emergency physician can maximize honest reporting by using some basic interviewing principles. First, the teenage girl who asks for a female physician is stating directly what will make her more comfortable. Her request should therefore be honored if possible. Second, questions to the teenager about sexual activity (as well as other potentially sensitive subjects such as contraception, sexual orientation, and substance abuse) should not be asked when a parent or sexual partner is present. Third, before any questions are asked, it is helpful to assure the teenager that if she wants, her answers will be kept confidential.[1] Finally, the physician who adopts an empathetic, nonauthoritarian interviewing style is most likely to win the teenager's trust.

[1]All 50 states and the District of Columbia allow most minors to consent to testing and treatment of sexually transmitted infections (STIs), and many explicitly include testing and treatment of HIV. Many states, however, allow physicians to inform parents that the minor is seeking or receiving STI services when they deem it in the best interests of the minor. Twenty-one states and the District of Columbia explicitly allow all minors to consent to contraceptive services, and 35 states require some type of parental involvement in a minor's decision to have an abortion. Emergency physicians should familiarize themselves with the relevant current laws of their own states. From www.guttmacher.org/statecenter/spibs/index.html. Accessed October 9, 2008.

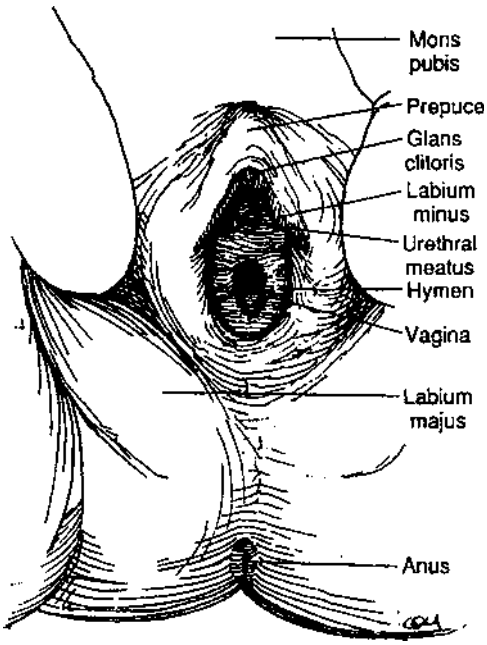

FIGURE 90.1 Anatomy of the normal female external genitalia.

Most virginal adolescents with menstrual cramps, mittelschmerz, or vaginal discharge do not require full pelvic examinations because the likelihood that occult pelvic pathology will be found is small. Rectoabdominal palpation can be used to evaluate the virginal patient with undiagnosed lower abdominal pain or a mass. However, trauma and vaginal bleeding are indications for pelvic examination, even among patients who have never been sexually active.

Every sexually experienced adolescent girl who comes to the emergency department (ED) for abdominal pain or a gynecologic complaint must receive a pelvic examination because such patients have high rates of pregnancy and STIs. Before the examination, the patient should be given a chance to empty her bladder. If urine nucleic acid amplification testing for *Neisseria gonorrhoeae* or *Chlamydia trachomatis* is planned, she should be instructed to void without cleaning the periurethral area and save the first 30 mL of urine in a specimen cup. A female chaperone is necessary when the examining physician is male and recommended when she is female. The examiner should take care to explain the examination and answer any questions because many sexually active adolescents have never had a pelvic examination. After the patient is situated in the lithotomy position and draped, her vulva is inspected and a narrow speculum is inserted for visualization of her vagina and cervix. A sterile cotton-tipped swab is used to collect endocervical secretions for culture of *N. gonorrhoeae*. A second endocervical specimen is obtained to test for *C. trachomatis* antigen. If nucleic acid amplification testing is performed, endocervical secretions or urine may be used. After a sample of vaginal discharge for microscopic examination has been taken with a third swab, the speculum is removed. If the physician suspects gonococcal infection, urethral and rectal swabs may also be taken. The endocervical specimens should be obtained before bimanual palpation is done because lubricating jelly can inhibit growth of *N. gonorrhoeae*. During the bimanual examination, the cervix is assessed for softness, patency of the os, and pain elicited by lateral cervical movement. The size and consistency of the uterus are determined, and the adnexal areas are palpated for masses and tenderness. Finally, rectovaginal palpation is performed, checking again for masses and local tenderness.

In addition to providing treatment of the patient's current problem, the emergency physician should determine the source of the patient's routine outpatient gynecologic care. The ED should maintain a list of local programs that provide health care to adolescents so that referral can be made easily. Many communities have specialized services for teenagers sponsored by hospitals, health departments, or private agencies. Similarly, because previously unrecognized pregnancy is a common ED diagnosis, procedures should be established to facilitate prompt referral of teenagers who need counseling, prenatal care, and therapeutic abortion to the appropriate services.

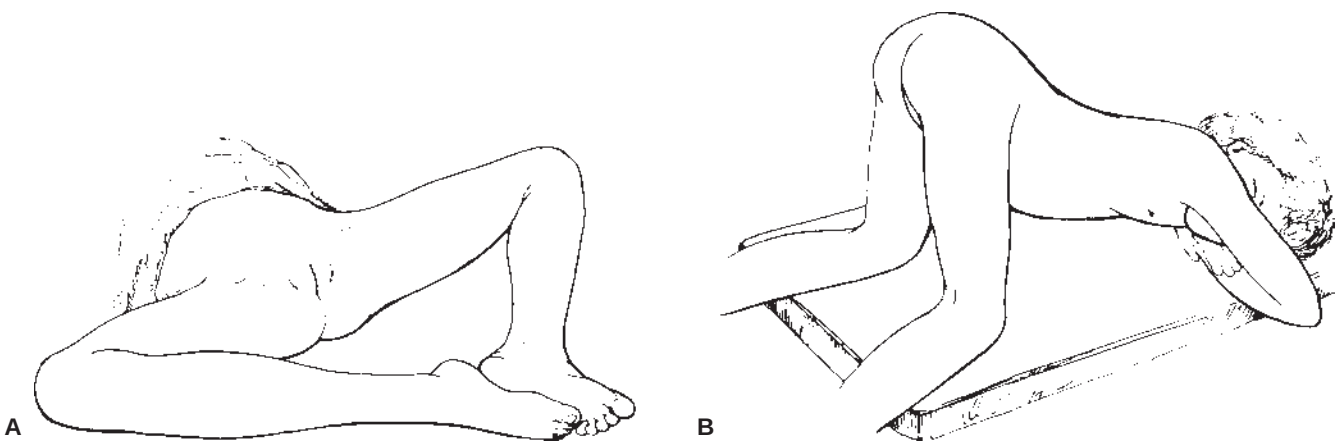

FIGURE 90.2 **A:** Girl in the frog-leg position for the examination of the external genitalia. **B:** Girl in the knee-chest position with exaggerated lordosis and relaxed abdominal muscles. The examiner can inspect the interior of her vagina by gently separating her buttocks and labia, using an otoscope without an attached speculum for illumination.

GYNECOLOGIC DISORDERS OF CHILDHOOD

Congenital Vaginal Obstruction

Background

Definition. In normal females, the vagina provides an outlet for genital secretions and menstrual blood. If the vagina is obstructed, accumulating fluid will eventually distend it, causing symptoms to develop either during infancy or after menarche. During infancy, vaginal distension with mucus secreted as a result of stimulation by maternal hormones is called hydrocolpos or mucocolpos. If the volume of secretions is so large that the uterus is also distended, this condition is called hydrometrocolpos. If an obstructing congenital malformation is not recognized before menarche, menstrual blood will gradually fill the vagina, producing hematocolpos or, less commonly, hematometrocolpos.

Etiology

For hydrocolpos or one of its variations to arise, a female must have vaginal obstruction, a uterus, and a patent cervix. The two most common anomalies with these features are transverse vaginal septum (sometimes called vaginal atresia) and imperforate hymen. These malformations are probably produced between the 16th and 20th weeks of gestation if the developing vaginal plate fails to perforate at its junction with either the fused paramesonephric (Müllerian) ducts proximally or the urogenital sinus caudally. Most patients with complete agenesis of the vagina (Rokitansky-Küster-Hauser syndrome) have rudimentary uteri or none at all, so hydrocolpos does not occur. Transverse vaginal septum occurs sporadically, with an estimated incidence of 1 in 4,000 to 5,000 girls. Imperforate hymen occurred in 0.1% of term female neonates.

Clinical Manifestations

Infancy. Although vaginal obstruction should be properly identified during the initial examination of the newborn female, infants with hydrocolpos often go unrecognized until days or weeks later when they develop the three hallmarks of this condition: (i) a lower abdominal mass, (ii) difficulty with urination, and (iii) a visible bulging membrane at the introitus. In more severe cases, infants may also have constipation, hydronephrosis, edema of the lower extremities, and hypoventilation. Inspection of the perineum should immediately indicate the proper diagnosis.

Adolescence. The girl with congenital vaginal obstruction that escapes notice during infancy will not come to attention until late in puberty when she presents with either primary amenorrhea or lower abdominal pain. She will have had satisfactory pubertal development until her menarche apparently fails to occur. Accumulating menstrual blood will then eventually produce vague lower abdominal pain that is not necessarily cyclic. As the hematocolpos grows, it will finally interfere with comfortable micturition, producing symptoms of urgency, frequency, or dysuria. The history of amenorrhea and the finding of a lower abdominal mass may lead the physician to suspect a tumor or even pregnancy, but the characteristic appearance of the introitus covered by a bluish bulging membrane is diagnostic of hematocolpos with imperforate hymen (Fig. 90.3). Patients with a high transverse vaginal septum will not be so easily diagnosed because the introitus will appear normal. However, palpation of the vagina will promptly show that it is obstructed and that the cervix cannot be felt.

FIGURE 90.3 Hematocolpos in a 15-year-old patient with an imperforate hymen. The membrane bulges at the introitus underneath the labia minora (see also Fig. 90.4).

Complications

The complication of congenital vaginal obstruction most likely to require urgent attention among both infants and adolescents is acute urinary retention. Patients without complete urethral obstruction can instead have variable degrees of hydroureter or hydronephrosis as a result of the chronic extrinsic pressure. Rarely, an infant may have respiratory insufficiency or inferior vena caval obstruction because of the large mass. Imperforate hymen is usually an isolated anomaly, but other types of obstruction, chiefly transverse vaginal septum, are regularly associated with renal malformations, including hypoplastic or single kidneys, and duplicated or ectopic collecting systems. Endometriosis can be a late complication of severe hematocolpos.

Differential Diagnosis

The differential diagnosis of hydrocolpos and its variations includes patients with either a lower abdominal mass or a pelvic mass but no vaginal obstruction and patients with apparent vaginal obstruction. In the former category, the physician simply needs to demonstrate that the patient has a patent genital tract. The latter group includes girls with microperforate hymen, labial adhesions, Gartner's (mesonephric) duct cysts,

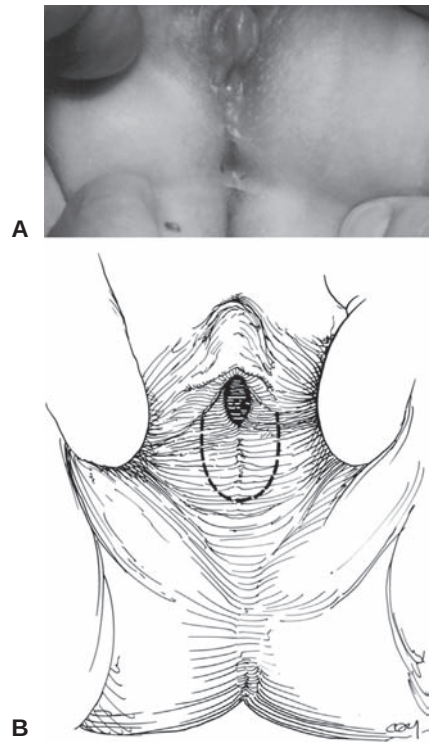

FIGURE 90.4 **A:** Labial adhesion in an asymptomatic 3-year-old girl. **B:** A flat surface, a dense central line of fusion, and an opening below the clitoris are characteristic features of labial adhesions, which cover the introitus (see also Fig. 90.3).

and, rarely, complete agenesis of the vagina and testicular feminization. The microperforate hymen has a tiny orifice just below the urethra and requires only careful inspection for its diagnosis. Adhesions of the labia minora are superficial to the plane of the hymen and are characterized by a central vertical line of fusion (Fig. 90.4). A large vaginal Gartner's duct cyst can resemble an imperforate hymen, but it can be seen to protrude through the hymenal ring, which is itself patent. Patients with complete agenesis of the vagina have only a rugated dimple or shallow indentation at the introitus. A short blind vagina also occurs in testicular feminization, a disorder characterized by end-organ insensitivity to androgen. These patients are phenotypic females with an XY karyotype who undergo breast development at puberty but lack pubic hair and female reproductive organs.

Management

Patients with congenital vaginal obstruction need surgical treatment. The management of simple imperforate hymen can be modified according to the patient's age. Surgery should be scheduled promptly for adolescents but can be performed electively for asymptomatic infants and children.

Labial Adhesions

Background

Labial adhesions are an acquired attachment of the medial surfaces of the labia minora to each other. The terms *labial fusion*, *synechiae*, and *agglutination* are also often used to describe this condition. Labial adhesions are a common gynecologic condition, occurring in approximately 0.6% to 7% of girls between the ages of 3 months and 6 years.

Pathophysiology

The etiology of labial adhesions are unclear, but conditions that lead to irritation of the vulva in the prepubertal girl with normally low levels of estrogen are thought to contribute to the fusion of the edges of the labia minora. The line of fusion usually advances anteriorly from the posterior frenulum of the labia minora.

Clinical Manifestations

Most labial adhesions are asymptomatic, being noted by a parent at home or a physician during the child's routine physical examination. The diagnosis of labial adhesions can be made by simple inspection of the child's genitalia. When the labia majora are gently retracted laterally, a flat plane of tissue marked by a central vertical line of adhesion obstructs the view of the introitus within (Fig. 90.4B). This thin vertical raphe is pathognomonic of labial adhesions. It is occasionally difficult to detect if the child's adhesions are old and dense. The length of the adhesions is variable, and they can be perforated. They are usually thickest posteriorly and stop below the clitoris. Even when adhesions appear to have closed the vulva completely, a pinpoint opening generally permits the egress of urine.

While most girls with labial adhesions have no symptoms, a few may have associated dysuria, frequency, or refusal to void that may be a result of either the obvious mechanical obstruction or concurrent urinary tract infection. Whether associated urinary tract infections are a cause or an effect of adhesions is uncertain, but these are recognized complications of the condition. For girls with urinary tract infections, urine cultures should be performed and appropriate medical follow-up provided. Because vaginal infection is not associated with adhesions, vaginal cultures are not indicated except in patients who have concurrent vaginal discharge. Asymptomatic girls need no laboratory evaluation.

Management

Treatment is not indicated for asymptomatic girls with labial adhesions because the condition spontaneously remits early in puberty as a result of increasing endogenous estrogen. Some parents, however, prefer that their daughters be treated. Of girls with labial adhesions, 90% can be treated successfully with a small amount of estrogen cream (Premarin® or Dienestrol) dabbed onto the adhesions at once or twice a day for 2 to 4 weeks. Parents should be warned specifically that prolonged use of the hormone could stimulate breast growth in children. Vulvar hyperpigmentation is a common, transient adverse effect of treatment. Labial adhesions should never be manually separated. The procedure is painful and usually results in relapse when the raw, newly separated labia adhere again. As recurrence rates vary from 15% to 40%, care after separation is important. Proper hygiene is recommended, as well as daily application of a bland emollient (petroleum jelly).

Urethral Prolapse

Background

Urethral prolapse is the protrusion of the distal urethral mucosa outward through its meatus, with a cleavage plane between the longitudinal and circular–oblique smooth-muscle layers of the urethra. Most happen spontaneously, but a sudden or recurrent increase in intraabdominal pressure (severe coughing, seizure, constipation, lifting heavy objects) has been noted to precede some cases. The prolapsed segment is constricted at the meatus and venous blood flow is impaired, so the involved tissue becomes swollen, edematous, and dark red or purplish. If the process is not corrected, the tissue can become thrombosed and necrotic.

About half of affected females are prepubertal children, and the majority of the remainder is postmenopausal women. Most prolapses during childhood occur in girls between the ages of 2 and 10 years. Of girls with urethral prolapse, the vast majority are African American.

Clinical Manifestations

Vaginal bleeding or spotting is the chief complaint of 90% of children with significant urethral prolapses. The bleeding is painless, occasionally misinterpreted as hematuria or menstruation, and accompanied by urinary frequency or dysuria in about one-fourth of cases. Only a minority of girls or their parents are aware of the presence of a vulvar mass. However, it is not rare for the physician simply to note a small prolapse during the routine examination of an asymptomatic child.

On examination of the child's vulva, a red or purplish, soft, doughnut-shaped mass is seen (Fig. 90.5). Most prolapses are not tender and measure 1 to 2 cm in diameter. By retracting the labia majora posterolaterally, the examiner can often demonstrate that the mass is separate from and anterior to the vaginal introitus, but this process may be difficult if the prolapse is large. A small central dimple in the mass indicates the urethral lumen. This dimple can be missed if lighting is inadequate, bleeding is active, or mucosal edema is significant. In most cases, the appearance of the prolapse is diagnostic. However, if the diagnosis is in doubt, sterile straight catheterization of the bladder through the mass can be performed to demonstrate the anatomic relationships safely and rapidly. No other test is needed. If urinalysis is performed on a spontaneously voided specimen, red blood cells are likely to be found, but urine cultures are routinely sterile. Urethral polyps, prolapsed ureterocele, sarcoma botryoides, and urethral carcinoma may be included in the differential diagnosis, but these entities are rare in children and lack the characteristically annular appearance of a urethral prolapse.

Management

For the symptomatic patient with a small segment of prolapsed mucosa that is not necrotic, warm moist compresses or sitz baths, combined with a 2-week course of topical estrogen cream, may be prescribed. Most patients treated in this way have improved within 10 to 14 days and remained normal thereafter, thus avoiding surgery. Patients with dark-red or necrotic mucosa should be treated surgically within several days by reduction of the prolapse and/or excision of necrotic tissue. After the diagnosis is confirmed by cystoscopy, the prolapse is excised and the cut edges are sutured together.

GYNECOLOGIC DISORDERS OF ADOLESCENCE

Dysmenorrhea

Background

Definition. Primary dysmenorrhea is painful menstruation that cannot be attributed to a specific pelvic abnormality such as endometriosis, PID, or a uterine malformation. Menstrual pain resulting from an underlying disorder is termed secondary dysmenorrhea.

Epidemiology

Among adolescents, primary dysmenorrhea is far more common than secondary dysmenorrhea. The incidence of primary dysmenorrhea is estimated to be 60% to 70%, with 15% of adolescents reporting symptoms severe enough to interrupt with daily activities. The prevalence of dysmenorrhea increases with increasing chronologic and gynecologic (postmenarcheal) age, reflecting the strong association of dysmenorrhea with ovulatory menstrual cycles. At gynecologic age 1, approximately 30% of girls have dysmenorrhea. By gynecologic age 5, the proportion increases to nearly 70%. Risk factors for dysmenorrhea include early menarche, cigarette smoking, and possibly low fish consumption.

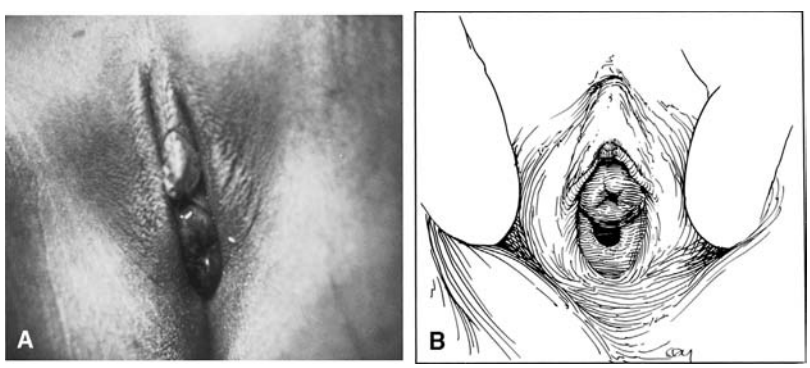

FIGURE 90.5 **A:** Urethral prolapse in a 6-year-old girl with "vaginal" bleeding. The vaginal orifice cannot be seen. **B:** The smooth doughnut shape and central lumen are characteristic features of a urethral prolapse, which, if large or swollen, often conceals the vagina below it.

Pathophysiology

The end of ovulatory menstrual cycles, prostaglandins $F_{2\alpha}$ and E_2 are synthesized by and released from endometrial tissue. The prostaglandins cause increases in both the uterine resting tone and the amplitude and frequency of myometrial contractions. Uterine contractions that exceed systolic blood pressure produce tissue ischemia and perceptible pain. Intravenous (IV) administration of prostaglandins can reproduce the systemic discomforts—vomiting, diarrhea, and headache—that often accompany dysmenorrhea. A dose–response relationship has been demonstrated in studies comparing the prostaglandin content of menstrual fluid from women with and without dysmenorrhea and from individual women during painful and pain-free cycles.

The role of ovarian hormones in endometrial prostaglandin production is not completely understood. Progesterone or its withdrawal appears to enhance prostaglandin synthesis during ovulatory cycles. Conversely, progesterone-impregnated intrauterine devices (IUDs) and the inhibition of ovulation by birth control pills are associated both with decreased prostaglandin production and with relief from dysmenorrhea.

The most common explanation for menstrual cramping is the overproduction of prostaglandins. Before menstruation, as progesterone withdrawal occurs, arachidonic acid (an omega-6 fatty acid) is released, prompting a cascade of prostaglandins and leukotrienes. This mediates the inflammatory response that causes both cramping and systemic symptoms. In particular, prostaglandin $F_{2\alpha}$ (a cyclooxygenase metabolite of arachidonic acid) causes potent vasoconstriction and myometrial contractions. The specific role of leukotrienes in dysmenorrhea is still under investigation.

Clinical Manifestations

Typical primary dysmenorrhea consists of cramping, dull, midline, or generalized lower abdominal pain at the onset of a menstrual period. The pain may coincide with the start of bleeding or may precede the bleeding by several hours. Many women have associated symptoms including backache, thigh pain, bloating, diarrhea, nausea or vomiting, and headache. The discomfort usually abates within 48 hours. Because dysmenorrhea is a hallmark of ovulation, adolescents characteristically do not experience dysmenorrhea until after several months of painless, anovulatory cycles. Menstrual pain that begins either at menarche or more than 4 years after regular cycles have been established is less common.

When pain is chronic (lasting throughout the cycle), begins at menarche, or is associated with dysparunia or metrorrhagia, causes of secondary dysmenorrhea should be considered. The most common cause of secondary dysmenorhea in adolescents is endometriosis. Other causes include adhesions, PID, abscess, ectopic pregnancy, miscarriage, ovarian cyst, and reproductive tract anomalies such as rudimentary uterine horn and obstructed genital duplications.

Diagnosis

Patients with straightforward dysmenorrhea have normal physical examinations and no associated abnormalities on routine laboratory evaluation. The virginal adolescent with a typical history of dysmenorrhea should undergo a routine physical examination, but a pelvic examination is unnecessary. However, virginal patients with atypical or severe pain should undergo rectoabdominal or one-finger vaginoabdominal palpation. Sexually experienced adolescents with pelvic pain cannot be adequately evaluated without a complete pelvic examination to screen for pelvic infection and unsuspected pregnancy. In most cases, no specific laboratory or radiologic evaluation is needed for otherwise healthy virginal adolescents. Qualitative serum or urine β-human chorionic gonadotropin (β-hCG) should be considered in these allegedly virginal adolescent females with severe pain, vaginal bleeding, or signs of shock because a history of never being sexually active, provided by a teenage girl, does not completely rule out the possibility of pregnancy. Pelvic ultrasound or laparoscopy may be helpful in the assessment of patients either with uncertain diagnoses or with pain unresponsive to adequate treatment.

Management

Nonsteroidal antiinflammatory drugs (NSAIDs) are the treatment of choice for patients with moderate or severe dysmenorrhea, providing pain relief for 60% to 80% of symptomatic women. Treatment is most effective when initiated 1 to 2 days before the onset of menses and is recommended until the dysmenorrhea resolves, typically by day 2 or 3 of the menstrual period. Examples of commonly used NSAID treatment regimens are as follows:

- Mefenamic acid: 500 mg once orally, followed by 250 mg four times a day
- Ibuprofen: 400 to 600 mg orally four times a day
- Naproxen sodium: 550 mg once orally, followed by 275 mg three times a day
- Celecoxib: 500 mg once orally, followed by 200 mg twice a day

Patients should be instructed to take NSAIDs with food and to drink adequate fluids. Celecoxib is prescribed for those with risk factors for gastrointestinal (GI) bleeding. It is approved for dysmenorrhea in women older than 18 years.

Patients who do not respond to NSAIDs administered for at least 3 menstrual periods should be offered a combination estrogen and progestin pill. All patients who smoke should be offered smoking cessation support. Some practitioners recommend increasing dietary intake of omega-3 polyunsaturated fatty acid. Other agents commonly recommended in the past for the treatment of dysmenorrhea—acetaminophen, caffeine, and propoxyphene—lack specific antiprostaglandin action and have only limited effectiveness.

Dysfunctional Uterine Bleeding

Background

Dysfunctional uterine bleeding (DUB) is best characterized as irregular, prolonged, or excessive menstrual bleeding associated with anovulation and unrelated to pregnancy. Ovulatory cycles occur in about 20% of adults with DUB, but this phenomenon is uncommon during the teenage years. Terms often used to categorize patterns of DUB are *metrorrhagia* (irregular or acyclic bleeding) and *menorrhagia* (excessive duration or quantity of bleeding). Menstrual bleeding that persists beyond 9 days, recurs at intervals of fewer than 21 days, or produces anemia is abnormal and warrants attention.

DUB is prevalent at the beginning and end of the reproductive years, paralleling the times when anovulatory cycles are most common. In girls during the first year after menarche, about half of menstrual cycles are anovulatory. This proportion decreases gradually, so only 5% of cycles are anovulatory 10 years or more after menarche. Of course, most adolescents with anovultory cycles experience self-limited, reasonably cyclic bleeding episodes.

Pathophysiology

From the standpoint of ovarian function, the normal ovulatory menstrual cycle is divided into an initial follicular and a subsequent luteal phase. The parallel phases of endometrial development are termed, respectively, *proliferative* and *secretory*. At the start of an ovulatory cycle, pituitary follicle-stimulating hormone (FSH) promotes the growth of ovarian follicles. In turn, the rising concentration of estradiol from these follicles stimulates the proliferation of endometrial stroma and glands and induces a midcycle surge of luteinizing hormone (LH) that triggers ovulation. The duration of the preovulatory phase of the menstrual cycle is variable but generally lasts about 14 days. After ovulation has occurred, the ruptured ovarian follicle forms a corpus luteum that secretes progesterone and estradiol and levels of both FSH and LH gradually decline. Although progesterone limits the ultimate thickness of the endometrium, it also promotes further growth of the endometrial secretory glands and spiral blood vessels, so they become coiled and tortuous. At the end of the corpus luteum life span (a highly consistent 14 days unless conception occurs), it degenerates, and circulating levels of both estrogen and progesterone fall, eventually stimulating a resurgence of LH and FSH. As hormonal support wanes, blood flow to the secretory endometrium diminishes, and the spiral arterioles constrict and relax rhythmically under the influence of local prostaglandins. The resulting progressive ischemia leads to endometrial necrosis and menstrual sloughing.

In contrast, during intervals of anovulation, luteal progesterone is not present either to limit the endometrium thickness or to promote its structural integrity. Parts of the endometrial surface undergo growth and sloughing sporadically, without cyclic coordination. The amount of estrogen secreted by ovarian follicles fluctuates unpredictably, and bleeding can occur either because of a fall in estrogen level (withdrawal bleeding) or despite a sustained level of production (breakthrough bleeding). Relatively constant low levels of estrogen tend to produce intermittent spotty bleeding (metrorrhagia). Larger amounts of estrogen cause greater endometrial proliferation and a cyclic pattern of amenorrhea followed by profuse bleeding (menorrhagia) whenever either the endometrial vessels and glands outstrip their stromal support or hormone levels spontaneously fall. Compared with the 35 to 80 mL of blood lost during a normal menstrual period, dysfunctional bleeding often results in the loss of 100 to 200 mL each month, which may produce iron deficiency and anemia.

Clinical Manifestations

DUB has a substantial capacity to disrupt the everyday lives of adolescents who may have unpredictable, urgent need for bathroom facilities due to risk of visible blood stains. Large amounts of bleeding often provoke considerable fear in both patients and their parents. These concerns can overshadow the history of the bleeding itself, but the details of the problem's chronology and an estimate of blood loss (in pads per day) will help the physician assess the severity of the bleeding, follow the patient's clinical course, and gauge her prognosis. The symptoms that characteristically accompany only ovulatory menstrual cycles—mittelschmerz, premenstrual breast tenderness, bloating, mood changes, and dysmenorrhea—should be absent. DUB is classically painless, but occasionally, a patient with active bleeding may experience crampy pain if a large quantity of blood is passed rapidly. Weakness or fainting should alert the examiner to the possibility of significant blood loss. Pertinent questions should include whether the patient is pregnant, whether she uses contraception if she has been sexually active, and whether she has an underlying platelet disorder (e.g., thrombocytopenia, von Willebrand's disease).

The physical examination starts with the measurement of the patient's vital signs, including a check for orthostatic changes in the pulse and blood pressure. Pertinent signs, including pallor, petechiae or bruises that might indicate a bleeding disorder, and hirsutism or obesity consistent with the polycystic ovary syndrome, should be noted. The pelvic examination is likely to be normal except for the presence of bleeding but should be performed to evaluate the patient for pelvic infections, previously unrecognized pregnancy, and functional ovarian cysts. If necessary, rectoabdominal palpation can be substituted for the standard bimanual examination. Ovarian enlargement is an uncommon finding even among adolescent patients with clear-cut polycystic ovary syndrome. The differential diagnosis of DUB is discussed at greater length in Chapter 76.

Management

A determination of the hemoglobin or hematocrit is essential for the emergency evaluation of patients with DUB because historical estimates of blood loss are imprecise. A platelet count should also be obtained because thrombocytopenia is the most common hematologic disorder that produces menorrhagia. The history and physical examination should be used to guide the choice of additional laboratory tests. Sexually active adolescents should receive a pregnancy test and an antigen-detection test for chlamydial infection and gonorrhea because STI-associated endometritis is a common cause of otherwise unexplained uterine bleeding. Patients with menorrhagia beginning at menarche, severe hemorrhage, or a history of bleeding problems should undergo further evaluation for possible disorders of platelet number or function.

For patients with brisk hemorrhage or hypotension, prompt volume resuscitation and hospitalization are necessary (see Chapter 3). Control of the bleeding itself is accomplished with hormonal treatment (Table 90.1). Regimens vary according to the severity of bleeding and individual preference, but each is designed first to stop the bleeding, second to convert the unstable proliferative uterine endometrium to the secretory state, and finally to allow a self-limited endometrial slough under controlled conditions. Pregnancy must be excluded in every case before hormonal treatment is begun. Estrogen is used to support the endometrium for short term and to stop the bleeding. A progestational agent must be administered simultaneously to produce a secretory endometrium; otherwise, the problem will recur predictably whenever the estrogen is stopped. Any of the oral contraceptive pills with 35 or 50 g

TABLE 90.1

MANAGEMENT OF DYSFUNCTIONAL UTERINE BLEEDING

Clinical situation	Treatment
Acute hemorrhage with shock	Volume resuscitation Rarely, red blood cell transfusion Conjugated estrogens 25 mg IV every 4 h until bleeding stops (up to six doses) Rarely, curettage if IV estrogen fails When able to take oral medications: Iron 60 mg/day Progestin 10–20 mg/day Antiemetics as needed
Severe bleeding Hb < 10 mg/dL	Estradiol 50 μg/norgestrel (0.5 mg) orally[a]: Every 4 h until bleeding stops (usually within 24 h) qid for 4 days tid for 3 days bid for 2 weeks Iron 60 mg/day Antiemetics as needed
Moderate bleeding Hb 10–12 mg/dL	Estradiol 50 μg/norgestrel (0.5 mg) orally[a]: tid until bleeding stops (usually within 48 h) bid for 5 days Daily to complete 21 days Iron 60 mg/day Antiemetics as needed
Not currently bleeding Hb > 12 mg/dL	Consider combined estrogen/progesterone hormonal contraception Iron 60 mg/day

qid, four times a day; tid, three times a day.
[a]Many different regimens of combination oral hormonal therapy appear to be equally effective.

of either ethinyl estradiol or mestranol and a progestin provides a convenient means of administering the two hormones together. Nausea is a common side effect of estrogen in each of these regimens and can be treated symptomatically. Vomiting rarely precludes oral therapy. Progestins alone in higher dosages can be used if estrogen is contraindicated or not tolerated, but the resulting hemostasis is less prompt and less predictable.

After the cessation of treatment, a self-limited, heavy menstrual period will follow within 2 to 3 days. The family must be forewarned so they anticipate this episode and do not misinterpret it as a recurrence of DUB. This withdrawal bleeding will stop spontaneously within several days. Subsequent therapy must be tailored to the individual patient. For sexually active adolescents and for those with chronic or recurrent DUB, long-term use of combined oral contraceptive pills is an excellent therapeutic choice.

Adolescents with severe, chronic, or recurrent DUB should receive diagnostic investigation to address the question of an underlying endocrinologic disorder (see Chapter 47). Iron supplementation is prudent for all patients with DUB; those without frank anemia are likely to have depleted marrow stores of iron. Patients should be encouraged to maintain a menstruation calendar to aid her clinician in future visits. Finally, outpatient follow-up is an essential component of management because treatment may be needed for months or years and because chronic anovulation is a risk factor for both infertility and the late development of endometrial carcinoma.

Sexual Abuse and Assault

The five major gynecologic aspects of treating a girl who has been sexually abused or assaulted are (i) collection of evidence, (ii) the management of injury, (iii) screening and treatment of STIs, (iv) prevention of pregnancy, and (v) referral for medical and psychological follow-up. The overall management of sexually abused children is discussed in Chapter 132.

Physical Examination and Evidence Collection

Police and prosecutors ask physicians to document observations and collect evidence that may corroborate a patient's history of sexual assault or abuse. This evidence may consist of a child's exact statement concerning the abuse; the finding of prostatic acid phosphatase in vaginal secretions, indicating the presence of seminal fluid; a small bruise on the labia majora; or the discovery of leaf or grass fragments in the underwear of a child who states that she was assaulted outdoors. In prepubertal children, physical evidence collection is usually recommended up to 72 hours after any sexual contact; however, most evidence is found when it is collected within 24 hours of the contact. In adolescents, some recommend evidence collection up to 120 hours after sexual contact. While some evidence collection kits are designed for use with children, most general collection kits involve the collection of specimens that are unlikely to yield usable evidence (e.g., pubic hair sample, fingernail scrapings) because they are rarely relevant to the circumstances of victimized children. Which types of samples to collect should be determined on a case-by-case basis. In cases involving prepubertal children, extra care should be taken to submit underwear and any involved bed linens because these materials may be more likely to yield evidence of abuse than samples taken from the genital area. If material is collected that may be used in court, its movement from the physician's possession to locked storage or a police officer's custody should be documented with signatures, times, and dates to preserve the chain of evidence that will allow the material's origin to be verified in court. When, as is often the case, a sexually abused child is not examined until several weeks after the most recent episode of sexual contact, the likelihood of the physician's finding physical evidence is very low.

The likelihood of identifying genital injury in an adolescent sexual assault victim depends on the nature of the assault, the time elapsed since the event, and whether magnification is used during examination. Most young women are sexually assaulted by acquaintances and do not sustain any injury, genital or otherwise. Genital injuries that do occur are usually located on the posterior fourchette or the labia minora. Any injuries noted should be clearly described, drawn, and, if possible, photographed.

Few girls sustain serious physical injuries as a result of sexual abuse or assault. Any sexually abused girl who has vaginal bleeding that cannot be attributed to a clearly visible injury or infection must be examined carefully to determine the source of the bleeding. This will usually require the use of sedation or general anesthesia in premenarcheal girls. The management of girls with vaginal bleeding is discussed at greater length in Chapter 76.

Laboratory Evaluation

STIs are seen in about 5% of abused children, generally mirroring their relative prevalence in the adult population. The most prevalent clinically evident STIs found in sexually abused children are gonorrhea, chlamydial infection, and genital warts. Rarely, syphilis and HIV can be transmitted by sexual abuse. Although common in adults, trichomoniasis is rarely seen in prepubertal abused girls because trichomonads do not proliferate in the absence of an estrogenic milieu.

For prepubertal children, STI testing should be limited to high-risk cases, including those (i) with a history of an STI or a sibling with an STI, (ii) victimized by multiple assailants or by an assailant known to have an STI, or (iii) exhibiting signs of infection (vaginal, urethral, or rectal discharge) or genital injury indicating history of vaginal or rectal penetration.

While there is agreement that adolescents are at higher risk of acquiring STIs and developing PID, some advocate for all adolescents to be tested while others prefer to treat presumptively for gonorrhea, chlamydial infection, and trichomoniasis without testing.

Because of the legal and psychosocial consequences of a false-positive diagnosis, only tests with high specificities should be used. Culture is the only acceptable method of testing for gonorrhea and chlamydial infection in sexually abused children; any positive indirect test (Gram stain, antigen testing) needs to be confirmed by culture.

Testing for other STIs, including syphilis, hepatitis C, and HIV, is based on signs and symptoms of disease, patient/family preference, and the overall risk-assessment of the case. Hepatitis B screening should be offered for those who have not completed a hepatitis B vaccination series. HIV pretest counseling, including implications of an unexpected positive result and importance of follow-up testing, should be performed before any child is screened for HIV.

Treatment

Antibiotic prophylaxis after sexual abuse is best limited to children victimized in high-risk situations (including any child with signs or symptoms of infection) and adolescents. The antibiotic regimen should include coverage for both chlamydial infection and gonorrhea. Adolescents should also be covered for trichomonasis and bacterial vaginosis. Those not immunized against hepatitis B should be given the first vaccine dose (followed in 1 and 6 months by the subsequent doses) and hepatitis B immune globulin (HBIG).

HIV Postexposure Prophylaxis

In adults, the risk for HIV transmission per episode of receptive penile-anal sexual exposure is estimated at 0.1% to 3%; the risk per episode of receptive vaginal exposure is estimated at 0.1% to 0.2%. Factors to consider and discuss with the family are (i) local rates of HIV/AIDS, (ii) the likelihood the perpetrator is infected, (iii) circumstances of the assault that may predispose to HIV transmission, (iv) the toxicity of recommended medications, and (v) unknown efficacy of the regimen. Postexposure prophylaxis (PEP) is believed to be most effective if given within 24 hours of the assault (Fig. 90.6). PEP is not typically recommended for cases in which the exposure occurred more than 72 hours before seeking care. However, in unusual circumstances in which the potential benefits outweigh the risks, PEP may be considered for exposure that occurred more than 72 hours before seeking care.

While both failures and successes have been reported, there are no data regarding the efficacy of PEP after sexual assault. Adverse effects, some of them serious, often limit the ability to complete the recommended 28-day course. The theoretic advantage of improved efficacy with a three-drug regimen needs to be considered against the lower toxicity and increased compliance with a two-drug regimen (a combination of two reverse transcriptase inhibitors). Prophylaxis offers a benefit only when the risk of transmission is high, therapy can be

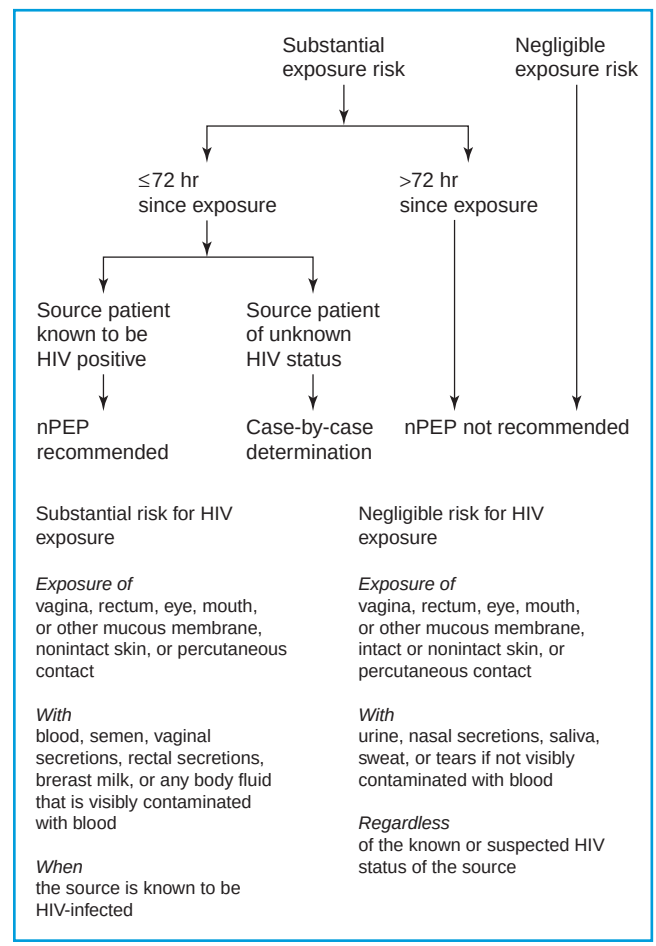

FIGURE 90.6 Algorithm for the evaluation and treatment of possible nonoccupational HIV exposure. nPEP, nonoccupational postexposure prophylaxis (Adapted from Centers for Disease Control and Prevention. Antiretroviral postexposure prophylaxis after sexual, injection-drug use, or other nonoccupational exposure to HIV in the United States. *MMWR Morb Mortal Wkly Rep* 2005;54(RR-2):1–20).

TABLE 90.2

SUGGESTED GUIDELINES FOR POSTEXPOSURE PROPHYLAXIS FOLLOWING SEXUAL ASSAULT

Prepubertal		
Zidovudine[a] 10 mg/mL 100 mg capsule 300 mg tablet	240 mg/m^2/dose Max 300 mg/dose	Orally, twice daily for 28 days
Lamivudine[a] 10 mg/mL 150 mg tablet	4 mg/kg/dose Max 150 mg/dose	Orally, twice daily for 28 days
Kaletra (lopinavir/ritonavir) Liquid: 80/20 mg/mL Regular tablet 200/50 mg/tablet Pediatric tablet 100/25 mg/tablet	Dosing based on lopinavir: If 7–15 kg: 12 mg/kg/dose If 15–40 kg: 10 mg/kg/dose Max 400 mg/dose	Orally twice daily for 28 days
Pubertal		
Truvada (300 mg tenofovir/200 mg emtricitabine)	1 tablet	Orally, once daily for 28 days
Kaletra (lopinavir/ritonavir) Regular tablet: 200/50 mg/tablet Pediatric tablet: 100/25 mg/tablet	25–35 kg: 3 pediatric tablets >35 kg: 2 adult tablets	Orally, twice daily for 28 days Orally, twice daily for 28 days

[a]Zidovudine/lamivudine (Combivir) available in 300/150 mg tablet.

started promptly, and adherence to the regimen is likely. When standard protocols are not available, a clinician with experience in the treatment of persons with HIV infection should participate in starting PEP. Current recommendations regarding medication regimens and associated toxicities can be found at www.aidsinfo.nih.gov. The University of California–San Francisco operates a hot line (1-888-HIV-4911) that is supported by the Centers for Disease Control and Prevention (CDC) and staffed 24 hours a day to aid clinicians through decision pathways and to provide information on choice of therapy. Recommendations regarding medication regimens change frequently. One set of PEP recommendations is listed in Table 90.2.

If PEP is initiated, baseline measurement of the complete blood cell count, creatinine, and alanine transaminases should be considered in anticipation of possible drug toxicity. The patient should be given a starter pack of 3 days of medication and a follow-up appointment with a pediatric infectious disease specialist within 2 to 3 days. This allows for the evaluation of medication side effects, drug toxicity, and assessment of psychosocial status.

Pregnancy Prophylaxis

The emergency physician must consider the possibility of pregnancy in every postmenarcheal girl who has been sexually abused or assaulted. A pregnancy test should be conducted in the ED to ascertain whether the patient is pregnant when she is first evaluated. If an adolescent is not pregnant and is not using hormonal contraception, her risk of becoming pregnant as a result of rape must be assessed. The risk of pregnancy from one occurrence of unprotected coitus at midcycle is estimated to be 15%. The risk from coitus occurring more than 6 days before or after ovulation is negligible. Plan B (two 0.75 mg pills of levonorgestrel given after intercourse) is the most commonly prescribed regimen. Plan B is 90% effective if used within 24 hours, 75% effective if used within 72 hours, and 60% effective if used within 120 hours. It is not recommended more than 5 days after intercourse. The patient can expect to have her next menstrual period within 21 days after treatment.

Patient Follow-up

Many victims of sexual assault experience guilt, shame, and grief. They may blame themselves for the assault. Discussion of common reactions to sexual assault and referral to psychological counseling to specifically address these feelings will give the patient the best chance for a full psychological recovery.

Many victims of sexual assault remember little of what was said during the short-term evaluation. Important information such as medications given, medications to be taken at home, and follow-up instructions should be given in verbal and written form to the patient. A visit to a primary care physician within 2 to 3 days of the assault is warranted in most cases and is necessary when PEP for HIV is initiated. Serologic tests for syphilis should be repeated 4 to 6 weeks after the assault. HIV testing should be repeated at 4 to 6 weeks, 3 months, and 6 months.

GENITAL TRACT INFECTIONS

Vaginitis

Background

Definition. Vaginitis, or inflammation of the vagina, can be produced by chemical and mechanical irritants, foreign bodies, and a variety of infectious agents including viruses, chlamydial species, bacteria, fungi, protozoa, and helminths. During childhood, vaginitis is characterized by the presence of vaginal discharge, bleeding, or both. After puberty has begun,

TABLE 90.3

TREATMENT OF VAGINITIS

Infection	Drug	Dose, route
Bacterial vaginosis	Metronidazole	500 mg orally bid for 7 days
	Metronidazole gel 0.75%	One full applicator vaginally daily for 5 days
	Clindamycin 300 mg	One orally twice daily for 7 days
Vulvovaginal candidiasis	Intravaginal agents	
	Butoconazole 2% cream[a]	5 g intravaginally for 3 days
	Butoconazole 2% cream (butaconazole 1-sustained release)	Singe intravaginal application
	Clotrimazole 1% cream[a]	5 g intravaginally for 7–14 days
	Clotrimazole 100 mg vaginal tablet	One vaginally daily for 7 days
	Clotrimazole 100 mg vaginal tablet	2 tablets vaginally for 3 days
	Miconazole 2% cream[a]	5 g intravaginally for 7 days
	Miconazole 100 mg vaginal suppository[a]	One vaginally daily for 7 days
	Miconazole 200 mg vaginal suppository[a]	One vaginally daily for 3 days
	Miconazole 1,200 mg vaginally suppository[a]	Once vaginally
	Nystatin 100,000-unit vaginal tablet	One vaginally daily for 14 days
	Ticonazole 6.5% ointment[a]	5 g intravaginally daily for 7 days
	Terconazole 0.4% cream	5 g intravaginally daily for 7 days
	Terconazole 0.8% cream	5 g intravaginally daily for 3 days
	Terconazole 80 mg vaginal suppository	One vaginally daily for 3 days
	Oral agent: fluconazole 150 mg	Once orally
Trichomoniasis	Metronidazole	2 g orally as single dose
	Tinidazole	2 g orally as single dose

girls normally have an asymptomatic vaginal discharge; vaginitis is then indicated by the discomfort it produces or by a change in the character of the discharge. The etiology, clinical manifestations, diagnosis, and treatment of common vaginal infections are presented in this chapter. For a review of the differential diagnosis of vaginal bleeding and discharge, see Chapters 76 and 77. Table 90.3 summarizes the treatment of common vaginal infections. Infections with *N. gonorrhoeae* and *C. trachomatis* are discussed in Chapter 92.

Epidemiology

At least half of all symptomatic premenarcheal girls with vaginal discharge visible on physical examination will prove to have specific vaginal infections that warrant antimicrobial treatment. Among prepubertal girls in the United States, *N. gonorrhoeae* causes the greatest number of these specific infections. Less common offenders include *Shigella* species, *Streptococcus pyogenes*, and in infants and after puberty has begun, *Trichomonas vaginalis*. Although staphylococci and *Haemophilus influenzae* usually colonize the lower genital tract without producing symptoms, they are associated with vaginal discharge in only a small proportion of patients. *Candida albicans* is the most common vaginal pathogen among both pubertal (but premenarcheal) and postmenarcheal girls.

The relative prevalence of vaginal infections in a population of postmenarcheal adolescents depends primarily on how many of them are sexually active. Bacterial vaginosis is found commonly and nearly exclusively among sexually active adolescents. Diabetes mellitus, pregnancy, immunodeficiency, and the use of broad-spectrum antibiotics and corticosteroids predispose patients to developing *Candida* vulvovaginitis, but the infection is most often seen in patients who lack any of these risk factors. Trichomoniasis is transmitted vertically or by sexual contact. Up to one-third of patients with trichomoniasis have concurrent gonorrhea, but there is no increased rate of infection with *C. trachomatis*.

Trichomonal Vaginitis

Clinical Manifestations

A small proportion of vaginally delivered female neonates acquire trichomonal vaginitis from their infected mothers. Infants harboring only a few trichomonads may never develop clinical disease, but the remainder will have a thin whitish or yellowish vaginal discharge that appears within 10 days after birth and may persist for several months if untreated. Infected babies may be irritable but are otherwise well.

The classic vaginal discharge of trichomonal vaginitis after puberty is pruritic, frothy, and yellowish. However, many infected women do not complain of excessive discharge and the discharge may be scant or nondescript. The so-called strawberry cervix with multiple punctate areas of hemorrhage is pathognomonic for trichomoniasis but is visible without colposcopy in only about 2% of infected patients.

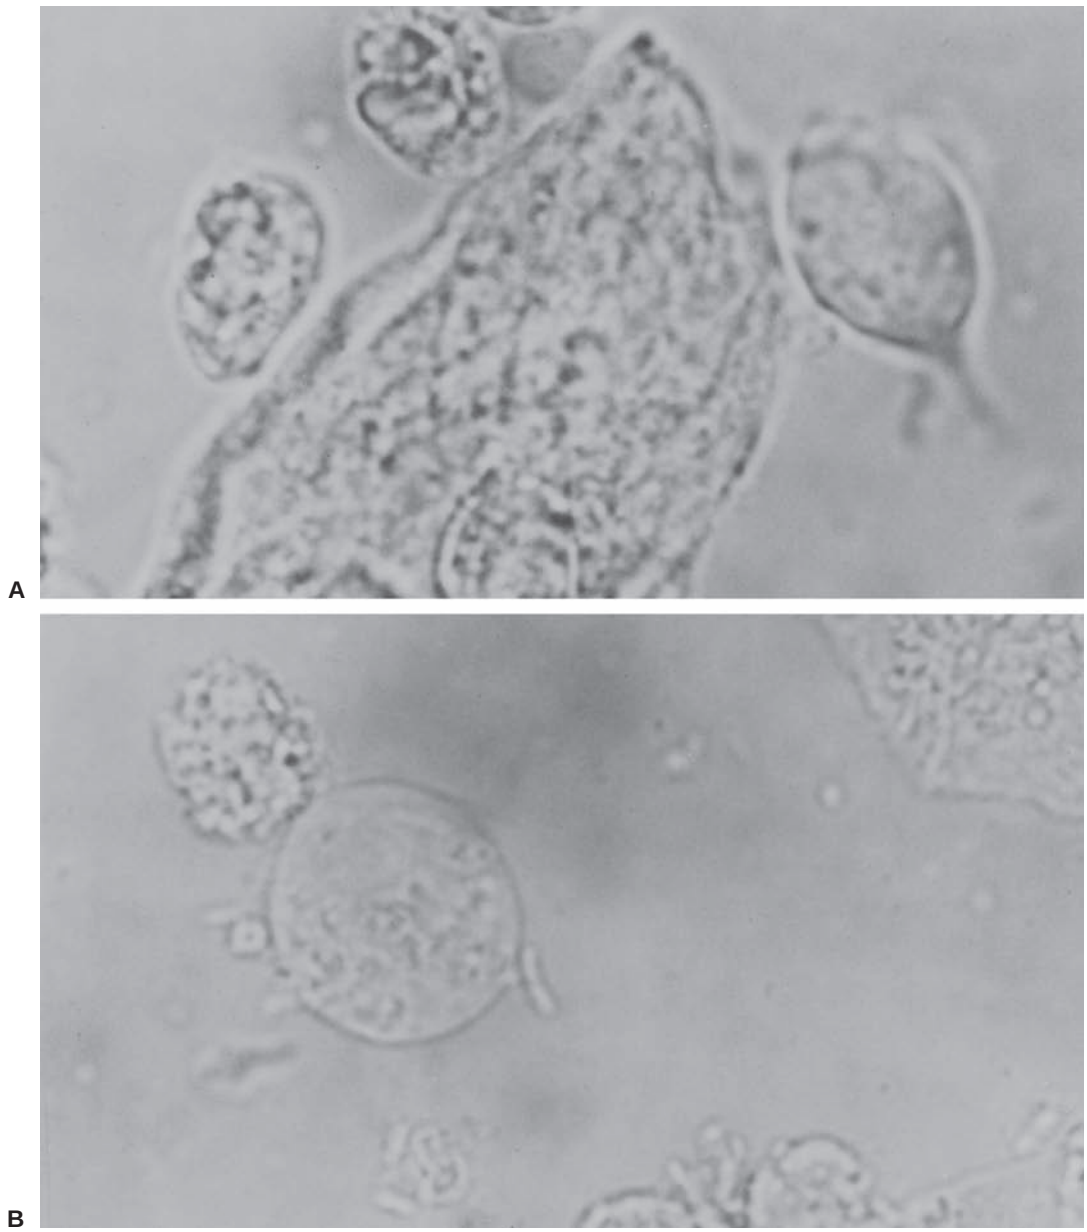

FIGURE 90.7 **A:** Trichomonad in the vaginal discharge of a 17-year-old patient with gonococcal pelvic inflammatory disease. The flagellated protozoan is elliptical and somewhat larger than the adjacent polymorphonuclear leukocytes (×225 magnification). **B:** After suspension in saline solution for microscopy, trichomonads gradually become swollen and immobile. This balloon-shaped trichomonad is barely recognizable (×225 magnification).

For patients of all ages, the diagnosis is made easily and rapidly if characteristically motile, flagellated trichomonads are seen in a saline suspension of discharge examined microscopically within about 15 minutes after the specimen has been obtained (Fig. 90.7). If a longer delay occurs, the organisms will gradually lose their mobility and normal shape, making them much more difficult to identify. The sensitivity rate for wet mount examinations is 50% to 70%. Cultures from a specialized parasite medium have a sensitivity of 85% to 95%, but results are delayed. Newer diagnostic methods such as DNA probes, monoclonal antibody kits, and polymerase chain reaction techniques provide rapid and more accurate results.

Management

Metronidazole is effective for the treatment of vaginal trichomoniasis. The dosage for infants is 15 mg per kg per day orally in two to three divided doses for 7 days. Recommended treatment of adolescents include metronidazole 2 g orally in a single dose or tinadazole 2 g orally in a single dose. Because trichomoniasis is a sexually transmitted disease, the adolescent patient's partner(s) must also be referred for treatment.

Nausea and an unpleasant taste are common side effects of nitroimidazoles. Alcohol should be avoided during treatment to prevent the occurrence of more severe abdominal pain, vomiting, flushing, and headache (disulfiram reaction). Recent data indicate that metronidazole is not a teratogen, but many clinicians prefer to postpone treatment of pregnant patients until the second trimester. Intravaginal clotrimazole (two intravaginal tablets at bedtime for 7 days) can provide symptomatic relief for pregnant patients but will cure only 10% to 20%.

Shigella Vaginitis

Clinical Manifestations

Shigella flexneri, *Shigella sonnei*, *Shigella boydii*, and *Shigella dysenteriae* can produce vaginal infections in infants and children but do not appear to cause genital disease after puberty. The vaginitis is characterized by a white to yellow discharge that is bloody in three-fourths of cases. Associated pruritus and dysuria are uncommon. One-third of patients have diarrhea that precedes, accompanies, or follows the vaginal discharge. On inspection, the vulvar mucosa is often inflamed or ulcerated. The diagnosis is established by culture of a specimen of vaginal discharge. Rectal cultures are positive for *Shigella* species in some cases.

Management

Patients with *Shigella* vaginitis should be treated with oral antibiotics chosen on the basis of sensitivity testing. If the antibiotic sensitivity is unknown, trimethoprim-sulfamethoxazole (8 mg per kg per day orally of trimethoprim in two divided doses for 5 days) should be used.

Streptococcal Vaginitis

Clinical Manifestations

S. pyogenes can be identified in cultures of vaginal specimens taken from about 14% of prepubertal girls with scarlet fever. Most of these vaginal infections produce either no symptoms or minor discomfort, but a few patients develop outright vaginitis with a purulent discharge. Streptococcal vaginitis can accompany or follow symptomatic pharyngitis and occurs uncommonly in girls with neither symptomatic pharyngitis nor scarlet fever. Most of these latter patients are pharyngeal carriers of the organism. Streptococcal vaginitis causes genital pain or pruritus and can mimic candidal or gonococcal vaginitis. A swab of the patient's discharge should be cultured to verify the clinical diagnosis, as well as to exclude gonococcal infection.

Management

As for any other infection with group A β-hemolytic streptococci, penicillin is the preferred antibiotic. Intramuscular benzathine penicillin G is an alternative if poor compliance with oral treatment is anticipated. Oral erythromycin ethylsuccinate or azithromycin can be prescribed for children who are allergic to penicillin.

Candidal Vulvovaginitis

Clinical Manifestations

C. albicans frequently colonizes the vagina after the onset of puberty when estrogen stimulates local increases in glycogen stores and acidity that both appear to enhance its growth. If the ecologic balance of the vagina is changed by inhibition of the normal bacterial flora, impaired host immunity, or an increase in the availability of nutrients (broad-spectrum antibiotics, immunodeficiency states, corticosteroids, diabetes mellitus, pregnancy), the resulting proliferation of *Candida* will produce symptoms in a fraction of affected patients. However, most patients with candidiasis have no identifiable predisposing risk factor for infection. Because of the importance of estrogen in promoting fungal growth, candidal vulvovaginitis is rare among prepubertal girls.

The most common clinical manifestation of vulvovaginal candidiasis is vulvar pruritus. In severe infections, vulvar edema and erythema can occur. "External" dysuria is produced when urine comes in contact with the inflamed vulva. Vaginal discharge is variable in quantity and appearance. In severe cases, the vaginal vault is red, dry, and has a whitish, watery, or curd-like discharge that may be relatively scanty. Patients with mild disease may have only intermittent itching and an unimpressive discharge.

Microscopic examination of a sample of vaginal discharge suspended in 10% potassium hydroxide solution to clear the field of cellular debris can provide a rapid diagnosis of candidiasis if hyphae are seen (Fig. 90.8). However, in as many as 50% of cases, wet mounts are falsely negative. Gram-stained smears of discharge are somewhat more sensitive because hyphae and yeast cells are gram positive and more easily visible. Culture can only corroborate or fail to corroborate the clinical impression of candidiasis because the vaginal flora includes *C. albicans* in up to 25% of young women who have no symptoms or signs of infection. Similarly, cultures from patients with classic signs of candidal infection may yield only a light growth of the organism, making heavy growth an inadequate criterion for diagnosis. From these considerations, it is apparent that, although the presence of *C. albicans* can be confirmed by laboratory tests, the diagnosis and subsequent treatment of this infection should be guided by the presence or absence of clinical disease.

Management

Topical imidazoles will promptly cure 80% to 90% of patients with candidal infections. Most are available without prescription. The creams are packaged with intravaginal applicators, but many premenarcheal and virginal girls can be treated adequately and more comfortably by applying cream to the vulva alone. Effective, nonprescription, short-course treatments of patients with mild to moderate candidal vulvovaginitis include butoconazole 2% cream (one full applicator at bedtime for three nights), clotrimazole 500-mg tablets (one tablet intravaginally as a single dose), miconazole 200-mg suppositories (one suppository at bedtime for three nights), and tioconazole 6.5% ointment (one full applicator as a single dose). For patients with severe discomfort, one of the 5- or 7-day formulations of a topical agent is likely to be more effective. Creams and suppositories in this regimen are oil-based and might

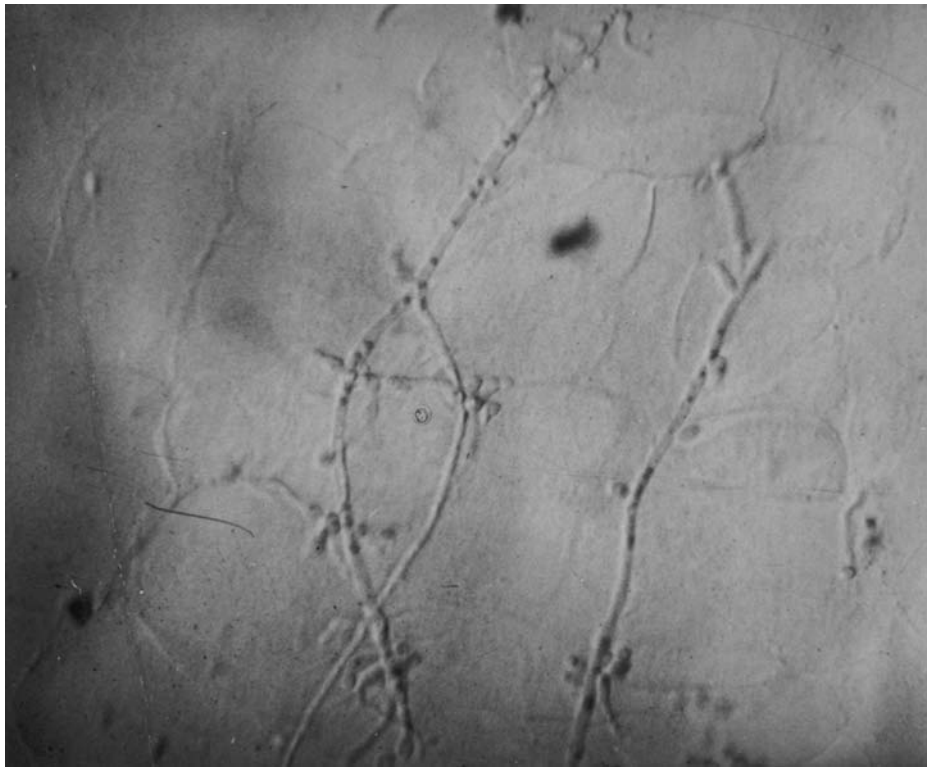

FIGURE 90.8 Branching hyphae of *Candida albicans* in vaginal discharge suspended in 10% potassium hydroxide solution. Ghosts of vaginal epithelial cells are also visible (×100 magnification).

weaken latex condoms and diaphragms. Patients should be referred to condom product labeling for more information. Fluconazole, 150 mg oral tablet in a single dose, cures candidal vulvovaginitis as effectively as the topical preparations, and many patients prefer oral to topical treatment. However, the potential for promoting fungal resistance and the risks, albeit low, of systemic toxicity and allergy are important disadvantages of oral antifungal agents.

Nonspecific Vaginitis in Children

Clinical Manifestations

The term *nonspecific vaginitis*, referring to a disorder of prepubertal girls, encompasses a variety of genitourinary symptoms and signs that are sometimes caused by poor perineal hygiene but that in other cases have no readily identifiable cause. Genital discomfort, discharge, itchiness, and dysuria are relatively common childhood complaints. When a girl with such symptoms has either a normal vulva and vagina or only mild vulvar inflammation on physical examination, a specific vaginal infection is unlikely, and other possible explanations for the complaint—smegma, pinworms, urinary tract infection, a local chemical irritant, or sexual abuse, for example—should be sought with appropriate questions and laboratory tests. (It should be noted that commercially available bubble bath is not often the culprit.) If, however, a vaginal discharge is present on physical examination, the specific vaginal infections discussed in this chapter are diagnostic possibilities and cultures should therefore be obtained. In a reported series of premenarcheal girls with vaginitis who have been systematically evaluated, between 25% and 75% are ultimately categorized as having nonspecific vaginitis. The diagnosis should not be made until other entities have been excluded. (A more comprehensive discussion of the differential diagnosis of genital complaints is presented in Chapters 76 and 77.)

Management

General measures to promote cleanliness and comfort should be initiated for the girl with nonspecific vaginitis. Daily soaking in a bath of warm water, either plain or with some baking soda added, gentle perineal cleaning with a soft washcloth, and the use of cotton underwear can be recommended. The girl should be taught to wipe toilet paper anteroposteriorly. Using these suggestions, most girls with perineal irritation will show improvement within 2 weeks. The remaining patients should be reevaluated to exclude any specific but previously unrecognized disorder. If none is found, these girls may benefit from a brief course of topical estrogen cream (a small amount dabbed onto the vulva nightly for 2 to 4 weeks) to stimulate thickening of the vaginal mucosa so that it is more resistant to local irritation. Parents should be cautioned that estrogen cream is capable of producing breast growth if it is used for a prolonged period of time.

Bacterial Vaginosis

Background

Bacterial vaginosis is a syndrome characterized clinically by the presence of three of the following four signs: (i) a homogeneous, white adherent vaginal discharge; (ii) vaginal pH above 4.5; (iii) a fishy, amine-like odor released when 10% potassium hydroxide solution is added to a sample of the discharge; and (iv) the presence of clue cells (Amsel criteria). The syndrome occurs when lactobacilli that normally predominate in

the genital tract are displaced by an overgrowth of mixed flora, including *Gardnerella vaginalis*, *Mobiluncus* species, other anaerobes, and *Mycoplasma hominis*. What accounts for this change in the vaginal microflora is not understood. The high prevalence of the syndrome in sexually active women and in women attending STI clinics suggests that a wide range of epidemiologic and microbiologic factors may contribute to its pathogenesis.

Clinical Manifestations

The symptoms of bacterial vaginosis—malodor and discharge—are not distinctive and can resemble those of trichomonal infection. A complaint of dysuria or pruritus goes against the diagnosis. As many as half of women who have signs of vaginosis are asymptomatic. The vaginal discharge is moderate or copious, grayish-white, and homogeneous. On examination, the vulva, vagina, and cervix are not inflamed, but concomitant infection with trichomonas or gonococci can complicate this picture.

Compared with the composite Amsel criteria, the use of single tests (e.g., pH, clue cells, or whiff test alone) produces lower positive and negative predictive values for the diagnosis of bacterial vaginosis. When a wet mount of vaginal discharge is examined, epithelial cells are seen to be studded with large numbers of small bacteria and have a granular appearance with shaggy borders (Fig. 90.9). The ratio of epithelial cells to polymorphonuclear leukocytes in the discharge is 1 or higher. Lactobacilli (long rods) are sparse. Gram stain can be used to confirm the presence of clue cells and the scarcity of long gram-positive rods (lactobacilli). Because 35% to 55% of women without bacterial vaginosis have positive cultures for *G. vaginalis*, culture is not a useful diagnostic test. Trichomonal infection is the major diagnostic alternative for patients suspected of having bacterial vaginosis.

Management

The standard treatment of bacterial vaginosis is oral metronidazole, 500 mg twice daily for 7 days. Treatment of patients' sexual partners does not reduce the recurrence rate and is not recommended. Common side effects of metronidazole include GI upset, headache, and a metallic taste. Metronidazole in standard doses is not a human teratogen; however, some clinicians prefer to postpone treatment of pregnant women until the second trimester. Intravaginal clindamycin cream (2%, 5 g) and metronidazole gel (0.75%, 5 g) are alternative treatment options for nonpregnant women. Oral clindamycin (300 mg twice a day for 7 days) is an alternative treatment regimen for pregnant patients with bacterial vaginosis.

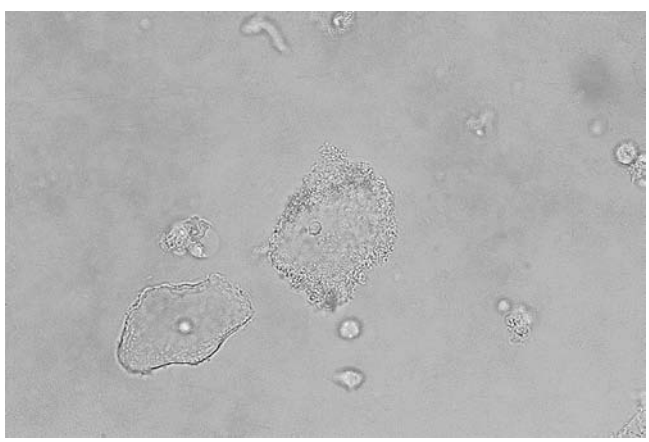

FIGURE 90.9 A clue cell. The vaginal epithelial cell on the right has shaggy borders obscured by coccobacilli (×100 magnification).

Gonococcal and Chlamydial Infections

Refer to Chapter 92 for information on gonococcal and chlamydial infections.

Bartholin Gland Abscess and Cyst

Background

Abscesses and symptomatic cysts of the Bartholin glands are relatively uncommon disorders during adolescence. The Bartholin glands lie at about the 4 and 8 o'clock positions in the vestibule and drain through ducts that open into folds between the hymen and the labia minora. Many Bartholin gland cysts are asymptomatic and need no treatment. The clinical distinction between a symptomatic cyst and an abscess can be arbitrary in some cases.

Clinical Manifestations

The patient with a Bartholin gland abscess presents with a painful, tender, fluctuant mass bulging on the involved side of the vestibule inferior to the labium minus. Pus can sometimes be milked upward from the gland to the duct orifice. Cultures of pus from abscessed glands yield *N. gonorrhoeae* in 10% to 50% of cases. Most of the remaining cases contain mixed growths of facultative, aerobic, and anaerobic organisms, often including *Bacteroides* species. Cultures from a small number of abscesses yield *C. trachomatis*, and in 15% to 30% of cases, the pus is sterile. The patient with a cyst complains of vulvar discomfort; the unilateral mass is typically 1 to 3 cm in diameter and mildly tender. Cyst fluid is usually sterile.

Management

Abscesses and symptomatic cysts are treated similarly, with placement of a Word catheter (Fig. 90.10), marsupialization, or a "window operation." Each procedure opens the cyst cavity widely and facilitates prolonged drainage. Many experts recommend against simple incision and drainage because of the high recurrence rate associated with this procedure. All patients with abscesses or purulent exudate should be treated for presumed gonorrhea (as outlined in Chapter 92), and their sexual partners should be referred for concurrent treatment. Complications of Bartholin gland abscess after treatment include slow healing, persistent discomfort, dyspareunia, and recurrence.

Pelvic Inflammatory Disease

Background

Definition. PID is a polymicrobial inflammatory condition of the upper genital tract, variably involving the endometrium, fallopian tubes, ovaries, adjacent structures, and pelvic peritoneum. The following discussion concerns acute PID caused

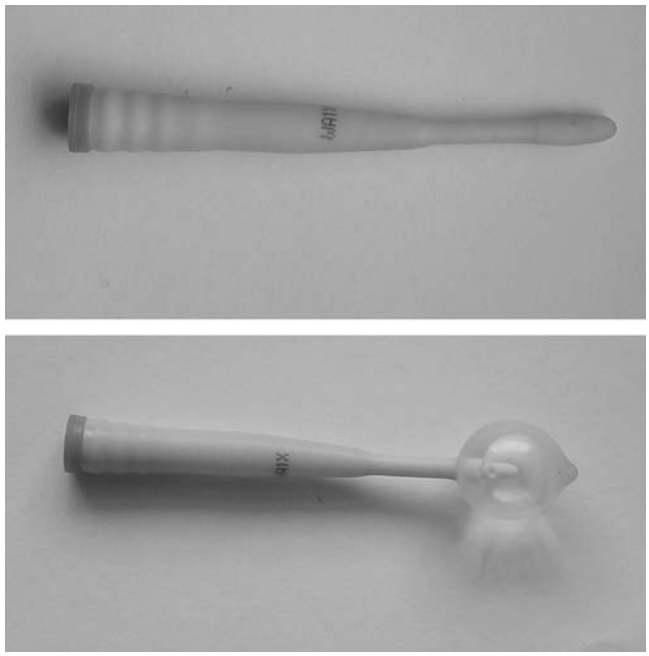

FIGURE 90.10 Word catheter before and after instillation of 3 mL of sterile water.

by sexually transmitted microorganisms ascending from the cervix and excludes infections associated with childbirth, spontaneous abortion, or pelvic surgery.

Epidemiology

PID disproportionately affects adolescents and young adults. An estimated one in eight sexually active adolescent girls develop PID before reaching 20 years of age. Young age, a large number of sexual partners, and nonbarrier contraceptive methods are risk factors for infection with *N. gonorrhoeae* and *C. trachomatis*, the microorganisms responsible for initiating most cases of acute PID. Recent douching is also a likely risk factor for the development of PID, but the mechanism by which it increases risk is unknown. Other risk factors include cigarette smoking, bacterial vaginosis, previous gynecologic surgery, and HIV infection. Compared with no contraceptive method, barrier methods—male and female condoms, diaphragms, and spermicides—decrease the overall risk of acquiring gonococcal and chlamydial cervicitis. Oral contraceptive pills decrease the likelihood that users with cervical gonorrhea will develop ascending infection. The effect of oral contraceptives on chlamydial disease is less uniform. The increased cervical ectropion produced by oral contraceptives increases the likelihood of chlamydial cervicitis, but the thickened cervical mucus and reduced menstrual flow appear to inhibit ascending infection. Patients with an IUD have an increased risk of developing PID within the first 3 weeks of device placement.

The sequelae of PID—chronic and recurrent pelvic pain, dyspareunia, tuboovarian abscesses, ectopic pregnancy, and involuntary infertility—affect large numbers of women. It has been estimated that 20% of women with PID will have chronic pelvic pain. It is estimated that half of all ectopic pregnancies result from tubal damage produced by PID. Women with a history of PID have a 10-fold risk of infertility. Repeated bouts of PID substantially increase the likelihood of infertility.

Etiology

Most episodes of PID in adolescents are the result of gonococcal or chlamydial infection, or both, ascending from the cervix. If lower genital tract infection is not treated, approximately 10% to 40% of women with gonococcal cervicitis and 20% to 40% of women with chlamydial cervicitis will eventually develop PID. Microorganisms that comprise the vaginal flora (e.g., anaerobes, *G. vaginalis*, *H. influenzae*, enteric gram-negative rods, and *Streptococcus agalactiae*) have been associated with PID. In addition, cytomegalovirus (CMV), *M. hominis*, *Ureaplasma urealyticum*, and *Mycoplasma genitalium* might be associated with some cases of PID.

Clinical Manifestations

Although the constellation of symptoms and signs associated with PID—abdominal pain, irregular uterine bleeding, abnormal vaginal discharge, and lower abdominal and pelvic tenderness—is well known, no single symptom or sign or a combination of symptoms and signs is both sensitive and specific. Clinical findings that improve the specificity of the diagnosis of PID (i.e., increase the likelihood that the diagnosis is correct) do so only at the expense of sensitivity (i.e., exclude patients who do in fact have PID). Criteria for the diagnosis of PID suggested by the CDC are shown in Table 90.4. Because the diagnosis of PID is imprecise, and the potential for damage to the reproductive health of the patient, even by mild disease, is great, providers should maintain a low threshold for the diagnosis of PID.

Complications

Perihepatitis (Fitz-Hugh-Curtis syndrome), consisting of right upper quadrant pain and tenderness produced by inflammation of the liver capsule in association with PID, occurs in 4% to 30% of cases of PID and is more likely to occur with gonococcal infection and more severe diseases. On transvaginal ultrasonography, about one-third of patients with PID will have visible fallopian tubes and about one-fifth will have a demonstrable tuboovarian abscess (Fig. 90.11).

A complication of PID that warrants prompt diagnosis is ruptured tuboovarian abscess. About 15% of tuboovarian abscesses rupture spontaneously. The symptoms and signs of a ruptured abscess may be mild if only a small amount of pus has leaked out, but the usual clinical picture includes peritonitis and shock. A pelvic mass is palpable in less than one-half the cases. Prompt surgical intervention can be lifesaving.

Laparoscopy confirms the diagnosis of PID in only about 60% of patients who are suspected, either by gynecologists or by primary care physicians, on clinical grounds of having the disease. Conditions most often mistaken for PID are acute appendicitis, endometriosis, hemorrhagic and nonhemorrhagic ovarian cysts, and ectopic pregnancy. In up to 25% of women judged clinically to have PID, no abnormality can be identified laparoscopically.

The emergency physician must consider the possibility of pregnancy in adolescents with presumed PID. Ascending genital tract infection is rare during pregnancy. As a result, alternative diagnoses to PID, including ectopic pregnancy, should be considered. Hospitalization is recommended for all pregnant patients with PID.

TABLE 90.4

DIAGNOSTIC CRITERIA FOR PELVIC INFLAMMATORY DISEASE

Minimum criteria	Sexually active patient with pelvic or lower abdominal pain, no cause other than PID identified, *and* one of the following: Cervical motion tenderness *or* Uterine tenderness *or* Adnexal tenderness
Additional criteria	These findings enhance the specificity of the minimum criteria and support a diagnosis of PID: Oral temperature > 101°F (>38.3°C) Abnormal cervical or vaginal mucopurulent discharge Abundant numbers of white blood cell on saline microscopy of vaginal secretions Erythrocyte sedimentation rate >15 mm/h Elevated C-reactive protein Documented gonococcal or chlamydial cervical infection
Specific criteria	These findings offer a definitive diagnosis of PID Endometrial biopsy with histopathologic evidence of endometritis Laparoscopic abnormalities consistent with PID Transvaginal sonography or magnetic resonance imaging techniques showing thickened, fluid-filled tubes or tuboovarian complex, or Doppler studies showing tubal hyperemia

PID, pelvic inflammatory disease.
Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines. MMWR *Morb Mortal Wkly Rep* 2006;55(RR-11):76–78.

An important pathophysiologic irony is the observation that tubal occlusion is associated more often with a relatively unimpressive clinical presentation of PID (i.e., long duration of symptoms, no signs of peritonitis, normal peripheral leukocyte count) than with a "hot" clinical disease (i.e., short duration of symptoms, fever, peritoneal signs, leukocytosis). Similarly, chlamydial PID is associated with both a longer duration of pain at patient presentation and a higher risk of infertility than is gonococcal PID. Thus, if the diagnosis of PID is allowed to depend substantially on patients' appearance—as either "well" or "sick"—clinicians may be tempted to reject the diagnosis of PID and to withhold antibiotic treatment of those patients at highest risk of subsequent ectopic pregnancy and infertility.

The Kahn approach to the clinical diagnosis of PID is recommended for the emergency physician (Fig. 90.12). This strategy emphasizes diagnostic sensitivity for women with relatively mild illness, encouraging clinicians to err on the side of providing rather than withholding antibiotic treatment, and diagnostic specificity for women with relatively severe illness, focusing on the consideration of major competing diagnoses.

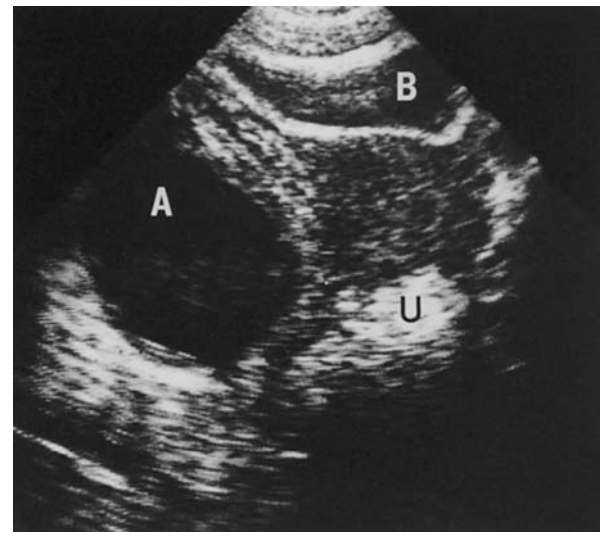

FIGURE 90.11 Transverse real-time sonogram of the pelvis of a 15-year-old patient with gonococcal salpingitis, demonstrating a 6 × 8-cm right tuboovarian abscess *(A)* containing a fluid-debris level. U, uterus; B, bladder.

Management

The 2006 CDC guidelines for the treatment of PID are summarized in Table 90.5. The antibiotics listed were selected for their effectiveness in combination against *N. gonorrhoeae*, *C. trachomatis*, and the aerobes and anaerobes responsible for polymicrobial PID. Hospitalization is recommended for any patient with PID whose diagnosis is uncertain, particularly if

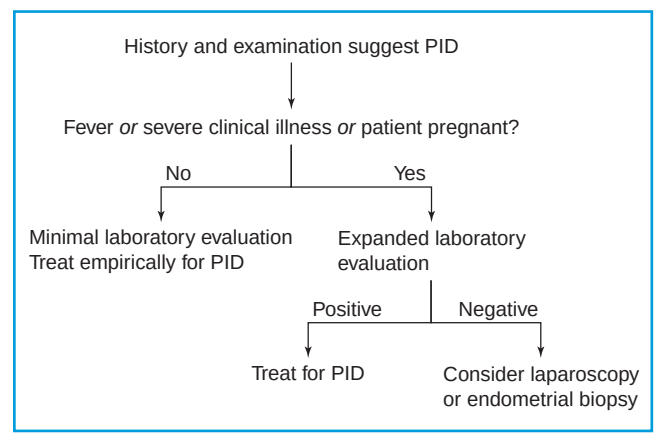

FIGURE 90.12 Strategy for diagnosis of pelvic inflammatory disease (PID). Minimal laboratory evaluation should include tests for gonococcal and chlamydial cervicitis. Expanded laboratory investigation may include, in addition to the minimal evaluation, complete blood cell count, C-reactive protein or erythrocyte sedimentation rate, and pelvic or transvaginal ultrasonography. (Adapted from Kahn JG, Walker CK, Washington E, et al. Diagnosing pelvic inflammatory disease. *JAMA* 1991;266:2594–2604.)

TABLE 90.5

TREATMENT REGIMENS FOR PELVIC INFLAMMATORY DISEASE

	Initial therapy	Subsequent therapy	Comments
Regimen A			
Extended parenteral treatment	Cefotetan 2 g IV every 12 h *or* Cefoxitin 2 g IV every 6 h *with* Doxycycline 100 mg po or IV every 12 h	Doxycycline 100 mg po bid to complete 14 days of therapy	Oral doxycycline is preferred to avoid infusion pain Parenteral treatment may be stopped 24 h after clinical improvement
Regimen B[a]			
Extended parenteral treatment	Clindamycin 900 mg IV every 8 h *with* Gentamicin 2 mg/kg and then 1.5 mg/kg IV or IM every 8 h (single daily dosing may be substituted)	Doxycycline 100 mg po bid *or* Clindamycin 450 mg po qid to complete 14 days of therapy	Clindamycin is preferred for oral treatment of tuboovarian abscess Parenteral treatment may be stopped 24 h after clinical improvement
Regimen C			
Combined parenteral/oral treatment	Ceftriaxone 250 mg IM *or* Cefoxitin 2 mg IM with probenecid 1 g po	Doxycycline 100 mg po bid for 14 days	Ceftriaxone has better coverage than cefoxitin against *Neisseria gonorrhoeae* Adding metronidazole (500 mg orally twice a day for 14 days) will treat the bacterial vaginosis associated with many cases of PID and will enhance anaerobic coverage

IV, intravenous; IM, intramuscular; po, orally; bid, twice a day; qid, four times daily.
[a]Fluoroquinolones are no longer recommended for the treatment of gonococcal infections.
Adapted from Centers for Disease Control and Prevention. Sexually transmitted diseases treatment guidelines, 2006. MMWR MMWR *Morb Mortal Wkly Rep* 2006;55(RR-11):76–78. Alternative regimens are available at: www.cdc.gov/STD/treatment/2006/updated-regimens.htm. Accessed November 2008.

ectopic pregnancy or appendicitis seems likely; for patients with severe clinical illness, including those with fever or suspected pelvic abscess; and for patients who are either immunodeficient or pregnant. Parenteral treatment is recommended for patients likely to fail a course of oral antibiotics because of either poor compliance or vomiting and for those whose illnesses have not responded to prior oral antibiotics.

The follow-up of outpatients should include a return visit after about 3 days of treatment. The average duration of symptoms among women with gonococcal salpingitis treated with oral antibiotics is 3 to 4 days; the corresponding interval for nongonococcal salpingitis is 4 to 6 days. A poor response to therapy should alert the physician to the possibilities of inadequate compliance, abscess formation, or an alternative diagnosis.

Follow-up for all patients should include reexamination at the end of antibiotic therapy to check for residual pelvic tenderness and adnexal masses. To identify patients with persistent or repeated infection resulting from noncompliance with antibiotics or an untreated sexual partner, follow-up tests for gonococcal and/or chlamydial cervicitis should be scheduled 4 to 6 weeks after the end of treatment. All patients with gonococcal and chlamydial infections should be counseled about the HIV infection and offered serologic screening for both syphilis and HIV infection.

The importance of identifying and treating sexual partners of women with PID cannot be overemphasized. About 25% of such men have asymptomatic urethritis and are unlikely to seek treatment on their own. If these men are not treated, they become part of the reservoir of undetected carriers of STIs. The success of various patient referral strategies conducted by public health care personnel to achieve treatment of partners ranges from 29% to 59%. The success rate of patient-initiated partner treatment is unknown.

Expedited Patient Therapy

When medical evaluation, counseling, and treatment of partners cannot be reliably done, the CDC recommends the consideration of expedited patient therapy (EPT), in which partners of infected patients are treated without previous medical evaluation or prevention counseling. Medications and/or prescriptions should be accompanied by treatment instructions, appropriate warnings about taking medications, and advice that partners should seek personal medical evaluations.

EPT is believed to be a useful option for male partners of women with chlamydial infection or gonorrhea but has a

limited role in partner management for trichomoniasis. Currently, EPT is not feasible in many settings because of legal and operational barriers. As of 2008, EPT is legal in 15 states, potentially allowable in 24, and prohibited in 11. An up-to-date discussion of legal issues with state-by-state restrictions can be viewed at www.cdc.gov/std/ept/legal/default.htm.

Genital Warts

Background

Genital warts, or condylomata acuminata, are multicentric, exophytic tumors on anogenital skin (Fig. 90.13) caused by the DNA-containing human papillomavirus (HPV), most commonly by HPV types 6 and 11. Although HPV infections are not reportable, many venereologists believe they are the most common STIs in the United States. There are 5.5 million new cases of HPV infection every year, and approximately 20 million Americans are infected. Most HPV infections are subclinical. The HPV types that produce most anogenital warts are considered to have low potential for malignant change. HPV infection of the cervix, which is associated with cervical dysplasia and cancer, occurs at an annual incidence of 9% to 20% in college-aged women. An HPV vaccine that targets subtypes 6, 11, 16, and 18 has been recently introduced into the general population.

Although HPV type 2 (associated with cutaneous, common warts) has been identified in anogenital warts in children, suggesting autoinoculation or heteroinoculation, nearly all genital warts in adolescents and adults, and some in children, are transmitted from person to person by sexual contact. The time from contact with an infected partner to the appearance of genital warts is estimated to be 1 to 3 months. However, the concept of an incubation period does not apply readily to the large number of infections that remain subclinical for long periods.

Pathophysiology

Grossly, genital warts are hyperplastic lesions that occur on squamous epithelium. On microscopic examination, the stratum granulosum contains foci of vacuolated cells. Acanthosis, parakeratosis, and hyperkeratosis are characteristic findings. The presence on Papanicolaou smear of koilocytes—intermediate, often multinucleated squamous cells with perinuclear halos, pyknotic nuclei, and dense peripheral cytoplasm—indicates cervical HPV infection.

Clinical Manifestations

Most patients with genital warts either have no complaint or report noticing "bumps" in the genital area. Uncommonly, large perianal warts can be painful and interfere with defecation. Prepubertal girls with vulvovaginal warts may have a bloody vaginal discharge. Because HPV infection in males is so consistently asymptomatic, most female patients are not aware of their exposure to an infected partner.

Warts can occur anywhere on the perineum, but their growth seems to be encouraged by moisture. The most common locations in females are the posterior fourchette, adjacent areas of the labia minora and majora, and the lower vagina (Fig. 90.13). Single warts, 1 cm or more in diameter, and clusters of seedlings, each a few millimeters across, are both common. Warts can be velvety and flat or papillomatous. Large warts often contain distinct cauliflower-like lobulations. On the cervix, acetowhite infected areas are usually seen only with a colposcope. Immunodeficient patients are particularly susceptible to extensive or severe disease with an increased risk of malignant change. Genital warts must be differentiated from condylomata lata, a contagious manifestation of secondary syphilis (Fig. 90.14) and molluscum contagiosum.

The diagnosis of genital warts is easy to make in patients with obvious lesions but can be more difficult in patients with flat warts or "microwarts" of the vulva. A magnifying lens or colposcope can be used to inspect suspicious areas that have been soaked in 5% acetic acid for 5 minutes. Infected skin, areas of nonspecific inflammation, and skin treated with

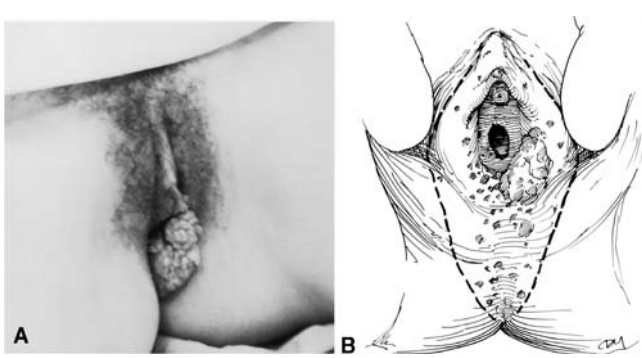

FIGURE 90.13 **A:** Large vulvar and perianal genital warts in a 15-year-old patient. **B:** In females, genital warts are most commonly located along the posterior margin of the introitus, inside the vagina, and on the labia minora.

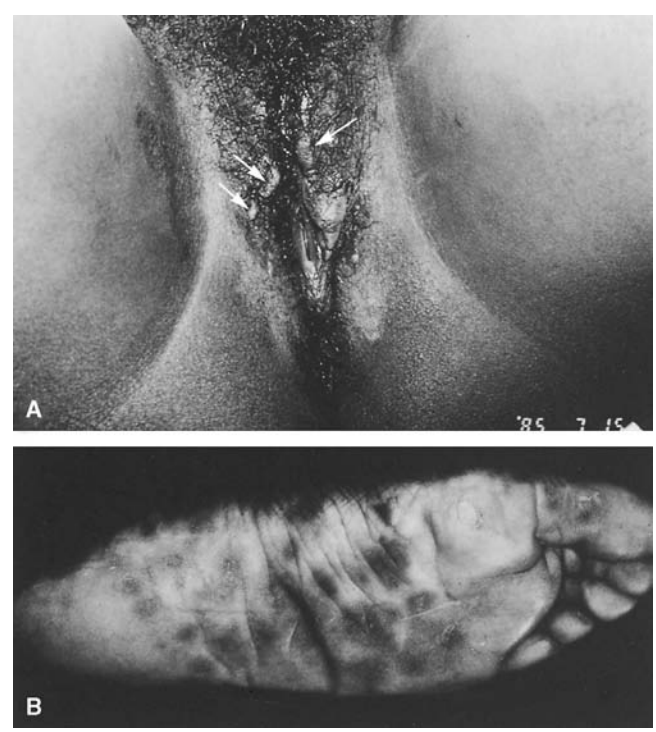

FIGURE 90.14 **A:** Vulvar condylomata lata of secondary syphilis in a 15-year-old patient. **B:** Macular rash on the sole of foot of same patient.

podophyllin will turn white after soaking. No data support the use of HPV nucleic acid tests in the routine diagnosis or management of visible genital warts. To exclude syphilis, patients should also receive serologic screening.

Management

Treatment of genital warts should be guided by the preference of the patient, the available resources, and the experience of the health care provider. Eradicating visible lesions does not end the viral infection. Whether it reduces contagiousness is uncertain. Spontaneous improvement or resolution of genital warts occurs in a minority of patients, so an acceptable alternative for some persons is to forego treatment and wait for spontaneous resolution.

Common recommended treatment options for genital wart removal are listed in Table 90.6. Recurrence rates for most therapies are relatively high, and treatment requirements or side effects limit some otherwise effective regimens. Each of the several available treatment methods has advantages and disadvantages; none is more than about 50% to 60% effective, and recurrences are common.

For extensive or recurrent disease or when repeated applications of podophyllin, trichloroacetic acid, or imiquimod are not successful, alternative treatment options include surgical removal, cryotherapy, and intralesional interferon. All women with genital warts should be referred to a primary care clinician for gynecologic care, including Papanicolaou screening.

Although anogenital warts in young children can result from vertical transmission or nonsexual contact with common warts, sexual abuse is another possible source of infection. The management of a child with genital warts should include either consultation with an expert in child abuse and neglect or a report to the state child protective service agency (see Chapter 132). Parents of children with genital warts should be examined for both common and genital warts. Excisional biopsy is preferred to ablative treatment of warts in children because histologic examination of the biopsy tissue can confirm the clinical diagnosis. Viral typing of anogenital warts in children may suggest abuse if a condylomatous HPV type is identified, but cannot exclude sexual contact if a cutaneous type is found because fondling is a common manifestation of child sexual abuse.

TABLE 90.6

TREATMENT REGIMENS FOR EXTERNAL GENITAL WARTS

	Dosing Info	Comments
Patient applied		
Podofilox[a] 0.5% solution or gel	Apply with a cotton swab twice daily for 3 days Follow by 4 days of no therapy Repeat cycle as needed up to 3 more times	Not for >10-cm^2 area Use < 0.5 mL/day Not for pregnancy
Imiquimod 5% cream	Apply cream nightly 3×/wk for 16 wk Area should be washed with soap and water 6–10 h after the application.	Not for pregnancy Local itching, erythema, and burning
Provider administered		
Cryotherapy Liquid nitrogen Cryoprobe	Apply to warts Repeat every 1–2 wk as necessary	
Podophyllin[a] resin 10%–20% in compound tincture of benzoin	Apply to each wart and allow to air dry May repeat weekly Wash area 1–4 hr after application	Each session, application should be limited to: <0.5 mL of podophyllin on <10-cm^2 area Not for use with open lesions near treatment area Not for pregnancy
Trichloroacetic acid 80%–90% Bichloroacetic acid 80%–90%	Apply to warts and allow to dry, at which time a white "frosting" develops If an excess amount of acid is applied, apply sodium bicarbonate or liquid soap May be repeated weekly	Safe in pregnancy Low viscosity may spread easily to unaffected skin
Surgical removal	Tangential scissor excision Tangential shave excision Curettage Electrosurgery	Requires special training
Interferon	Injected intralesionally	Systemic interferon not effective Local pain/irritation common Not recommended as primary modality

[a]Systemic absorption of podophyllin can produce bone marrow suppression, peripheral neuropathy, coma, and death.
Adapted from Centers for Disease Control and Prevention: Sexually transmitted diseases treatment guidelines. *MMWR Morb Mortal Wkly Rep* 2006;55(RR-11):76–78.

TABLE 90.7

RISK FACTORS FOR ECTOPIC PREGNANCY

High risk factors	Moderate risk factors	Weak association
Previous ectopic pregnancy Exposure to diethylstilbesterol Prior tubal surgery Current IUD in place History of > 2 episodes of chlamydial infection	History of PID History of chlamydial or gonorrhea infection Endometriosis Infertility	More than 1 sexual partner History of IUD History of threatened abortion Cigarette smoking Vaginal douching Previous pelvic surgery

IUD, intrauterine device.

Ectopic Pregnancy

Background

Ectopic pregnancy occurs in nearly 1% of pregnancies in North American women aged 15 to 24 years and is a leading cause of maternal mortality in the first trimester. Although the overall incidence of ectopic pregnancy in teenagers is low, this group has the highest mortality rate, largely caused by delays in seeking care. Despite improved methods of detection, ectopic pregnancy is misdiagnosed in up to 40% of patients on the initial ED visit and is an important cause of emergency medicine malpractice risk.

Risk factors of ectopic pregnancy are associated with conditions that inhibit normal transport of the blastocyst through the fallopian tube. In nearly half of ectopic pregnancies, a history of acute salpingitis is present. Other risk factors for ectopic pregnancy are listed in Table 90.7. The absence of risk factors is not reassuring, however, because 40% to 50% of those with ectopic pregnancy have no identifiable risk factors.

Pathophysiology

Ectopic pregnancy is any pregnancy in which the fertilized ovum implants in a location other than the intrauterine cavity. More than 95% of ectopic pregnancies occur in the fallopian tubes. Less common places for ectopic pregnancy include cornua of the uterus, cervix, ovary, and abdominal cavity. A heterotopic pregnancy is an ectopic pregnancy that coexists with an intrauterine pregnancy. Heterotopic pregnancies occur in 1 in 4,000 to 8,000 patients not treated with fertility agents.

After implantation in any of these extrauterine sites, β-hCG values rise, the uterus begins to enlarge, the patient is amenorrheic, and symptoms are similar to those of normal early pregnancy. Inevitably, the gestation begins to fail because of inadequate blood supply in the implantation site. β-hCG produced by trophoblastic tissue plateaus or declines. The endometrium of pregnancy, known as decidua, loses its hormonal support and begins to bleed and slough in a process analogous to menstruation. Occasionally, the decidua sloughs as one piece and passes as tissue, known as a decidual cast. Eventually, the placenta may erode through blood vessels or rupture the wall of the tube. Intraperitoneal hemorrhage, which may be gradual or catastrophic, may result.

Clinical Manifestations

The most common symptoms of ectopic pregnancy are amenorrhea, abdominal pain, and vaginal bleeding. However, this classic triad is nonspecific for ectopic pregnancy and is actually more commonly a presentation of threatened miscarriage. Incidence of common signs and symptoms of ectopic pregnancy is listed in Table 90.8.

The physical examination in any patient with suspected ectopic pregnancy should focus on the vital signs and the abdominal and pelvic examination. It should be noted that, although 50% of women with ectopic pregnancies have an adnexal mass, it is on the opposite side of the ectopic pregnancy in 20% to 30% of cases.

Laboratory evaluation should begin with testing for β-hCG. The standard urine pregnancy test is 99% sensitive and 99% specific for pregnancy. False-negative results can occur with urine testing, especially if the urine is very dilute. Therefore, when there is a high index of suspicion of pregnancy and a negative urine pregnancy test, a more sensitive, serum β-hCG measurement should be done.

In the patient with tachycardia, hypotension, or an acute abdomen, two large-bore IV catheters should be placed and blood should be sent for hematocrit, Rh and ABO typing and cross-matching, and quantitative serum β-hCG measurements. Serial serum β-hCG measurements will help the obstetrician to monitor the resolution of the ectopic pregnancy after surgery.

TABLE 90.8

SIGNS AND SYMPTOMS OF ECTOPIC PREGNANCY

Symptoms	% of patients with symptom
Abdominal pain	90–100
Amenorrhea	74–95
Vaginal bleeding	50–80
Dizziness/fainting	20–35
Urge to defecate	5–15
Pregnancy symptoms	10–25
Passage of tissue	5–10
Signs	**% of patients with sign**
Adnexal tenderness	75–98
Abdominal tenderness	80–95
Adnexal mass	10–50
Uterine enlargement	20–30
Orthostatic changes	10–15
Fever	5–10

When the β-hCG gives a positive result and the patient has any signs or symptoms of ectopic pregnancy, the emergency physician must differentiate between an intrauterine pregnancy (IUP) and an ectopic pregnancy. See Chapter 76 for discussion of the distinction between spontaneous abortion and ectopic pregnancy. Abdominal ultrasonography should be able to identify a gestational sac when the serum β-hCG is higher than 6,500 mIU per mL. Similarly, transvaginal ultrasonography should allow visualization of an IUP at β-hCG levels between 1,000 and 1,500 mIU per mL (correlating to 4.5 to 5 weeks' gestation). When ultrasonography cannot identify an IUP and β-hCG levels are greater than those listed previously, an ectopic pregnancy is very likely. The only true ultrasound finding diagnostic of an ectopic pregnancy is the visualization of a gestational sac outside the endometrial cavity.

Management

Findings consistent with ectopic pregnancy mandate obstetric consultation in the ED. Any Rh-negative pregnant female with vaginal bleeding or ectopic pregnancy should receive RhoD immune globulin (RhoGAM).

Care directed by the obstetrician may include either emergent laparotomy for unstable patients or laparoscopy to perform a linear salpingostomy. Expectant management (allowing resolution without intervention) or medical management with chemical agents (most commonly methotrexate) has been successfully used in certain cases in which the level of β-hCG is low and the ectopic mass is small; however, outpatient management is not appropriate for most adolescents with ectopic pregnancy.

CHAPTER 91 ■ HEMATOLOGIC EMERGENCIES

COLIN A. SIEFF, MD, AND JENNIFER C. KESSELHEIM, MD, M.ED

Hematologic emergencies arise in children who have been previously well, who have known blood disorders, or who have systemic diseases. Although the particular setting in which a serious blood abnormality occurs affects some facets of emergency care, the initial measures of support, diagnosis, and treatment are based on general principles that often cross the boundaries between the usual categories of blood disorders. This chapter emphasizes these principles as they apply to disorders of red blood cells, white blood cells, platelets, and coagulation. The initial evaluation and treatment of life-threatening disorders are described in detail. When controversy exists regarding specific management problems, alternative approaches are presented.

DISORDERS OF RED BLOOD CELLS

Severe anemia is a pediatric emergency that requires rapid evaluation and treatment to prevent hypoxia, congestive heart failure, and death. The classification of causes of anemia according to (i) blood loss, (ii) increased red blood cell destruction, and (iii) decreased red blood cell production is familiar to most physicians and provides an excellent starting point for the evaluation of the anemic child. In the next section, the same classification is applied to the emergency management of specific hematologic disorders.

Blood Loss

Trauma (see Chapters 104 and 105) is the leading cause of major hemorrhage in children. Every emergency physician must be prepared to act quickly and systematically when confronted with an actively bleeding child. The initial approach often requires the joint effort of a team of doctors and nurses to accomplish numerous tasks simultaneously. Within the first few minutes, the nature of the accident, an estimate of blood loss, and the presence of major current or chronic illnesses, including bleeding disorders, should be determined. The adequacy of the airway must be ensured. Vital signs should be measured frequently to detect early signs of hypovolemic shock. All clothing should be removed, and the child should be examined for sites of bleeding other than those found on initial inspection. In cases of significant hemorrhage, standard protocols recommend the insertion of two large-bore catheters, preferably in peripheral veins, with at least one being placed above the diaphragm. Blood samples should be drawn for cross-matching of donor blood, a complete blood cell (CBC) count (including platelet count), and screening coagulation studies [prothrombin time (PT) and partial thromboplastin time (PTT)]. A spun hematocrit should be measured immediately in the emergency department (ED) if a CBC count cannot be obtained quickly. If bleeding is brisk and sustained or if there is any suggestion of hypovolemic shock, volume expanders should be infused. Both colloid preparations, such as 5% blood (O negative when necessary), and crystalloids, such as saline or Ringer's lactate, are effective for the maintenance of intravascular volume, but the latter solutions may be more readily available and should be used initially.

After immediate stabilization has been achieved and external hemorrhage has been slowed or stopped, the child, who had sustained blunt trauma, should be evaluated for internal hemorrhage. This evaluation is especially important when the nature of the trauma is unclear or when multiple areas of the body may have been involved, as in automobile or bicycle accidents. The importance of suspecting and identifying internal hemorrhage is underscored by the occurrence of hypovolemic shock and death in the child whose skin lacerations were sutured but whose ruptured spleen went undetected. Suspicion of internal bleeding should be raised in the presence of a continuously falling hematocrit or continuing signs of hypovolemic shock, despite control of external bleeding and the replacement of seemingly adequate volume. Respiratory compromise, a protuberant abdomen, or changing sensorium may be further clues to the presence of internal hemorrhage. Further studies, including radiographs of the chest and abdomen, computed tomography (CT) of the head and/or abdomen, and rarely peritoneal lavage, should be instituted when appropriate.

Gastrointestinal (GI) bleeding and other forms of nontraumatic hemorrhage can also be life threatening. In some cases, the severity of bleeding is accentuated by the combination of an anatomic lesion and a related bleeding disorder, such as esophageal varices with a coagulopathy caused by liver failure. Unexplained severe anemia requires a careful search for bleeding in the GI tract, retroperitoneal space, or elsewhere.

The approach to blood transfusion (Table 91.1) can be divided into three levels of intervention, depending on the clinical findings and the laboratory data:

1. If bleeding has been controlled, vital signs are stable, the hemoglobin/hematocrit level remains above 7 g per dL, and further bleeding is considered unlikely, the initially cross-matched blood should be held for at least 24 hours and then released for other use if no longer required for this patient.
2. If bleeding has led to hypovolemic shock but tissue oxygenation is not critically affected, intravascular volume should be supported with crystalloid or colloid solutions until a cross-match has been performed and compatible

TABLE 91.1

GUIDELINES FOR TRANSFUSION THERAPY

Blood component	Indication	Dose
Whole blood	Immediate restoration of blood volume and red blood cell mass after trauma or surgery; exchange transfusion	Calculation of red blood cell transfusion requirements[a]
Packed RBCs	For all nonemergency transfusions or emergency restoration of red blood cell mass (may be combined with saline or fresh-frozen plasma for volume expansion or exchange transfusion)	Calculation of red blood cell transfusion requirements[a]
Leukoreduced RBCs	Same indications as packed RBCs but contains few leukocytes; helpful in preventing febrile transfusion reactions and platelet alloimmunization	Calculation of red blood cell transfusion requirements[a]
White blood cells	Recommended only for some severely neutropenic patients with documented or strongly suspected sepsis	One unit daily (each unit should contain at least 10^{10} granulocytes)
Platelets	For hemorrhagic complications caused by thrombocytopenia or abnormal platelet function	5–10 mL/kg
Fresh-frozen plasma	To provide multiple coagulation factors	10–20 mL/kg/dose

RBC, red blood cell.
[a]Calculation of RBC transfusion requirements:
Required volume of packed RBCs = blood volume × [(desired hematocrit – present hematocrit)/hematocrit of packed RBCs].
Blood volume (mL) = weight (kg) × 70 mL/kg.
Packed RBCs usually have a hematocrit of 60%–75%; whole blood has a hematocrit of 44%–48%.

donor blood is available. If necessary, group and Rh-type-specific but noncross-matched blood can be used. A similar approach should be used if the hemoglobin/hematocrit level slowly falls to a level less than 6 g per dL or if the hematocrit remains stable at a low level, but further bleeding is considered likely (e.g., esophageal varices).

3. Only when bleeding is life-threatening should noncross-matched group O, Rh-negative blood be administered. Transfusion of blood with minor blood group incompatibilities may result in immediate hemolysis and renal failure or, more commonly, may result in sensitization of the recipient to red blood cell antigens, making future blood compatibility testing difficult. The determination of the patient's ABO or Rh blood group can be performed within a few minutes, so selection of ABO- and Rh-compatible donor units is almost always feasible.

A common pitfall in the assessment and treatment of the bleeding patient is the underestimation of the amount of blood loss. Neither the history of bleeding nor the initial hemoglobin level may accurately reflect the severity of hemorrhage. For example, a child with upper GI tract bleeding may have a modest amount of hematemesis or melena and hemoglobin of 8 g per dL when initially evaluated in the ED. However, within an hour, the child may pass a large amount of tarry stool and the hemoglobin level may fall to 3 g per dL. Tachycardia or hypotension in a patient with only a moderate degree of anemia should serve as a warning that intravascular blood loss is out of proportion to the hemoglobin level and that early replenishment of intravascular volume is essential.

Increased Red Blood Cell Destruction

Membrane Disorders

The underlying anemia in disorders of the red blood cell membrane (hereditary spherocytosis, hereditary elliptocytosis, stomatocytosis, liver disease) is rarely severe enough to constitute a hematologic emergency. However, the hemoglobin level may fall even further when red blood cell destruction increases (hemolytic crisis) or red blood cell production slows (aplastic crisis). Hemolytic crises are usually associated with acute infections and are self-limiting. Most aplastic crises accompany parvovirus infection; anemia may be the only manifestation of the infectious process.

The hemoglobin level and reticulocyte count should be routinely checked when children with known disorders of the red blood cell membrane develop increasing jaundice or pallor associated with an infectious illness. The hemolytic crisis is characterized by worsening jaundice, falling hemoglobin level, and increasing reticulocyte count. In contrast, the aplastic crisis is associated with slowly increasing pallor, worsening anemia, and low or absent reticulocytes. In children whose underlying red blood cell membrane disorder is associated with brisk hemolysis (hemoglobin level less than 8 to 9 g per dL and reticulocytes greater than 5% to 7%), these crises may produce acute symptoms of anemia. If the hemoglobin level falls below 3 to 4 g per dL or if cardiovascular stability is threatened, red blood cell transfusions may be necessary. One unit or less of red blood cells is usually sufficient to support the patient until the hemolytic or aplastic crisis is over.

For some children, an aplastic crisis may be the first clinical manifestation of an undiagnosed membrane disorder or other chronic hemolytic anemia. The low hemoglobin level and reticulocyte count may suggest a pure problem of red blood-cell production, such as transient erythroblastopenia of childhood or Diamond-Blackfan anemia (DBA). However, a careful history for features such as neonatal jaundice or splenectomy in other family members, a thorough physical examination to assess spleen size, and a review of the peripheral smear to look for spherocytes or other abnormalities may identify the underlying hemolytic anemia.

The need for transfusions in an aplastic crisis should be considered carefully because the relatively slow development of the anemia usually allows adequate time for compensatory physiologic responses to the anemia. An increase in cardiac output keeps the patient hemodynamically stable even at very low hemoglobin levels. Moreover, many patients with aplastic crises are already beginning to resume red blood cell production when the crises are recognized, and the reemergence of reticulocytes in the peripheral blood or the presence of mature erythrocyte precursors in the bone marrow often precludes the need for red blood cell transfusions.

Older children and adolescents with red blood cell membrane disorders may develop gallstones because of increased red blood cell destruction and bilirubin release. Cholelithiasis or cholecystitis in affected patients should be managed the same way as in patients without underlying hematologic disease (see Chapter 89).

Metabolic Abnormalities

Like the red blood cell membrane disorders, erythrocyte metabolic abnormalities usually do not cause severe anemia. However, episodes of acute and sometimes life-threatening hemolysis can occur in many variants of glucose-6-phosphate dehydrogenase (G6PD) deficiency, including the A^- variant found in 10% of African-American boys, after exposure to drugs or chemicals (Table 91.2) or during an infectious illness. Ingestion of naphthalene-containing mothballs is the most common cause of severe hemolysis in American children with G6PD deficiency, and parents should be asked about the presence of mothballs as part of the evaluation of any child with an acute hemolytic anemia. The acute intravascular hemolysis of G6PD deficiency usually occurs within 1 to 3 days of oxidant exposure and is characterized by pallor, malaise, fever, scleral icterus, abdominal and back pain, and dark urine. The anemia is accompanied by an increased reticulocyte count, and diagnostic "bite" or "blister" cells are present on the peripheral smear as well as the transient presence of Heinz bodies after supravital staining with methyl violet. Hematologic changes may be minimal or absent in the first 24 hours after ingestion. Careful monitoring of the patient should continue for at least another day. Treatment should include removal of the offending agent and fluid administration to prevent renal tubular damage. When hemolysis is severe, red blood cell transfusions may be required. However, if the diagnosis is uncertain, a pretransfusion blood sample should be saved for the measurement of specific enzyme levels. Because enzyme levels are higher in younger red blood cells, the diagnosis of G6PD or other enzyme deficiencies may be obscured at the time of acute hemolysis and a high reticulocyte count.

TABLE 91.2

DRUGS AND SUBSTANCES ASSOCIATED WITH ACUTE HEMOLYSIS IN CHILDREN WITH GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) DEFICIENCY

Antimalarials (primaquine)
Sulfonamides (including sulfasalazine and trimethoprim-sulfamethoxazole)
Nalidixic acid and nitrofurantoin
Naphthalene (mothballs)
Fava beans
Aspirin (does not cause acute hemolysis with G6PD deficiency in African Americans when used in therapeutic doses)

Aplastic crises may occur in more severe variants of G6PD deficiency and other red blood cell metabolic disorders such as pyruvate kinase deficiency that are associated with chronic hemolysis. Diagnosis and treatment of this complication are the same as described in the previous section regarding membrane disorders.

Autoimmune Hemolytic Anemia

Background. One of the most serious causes of severe anemia in children is autoimmune hemolytic anemia (AIHA). This antibody-mediated disorder occurs most commonly in young children. Affected erythrocytes are lysed intravascularly or removed prematurely from the circulation by macrophages of the reticuloendothelial system. AIHA may be associated with infections, drugs, inflammatory diseases, or malignancies, but a specific cause is rarely identified in pediatric patients.

Clinical Manifestations. Although this disorder may occasionally be indolent and may go undetected for days or weeks, AIHA is usually associated with the sudden onset of pallor, jaundice, and dark urine. The hemoglobin level may be as low as 1 to 2 g per dL at the time of diagnosis. When the anemia is this severe, the child may appear moribund and desperately ill. Signs of congestive heart failure may be prominent.

The anemia is usually accompanied by reticulocytosis, although the reticulocyte count may be below 5% during the first few days of the illness. Occasionally, patients remain reticulocytopenic for prolonged periods. Spherocytes are often found on the peripheral smear, and red blood cell agglutination may be present. If there is intravascular hemolysis, free hemoglobin in the urine produces a positive dipstick reaction for blood in the absence of red blood cells on microscopic urinalysis; when hemolysis is severe enough to exceed the renal clearance of hemoglobin, the plasma will be pink, and careful inspection of the plasma layer of a spun hematocrit may provide an early diagnostic clue. Unfortunately, it is often not easy to get this simple procedure done, but if available, it can be very useful. The direct antiglobulin (Coombs) test using broad-spectrum Coombs serum (IgG, IgM, and complement) is usually positive in childhood AIHA. Acute hemolysis is most commonly associated with a warm (37°C)-reactive IgG antibody with or without complement that is usually panreactive or reactive with the proteins of the Rhesus complex. This type of hemolysis is usually extravascular (spleen). IgM-mediated cold agglutinin disease is less common in children than in adults, but can occur following *Mycoplasma* (anti-I) or infectious

mononucleosis (anti-i). These antibodies bind to red blood cells in the cold and characteristically cause intravascular hemolysis, as complement is bound and activated at warmer temperatures. Cold-reactive IgG antibodies (Donath-Landsteiner test) cause paroxysmal cold hemoglobinuria (PCH), which in children frequently follows a virus infection. The direct antiglobulin test can be negative or positive for complement only, and the antibody can be demonstrated by the Donath-Landsteiner test on a blood specimen maintained at 37°C during transport to the laboratory [a cup of warm (not hot!) water is the best method].

Management

The management of the child with AIHA should be aggressive because the hemoglobin level may fall precipitously (Table 91.3). Hospitalization for careful observation and treatment is usually necessary. In patients with warm-reactive AIHA or PCH, the immediate institution of corticosteroid therapy (methylprednisolone 1 to 2 mg per kg administered intravenously every 6 to 8 hours) may prevent or reduce the need for red blood cell transfusions. Alternatively, the patient may be treated with intravenous γ-globulin (IVIG) 1 g per kg. For life-threatening AIHA, the use of steroids and IVIG should be considered. Patients with cold-reactive IgM antibodies do not respond as favorably to steroids and IVIG as those with warm-reactive antibodies (most IgG antibodies), but a trial of either therapy is still warranted in the severely anemic patient. These parents must be kept warm. The response to steroids or IVIG in AIHA usually occurs within a few hours or days.

Red blood cell transfusions are hazardous in patients with AIHA and should be reserved for children with severe anemia and signs of hypoxia or cardiac failure. The presence of a nonspecific antibody in the patient's serum makes it difficult to find a unit of donor blood compatible in the major cross-match (donor cells and patient serum) and sufficient serum and cells must be obtained well in advance of the anticipated transfusion if possible. The finding of an apparently compatible unit may pose even greater danger because the physician is lured into a false sense of confidence when, in fact, an undetected antibody may still cause a severe hemolytic transfusion reaction. The use of the "least incompatible" unit is a common practice, although data to support this approach are lacking. Fortunately, acute transfusion reactions are infrequent, but the best policy is to avoid transfusion when possible. If red blood cells are required and a compatible donor unit can be found, this unit should be used. Otherwise, ABO- and Rh-compatible units should be administered despite the incompatibility in vitro. The recognition of the risks of transfusion in children with AIHA should not lead to the withholding of "incompatible" blood when transfusion therapy is required to prevent severe morbidity or death.

Whether the unit of red blood cells appears compatible or incompatible on the basis of serologic studies, special precautions should be taken during the actual transfusion. The first 5 mL should be administered in 10 to 15 minutes, and the patient should be observed closely for malaise, back pain, fever, and other signs of acute hemolysis. If any of these findings is present, the transfusion should be stopped and normal saline should be administered until a new unit can be prepared. If the patient is asymptomatic and the plasma is clear, the remainder of the unit should be given with continuing close observation. Blood administered to patients with cold antibodies should be infused through a warmer.

In rare instances, the hemoglobin level continues to fall despite steroids, IVIG, and red blood cell transfusion, necessitating alternative therapeutic attempts to sustain life. Plasmapheresis may remove sufficient antibody to reduce the destruction of the patient's erythrocytes and to allow improved survival of transfused red blood cells. If this measure fails, emergency splenectomy may be required. Immunosuppressive agents are useful in the long-term management of refractory AIHA but do not have a role in the emergency management of this disorder.

TABLE 91.3

TREATMENT OF SEVERE AUTOIMMUNE HEMOLYTIC ANEMIA

- Maintain normal or increased urine output with intravenous fluids.
- Immediately begin corticosteroid therapy with prednisone 2–4 mg/kg/day or a parenteral preparation in an equivalent dose. Alternatively, administer γ-globulin 1 g/kg administered intravenously, alone or in combination with corticosteroid.
- Administer red blood cell transfusions when severe anemia is accompanied by signs of hypoxia or cardiac failure:
  - Give first 5 mL in 10–15 min and observe for symptoms of acute hemolysis.
  - Check plasma layer of a spun hematocrit for pink color indicative of hemolysis of the transfused red blood cells.
  - If the antibody is cold-reactive, the blood should be warmed.
  - If symptoms or signs of worsening hemolysis are present, try a different unit of red blood cells.
- If hemoglobin level does not increase after these measures, including transfusion:
  - Begin plasmapheresis or exchange transfusion; *or*
  - Perform splenectomy.

Nonimmune Acquired Hemolytic Anemia

Acute hemolytic anemia in children may be caused by infections, chemicals, or drugs that damage the red blood cell directly. These disorders resemble AIHA in their clinical presentation and should be considered in the child with acquired hemolytic anemia and a negative antiglobulin test result. Infectious agents that may induce hemolytic anemia include malaria (which is of particular importance in immigrants from, and travelers to, Southeast Asia and Africa), other protozoa, and a wide variety of gram-positive and gram-negative organisms. Treatment is directed at the elimination of the offending agent. Red blood cell transfusions are usually unnecessary unless anemia is severe (hematocrit less than 15%) or accompanied by signs of cardiovascular compromise.

Erythrocyte Fragmentation Syndromes

Red blood cells undergo fragmentation and lysis when subjected to excessive physical trauma within the cardiovascular system. Hemolytic anemias as a result of red blood cell fragmentation have been associated with abnormalities of the heart (valve homografts, synthetic prostheses, or uncorrected valvular disease), great vessels (coarctation of the aorta), small vessels [hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura (TTP), collagen vascular disease, giant hemangiomas in infancy (Kasabach-Merritt syndrome)], and bone marrow transplantation.

Physical findings are related to the underlying disorder. The presence of red blood cell fragments on the peripheral smear strongly suggests mechanical damage to the erythrocyte. When small vessels are involved, thrombocytopenia may also be present. Hemolytic anemia associated with valvular or great vessel disease rarely causes severe anemia. However, iron deficiency as a result of intravascular lysis and urinary excretion of hemosiderin in renal tubular epithelial cells may aggravate the hemolytic anemia. Oral iron supplementation may obviate the need for transfusions. When hemolysis is a result of small vessel disease, treatment of the underlying disorder (e.g., collagen vascular disease) or primarily affected organs (e.g., renal failure in hemolytic-uremic syndrome) is the first priority. The diagnosis of TTP is important and should be considered in the presence of fever, neurological abnormalities, renal abnormalities, thrombocytopenia, and microangiopathy. Serum lactate dehydrogenase is frequently markedly increased. TTP is due to either mutation in the gene for or antibodies to the ADAMTS13 protease that cleaves large multimers of von Willebrand factor (VWF). The prompt institution of plasma exchange can be lifesaving. Red blood cell transfusions should be reserved for the treatment of symptomatic anemia. Because the hemolysis is caused by extracorpuscular factors, survival of transfused cells may be markedly shortened. The management of intravascular coagulation associated with several of these disorders is discussed later in this chapter.

Decreased Red Blood Cell Production

Disorders of red blood cell production, unless accompanied by shortened red blood cell survival, are characterized by a slowly progressive anemia. Consequently, the physician does not often encounter many of the difficulties associated with acute, life-threatening hemolysis or severe bleeding. However, the insidious onset of anemia when erythropoiesis is impaired may delay recognition of the disorder, and severe anemia and cardiac failure may be present at the time of diagnosis. Tissue oxygenation may be inadequate because of the low hemoglobin level, and conditions that increase the cardiac rate or output (fever, exercise) may precipitate congestive heart failure in the previously compensated patient. In addition, anemia secondary to diminished red blood cell production may be associated with an underlying, severe illness such as leukemia, neuroblastoma, or aplastic anemia in which other life-threatening hematologic abnormalities (severe neutropenia or thrombocytopenia) may be present. Thus, the patient with impaired production of erythrocytes may be as ill as the patient with acute hemolysis.

The important role of the history, physical examination, and laboratory studies in the initial evaluation of the child with decreased red blood cell production is described in Chapter 58. Initial management should include basic support of cardiorespiratory function and identification and treatment of conditions such as fever that may be compounding the problems of severe anemia. The patient with hypoxia or cardiac failure requires red blood cell transfusions. As described earlier, the urgency of the clinical situation rarely dictates the need to abbreviate the standard cross-matching procedures. A pretransfusion anticoagulated blood sample and a serum sample should always be saved for further diagnostic studies, as well as for the determination of the patient's red blood cell antigen profile should long-term transfusion therapy be necessary. The initial transfusion should be given as a small aliquot of packed red blood cells. In many instances, the symptoms of severe anemia will be relieved after the hemoglobin level has risen to only 1 or 2 g per dL. The administration of additional blood is rarely necessary in the early stages of therapy. Furthermore, the added volume may precipitate cardiac failure in the face of a preexisting high-output state. A helpful rule is to administer a number of milliliters per kilogram of packed red blood cells equivalent to the hemoglobin level. For example, in a child with aplastic anemia, a hemoglobin level of 3 g per dL and early signs of cardiovascular compromise would indicate that 3 mL per kg of packed red blood cells should be given. Some physicians routinely administer diuretics (e.g., furosemide 1 mg per kg per dose) during the transfusion in a severely anemic patient. An alternative approach is to reserve diuretic therapy for those patients who develop signs of increasing cardiac compromise during the transfusion.

Aplastic and Hypoplastic Anemias

The differential diagnosis of aplastic and hypoplastic anemias is discussed in Chapter 58. Most of these disorders have a protracted course and, after initial stabilization of the patient, require intensive diagnostic evaluation and careful assessment of long-term therapy rather than emergency management. Transfusion should be used with particular caution in the initial management of patients with hypoplastic and aplastic anemias because exposure to human leukocyte antigen (HLA) and other antigens may adversely affect engraftment of transplanted bone marrow in patients who might otherwise have benefited from this procedure. If transfusions are required for severe anemia and signs of cardiac failure or poor oxygenation, the goal of treatment should be relief of symptoms, not restoration of a normal hemoglobin level. When possible, leukoreduced red blood cells should be used to reduce the likelihood of alloimmunization. Cytomegalovirus (CMV)-negative products should be used unless the patient is known to be CMV positive, or stem-cell transplantation is not a treatment option. First-degree relatives should not be chosen as blood donors to avoid allosensitization to family minor HLA antigens.

Patients with pure red blood cell aplasia most likely have DBA or transient erythroblastopenia of childhood (TEC). In DBA, the level of red blood cell adenosine deaminase is frequently elevated, and blood for this test should be obtained before transfusion. For patients with a hypoplastic anemia suggestive of TEC, a bone marrow aspirate may be helpful in predicting the course of the disease during the next few days and, in particular, the likelihood that red blood cell transfusions will be required later. For example, a patient with TEC has a hemoglobin level of 4 g per dL and the absence of reticulocytes at the time of diagnosis. If examination of the bone marrow reveals only an occasional pronormoblast, a further decrease in the hemoglobin concentration should be anticipated and red blood cell transfusions will almost certainly be required. However, if the bone marrow aspirate shows numerous erythrocyte precursors progressing through all levels of red blood cell maturation, a peripheral reticulocytosis can be expected within 24 hours and red blood cell transfusions may be unnecessary.

Nutritional Anemias

Nutritional anemias in children constitute more of a public health problem than a hematologic emergency. However, on

occasion, the hemoglobin level may be very low at the time of diagnosis. Severe iron deficiency occurs mainly in 1- to 2-year-old children who drink 1 quart (32 fl oz or 1 L) or more of cow's milk daily and have little room for other foods richer in iron. Adolescent girls make up another group at high risk for iron deficiency because a diet normally marginal in iron content becomes totally inadequate in the face of menstrual blood losses. The presenting complaint in severe iron-deficiency anemia is usually pallor, lethargy, irritability, or poor exercise tolerance. In megaloblastic anemias such as vitamin B_{12} deficiency in an infant exclusively breast-fed by a vegetarian mother or in folic acid deficiency caused by impaired folate absorption, nonhematologic symptoms such as diarrhea, slowed development, or coma may be more prominent than the symptoms of anemia.

Stabilization and improvement can usually be achieved with replacement of the deficient nutrient. Nucleated red blood cells or reticulocytes usually appear within 48 hours of replacement therapy in folic acid or vitamin B_{12} deficiency and within 72 hours of therapy in severe iron-deficiency anemia. Because of this rapid response, red blood cell transfusions are rarely required unless symptoms associated with the anemia pose a serious threat. A response to replacement therapy should not preclude further investigation of the origin of the anemia, especially when the dietary history is inconclusive. For example, iron-deficiency anemia may result from repeated small pulmonary hemorrhages or chronic bleeding from an intestinal lesion rather than from inadequate iron intake. Similarly, megaloblastic anemias may be caused by deficient intrinsic factor or abnormalities of folic acid transport rather than from a seriously altered diet.

Iron replacement therapy consists of 3 to 6 mg per kg per day of elemental iron given orally as ferrous sulfate at night on an empty stomach as a single daily dose. Intramuscularly administered iron is painful and should be avoided. Intravenously administered iron has been associated with anaphylaxis, but such reactions are infrequent, and preparations such as iron-dextran can be given after a small test dose. Other IV iron preparations (iron-sucrose or iron-gluconate) are also safe and can be used if noncompliance with or poor tolerance of oral iron therapy is an issue. The hematologic response to parenterally administered iron is no faster than the response to orally administered iron. When considering replacement of folic acid or vitamin B_{12}, traditional replacement doses of 1 mg of folic acid and 100 μg of vitamin B_{12} daily are undoubtedly excessive, but their common use reflects the safety and concentrations of the available compounds.

The administration of supplemental iron, vitamin B_{12}, or folic acid should not be considered a substitute for adequate dietary intake when nutritional deficiency is recognized. Unlike most hematologic emergencies, the rapid improvement after treatment of these disorders may reduce the likelihood of further visits despite attempts to ensure adequate follow-up care. Therefore, a strong effort to restructure the diet should begin at the time of the initial contact.

DISORDERS OF HEMOGLOBIN STRUCTURE AND PRODUCTION

The disorders of hemoglobin structure and production that are most often encountered in a pediatric ED are the sickle hemoglobin syndromes [e.g., sickle cell anemia, hemoglobin S–hemoglobin C (SC) disease, hemoglobin S-β-thalassemia]. Thalassemia major and methemoglobinemia occur much less commonly than the sickling disorders. Lack of familiarity and vigilance with these diseases may delay recognition of serious illness, resulting in severe morbidity and even death. In the section that follows, particular attention is paid to the recognition of unusual but serious diseases and the management of the many and diverse complications associated with the hemoglobinopathies.

Sickle Hemoglobin Disorders

The sickling disorders are responsible for a large percentage of hematologic emergencies and a major proportion of total visits for any reason in many urban pediatric EDs. Although the basic molecular lesion in these disorders is well defined, treatment of the numerous complications is often unsatisfactory. Early recognition and aggressive management of specific problems may alleviate unnecessary suffering and prevent much of the morbidity and mortality associated with the sickling disorders. Optimal long-term care should be provided at a center with specialists who are familiar with sickle cell disease and its complications. The long-term management of many of the complications of sickle cell disease is beyond the scope of this chapter. In most instances, a thorough knowledge of the patient's clinical course and previous laboratory data are necessary for correct management of the hematologic complications presenting in the ED. Therefore, the treatment of hematologic emergencies in children with sickle cell disease is accomplished best in the center that also provides comprehensive care to affected patients.

Many complications of sickle cell disease include red blood cell transfusion, either simple or exchange, as part of their management. The indications for red blood cell transfusions are discussed in the following text with the complications of sickle cell disease. But, in general, in considering transfusions in this patient population, it is important to remember that patients with sickle cell disease may receive many transfusions throughout life. They are therefore at risk for developing new alloantibodies that may cause them to hemolyze if incompatible blood is given. As a result, extended red blood cell antigen testing is to be performed early in the course of the disease before the first transfusion and after each subsequent transfusion by hematologists as a routine part of sickle cell disease management. This is intended to screen for the development of new antibodies to donor blood, which would affect the type of blood the patient can receive in the future. The ED need not obtain this testing but should inform the blood bank when ordering blood for a frequently transfused patient so that the blood bank can consult this patient's transfusion history and immune profile. Attention should be paid to whether patients with sickle cell disease need premedications before red blood cell transfusions. Because these patients have likely required blood transfusions before, the history in the ED should include asking whether the patient has had a transfusion reaction and whether premedication with acetaminophen, diphenhydramine, and/or hydrocortisone may be needed. When administering a simple blood transfusion, clinicians should consider the following:

1. Whether the patient's long-standing anemia could have impacted his or her cardiac function, which might make patient sensitive to standard volumes of blood (10 to 15 mL

per kg up to 40 to 50 kg of body weight at which point the dose becomes 2 units). When needed, smaller aliquots can sometimes be used to restore tissue oxygenation without causing symptoms of cardiac failure or fluid overload.
2. Whether it is possible to administer an adequate volume of red blood cells while exposing the patient to as few donors as possible, in an effort to limit allosensitization.
3. Exchange transfusion is a special type of red blood cell transfusion that can be useful in multiple clinical settings. Sometimes exchange transfusions are needed to manage patients with sickle cell disease. This usually occurs when the patient experiences significant complications from sickling disorders, such as acute chest syndrome or stroke, in the setting of a hematocrit that is near the patient's baseline. A simple transfusion that would elevate the hematocrit much higher than the patient's baseline level should be avoided, as this would increase blood viscosity and lead to further complications. In this setting, exchange transfusion should be considered, in collaboration with the blood bank specialists, to decrease the percentage of sickled cells in the patient's circulation without increasing the hematocrit overall. Exchange transfusions require the same precautions as simple transfusions with regard to blood typing, screening for antibodies, and premedications. In addition, the following considerations apply:
   a. Should sophisticated blood banking services be unavailable, serious consideration should be given to transferring the patient to such a center if it is considered safe to do so.
   b. This procedure requires adequate IV access to both remove and transfuse blood and often requires a pheresis machine. Infants may be exchange transfused with simple syringes, but this too should occur in consultation with a hematologist.

DIAGNOSING SICKLING DISORDERS IN THE EMERGENCY DEPARTMENT

Clinical Manifestations/Management

Newborn screening for sickling disorders is now performed throughout the United States. However, newborns may occasionally elude testing or may rarely be misidentified as having sickle trait. Regardless, the information regarding the newborn screening is frequently unavailable at the time of the ED visit.

It is important to identify the ill child with an undiagnosed or unrevealed sickling disorder so that appropriate therapy is instituted. The diagnosis of sickle cell disease should be considered in African–American children with unexplained pain or swelling (especially of the hands or feet), pneumonia, meningitis, sepsis, neurologic abnormalities, splenomegaly, or anemia. The hemoglobin level and reticulocyte count are inadequate screening tests for the sickle hemoglobinopathies because values in affected patients (especially those with hemoglobin SC disease and S-β-thalassemia) may overlap with normal values. Similarly, the peripheral smear may be devoid of sickled cells. Definitive testing for sickling disorders is not usually performed in the ED. Hemoglobin electrophoresis should be performed on all patients with hematologic or nonhematologic emergencies that may be related to sickle cell disease. Because the results of the electrophoresis will take several days, it is imperative that adequate follow-up is ensured, either with the patient's primary care provider or with a hematology specialist.

The major complications of sickle cell disease include infections, sickle cell crises, which may be vasoocclusive, sequestration or aplastic, and chronic organ damage, which will not be fully considered further here, except for complications that may present to the ED.

Sepsis. Impaired immunologic functions, including early loss of normal splenic activity, contributes to the significantly increased frequency of sepsis in patients with sickle cell disease. The risk of bacterial sepsis in the patient with sickle cell disease is increased several hundredfold in comparison with the normal population. *Streptococcus pneumoniae* and *Haemophilus influenzae* are the most common pathogens in young children, although *Escherichia coli* and *Salmonella* are more frequent causes of bacteremia in older children. Mortality from bacteremic episodes may be as high as 20% to 30%. While patients with hemoglobin SC disease have a lower incidence of bacteremia and a lower mortality rate from these episodes, their risk of sepsis is still much elevated over the general population. The period of greatest risk is between the ages of 6 months and 5 years, when development of protective antibodies is limited and splenic function is diminished or absent. Children with hemoglobin SC or SS disease are prescribed prophylactic penicillin (or erythromycin should a penicillin allergy be present) through age 5 years to prevent *S. pneumoniae* sepsis. Immunization with pneumococcal and *H. influenzae* vaccines and administration of prophylactic penicillin through age 5 years help prevent serious infections but certainly do not eliminate this complication of sickling disorders.

The common occurrence of fever with no obvious source in young children with sickle cell disease makes the distinction between serious bacterial infections and benign, self-limiting viral disorders a particularly frustrating problem. Unfortunately, no single physical finding or laboratory test (other than blood culture) can accurately identify the septic patient. ED management of the febrile patient with a sickling disease must include a through history and physical examination, consideration of laboratory and radiographic tests, a decision about the use of antibiotics, and careful deliberation about patient disposition. The history should focus on whether the patient has experienced symptoms, beyond the fever, that could indicate a serious bacterial infection. A complete physical examination should investigate sources of the fever and should include auscultation of the lungs, abdominal examination looking for splenomegaly or tenderness, and a skin examination to assess pallor or jaundice. All patients with fever and sickle cell disease should receive a basic laboratory evaluation including a CBC count, blood culture, urine analysis, and, in some cases, cultures of the urine and throat. A lumbar puncture to look for meningitis need not be routinely performed (see the following text). The emergency physician should have a low threshold for obtaining a chest radiograph to screen for new infiltrates.

In deciding about antibiotic use and patient disposition, the physician must choose among several options, including routine admission, prolonged observation, or outpatient management. In many centers, children with sickle cell disease and fever who do not appear to be seriously ill, but who nonetheless

are at increased risk for sepsis, continue to be admitted to the hospital for at least 48 hours. During these hospital stays, ampicillin or a third-generation cephalosporin is usually administered intravenously until the culture results are confirmed to be negative. As an alternative to conventional inpatient management, other centers treat selected children with sickle cell disease and fever in short-stay units or as outpatients. This approach is usually restricted to children who do not appear acutely ill and who, on physical examination, do not have findings such as pallor, rales, or increased spleen size that indicate additional problems.

Some centers employ additional criteria such as age, previous history, temperature, and white blood cell count. Young children (younger than 2 years) are at higher risk of bacterial sepsis and may be more difficult to assess for early signs of sepsis than older children. A history of bacterial infection may be a risk factor for a subsequent episode. Temperatures greater than 39°C to 40°C may suggest an increased likelihood of sepsis, although lesser degrees of elevation do not guarantee negative blood culture results.

Those children who do not appear to be seriously ill and who, on the basis of physical findings and results of laboratory tests, are judged to be at low risk for bacteremia are treated in the ED with a long-acting cephalosporin such as ceftriaxone (50 to 75 mg per kg) and then most commonly discharged or admitted for 4 to 24 hours. Further therapy after discharge from the short-stay unit or ED varies among centers but may include 1 to 3 days of an oral antibiotic such as amoxicillin. A key component of the outpatient management of children with sickle cell disease and fever is a return visit or telephone report within 24 hours after discharge from the ED or short-stay unit. Inpatient care should be strongly considered for children whose families are unlikely to comply with this follow-up.

No matter which option for patient disposition is selected, the goal is to be certain that all children with sickle cell disease and sepsis receive appropriate antimicrobial therapy. Thus, the cornerstone of management in the ED is rapid initiation of antibiotics after obtaining appropriate cultures. Differences in subsequent management should not detract from the importance of this early step.

The treatment of the very ill-appearing child with sickle cell disease, fever, and probable sepsis should include the rapid institution of antibiotic therapy and aggressive management of septic shock. As in other patients with reduced or absent splenic function, clinical deterioration may be extremely rapid. The patient who is alert on arrival to the ED may be moribund and hypotensive 30 minutes later. Because of the emergence of penicillin-resistant strains of *S. pneumoniae*, children in whom sepsis is strongly suspected should receive a third-generation cephalosporin (cefotaxime or ceftriaxone), and vancomycin. Septic shock should be treated in the same way as in patients without hematologic disorders (see Chapter 70). Simple red blood cell transfusions or exchange transfusions may be needed to correct severe anemia or to reduce the likelihood of secondary organ damage caused by massive sickling in the presence of hypoxia, stasis, and acidosis.

Because unexplained fever is somewhat uncommon in children older than 10 years in general, the diagnosis of bacterial sepsis should be strongly considered in the older child with sickle cell anemia and fever. A careful assessment of the child's clinical condition should take into account the factors noted earlier. If the child appears toxic with pallor or cyanosis, inconsolable irritability, poor capillary refill, tachypnea, or tachycardia, admission for antibiotic treatment is advisable even in the absence of high fever or leukocytosis. Once again, good follow-up care must be ensured if the patient is managed as an outpatient.

Other Infections. Children with sickle cell disease are affected more often with infections other than sepsis in comparison with their hematologically normal counterparts. Meningitis, pneumonia, septic arthritis, and osteomyelitis may be responsible for substantial morbidity and mortality unless promptly recognized and appropriately treated. The level of suspicion for meningitis should be particularly high in the young, irritable child with sickle cell disease and unexplained fever. A lumbar puncture should be performed on toxic children and anyone with signs or symptoms for meningitis. Antibiotic therapy for meningitis is similar to that recommended for hematologically normal children with this disorder (see Chapter 92) and should include ceftriaxone and vancomycin. Exchange transfusion to lower the percentage of sickle hemoglobin may reduce the risk of intracerebral sickling and infarction in areas of local swelling and possible red blood cell sludging. When hemoglobin S is less than 30% of the total hemoglobin, sickling is unlikely, allowing fluid management to be dictated by the central nervous system (CNS) findings as opposed to the need to ameliorate sickling. Septic arthritis and osteomyelitis present particularly difficult diagnostic problems in children with sickle cell disease because the clinical findings so closely resemble those found in infarctions of the bone. A careful physical examination and judicious use of laboratory tests help the physician weigh the relative likelihood of infection and infarction. Diagnostic imaging with a ^{99m}Tc-diphosphonate bone scan, gallium scans, radiolabeled white blood cell scans, or magnetic resonance imaging (MRI) usually cannot distinguish between osteomyelitis and bone infarction secondary to vasoocclusion. Frequently, these studies yield results that do not point unequivocally to any one diagnosis. When possible, closed or open bone aspiration should precede the institution of antibiotic therapy in the patient with suspected osteomyelitis. Similarly, aspiration of an affected joint should be performed if septic arthritis is strongly suspected. In most instances, swollen, warm, and tender joints are caused by local infarction. The presence of other sites of concurrent infarction and the patient's description of the pain as typical "crisis pain" may be helpful in identifying the cause as vasoocclusion. The total white blood cell count and differential count of the joint fluid may be similar in both septic arthritis and sterile effusion secondary to infarction. Therefore, the Gram stain and culture are especially important. Septic arthritis of the hip deserves special mention because delayed intervention may result in necrosis of the femoral head. Children with this complication usually appear quite ill and hold the limb in a "frog-leg" position. Confirmation of septic arthritis of the hip by joint aspirate should be followed as soon as possible by surgical decompression.

Acute chest syndrome. Acute chest syndrome, which includes pneumonia as well as pulmonary infarction, is one of the most common reasons for hospital admission of children with sickle cell anemia. The affected patient is usually tachypneic, even after antipyretic therapy. Rales, rhonchi, and physical findings of lobar consolidation may be present. However, in some children, particularly those who are somewhat dehydrated, physical findings may be far less striking. Rales may be heard only after

several hours of rehydration. Because acute chest syndrome may escape detection on physical examination, a chest radiograph should be obtained in children with sickle cell disease and unexplained fever or chest pain. A decrease in oxygen saturation, readily measured in the ED and compared with baseline values, may identify patients with early acute chest syndrome.

The problem of identifying a responsible pathogen in patients with sickling disorders and acute chest syndrome is similar to that encountered in hematologically normal children with pneumonia (see Chapter 93). Although pneumonia caused by *Mycoplasma pneumoniae*, *S. pneumoniae*, *Chlamydia trachomatis*, and gram-negative organisms is more common in sickle cell disease, a causative organism is rarely identified in cultures of the blood and sputum. The initial white blood cell count and differential count are usually not helpful in distinguishing patients with bacterial pneumonia from those with viral pneumonia or pulmonary infarction. The hemoglobin level is more likely to fall and the fever is more likely to persist during the course of bacterial pneumonia, but this information is not yet known, of course, when the patient is first seen in the ED.

Because a responsible organism for acute chest syndrome is rarely known at the outset, treatment is begun with intravenously administered ampicillin or a third-generation cephalosporin and modified according to the clinical response. Azithromycin or another macrolide antibiotic is usually added to cover atypical bacterial pneumonia, as it is more common in this patient population. In the very ill child, the identification of the causative organism should be pursued more vigorously with tracheal aspirate or aspiration of pleural fluid when present. Oxygen should be administered to children with acute chest syndrome who have evidence of respiratory distress or hypoxia. Red blood cell transfusions or exchange transfusion should be performed very early in the course when the patient is severely anemic (e.g., hemoglobin less than 5 g per dL), is hypoxic, or has radiologic or other evidence of severe or rapidly progressive disease. Therapy with corticosteroids is not usually indicated unless the patient has a history of asthma or a reactive lower airway that is further complicating their respiratory picture.

Vaso-Occlusive crises/Pain crises. Infarction of bone, soft tissue, and viscera may occur as a result of intravascular sickling and vessel occlusion. Physiologic or environmental factors that initiate the process of vasoocclusion and pain are rarely identified, although swimming in cold water may be one important cause of painful crisis. Children may have only pain or may have symptoms related to the affected organ (e.g., right upper quadrant pain and jaundice in hepatic infarct). Initial management usually centers on control of pain, general supportive measures, and differentiation of vasoocclusion and disorders unrelated to the hematologic abnormality.

The treatment of the child with a painful crisis requires an objective assessment of the severity of the discomfort and an appropriate use of analgesic therapy (Table 91.4). Once nonsickling disorders have been ruled out, hydration should be undertaken with D51/4 normal saline solution (D5W 1/4 NS) or D51/2 NS at a rate of 1.5 maintenance fluid requirements (see Chapter 17). The choice of analgesic is aided by familiarity with the patient's previous crises. Hesitancy to use parenteral narcotics may result in inadequate pain relief, mounting anxiety, and a loss of trust between physician and patient. This is a particularly common occurrence when the patient has had repeated visits to the ED and physicians are suspicious of the stated degree of discomfort. For moderate or severe vasoocclusive pain, morphine sulfate (0.1 to 0.15 mg per kg) should be administered intravenously, and further therapy should be based on the degree of pain and the duration of pain control. Use of IV ketorolac or another NSAID should also be instituted in the ED as the antiinflammatory properties of these medications are of definite value in treating vasoocclusive pain. Admission to the hospital is necessary if continuing parenteral analgesic therapy is required, fluid intake is inadequate, or the child has had several visits for the same problem. Repeated prolonged stays in the ED often leave the child and family exhausted and rarely prevent hospital admission. Timely and efficient use of pain control early in the crisis has been shown to decrease the length of hospital stays. One strategy may include initiation of PCA (patient controlled analgesia) in appropriate patients while still in the ED.

Several specific areas of vasoocclusion deserve special attention. Between 6 and 24 months of age, dactylitis is a common manifestation of sickle cell disease. Infarction of the metacarpals and metatarsals results in swelling of the hands and feet. These episodes recur frequently. Pain usually resolves after several days, but swelling may persist for 1 or 2 weeks. Treatment is similar to that described for a painful crisis.

Infarction of abdominal and retroperitoneal organs may produce clinical findings that closely resemble the findings in a variety of nonhematologic diseases. The distinction between occlusion of the mesenteric vessels and appendicitis or other causes of an acute abdomen is, at times, particularly difficult. Physical findings and laboratory studies are remarkably similar. The onset and quality of the pain may be familiar to the patient and readily recognized as typical "crisis pain." The patient may describe the symptoms as distinctly different from episodes of infarction, however, giving support to the diagnosis of an acute abdomen. Because painful crises occur far more often than appendicitis and other causes of acute abdomen, a period of careful observation is warranted unless the patient is severely ill (e.g., peritonitis or other convincing signs of perforated appendix). Repeated assessment of the abdominal examination and the clinical response to fluid therapy help identify the child with an acute abdomen and reduces unnecessary and risky emergency surgical procedures in children with sickle cell disease. Hepatic infarction may also create a diagnostic dilemma because the acute onset of jaundice and abdominal pain that characterize this disorder are similar to the symptoms of hepatitis, cholecystitis, and biliary obstruction. In addition, vasoocclusion elsewhere in the abdomen that causes right upper quadrant pain may mimic biliary tract disease. The distinction between infarction and cholecystitis or biliary obstruction is particularly important because recurrent gallbladder disease is an indication of cholecystectomy. In both hepatic infarction and biliary obstruction, the alanine aminotransferase and direct bilirubin levels may be increased. Ultrasonography of the abdomen often shows a dilated common bile duct or the presence of stones in the duct in children with biliary tract disease when the study is performed shortly after the onset of symptoms. In many instances, however, biliary tract disease and vasoocclusion cannot be definitively distinguished, and the clinician must depend on a pattern of recurrence for additional information. The initial management

TABLE 91.4

SIGNIFICANT COMPLICATIONS OF SICKLE CELL ANEMIA

Complication	Symptoms	Management	Comments
Vasoocclusive crisis	1. Pain derived from sickling and vasoocclusion in bone, soft tissue, or viscera 2. Patients aged 6–24 mo may manifest dactylitis 3. Vasoocclusion in the abdomen or retroperitoneum may mimic an acute abdomen	1. Mild or moderate pain ■ Oral or IV hydration at 1½ times maintenance volume ■ Analgesia ■ Oral medications such as acetaminophen with codeine or oxycodone may be sufficient for some patients ■ IV (intermittent) doses of morphine or hydromorphone ■ NSAIDs ■ Consider admission if pain worsens, oral fluid intake is inadequate, or repeat visits to the emergency department have occurred. 2. Severe pain ■ IV hydration at 1½ times maintenance volume ■ Analgesia ■ IV (intermittent) doses of morphine or hydromorphone ■ Patient controlled analgesia with morphine or hydromorphone ■ NSAIDs ■ Admit unless pain markedly reduced and patient tolerates oral fluids	IV fluid can be D5 ½ normal saline solution NSAID may be ibuprofen or ketorolac and should continue after discharge until pain resolves Patient controlled analgesia may include a continuous infusion of opioid
Priapism	1. Prolonged erection lasting more than 4 h 2. Pain 3. May experience difficulty urinating	1. Oral or IV hydration at 1½ times maintenance volume for 24–48 h 2. Analgesia as needed to control pain 3. Consider simple red blood cell transfusion to raise hemoglobin to 9–10 g/dL. 4. If simple transfusion not helpful or feasible, consider exchange transfusion to reduce HbS to <30% total hemoglobin 5. Consult with urology 6. Admit to the hospital for hydration and analgesia	Urology may consider aspiration of the corpora
Splenic sequestration	1. Left upper quadrant pain 2. Pallor 3. Lethargy 4. Splenomegaly 5. May have altered vital signs (tachycardia, hypotension) 6. Worsened anemia with elevated reticulocytes and mild to moderate thrombocytopenia	1. Immediate volume replacement ■ IV fluids ■ Simple red blood cell transfusion 2. Admission to hospital	Onset of symptoms is often sudden Usually occurs before age 5 years but may develop later in patients with hemoglobin SC disease
Acute chest syndrome	1. Oxygen saturation below patient's baseline 2. Symptoms of respiratory distress 3. New finding on chest radiograph 4. Fever is often present	1. Antibiotic therapy ■ Third-generation cephalosporin ■ Macrolide 2. Consideration of red blood cell transfusion ■ Simple transfusion if hematocrit has fallen ■ Exchange transfusion to decrease % HbS without raising hematocrit	Therapy with steroids not usually needed unless patient has a history of asthma and signs of an asthma exacerbation

IV, intravenous; NSAID, nonsteroidal antiinflammatory drug.

of these disorders is similar to that described for vasoocclusive crises (i.e., fluids, analgesics).

Priapism. Priapism is an unusually painful and frightening complication of sickle cell disease. The penis becomes swollen, edematous, and very tender. Urination may be difficult. The initial treatment consists of fluid therapy and analgesics (Table 91.4). Once again, red blood cell transfusions or exchange transfusion may promote resolution, but these forms of therapy should be reserved for patients without a rapid response to other measures. Early aspiration of the corpora has been recommended to abort the course of priapism and preserve later potency. The relationship between the duration of priapism and later potency in boys with sickle cell disease is still unclear, adding to the uncertainty of when to use particular therapies. However, the trend is toward more aggressive treatment to promote earlier resolution. Priapism should be managed in the ED with an involvement of a hematologist and an urologist.

Stroke. Infarction of the CNS is a catastrophic complication that affects about 7% of children with sickle cell disease. Early detection of cerebral vascular disease using transcranial Doppler screening may reduce the frequency of stroke by allowing the preemptive use of long-term transfusion therapy. The initial presentation varies from the mild and fleeting symptoms of a transient ischemic attack to seizures, hemiparesis, coma, and death. Physical findings usually define, and CT usually confirms, the area of cortical infarction. Supportive therapy should be instituted immediately. A 1.5- or 2-volume exchange transfusion should begin as soon as the blood is ready. This procedure reduces the likelihood of further intravascular sickling and may prevent extension of cortical damage. Long-term transfusion therapy designed to maintain HbS to less than 30% is the standard of care, since the risk of recurrence is reduced from 70% within 3 years to 10% to 15% with therapy. Transfusion therapy carries the risks of allosensitization, infection, and iron overload, but recurrence rate for stroke is high after stopping transfusion. Other approaches to be considered include stem-cell transplantation and maintenance therapy with hydoxyurea, which increases the level of HbF, has prevented secondary stroke in one study, and is under evaluation in a randomized prospective trial.

Cerebral aneurysms occur with increased frequency in patients with sickle cell disease. The origin of this complication, which is usually detected in teenagers or adults, remains obscure but may be related to local vessel damage. Unfortunately, the aneurysm often escapes detection until after major, and often fatal, subarachnoid or intracerebral bleeding. The severe morbidity and high mortality associated with ruptured cerebral aneurysms require careful evaluation of patients with sickle cell disease and headaches or other neurologic findings (vertigo, syncope, nystagmus, ptosis, meningismus, or photophobia). If the aneurysm is accessible and bleeding persists, surgical intervention should follow radiologic confirmation.

Splenic Sequestration. The sudden enlargement of the spleen with resulting sequestration of a substantial portion of the blood volume is a life-threatening complication of sickle cell disease. Because this crisis requires the presence of vascularized splenic tissue, it usually occurs before 5 years of age in patients with hemoglobin SS disease but may occur much later in children with milder sickling disorders, such as hemoglobin SC or S-β^0-thalassemia, in which splenic vasculature may remain viable for a greater number of years. The patient undergoing a severe sequestration crisis may first complain of left upper quadrant pain (Tables 91.4). Within hours, the patient becomes very pale, lethargic, and disoriented and appears ill. The physical examination shows evidence of cardiovascular collapse; hypotension and tachycardia are often present. The level of consciousness decreases. The hallmark of a severe sequestration crisis is a spleen that is significantly enlarged in comparison with previous examinations and is unusually hard. The hematocrit or hemoglobin level is much lower than during routine visits, and the reticulocyte count is usually increased. Mild neutropenia or thrombocytopenia may be present.

Recognition of this complication should be immediate so that lifesaving therapy is begun without delay. The rapid infusion of large amounts of normal saline or albumin is necessary to restore intravascular volume. Although a sufficient number of red blood cells to relieve tissue hypoxia may be released by the spleen after initial fluid resuscitation, transfusion with packed red blood cells (5 to 10 mL per kg, beginning carefully with 2 to 3 mL per kg) is often required in more severe cases and relieves the dual problems of intravascular volume depletion and impaired tissue oxygenation. Reversal of shock and a rising hematocrit signal improvement of a sequestration crisis. The spleen gradually becomes less firm and smaller.

Aplastic Crisis. Under normal circumstances, increased bone marrow erythroid activity (as reflected by the elevated reticulocyte count and presence of nucleated red blood cells in the peripheral blood) partially compensates for the shortened red blood cell survival in sickle cell anemia and other hemolytic disorders. If erythropoiesis slows or ceases, this precarious balance is disturbed and the hemoglobin level may gradually fall. The event that most commonly causes erythroid aplasia is a parvovirus infection. Progressive pallor is unaccompanied by jaundice or other signs of hemolysis. Severe anemia may result in dyspnea and changes in the level of consciousness. The hemoglobin level is unusually low, and reticulocytes are decreased or absent. If a red blood cell transfusion is required because of symptomatic anemia in the absence of reticulocyte response, a small aliquot is usually sufficient to raise the hemoglobin concentration to a level that ensures adequate oxygenation until red blood cell production recovers.

Papillary Necrosis. Papillary necrosis in the kidneys causes hematuria that is usually sudden and painless and that is often persistent. A history of recent trauma, streptococcal infection, or recurrent urinary tract infection should alert the physician to other causes of hematuria. Similarly, hypertension suggests the presence of nephritis rather than simple vasoocclusion. In papillary necrosis, microscopic examination of the urine shows numerous red blood cells but red blood cell casts are rarely seen. Pyuria and proteinuria in excess of what might be attributed to the blood in the urine are not found in papillary necrosis but may indicate nephritis. The hematocrit or hemoglobin level should be measured because the hematuria, if persistent or severe, may markedly worsen the chronic anemia. In many instances, however, admission to the hospital is required for IV hydration. When hematuria is severe, red blood cell

transfusions are sometimes required for the treatment of anemia. Transfusions or exchange transfusions may also be useful in shortening the course of persistent hematuria.

Hepatobiliary. Cholelithiasis is the most common hepatic and biliary tract complication in children with sickle cell disease, with an incidence of around 12% in 2- to 5-year-olds and approximately 40% by the age of 15 to 18 years. Patients can present with acute right upper quadrant pain and tenderness, hyperbilirubinemia, and elevated liver enzyme levels. The optimal treatment is elective laparoscopic cholecystectomy after adequate preparation for surgery (transfusions) once the acute inflammation has subsided. Acute cholecystectomy is associated with a significant risk of complications.

More rarely, acute intrahepatic sickling or viral hepatitis can result in a similar clinical presentation with massive hyperbilirubinemia and elevated enzyme levels. Fulminant hepatic failure with hepatic encephalopathy and shock can also occur as a rare, often fatal, syndrome that may be amenable to exchange transfusion.

Femoral Avascular Necrosis. The most common cause of avascular necrosis of the femoral head in children is sickle cell disease, and this complication is even more common in patients with SS and coexisting α-thalassemia. It is also more common if the hematocrit is high and the clinical course severe, with frequent painful crises. Treatment options are limited, with bed rest and core decompression the initial approaches. Total hip replacement may eventually be necessary.

Thalassemias

Background

The thalassemias are disorders characterized by mutations in globin genes that diminish or abolish production of either the α- or β-globin chains of hemoglobin. The β-thalassemia gene mutations occur most commonly in countries that border the Mediterranean, parts of the Middle East, Southeast Asia, India, and Indonesia. In β-thalassemia major, the most common of the homozygous thalassemia syndromes, the affected child produces little (β^+) or no (β^0) hemoglobin A and usually presents only after 2 to 3 months of age with the switch from γ- to β-globin chain production. Although most of the problems associated with thalassemia major are the result of long-term transfusion therapy, severe anemia at the time of diagnosis may constitute a hematologic emergency. Other thalassemic disorders that may be associated with severe anemia include hemoglobin E-β^0-thalassemia and hemoglobin C-β^0 thalassemia. Although some patients with these disorders (especially E-β^0-thalassemia) are transfusion dependent, many with β^+ alleles require transfusions only for acute exacerbations of their anemia and are characterized as having thalassemia intermedia. The α-thalassemia mutations are also found in the Mediterranean basin, but gene frequencies are even higher in parts of West Africa and are very high in Southeast Asia. Loss of one or two of the four α-globin genes is clinically trivial and manifests as a silent carrier or α-thalassemia trait, respectively. Loss of three α-globin genes causes hemoglobin H disease, which is usually associated with a moderate anemia with chronic hemolysis and the thalassemia intermedia phenotype. Loss of all four α-globin genes results in hydrops fetalis (stillborn or death soon after birth).

Clinical Manifestations

Children with β-thalassemia major usually develop a sallow complexion and increasing fatigue between the ages of 6 and 24 months. Weight gain and linear growth may be retarded. Physical examination shows pallor and enlargement of the liver and spleen. The hemoglobin level may be as low as 3 or 4 g per dL, and the mean corpuscular volume is often low. The red blood cells are hypochromic and microcytic, with striking variation in size and shape; nucleated red blood cells are present in the peripheral smear. Thalassemia major is readily distinguishable from severe nutritional iron deficiency. In the latter disorder, the dietary history is grossly abnormal, organomegaly is uncommon, changes in red blood cell morphology are less impressive, and nucleated red blood cells are rarely seen in the peripheral smear. The diagnosis of thalassemia major should be considered in a child with severe microcytic anemia and an appropriate ethnic background.

Children and adolescents with thalassemia intermedia have a moderate hemolytic anemia, with hemoglobin levels usually between 7 and 10 g per dL. Other findings often include scleral icterus and splenomegaly. Because of their constant dependence on a compensatory increase in red blood cell production, patients with thalassemia intermedia are subject to exacerbations of their anemia during febrile or other illnesses, perioperatively, or during pregnancy. In addition, in hemoglobin H disease, the increased sensitivity of red blood cells to oxidative damage makes acute exacerbations of the anemia during febrile illnesses or as a result of oxidant drugs, both common and serious. For some patients, the acute exacerbation may bring the thalassemia disorder to initial medical attention.

Management

The moderate anemia usually apparent at the presentation of thalassemia major allows sufficient time for a careful diagnostic evaluation and outpatient transfusion therapy. However, when anemia is severe and congestive heart failure is present or imminent, the need for red blood cell transfusion may be urgent. In such instances, pretransfusion blood should be saved for appropriate diagnostic studies (hemoglobin electrophoresis) and initial red blood cell antigen typing. If transfusion is necessary, small aliquots of red blood cells (3 to 5 mL per kg) should be given slowly. The administration of a rapid-acting diuretic (furosemide 1 mg per kg per dose, maximum 20 mg per dose) may diminish the risk of fluid overload. Because patients with thalassemia major have a lifelong dependence on red blood cell transfusions, the use of noncross-matched blood should be scrupulously avoided at the time of presentation to prevent sensitization to foreign red blood cell antigens. The use of leukoreduced red blood cells is important for the prevention of febrile reactions and to reduce the likelihood of CMV infection in patients who may later be candidates for stem-cell transplantation.

Patients with thalassemia intermedia most commonly present to the ED when their hemoglobin level falls during an acute illness. The decision regarding transfusion with red blood cells in this situation depends on the severity of the anemia and the status of the underlying illness. If the hemoglobin level is mildly decreased from baseline levels and the patient has no evidence of cardiovascular compromise, transfusion

may be unnecessary. However, transfusion of red blood cells is appropriate when there is a more significant fall in the hemoglobin level during a serious illness. The balance tips toward transfusion even more readily in hemoglobin H disease because the tissue oxygen deficit from the worsening anemia is aggravated further by the inability of HbH to deliver oxygen normally.

Methemoglobinemia

Background

Methemoglobinemia is an uncommon cause of cyanosis in infants and children but is capable of causing severe problems and even death. Cyanosis results from a disproportionate amount of heme iron being present in the ferric rather than ferrous state. Under these conditions, oxygen binding of hemoglobin is severely impaired. The diagnosis of methemoglobinemia should be considered when cyanosis occurs in the absence of demonstrable cardiac or pulmonary disease.

The disturbance in the usual balance between ferrous and ferric iron may be a result of inherited alterations of hemoglobin structure (hemoglobin M) or abnormalities of red blood cell enzymes (cytochrome b5 reductase), or acquired conditions such as acute infectious illnesses [in particular, gastroenteritis in infancy (nitrite generation)] or exposure to oxidant drugs (nitrates, primaquin) or chemicals. Infants are particularly susceptible to acute methemoglobinemia because of the relative immaturity of the NADH-dependent enzyme system required to maintain hemoglobin iron in a reduced state (cytochrome b5 reductase and cytochrome b5 itself).

Clinical Manifestations

Symptoms depend on the concentration of methemoglobin. Only when methemoglobin constitutes approximately 10% to 30% of total hemoglobin does cyanosis occur. As the level rises to 30% to 50%, dyspnea, tachycardia, dizziness, fatigue, and headache may be noted. Severe lethargy and stupor are often present when the methemoglobin concentration exceeds 50%, and death may occur at concentrations greater than 70%. If anemia is present, oxygen delivery is further compromised and toxicity may be more severe at lower concentrations of methemoglobin.

Accurate diagnosis and rapid therapy prevent serious damage. The diagnosis should be strongly suspected when a cyanotic patient has a normal arterial Po_2 from an arterial blood gas and when the oxygen saturation as reported on pulse oximetry (usually more than 85%) is significantly less than that calculated from the arterial blood gas analysis. For patients with methemoglobinemia, oxygen administration fails to affect the cyanosis and the blood typically appears brown when dried on a filter paper.

Management

The treatment of methemoglobinemia depends on the clinical severity. In all cases, an attempt should be made to identify an oxidant stress and, once identified, to remove the causative substance. If symptoms are mild after oxidant exposure, therapy is unnecessary. Red blood cells with normal metabolism will reduce the methemoglobin in several hours. If the symptoms are severe, 1 to 2 mg per kg of methylene blue as a 1% solution in saline should be infused intravenously over 5 minutes, as it can reduce Hb Fe^{3+} to Fe^{2+} in an NADPH-dependent manner (hexose monophosphate shunt). A second dose can be given if symptoms are still present 1 hour later. Because methylene blue can act as an oxidant at high dosages, the total dosage should not exceed 7 mg per kg. Failure of methylene blue to improve the course of methemoglobinemia may be a result of concomitant G6PD deficiency because the therapeutic effect requires an intact hexose monophosphate shunt. For patients with G6PD deficiency, ascorbic acid (500 mg orally) may be of some value, but if symptoms are severe, exchange transfusion or hyperbaric oxygen may be required. Even if treatment with methylene blue or ascorbic acid in the ED is successful, any child with symptomatic methemoglobinemia should be admitted to the hospital for close observation and further evaluation of the underlying abnormality or causative agent.

DISORDERS OF WHITE BLOOD CELLS

Infection is the most significant complication associated with quantitative or qualitative white blood cell disorders. In some children, death may follow a single episode of acute, overwhelming sepsis. In others, repeated local infections may cause severe organ damage or may culminate in a fatal, disseminated fungal infection. The appropriate emergency management of the child with white blood cell abnormalities and fever or other signs of infection may have a profound impact on the length and quality of the patient's life.

Neutropenia

The most common forms of neutropenia and abnormal neutrophil function are listed in Table 91.5. Neutropenia is usually defined as an absolute neutrophil count below 1,000 to 1,500 per μL. When the neutrophil count falls below 500 per μL, the patient exhibits an increased susceptibility to infections caused by normal skin, respiratory, or GI tract flora. Between 500 and 1,000 per μL, susceptibility to infection is less significant but the host's ability to combat more typical infections is impaired. However, management of the patient cannot be based on the absolute neutrophil count alone because other factors contribute to the severity of the clinical course. For example, serious, recurrent bacterial infections are common in severe congenital neutropenia, and in the absence of treatment with growth factors, death often occurs in early childhood. Similarly, severe morbidity and substantial mortality may be the result of infection in children with leukemia undergoing chemotherapy. In contrast, serious infection is unusual in immune-mediated neutropenia, although the absolute neutrophil count may be less than 500 per μL.

The management of localized infection or unexplained fever in the child with neutropenia depends in large part on the underlying disorder and on the patient's history of infection. In neutropenic states associated with repeated, severe infections, an aggressive attempt to identify a causative organism should be undertaken. Blood and urine cultures, along with appropriate cultures from identified areas of infection (e.g., skin abscess, cellulitis), should be obtained. The cerebrospinal fluid

TABLE 91.5

CAUSES OF NEUTROPENIA AND DISORDERS OF NEUTROPHIL FUNCTION IN CHILDREN

Inherited neutropenia
Severe congenital neutropenia, includes autosomal dominant [neutrophil elastase (ELA2) mutation], autosomal recessive Kostmann disease (HAX1 mutation)
Cyclic neutropenia (ELA2)
Dyskeratosis congenita (DKC1 X-linked), TERC, TERT, or TINF2 mutations)
Shwachmann-Diamond syndrome (SBDS mutation in 90%)
Congenital neutropenia associated with pigmentation and or immune disorders—Chediak-Higashi syndrome, Griscelli syndrome, Hermansky Pudlak syndrome type 2 and p14 mutation
Reticular dysgenesis, myelokathexis/WHIM syndrome
Other neutropenias—Metaphyseal chondrodysplasia or cartilage-hair hypoplasia, Barth syndrome, glycogen storage type 1b

Acquired neutropenias
Drugs and chemical toxins
Infection (bacterial, viral, rickettsial, protozoal)
Bone marrow infiltration or failure (leukemia, aplastic anemia)
Nutritional deficiencies (starvation; anorexia nervosa; vitamin B_{12}, folate, and copper deficiencies)
Immune neutropenias (collagen vascular diseases, Felty's syndrome, neonatal isoimmune neutropenia, autoimmune neutropenia including chronic benign neutropenia of childhood)

Disorders of neutrophil function
Abnormal adhesion (leukocyte adhesion deficiency)
Abnormal chemotaxis (hyperimmunoglobulin E syndrome)
Abnormal opsonization and ingestion (complement deficiency, leukocyte adhesion deficiency)
Abnormal degranulation (Chediak-Higashi syndrome)
Abnormal oxidative metabolism (chronic granulomatous disease, myeloperoxidase deficiency)
Acquired disorders of phagocytic dysfunction (malnutrition, malignancies, severe burns)

should be examined and cultured when CNS infection is suspected. If the child appears ill or toxic, broad-spectrum IV antibiotic therapy should be instituted with modification of therapy when culture results are available. Initial treatment should include antibiotics effective against *Staphylococcus aureus* and other gram-positive organisms as well as gram-negative bacteria, including *Pseudomonas aeruginosa* (e.g., vancomycin and ceftazidime). If no source of fever is identified and the child appears well, observation in the hospital or close follow-up without antibiotic therapy may be considered.

Decisions regarding admission to the hospital and treatment are often more difficult in children with significant fever (more than 101.4°F) and a more benign neutropenic state. Although infections are usually mild and localized in these patients, severe infections may rarely occur. A white blood cell count with differential and a blood culture is valuable. As a practical approach, if the absolute neutrophil is less than 500 per μL and the child is well, ceftriaxone can be given intramuscularly or intravenously with follow-up the next day; if the child appears ill, admission for IV antibiotics is necessary. If the ANC is more than 500 per μL, the child can be managed as one would a non-neutropenic patient. In some children, the white count will rise to normal or near normal levels during acute infection.

A particularly perplexing problem arises when a child is first found to be neutropenic during an evaluation of fever. In most instances, both the fever and neutropenia are results of a viral illness. Under these circumstances, serious secondary bacterial infections are unlikely to occur, and admission to the hospital and antibiotic therapy are probably unnecessary. However, because the neutropenia usually cannot be attributed with certainty to a viral illness, other causes of neutropenia should be carefully sought. The patient or parents should be questioned about the use of drugs associated with neutropenia (e.g., penicillins, cephalosporins, phenothiazines, phenytoin). The family history should be explored for recurrent infections or deaths in early childhood that might suggest a congenital neutropenia. Underlying disorders such as malignancies or nutritional disturbances should be considered. If the child appears even moderately ill, admission to the hospital for further evaluation is appropriate.

Disorders of Neutrophil Function

Numerous disorders of neutrophil function have been described. These disorders are associated with serious infections to a variable extent. Therefore, the evaluation and treatment of the patient with abnormal neutrophil function should be based on the specific cause and the history of serious infection. Guidelines for the management of febrile illnesses are generally similar to those for the management of patients with neutropenia. However, particular attention should be paid to disorders such as chronic granulomatous disease, which have characteristic differences at the site of infection (liver, bones, GI tract) and causative organisms (*Aspergillus* species, *Pseudomonas cepacia*, *Serratia marcescens*).

DISORDERS OF PLATELETS

The clinical course and management of patients with platelet abnormalities are determined primarily by the cause of the underlying disorder. For example, at the same level of thrombocytopenia, bleeding is more common in disorders of platelet production than in immune-mediated disorders of platelet survival. Consequently, the treatment of bleeding should be more aggressive in the former disorder. In this section, emphasis will be placed on the management of bleeding in accordance with the underlying causes.

Idiopathic Thrombocytopenic Purpura

Background

Idiopathic thrombocytopenic purpura (ITP) is the most commonly encountered platelet disorder in children. Serious bleeding is rare, occurring in only 2% to 4% of cases. This low incidence is particularly remarkable because the disease is most common between the ages of 1 and 4 years, when children are particularly prone to trauma as they learn to walk, run, and

climb. The risk of serious bleeding decreases sharply after the first week of illness, reflecting the presence of newly formed platelets with greater hemostatic capability.

Clinical Manifestations

The diagnosis of ITP is made readily in the well-appearing child with newly acquired petechiae and ecchymoses, thrombocytopenia, normal or increased megakaryocytes in the bone marrow, and the absence of any underlying disease. The children with this diagnosis are usually without major systemic illness and have a physical examination that is entirely normal except for the bleeding. Epistaxis, gum bleeding, and hematuria occur less commonly than simple bruising and petechiae, but when persistent, these hemorrhagic manifestations can lead to moderate or even severe anemia. In teenage girls with ITP, heavy and prolonged menstrual bleeding can also cause a severe fall in the hemoglobin level. Fortunately, the development of anemia in children with ITP is gradual; acute, massive blood loss is extremely rare.

The major life-threatening complication of ITP is intracranial hemorrhage. This rare but catastrophic problem may occur within a few days of diagnosis of the platelet disorder or months later. Although a history of head trauma in a child with ITP should alert the physician to the possibility of intracranial bleeding, the absence of any recognized injury is surprisingly common in patients with this complication. The symptoms of intracranial hemorrhage may be subtle, such as persistent mild headache, or they may be dramatic, such as severe headache, vomiting, and generalized or localized weakness. Intracranial bleeding in ITP is unusual once the platelet count has risen above 20,000 per μL unless a significant injury has occurred or platelet function is also impaired (e.g., as in the patient who has received aspirin).

Management

Controversy continues to surround the management of the patient with newly diagnosed ITP who has no serious bleeding. Not every physician considers it necessary to treat all patients newly diagnosed with ITP. The usually benign course of this disease must be weighed against the potential side effects and cost of the various therapeutic options. In patients older than 1 year, with no active bleeding, for whom close follow-up is ensured, treatment may entail observation alone. Aspirin and nonsteroidal drugs that interfere with platelet function should be avoided and activities limited while the platelet count is very low. Specific therapy may be reserved for patients with sufficient bleeding to cause moderate or severe anemia, for patients who remain severely thrombocytopenic (platelet count less than 10,000 per μL) several weeks after diagnosis, for patients younger than 1 year, or for patients whose physical activities cannot be effectively restricted. Decisions about whether and how to treat a patient with ITP should be made in collaboration with a hematologist.

One of the traditional approaches to the treatment of the stable patient with ITP is a 4-day course of prednisone, at 4 mg per kg per day, divided into two daily doses. Steroids, especially at these high doses, can cause side effects such as gastritis, emotional lability, hyperphagia, hypertension, and hyperglycemia. Whether a bone marrow aspiration and biopsy should be performed to confirm the diagnosis of ITP before beginning therapy with steroids remains the subject of debate. If a patient with acute leukemia is mistakenly diagnosed as having ITP and treated with steroids, the correct diagnosis of leukemia may be delayed and long-term outcome may be affected adversely. For patients with a classic presentation of ITP, in the common age range and without associated anemia, neutropenia, abnormalities on the peripheral blood smear, or abnormalities on physical examination, a bone marrow aspirate to confirm the diagnosis of ITP may be unnecessary. However, careful examination of the peripheral blood smear by a hematologist is certainly indicated before initiation of steroid therapy to identify the large platelets characteristic of ITP and to be certain no signs of leukemia are evident on the smear. Table 91.6 provides complete guidelines for when a bone marrow aspirate and biopsy should be included in the management of ITP.

A second option for the treatment of acute ITP is the administration of antibody directed against the D-antigen of red blood cells. The antibody-coated erythrocytes are sacrificed to the reticuloendothelial system so that antibody-coated platelets can continue to circulate. The effect of anti-D (WinRho), usually given at a dosage of 50 to 75 μg per kg administered intravenously, is slightly delayed compared with γ-globulin, and the peak platelet count may be somewhat lower. However, anti-D has the advantage of being administered over minutes rather than hours, and it causes severe headache less commonly than γ-globulin. Mild to moderate hemolysis may follow the administration of anti-D, with a fall in hemoglobin level of 0.5 to 2.0 g per dL; occasionally, the hemolysis is more severe. This therapy is effective only in Rh-positive patients and should be used with caution if patients are anemic (hemoglobin $<$ 10 g per dL) at presentation.

Some patients with ITP are treated with IVIG at a dosage of 0.8 to 1 g per kg, with a second dose 24 hours later if the platelet count remains below 40,000 to 50,000 per mm^3. This therapy is effective in raising the platelet count in the majority

TABLE 91.6

INDICATIONS FOR PERFORMING A BONE MARROW ASPIRATE/BIOPSY IN THE SETTING OF IDIOPATHIC THROMBOCYTOPENIC PURPURA

History findings
- Age $<$ 1 yr
- Adolescent patients
- Complaints of systemic illness (e.g., fever, weight loss, anorexia, fatigue)

Physical examination findings
- Splenomegaly
- Hepatomegaly
- Lymphadenopathy
- Clinical signs suggesting possibility of mass in chest, abdomen, pelvis, extremity

Peripheral blood findings
- Anemia
- Elevated mean corpuscular volume
- Leukopenia
- Neutropenia
- White blood cell differential with blasts or immature forms (e.g., metamyelocytes)
- Nucleated red blood cells
- Red blood cells with tear drop morphology

of patients with acute ITP. However, the low incidence of serious hemorrhagic complications of ITP, such as intracranial bleeding, has made it impossible to ascertain the overall benefits of this or other therapies. Unfortunately, one of the more common side effects of IVIG is headache, and when this symptom persists despite slowing the rate of infusion, imaging studies of the brain may be necessary to investigate possible intracranial bleeding. Also, IVIG requires patients to be exposed to donor blood product that can carry with it risks such as allergic reaction, transfusion reactions, and a theoretical risk of viral transmission. Symptoms such as fever, chills, flushing, and rash can develop in the setting of IVIG.

For the patient with ITP and active bleeding, local therapeutic measures may be of additional help until corticosteroids, infusions of γ-globulin, or anti-D raise the platelet count to a hemostatic level or when these drugs are ineffective. Nasal packing and topical phenylephrine are useful for persistent epistaxis. Excessive menstrual bleeding may require hormonal therapy. If bleeding does not stop despite these measures, plasmapheresis should be undertaken and, if necessary, followed by a transfusion of 5 to 10 mL per kg (0.2 units per kg) of platelets. The removal of antiplatelet antibody by plasmapheresis may increase the survival of transfused platelets sufficiently to stop or retard active bleeding, as outlined in Table 91.7.

Intracranial hemorrhage in the setting of ITP is extremely rare (incidence less than 0.5%), but it is also the major cause of death in ITP and therefore requires immediate recognition and therapy. Table 91.7 provides guidelines for managing head trauma in the setting of ITP. In general, management of head trauma in a patient with ITP hinges on whether the trauma was mild or severe and whether the patient demonstrates neurologic findings.

TABLE 91.7

MANAGEMENT OF HEAD TRAUMA IN IDIOPATHIC THROMBOCYTOPENIC PURPURA

Mild head trauma without neurologic findings	
Management	**Comments**
1. Carefully observe and consider hospitalization 2. CT of the head 3. Check platelet count 4. Assess for signs of spontaneous bleeding 5. Initiate ITP-directed therapy if bleeding is evident 6. Evaluate certainty of follow-up	Even if the head CT is negative, inpatient management encouraged for patients with platelet count <20,000, for spontaneous bleeding (especially of the head or neck), and when follow-up is uncertain
Severe head trauma or neurologic abnormalities	
Management	**Comments**
1. Hydrocortisone 8–10 mg/kg administered intravenously 2. ITP directed therapy as appropriate 3. CT of the head 4. Platelet transfusion 10 mL/kg	ITP-directed therapy such as intravenous γ-globulin or WinRho may be selected on the basis of risk–benefit profile for the particular patient
Clinical status deteriorating due to ongoing bleeding	
Management	**Comments**
1. Consider splenectomy 2. Exchange transfusion of plasmapheresis followed by platelet transfusion 10 mL/kg (0.2 units/kg)	Full recovery unlikely in this situation

CT, computed tomography; ITP, idiopathic thrombocytopenic purpura.

Alloimmune Neonatal Thrombocytopenia

Serious bleeding may occur in the newborn or young infant with isoimmune thrombocytopenia or in the infant born to a mother with ITP. A discussion of the pathophysiology and diagnosis of these disorders is beyond the scope of this section. However, because mortality may be high in these disorders, particularly in isoimmune thrombocytopenia, the management of actual or potential bleeding deserves special emphasis. The brain is the major site of serious bleeding, perhaps because of trauma sustained during vaginal delivery. IV administration of γ-globulin raises the platelet count in infants with isoimmune thrombocytopenia or alloimmune thrombocytopenia caused by maternal ITP. Steroid therapy may also be effective. In isoimmune thrombocytopenia, transfusion of random donor platelets is usually ineffective; the platelets are destroyed rapidly because of the presence of the same offending antigen as that found on the infant's platelets. However, the blood bank may be able to provide platelets free of the offending antigen. Maternal platelets will survive normally and may be used for the affected infant after the removal of the maternal plasma, which contains the offending antibody. Transfusion of the thrombocytopenic infant born to a mother with ITP is more difficult because survival of all donor platelets is significantly shortened. However, serious bleeding is unusual in this disorder. If signs of generalized bleeding are present or if vital organs are impaired by local hemorrhage, and if IVIG fails to raise the platelet count, a 2-volume exchange transfusion should be performed to remove a portion of the circulating antiplatelet antibody. A platelet transfusion should be administered immediately after completion of the exchange transfusion.

The recognition of immune-mediated neonatal thrombocytopenia is important for the counseling of the parents and for the preparation for future deliveries, as well as for the treatment of the affected child. In some instances, maternal ITP has been recognized only after the delivery of a thrombocytopenic newborn. In isoimmune thrombocytopenia, accurate diagnosis allows appropriate counseling regarding the risk to infants born of subsequent pregnancies and the management of the mother and the affected fetus. If necessary, maternal platelets can be prepared just before future deliveries so that they are available for immediate transfusion if required. These factors make it imperative for the physician to obtain appropriate diagnostic studies in the thrombocytopenic infant.

Heparin-Induced Thrombocytopenia

Children treated with heparin are at risk for developing heparin-induced thrombocytopenia (HIT), although this is more common in adults. This diagnosis becomes relevant to the clinician in the ED because HIT is high on the list of differential diagnosis for isolated thrombocytopenia and because missing this diagnosis can cause significant harm to the patient.

Interactions between heparin and platelet factor 4 (PF-4) creates a new antigen that provokes the development of an IgG antibody in patients with HIT. The IgG mediates destruction of platelets and thrombocytopenia results. Platelet levels may not become very low, but may fall to less than 100,000 per μL or below 50% of baseline counts. Importantly, these patients do not often bleed but instead clot, and thromboses of the arterial or venous circulation can become life or limb threatening in these patients.

HIT more frequently develops in the setting of unfractionated heparin use but can evolve in patients receiving low-molecular-weight heparin (Lovenox®) as well. The immune response emerges 5 to 10 days after heparin is initiated, unless the patient has received heparin before, in which case antibodies can form in 2 days time. The antibody can be detected using an HIT assay, which may include either enzyme-linked immunosorbent assay or serotonin release. In patients exposed to heparin whose platelets counts have fallen below 100,000 per mm^3 or below 50% of the previous baseline levels, testing for HIT should be sent. While this testing is pending, the patients should be given no more lovenox or unfractionated heparin. Anticoagulation should change to alternative agents such as lepirudin, argatroban, and danaparoid in consultation with a hematologist.

Nonimmune Thrombocytopenia

Although thrombocytopenia in the pediatric setting is often immune-mediated, nonimmune thrombocytopenias do exist. These are usually due to deficient platelet production, platelet sequestration, or bone marrow replacement. Platelet production deficits result from insults to the bone marrow that can be due to infections (typically viral), but serious bacterial infections and sepsis can also suppress thrombopoiesis, toxins, or side effects from a medication. Rarely, bone marrow failure processes can present with isolated thrombocytopenia. Examples include idiopathic acquired aplastic anemia, the thrombocytopenia with absent radii syndrome or congenital amegakaryocytic thrombocytopenia. Wiskott-Aldrich syndrome is an X-linked inherited immunodeficiency that also causes thrombocytopenia, and peripheral blood smear reveals characteristically small platelets. Bone marrow replacement, most commonly due to a malignancy such as leukemia or another cancer that has metastasized to the marrow compartment, does not usually present with isolated thrombocytopenias but instead is usually accompanied by other abnormalities in the physical examination or the CBC count. Platelet sequestration is most commonly due to splenomegaly.

Serious bleeding as a result of decreased platelet production usually responds rapidly to the transfusion of platelets (0.4 units per kg or 20 mL per kg, maximum 8 units of random donor platelets prepared from whole blood or 1 unit of single-donor platelets prepared by apheresis).

However, unless they are part of a program of prophylactic therapy, transfusions should be reserved for severe or persistent bleeding or for significant trauma. Many affected patients have chronic disorders and require repeated transfusion. The excessive use of platelet transfusions, whether prepared from multiple, single, or HLA-matched donors, may contribute to the early formation of antiplatelet antibodies, making future transfusions more difficult and, in many instances, less effective. Single-donor transfusions should be carried out whenever possible. The use of leukocyte-depleted blood products reduces the risk of alloimmunization and is strongly recommended in this setting.

DISORDERS OF COAGULATION

Coagulation abnormalities are responsible for a large proportion of hematologic emergencies. Indeed, parents of children with hemophilia may use the ED as their primary source of acute care facility because bleeding episodes often require immediate evaluation and treatment at times when other health care facilities are closed. This section places particular emphasis on the prevention and management of bleeding that poses a direct threat to life or to normal, long-term organ function in children with common inherited and acquired coagulopathies. The more rare inherited disorders of coagulation are not discussed in detail. Bleeding episodes are usually similar to those found in the more common disorders. Appropriate replacement products are listed in Table 91.8.

TABLE 91.8

SPECIFIC FACTOR DEFICIENCIES AND REPLACEMENT THERAPY

Factor deficiency	Replacement therapy
Fibrinogen (I) (also dysfibrinogenemias)	Cryoprecipitate, fresh-frozen plasma
Prothrombin (II)	Fresh-frozen plasma Prothrombin complex concentrate
Factor V	Fresh-frozen plasma
Factor VII	Factor VIIa (recombinant) concentrate
Factor VIII	Factor VIII concentrates (recombinant and plasma derived), DDAVP if mild
Factor IX	Factor IX concentrates (recombinant and plasma derived) Prothrombin complex concentrates
Factor X	Fresh-frozen plasma Prothrombin complex concentrates
Factor XI	Fresh-frozen plasma
Factor XIII	Cryoprecipitate
von Willebrand disease	DDAVP Factor VIII concentrates high in von Willebrand factor

Approach to the Patient with Abnormal Coagulation Studies

Coagulation studies such as PT and PTT are sometimes obtained for children by their primary care pediatricians. Sometimes this occurs because of a parent of family member expressing concern for bleeding or bruising in the child and other times these laboratory tests are performed because of a family history of a bleeding problem. Whatever the reason, screening coagulation studies will at times be performed and children may be referred to the ED when the results of these studies are abnormal. The ED physician should therefore develop an initial approach to these patients (Table 91.8).

A thorough history should reveal whether the patient has experienced any significant bleeding and whether the family history truly reveals concern for a bleeding disorder. A physical examination should also be performed to determine whether there is evidence of bleeding. The usual initial screening tests include quantitation of platelets, examination of the peripheral blood smear, PT, and activated partial thromboplastin time (aPTT), thrombin time (TT), and fibrinogen. These studies should be performed to confirm or dispute the findings of the laboratory test results leading to the patient's referral to the ED. If a bleeding disorder is still suspected on the basis of these results, and the patient is not actively bleeding, further workup can occur in the setting of a hematology consultation. If active bleeding is present, or an imminent threat, further evaluation and possible treatment may be needed in the ED.

Of note, proper collection of the blood sample is essential for interpreting the results of clotting tests. Blood for coagulation tests should not be drawn from an existing heparinized indwelling catheter. A cleanly drawn venipuncture sample without air bubbles or tissue fluid contamination is the most appropriate sample for coagulation tests, and the citrate tube must be filled exactly to the appropriate mark.

Inherited Bleeding Disorders

Background

The most common inherited bleeding disorders are factor VIII deficiency (hemophilia A), factor IX deficiency (hemophilia B), and von Willebrand disease (VWD). The severity of bleeding in the hemophilias can usually be predicted from the level of factor coagulant activity. If less than 1% of the functional factor is present (severe hemophilia), bleeding episodes occur frequently and are often unrelated to trauma. If the factor level is between 1% and 5% (moderate hemophilia), spontaneous hemorrhage is less common, but bleeding often occurs in response to minor trauma. If the factor level is greater than 5% (mild hemophilia), significant trauma is usually required to induce bleeding. VWD is a dominantly inherited bleeding disorder characterized by loss of both VWF, important for platelet adhesion to subendothelium, and stability of the protein that it carries in plasma, factor VIII (FVIII:C). VWF is measured both by its antigen level (VWF:Ag) and by its function, most commonly as a cofactor for ristocetin-induced platelet aggregation (VWF:RCo). Most patients (70% to 80%) have type 1 VWD, which is characterized by a quantitative moderate decrease in VWF:Ag, VWF:RCo, and FVIII:C; levels of 20% to 30% are usual. Because of variable penetrance and overlap with normal individuals, especially those of blood type O, assays in the 30% to 50% range are referred to as low normal, not VWD; only a subset of patients is likely to experience clinically relevant bleeding problems, which are often mucocutaneous in character. Type 2 patients have various functional defects in VWF, and type 3 patients, who are rare and often referred to as autosomal recessive, have compound heterozygous inheritance of a VWF null allele and no detectable VWF.

The classification of inherited bleeding disorders according to severity is important in assessing patients who have sustained trauma or who have signs of active bleeding. For example, after mild head trauma, the patient with severe hemophilia is at greater risk of developing intracranial bleeding than the patient with mild hemophilia and therefore must be managed more aggressively. When extensive hemorrhage is seen in a child with mild hemophilia, however, significant trauma has probably occurred and injury to deeper organs should be suspected.

Many children and young adults with severe hemophilia now receive regular infusions of factor VIII or IX in programs of prophylaxis designed to reduce the frequency of bleeding. In general, these programs maintain the minimum factor VIII or IX level above 1% to 2% so that bleeding should be no worse than would be expected in moderate hemophilia. At times, the level of factor may be normal. Unfortunately, at the time of trauma, it may be difficult to predict the degree of hemostatic protection conferred by prophylaxis. Thus, patients on prophylaxis who have head trauma or other types of injuries that may lead to serious complications should be treated as patients with severe disease at high risk of hemorrhage.

Clinical Manifestations and Management

Joint Bleeding. Hemarthrosis is the most common complication in hemophilia and may occur in the absence of known trauma in severe disease. The knees, ankles, and elbows are the most commonly affected joints. Initial replacement therapy should be designed to raise the factor level to 50% to 70%, and the cornerstone of management is to treat as early as possible. Patients with severe hemophilia are often aware of a bleed long before clinical signs are evident, and so the patient must be believed! Many centers treat all joint bleeds with one or two additional doses of factor replacement, whereas others reserve further treatment of patients with persistent pain or increasing swelling. When the involved joint has been the site of recurrent hemorrhages, several doses of replacement therapy are usually required. Initial immobilization of the joint is often helpful and can be easily accomplished with a splint that extends to the next joint distally. The pain associated with joint bleeding usually resolves within a few hours of treatment; therefore, only short-term, orally administered analgesics are necessary. Rarely, pain is severe and analgesic therapy should be given parenterally. Aspirin must not be used because its inhibitory effect on platelet function may further aggravate the clotting disorder. Acetaminophen, either alone or in combination with codeine, is usually sufficient.

The role of arthrocentesis in the management of a hemarthrosis varies from center to center. Although removal of the blood from a joint has been helpful in allowing early mobilization and maintaining normal range of motion, arthrocentesis is generally unnecessary and should only be considered after consultation with a hematologist and an orthopedist.

Muscle Bleeding. Most muscle bleeding is superficial and, if treatment is deemed necessary, can be easily controlled with a single dose of replacement therapy to achieve 30% to 50% correction. However, emergencies may arise when substantial blood loss occurs or when nerve function is impaired. Extensive hemorrhage is most commonly found in retroperitoneal bleeds (e.g., ileopsoas) or thigh bleeds. Retroperitoneal bleeds are often accompanied by lower abdominal pain. A mass is sometimes palpable deep in the pelvis, and sensation in the distribution of the femoral nerve may be diminished. Loss of the psoas shadow may be seen on an abdominal radiograph, and a hematoma may be demonstrated by ultrasonography. The hemoglobin level should be measured initially and, if bleeding persists, at regular intervals thereafter. Treatment consists of hospitalization, bed rest, initial correction to 70% to 100%, and maintenance of a 30% to 50% factor level until pain has resolved and ambulation has been successfully achieved.

Subcutaneous Bleeding. Hemorrhage under the skin may cause extensive discoloration but is rarely dangerous and usually requires no therapy unless compression of critical organs occurs. However, pressure on the airway from a subcutaneous bleed of the neck may be life threatening, requiring steps to ensure airway patency, such as placement of an endotracheal tube, in addition to correction of the factor level to 100%.

Infants with undiagnosed hemophilia may present to the ED with prolonged bleeding from the site of circumcision. A careful family history may lead to a specific diagnosis in patients with an affected relative (see Chapter 65). A PTT should be measured and interpreted carefully because of the wide normal range in healthy newborns. Additional blood should be saved for assays of specific factors. If bleeding is not severe, correction can await determination of the type of hemophilia so that a treatment product specific for the identified deficiency can be used. If immediate replacement therapy is necessary, fresh-frozen plasma should be used because it will correct both factor VIII and factor IX deficiency, as well as less common inherited clotting factor deficiencies.

Oral Bleeding. Mouth bleeds are particularly common in young children with hemophilia. The presence of fibrinolysins in saliva may lead to persistent oozing in the absence of aggressive management. The site of bleeding should be identified. If a weak or redundant clot is present, it should be removed and dry topical thrombin placed on the site. Initial correction should be 70% to 100%. Often, one or more additional treatment options are necessary to achieve adequate clot formation and to prevent rebleeding when the clot falls off. The antifibrinolytic agent, ϵ-aminocaproic acid (Amicar), is a useful adjunct in the treatment of oral bleeding. Amicar should be administered orally for 5 days at a dosage of 100 mg per kg every 6 hours, with a maximum of 24 g per day. Because children with oral bleeding may swallow a substantial amount of blood, the actual amount and duration of blood loss may be underestimated by the patient or family and measurement of the hemoglobin level is helpful. As in bleeds of the neck muscles, careful evaluation of airway patency is essential. Complete airway obstruction may result from extensive bleeding in the tongue.

Gastrointestinal Bleeding. Hemorrhage from the GI tract is rarely severe in hemophilia unless an anatomic lesion such as a duodenal ulcer or diverticulum is present. Maintenance of the factor level above 30% to 50% for 2 or 3 days after initial correction to 70% to 100% is usually sufficient. If bleeding persists, appropriate diagnostic studies are necessary.

Urinary Tract Bleeding. Atraumatic, painless hematuria is the most common manifestation of renal bleeding in children with hemophilia. If bleeding is persistent, moderate to severe anemia may develop and the hemoglobin level should be carefully monitored. In the absence of trauma of a demonstrable lesion, one or more doses of factor replacement (70% to 100%) are used in combination with bed rest for at least 24 hours after gross hematuria has ceased. A brief course of orally administered prednisone may also be effective.

Although approaches to the treatment of painless hematuria differ, most clinicians agree about the potential hazard of Amicar in affected patients. The strong, antifibrinolytic activity of this drug may cause the formation of ureteral clots and outflow obstruction and should therefore be avoided.

When the child with hemophilia develops hematuria or flank tenderness after trauma, a more aggressive approach to diagnosis and treatment is required. Ultrasonography, MRI, or IV pyelography should be performed as soon as possible to look for subcapsular or intrarenal bleeding or an obstructive clot at the pelvic–ureteral junction. To prevent parenchymal damage and deterioration of renal function, replacement therapy to achieve a level of 70% to 100% should be administered immediately. If a lesion is demonstrated using the techniques already noted, replacement therapy should be continued for 5 to 10 days. If no lesion has been identified, a shorter course of therapy is usually sufficient, using resolution of pain and hematuria as an end point. The hemoglobin level and renal function tests should be followed carefully.

Intracranial Hemorrhage. Bleeding within the cranial vault is the most common cause of death in hemophilia, justifying the concern, anxiety, and urgency attached to it. In practical terms, however, head trauma in children with hemophilia is common, whereas intracranial hemorrhage is comparatively rare. Thus, the physician must be able to recognize and treat the child at risk without exposing other patients to unnecessary hospitalization, diagnostic studies, or therapy.

The management of the hemophiliac child with head trauma, but no neurologic signs, requires careful attention to the severity of the bleeding disorder, type of trauma, history of intracranial bleeding, and likelihood of close follow-up. Children with seemingly insignificant trauma may develop the first obvious signs of intracranial bleeding several days later when concern has diminished. If the trauma is mild (e.g., a light bump on the forehead), patients may be observed at home for the usual signs of intracranial hemorrhage or increased intracranial pressure. When the trauma is somewhat more substantial (e.g., falling down two or three carpeted stairs), the child with severe hemophilia must be evaluated by a physician, given replacement therapy to achieve a level of 70% to 100%, observed for several hours in the office or ED, and, if well, discharged. The child with mild hemophilia usually does not need replacement therapy under these circumstances, whereas the child with moderate hemophilia needs particularly careful attention to the type of trauma and bleeding history for the physician to decide whether to use replacement therapy.

A CT scan is extremely important in identifying intracranial bleeding that requires more intensive and prolonged treatment. A normal neurologic examination in a child with hemophilia who has sustained significant head trauma does not preclude the presence of an intracranial bleed or, therefore, the need for a CT scan. Equally important, the imaging study should not be used to decide on the administration of an initial dose of replacement factor. Patients undergoing CT scans for the assessment of possible intracranial bleeding should always receive factor replacement therapy before the study in order to avoid unnecessary delays in the treatment of potentially devastating bleeding.

If more severe trauma (e.g., hitting the head on the dashboard, falling off a changing table onto a hard floor) has occurred in any hemophiliac child, hospital admission and repeated doses of replacement therapy are essential. The initial dose of replacement should be administered as soon as it is available. A CT scan should be performed after initial correction to search for intracranial bleeding and help determine the duration of treatment.

The management of the patient with hemophilia who has neurologic findings in the presence or absence of head trauma begins with replacement therapy and those measures required for life support and treatment of increased intracranial pressure. Levels of the appropriate factor should be raised to 100%. The indications for surgery are similar to those for children without coagulation disorders, provided an appropriate correction of clotting abnormalities has been achieved.

Preparation of the Hemophiliac for Emergency Surgery. The child with hemophilia is subject to the surgical emergencies that affect children with normal hemostasis (e.g., appendicitis, compound fractures), as well as those hemorrhagic complications that require immediate operative intervention. When the need for surgery has been definitely established, correction up to 100% should be given and the PTT should be measured to ensure its normalization. Because the PTT may be normal when the factor VIII or IX level is as low as 20% to 30%, the measurement of factor coagulant level is needed to assess the adequacy of response to treatment when levels above 30% are desired. This test cannot always be performed before surgery but is essential in the postoperative management of the patient with hemophilia. Therefore, surgery in a child with hemophilia should rarely, if ever, be undertaken in a hospital without appropriate laboratory facilities.

Von Willebrand Disease. The sites of bleeding in mild VWD resemble those found in patients with platelet disorders. Bruising, epistaxis, oral bleeding, and menorrhagia are common, whereas joint bleeding is very unusual. Seventy to eighty percent of patients have type 1 VWD. Children affected with more severe form of VWD (type 3), in which the factor VIII level is very low, may have bleeding problems that resemble those found in both hemophilia and VWD. Massive or persistent GI bleeding with angiodysplasia of the bowel is an unusual complication of VWD that requires prolonged factor replacement therapy and, in some cases, surgical resection of the involved area.

1-Deamino-8-D-Arginine Vasopressin. After the administration of DDAVP (desmopressin), levels of factor VIII coagulant activity, von Willebrand antigen, and ristocetin cofactor activity increase by about twofold in most people with type 1 VWD. This activity makes DDAVP an excellent alternative to blood products for the treatment of minor bleeding episodes in patients with mild hemophilia and for the treatment of most bleeding episodes in patients with the common form (type 1) of VWD and some forms of type 2; it should not be prescribed to patients of type 2B, whose VWF binds spontaneously to platelets, as DDAVP can exacerbate the mild thrombocytopenia that these patients often have. Because some patients with these disorders do not respond to DDAVP, it is strongly recommended that children with mild hemophilia or type 1 VWD receive a trial dose of DDAVP to assess individual responses to this therapy before needing treatment of a bleeding episode. The dose of DDAVP is 0.3 μg per kg, administered intravenously over 30 minutes. Side effects include facial flushing, headache, and, rarely, hypertension, hypotension, and water retention. Hyponatremic seizures have occurred, and the patient should avoid excessive water intake. Patients younger than 2 years should not be given DDAVP. Subsequent doses may be less effective because the drug acts by releasing factors VIII and VWF from stores rather than by increasing their synthesis. In patients with severe factor VIII deficiency, DDAVP is ineffective. This is also true for many patients with type 2 and 3 VWD.

DDAVP is also available as a concentrated nasal spray that should be distinguished from the more diluted form used for enuresis or diabetes insipidus. For patients who have been previously shown to respond adequately to this form of therapy, the nasal spray is an alternative to an IV administration. However, the nasal spray is designed primarily for use at home. DDAVP-responsive patients who come to the ED may have already tried the intranasal spray unsuccessfully or may have bleeding that requires other therapy.

Replacement Products

The products commonly used for the treatment of children with hemophilia and VWD are recombinant factor concentrates or plasma-derived factor concentrates (Table 91.9). Fresh-frozen plasma and cryoprecipitate are rarely used in the management of hemophilia and VWD because alternative products are safer and more potent.

Most patients are accustomed to receiving a particular product in their regular hemophilia care, and parents often bring their prescribed factor concentrate with them when they come to the ED. The treating physician should pay careful attention to the patient's treatment plan as developed by the hemophilia treatment center. The ED is rarely the place to alter the long-term treatment program for a patient with hemophilia. A particularly important situation is the treatment of a child with a previously undiagnosed bleeding disorder. Whenever possible, the diagnosis should be established before treatment is begun. For example, the diagnosis of factor VIII or IX deficiency might save a child a one-time exposure to a plasma product. However, establishment of a diagnosis of a specific factor deficiency should not take precedence over the timely management of a serious bleeding episode.

Factor Concentrates. In more recent years, the development of new factor concentrates has dramatically improved the care of children with hemophilia. Recombinant factor VIII and IX products are presently prescribed for almost all children and adolescents with hemophilia in the United States.

TABLE 91.9

EVALUATION OF A PROLONGED PROTHROMBIN TIME (PT) OR ACTIVATED PARTIAL THROMBOPLASTIN TIME (APTT)

PT	aPTT	Causes of laboratory findings	Next steps in evaluation in addition to hematology referral
Prolonged	Normal	■ Inherited ■ Factor VII deficiency ■ Acquired ■ Acquired factor VII deficiency ■ Inhibitor to factor VII ■ Vitamin K deficiency ■ Liver disease ■ Warfarin (Coumadin)	Mixing study Factor VII level Liver function testing
Normal	Prolonged	■ Inherited ■ Deficiency in factors VIII, IX, or XI ■ von Willebrand disease ■ Deficiency in factor XII, prekallikrein, or high-molecular-weight kininogen ■ Acquired ■ Heparin administration ■ Inhibitor to factors VIII, IX, or XI ■ Acquired von Willebrand disease ■ Lupus anticoagulant	Factor VIII, IX, and XI levels von Willebrand panel Mixing study Lupus anticoagulant
Prolonged	Prolonged	■ Inherited ■ Deficiency in factor V or X, prothrombin, fibrinogen ■ Acquired ■ Liver disease ■ Disseminated intravascular coagulation ■ Supratherapeutic doses of warfarin or heparin ■ Combined administration of warfarin and heparin ■ Inhibitor to factor V or X, prothrombin, fibrinogen	Factor V, X, prothrombin levels Mixing study D-dimer Liver function testing

For children with VWD who do not achieve hemostasis after treatment with DDAVP or are not appropriate candidates for DDAVP, treatment of bleeding episodes with plasma-derived, intermediate purity factor VIII concentrates with VWF is indicated. Dosing is based on the ristocetin cofactor activity, and vials of the concentrate are labeled with the content of VWF:RCo activity. One IU of VWF:RCo per kg body weight raises the plasma level by 1.5% to 2.0%. For minor bleeding episodes, raising the VWF:RCo level above 50% should provide adequate hemostasis. For more serious bleeding or for the prevention of surgical bleeding, an initial dose calculated to raise the VWF:RCo to 100%, followed by repeat dosing every 12 hours, is recommended. Prothrombin complex concentrates are used primarily both for the treatment of patients with hemophilia and inhibitors and for the treatment of the relatively rare disorders of factor II and X deficiency. The use of this product for factor VII and IX deficiency has diminished since plasma-derived and recombinant factor IX concentrates and recombinant factor VII concentrates became available.

Calculation of Dosage for Factor VIII and IX Replacement. A formula commonly used for determining the number of units of factor VIII or IX necessary to achieve a specific level:

Factor VIII:
One unit of recombinant or plasma-derived factor VIII per kg raises the measured factor level by 2% [number of units = desired level × weight of patient (kg) × 0.5].

Factor IX:
One unit of recombinant factor IX per kg raises the measured factor IX level by 0.83% for recombinant product [number of units = desired level × weight of patient (kg) × 1.2) or by 1% for plasma-derived factor IX number of units = desired level × weight of patient (kg)].

In the treatment of major hemorrhages, the achieved level of factor activity should be measured directly because the recovery in vivo varies widely among patients and because inadequate hemostasis may lead to severe morbidity or death. In addition, the dose of plasma-derived factor VIII required in children to achieve a particular factor VIII level may be 50% to 100% greater than in adults. If a minor bleed fails to respond to conventional dosing, a pre- and posttreatment factor level should be measured to be certain that the desired level is being achieved.

Fresh-frozen Plasma. Fresh-frozen plasma contains all plasma clotting factors and is therefore particularly useful when a child

with a previously undiagnosed bleeding disorder presents to the ED with a hemorrhage that requires therapy before the specific factor deficiency can be ascertained. Its use is generally restricted to the treatment of an unknown inherited factor deficiency or a deficiency of a factor, such as factor XI, for which there is no available factor concentrate. Although the average concentration of factor in fresh-frozen plasma is 1 unit per mL, the actual concentration in a particular unit may vary widely (0.5 to 1.5 unit per mL) and is rarely measured. A typical dose for fresh frozen plasma is 15 mL per kg.

Cryoprecipitate. When plasma is frozen and then slowly thawed, the precipitate that forms contains enriched factor VIII coagulant activity, VWF, fibrinogen, and factor XIII. However, like fresh-frozen plasma, the actual amount of these clotting factors in a single unit depends on the level in the donor and may vary. The usual content in a 10-mL bag or "unit" is only 100 units of factor VIII and 200 mg of fibrinogen. A typical dose for cryoprecipitate is 1 to 2 units for every 10 kg of body weight. However, this product is not the first choice in the treatment of hemophilia since purified factor VIII concentrates have become available but may be used in areas of the world where concentrates are unavailable.

Management of Patients with Inhibitors

Neutralizing inhibitors against factors VIII and IX occur in 20% to 30% of children with factor VIII deficiency and 3% to 5% of patients with factor IX deficiency. The treatment of bleeding episodes in the child with hemophilia and antibodies against the missing or diminished factor is difficult and requires consultation with the hematology service. Extensive resources, experience, and ingenuity are necessary to achieve hemostasis. For serious bleeding in patients with factor VIII deficiency and relatively low inhibitor titers (less than 10 Bethesda units), large doses of factor VIII may overwhelm the antibody and raise the factor VIII level to hemostatic levels. Doses as high as 100 to 200 units per kg may be necessary. However, those patients who are "high responders" to the factor VIII antigen will develop rising titers of antibody within 3 to 5 days, reducing or eliminating the usefulness of further therapy with factor VIII. Despite the subsequent rise in inhibitor titer, this brief period of initial factor VIII therapy may be sufficient to stop bleeding in critical organs such as the brain. In contrast, factor VIII replacement should not be used as initial therapy for a minor bleed in a patient with a high-responding inhibitor because the anamnestic antibody response may impair the management of a later, more serious bleed.

If the initial inhibitor titer in a patient with critical bleeding is too high to warrant a trial of factor VIII therapy or if no response to factor VIII is obtained, alternative approaches should be initiated. Recombinant factor VIIa concentrate has assumed a prominent role in the treatment of bleeding in children with high-titer inhibitors. This product has proven effective in achieving hemostasis in most patients with inhibitors. However, factor VIIa is expensive and must be administered every 2 hours because of its very short half-life. The success of treatment must be judged clinically rather than by changes in laboratory values. Another approach to the treatment of serious bleeding in the patient with factor VIII deficiency and inhibitors is the administration of activated prothrombin complex concentrate (aPCC). These products presumably are effective because of their ability to bypass factor VIII through the presence of factors II, VII, and X. The relative efficacy of aPCC and factor VIIa is uncertain. Treatment with aPCC, such as treatment with factor VIIa, cannot be monitored by the PTT or factor levels but by clinical response. Factor VIIa and aPCC should not be administered simultaneously because of the potential for developing thrombosis.

Occasionally, the condition of the patient with inhibitors will worsen despite factor therapy. For example, the child with an intracranial hemorrhage may have continued bleeding and neurologic deterioration despite high-dose factor VIII or VIIa. In such instances, plasmapheresis may remove sufficient antibody to allow a response to factor VIII administration. However, because 50% of the IgG inhibitor is tissue bound and will rapidly return to the plasma, further infusions of factor VIII will be unsuccessful unless preceded by additional plasmaphereses.

The treatment of patients with factor IX deficiency and inhibitors employs high-dose factor IX therapy, factor VIIa, and aPCCs in approaches that are similar to those used for patients with factor VIII inhibitors. However, the treatment of patients with factor IX inhibitors is particularly challenging because of the risk of anaphylaxis and proteinuria on further exposure to products containing factor IX, even if similar problems did not occur prior to the development of the inhibitor. Patients with factor IX inhibitors who are receiving their first dose of either aPCCs or factor IX concentrate after the development of an inhibitor should be monitored carefully for adverse reactions. Exchange transfusion followed by infusion of factor IX concentrate may also be useful if the hemorrhage is severe or life threatening.

The recognition of a newly developed inhibitor may be equally important as the treatment of choice for a patient with a known inhibitor. With the development of an inhibitor, patients with severe hemophilia often experience no change in their pattern of bleeding. However, the response to previously effective therapy is usually noted to be less satisfactory. Patients with moderate hemophilia who develop inhibitors have more bleeding and an inadequate response to treatment. If an inhibitor is suspected at the time of emergency therapy, a PTT should be measured after therapy because, in the presence of a strong inhibitor, a level of factor activity adequate to normalize the PTT (20% to 30% factor VIII) is rarely achieved. An inhibitor screen can also be performed by mixing the patient's plasma with normal plasma and by demonstrating a prolonged PTT compared with normal plasma mixed with saline. The level of inhibitor should be measured using more sophisticated techniques. Although the PTT need not be measured after routine treatment of minor hemorrhages, it should always be used to demonstrate an appropriate response in vitro to the treatment of major hemorrhage because a failure to respond to initial therapy may compromise organ function or life itself.

Inherited Hypercoagulable Conditions

Background

Hemostasis is a balance between the activities of proteins that promote and inhibit clotting. Deficiencies of the factor that promote clotting, such as factors VIII and IX, lead to abnormal bleeding, and the recognition and emergency treatment of

the hemophilias and related disorders are familiar to many physicians. Deficiencies of the factors that inhibit coagulation lead to local and sometimes disseminated thrombosis. In contrast to bleeding disorders, the identification and emergency management of these unusual hypercoagulable disorders are likely to be unfamiliar to many clinicians. In fact, the role of these inhibitory proteins is only now being fully characterized.

Clinical Manifestations

The three major proteins that serve as brakes on the coagulation pathway are antithrombin (formerly called antithrombin III), protein C, and protein S. Antithrombin inactivates the serine proteases that normally promote hemostasis. Patients heterozygous for antithrombin deficiency have an increased risk of developing deep vein thrombosis and pulmonary embolus. Protein C, with its cofactor protein S, is activated (APC) by thrombin binding to vascular thrombomodulin, and inactivates activated factors V and VIII. Persons heterozygous for protein C or protein S deficiency have an increased risk of venous thrombosis. Clinical findings in heterozygotes usually appear during adolescence or adulthood. In contrast, homozygous protein C deficiency causes widespread thrombosis in the neonatal period; homozygous protein S deficiency is uncommon but may have similarly severe and early clinical manifestations. This syndrome of purpura fulminans, sometimes accompanied by cerebral thrombosis, is a dire emergency that requires immediate intervention to preserve any chance of a good outcome.

The most common inherited cause of thrombosis, factor V Leiden (FVL), is a single gene mutation that alters the amino acid composition of factor V and makes this coagulation protein resistant to the antithrombotic activity of activated protein C. Heterozygosity for FVL is found in 3% to 6% of the Caucasian population in the United States, but it is rare in those of African-American or Asian descent. Heterozygosity carries a 2- to 7-fold increased relative risk of venous thromboembolism compared with normal individuals, whereas the risk for homozygotes is 80-fold. FVL may be a risk factor for both venous and arterial thrombosis in ill neonates. Other inherited conditions that may increase the risk of developing thrombosis include the prothrombin 20210 gene mutation (threefold), dysfibrinogenemias, severe hyperhomocystinemia, and elevated levels of lipoprotein (a). An important acquired condition associated with an increased risk of venous or arterial thrombosis is the antiphospholipid antibody syndrome, which is more common in teenagers than in young children.

Management

Patients who develop a deep venous thrombosis, in the presence or absence of a discernible underlying risk factor, should be treated initially either with unfractionated heparin (UFH) by IV bolus or low-molecular-weight heparin (LMWH) given subcutaneously. Treatment with UFH is usually initiated with a bolus injection of 75 units per kg body weight followed by a constant infusion of 20 units per kg per hour for children older than 1 year and 28 units per kg for neonates and infants. The UFH dose should be adjusted to maintain an anti-factor Xa level of 0.3 to 0.7 units per mL according to readily available nomograms. Anticoagulation with LMWH is equal in safety and efficacy to UFH. The initial dose of LMWH for the treatment of DVT is 1 mg per kg every 12 hours by subcutaneous injection. Young children may require higher doses, generally 1.5 mg per kg every 12 hours. The anti-factor Xa assay is used to monitor treatment with LMWH, generally arranged 4 hours after the second or third dose. The therapeutic goal is an anti-factor Xa level of 0.5 to 1 units per mL. Once this level is achieved, further monitoring is usually unnecessary. The PTT is suboptimal as a monitoring assay, particularly in children younger than 1 year.

Once adequate anticoagulation with heparin or LMWH has been achieved, long-term therapy with subcutaneously administered LMWH or orally administered warfarin should begin. Warfarin inhibits synthesis of the vitamin K–dependent clotting factors. However, in the first few days of therapy, warfarin may disproportionately inhibit the synthesis of protein C, which is also vitamin K dependent and short lived, leading to the paradoxical effect of increased hypercoagulability. Thus, the use of warfarin as initial therapy (i.e., without heparin) should be avoided because it may cause increased clotting, which manifests as skin necrosis.

Newborns with homozygous protein C deficiency and purpura fulminans should receive fresh-frozen plasma 8 to 12 mL per kg of body weight every 12 hours. Both recombinant and plasma-derived protein C concentrates are now available. Long-term therapy includes regular infusions of fresh-frozen plasma or oral anticoagulation. Cryoprecipitate plays an analogous role in the short- and long-term therapy for homozygous protein S deficiency.

In many instances, a venous thrombosis is diagnosed in a patient without previous knowledge of an inherited hypercoagulable condition. The family history should be carefully reviewed for the occurrence of venous thrombosis or pulmonary embolus, in otherwise healthy adults, for strokes, and also for frequent miscarriages. Pretreatment plasma should be obtained for the measurement of antithrombin, protein C, and protein S. Because levels of these proteins may be transiently decreased after a large thrombosis, the diagnosis of a specific deficiency may be difficult.

It is important to understand that most pro- and anticoagulant factors are reduced at birth and only approach normal adult levels by 6 months of age. Measurement of antithrombin, protein C, and protein S levels in both parents may help clarify the diagnosis of both a possible thrombosis and a possible inherited hypercoagulable condition in the child. Molecular analysis for the FVL mutation and prothrombin mutation can be performed before or after treatment.

When venous or arterial thrombosis results in extensive thrombosis or occlusion of blood flow that poses a threat to a patient's life or to the integrity of a limb or vital organ, infusion of a thrombolytic agent can result in the dissolution of the thrombus and reestablishment of blood flow. Thrombolytic agents such as tissue plasminogen activator (tPA), streptokinase, and urokinase have been used extensively in adult practice for three decades, but tPA is the agent of choice in pediatric patients. For maximum effectiveness in the appropriate clinical setting, tPA is given as soon as possible after the symptoms begin and the extent of vascular occlusion is documented. However, thrombolysis may still be successful days to weeks after thrombus formation. Therapy can be administered systemically or directed to the distal end of the thrombosis by catheter placement. Most clinicians use tPA, 0.1 to 0.5 mg per kg per hour. Unanswered questions regarding thrombolysis in children include whether concomitant heparin infusion is safe, how long therapy can be safely administered, and how to best

monitor the degree of thrombolysis that has been achieved. The thrombolytic state is monitored by increases in PT and PTT, reduction in the fibrinogen concentration, and rise in the concentration of fibrin degradation products or D-dimer. The major risk of thrombolytic therapy is bleeding; therefore, thrombolysis is contraindicated in patients who have had recent abdominal or brain surgery.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is an acquired disorder of hemostasis that may be a result of numerous causes, but in children, it most commonly accompanies septic shock. The clinical and laboratory findings of DIC are described in Chapter 65. The treatment of this disorder should be directed primarily toward correction of the underlying disorder. Although correction of the hemostatic abnormality may temporarily decrease bleeding or prevent formation or extension of thrombosis, mortality remains extremely high when shock is not reversed in the first several hours.

Moderately abnormal coagulation studies are often found in the absence of actual bleeding in DIC. Attempts to correct these abnormalities are of little or no value in preventing later bleeding or in altering the outcome of the underlying illness. If persistent or severe bleeding occurs, replacement of the consumed blood products may be helpful. Platelet transfusions 10 mL of kg or 0.2 units per kg and fresh-frozen plasma (15 mL per kg) should be used to correct severe thrombocytopenia or severely abnormal tests of clotting function. As a useful rule of thumb, 1 random donor unit contains $(5–7) \times 10^{10}$ platelets and will increase the platelet count by 40 to 50,000/μL per 10 kg body weight; this is one-sixth of the platelet content of an apheresis unit [$(3–5) \times 10^{11}$]. Although the administration of platelets and clotting factors may theoretically provide the necessary ingredients for further pathologic clotting, there is little evidence to suggest that such therapy is, in practice, responsible for worsening organ damage. One unit of cryoprecipitate for every 10 kg of body weight can be administered if fibrinogen is low in a bleeding patient. However, replacement therapy should be stopped if bleeding does not improve after one or two infusions of the appropriate product. More recent studies suggest a potential role for activated protein C concentrates in reducing intravascular clotting and improving clinical outcomes both for children with meningococcemia and purpura fulminans and for adults with severe sepsis.

The role of therapy with heparin in DIC remains controversial. Although anticoagulation may slow the progression of disseminated thrombosis and resulting ischemia and hemorrhage, such therapy itself may lead to fatal bleeding complications. Furthermore, as noted earlier, anticoagulation does not appear to affect patient survival and therefore should not interfere with the primary goal of reversing shock.

Nevertheless, administration of heparin is commonly recommended for patients with DIC and purpura fulminans (see Chapter 65) or severely compromised renal function caused by thrombosis and ischemia. Heparin may be given by intermittent IV injection (50 to 100 units per kg every 4 hours) or continuous IV administration (12.5 to 25 units per kg per hour after an initial bolus injection of 50 to 100 units per kg). The dosage should be adjusted to maintain the PTT at 1.5 to 2 times the normal value. Once further consumption of coagulation factors has been slowed or halted, administration of plasma and platelets may restore normal components of clotting. However, the actual benefit of the seemingly paradoxical use of anticoagulants and coagulation factors is unproven.

OTHER HEMATOLOGIC EMERGENCIES

Postsplenectomy Sepsis

Splenectomy may cure or ameliorate several hematologic disorders. However, loss of the spleen is associated with a greatly increased risk of sepsis caused by *S. pneumoniae*, *Neisseria meningitidis*, *E. coli*, *H. influenzae*, and other bacteria, especially in young children. The frequency of pneumococcal sepsis is particularly high; this organism accounts for 50% of the episodes of postsplenectomy sepsis. If the hematologic disorder is immunologic in origin (AIHA) or accompanied by other gaps in host defense (Wiskott-Aldrich syndrome), the incidence of sepsis is especially high. Children younger than 5 years and infants have a much higher risk of sepsis. More important, the mortality from sepsis in asplenic patients is significantly increased. In one review of 5,902 patients over a 35-year period (1952–1987), the incidence of infection in children younger than 16 years was 4.4% with a mortality of 2.2%, whereas for adults the corresponding values were 0.9% and 0.8%, respectively.

Although pneumococcal, *H. influenzae*, and meningococcal immunization and prophylactic antibiotics may reduce the occurrence of postsplenectomy sepsis, the most important facet of management is early detection and treatment. The presence of fever in an asplenic patient demands an immediate and careful evaluation to identify a source of infection.

If the fever cannot be definitely attributed to a benign process such as an upper respiratory infection or if the patient appears ill, the institution of parenteral antibiotic therapy pending results of cultures is usually indicated. The rapidity with which patients develop irreversible shock makes even a brief period of observation very risky and underscores the need for aggressive management of the symptomatic child. Antibiotic therapy is similar to that described previously for children with sickle cell disease and fever.

Transfusion Reaction

Background

Acute hemolytic transfusion reactions that result from blood group incompatibility constitute a major hematologic emergency and may result in massive hemorrhage, renal failure, and death. The uncommon occurrence of this problem is, in large part, a tribute to careful blood banking practices and close attention to the administration of the properly identified red blood cell product to the correct recipient. Unfortunately, the rarity of acute hemolytic reactions may lead to a sense of complacency regarding transfusion and a loss of familiarity with the signs and symptoms of massive red blood cell destruction.

Clinical Manifestations and Management

The characteristic findings of an acute hemolytic transfusion reaction include apprehension, fever, chills, abdominal or flank pain, chest tightness, and hypotension. If one or more of these findings develops, the transfusion should be stopped immediately because the severity of symptoms is related directly to the amount of hemolysis. Saline should be administered at 1.5 to 2 times the maintenance rate (see Chapter 17). A spun hematocrit should be examined for the presence of hemoglobin, which imparts a pink color to the plasma. The urine should also be examined for hemoglobin, which causes a positive result for dipstick reaction for blood in the absence of red blood cells on microscopic analysis. The name, identification number, and blood type of the patient should be compared with those on the unit of blood to ensure that the blood was given to the patient for whom it was intended. Finally, an aliquot of the unit should be returned to the blood bank for confirmation of the original compatibility testing and labeling. A newly positive direct antiglobulin test result confirms the diagnosis.

Further management of an acute hemolytic transfusion reaction is directed toward maintenance of normal blood pressure and urine output and treatment of intravascular coagulation. Rapid IV hydration is mandatory to prevent renal shutdown. Diuretics, including mannitol (1 g per kg), may also be helpful. Intravascular coagulation should be treated with supportive therapy, using doses similar to those described earlier for DIC from other causes.

Delayed hemolytic transfusion reactions occur 3 to 14 days after the administration of red blood cells. These reactions may be due to late formation of an antibody in response to a newly encountered red blood cell antigen or, alternatively, to an anamnestic response of an antibody that originally developed in response to a previous transfusion but was undetectable at the time of the most recent cross-match. The rate of red blood cell destruction is usually slower with a delayed hemolytic transfusion reaction than with an acute hemolytic reaction. Therefore, the most prominent signs and symptoms are those of anemia and hyperbilirubinemia rather than shock and renal shutdown. Laboratory testing demonstrates a positive direct antiglobulin test result. Antibody in the serum or in the red blood cell eluate is specific for the offending red blood cell antigen. Transfusion with compatible red blood cells will relieve severe or symptomatic anemia.

Nonhemolytic transfusion reactions are more common and, in most instances, less severe than hemolytic reactions. Sensitization to plasma proteins may cause urticaria. Fever, chills, and headache previously occurred commonly in repeatedly transfused patients but are less frequent since the implementation of leukoreduction has decreased the likelihood of sensitization to white blood cell antigens. Although these febrile reactions pose little danger to the patient, they may be difficult to distinguish from the more dangerous hemolytic reaction. Before continuing the transfusion, urine and plasma should be checked for the presence of hemoglobin. If these studies are unrewarding, the physician must decide whether the clinical condition of the child warrants discarding the remainder of the unit or finishing the transfusion with supportive therapy such as antipyretics or antihistamines. Because the use of filters to reduce the number of passenger white blood cells has sharply reduced the incidence of nonhemolytic reactions in chronically transfused patients, a hemolytic reaction or bacterial contamination of the donor red blood cell unit should be given particularly strong consideration when fever and chills occur in a child receiving leukoreduced red blood cells.

CHAPTER 92 ■ INFECTIOUS DISEASE EMERGENCIES

MARVIN B. HARPER, MD, AND GARY R. FLEISHER, MD

Although not as dramatic as multiple trauma or cardiac arrhythmias, infection precipitates more emergency department (ED) encounters than either of these other two conditions. Fever is the single most common chief complaint among children seen in the ED at most children's hospitals. Although only a small fraction of patients with infections die, their high prevalence accounts for a large percentage of deaths in the ED.

The approach to the febrile child is outlined in Chapter 27. In this chapter, infections are divided anatomically as follows: generalized (bacterial), central nervous system (CNS), upper respiratory, lower respiratory, gastrointestinal, bone and soft tissue, and genitourinary. Systemic nonbacterial illnesses, including the childhood exanthems, and several miscellaneous syndromes are dealt with as a group at the end of this chapter. Infections of the heart are discussed in Chapter 84, and encephalitis is covered as a neurologic emergency in Chapter 96; human immunodeficiency virus (HIV) and other sexually transmitted diseases are discussed in Chapter 93.

For each anatomic region, the relative frequency of disease caused by various pathogens is quantitated and an approach is given for establishing a specific cause. A more extensive description is provided for the serious and/or treatable conditions. Similar or less significant pathogens are often clustered as a group. The recommendations for management are derived from published literature and represent a widely accepted approach, but not the only standard of care. In certain areas, particularly as regards the indications for admission, scant information exists. Thus, it has been necessary at times to offer, as guidelines, the protocols that the authors have found successful in clinical practice in the ED, even though they may not have been subjected to vigorous clinical trials.

BACTEREMIA AND SEPSIS

Bacteremia refers to the presence of bacteria in the bloodstream. When bacteremia occurs in a young child and produces relatively few signs or symptoms, other than fever, the patient is considered to have the syndrome of occult bacteremia. The presence or absence of toxicity differentiates occult bacteremia, which is relatively asymptomatic, from sepsis, which is accompanied by findings of serious systemic illness and can be subcategorized into additional categories such as severe sepsis and septic shock. Because these syndromes represent a continuum, whereby some children with occult bacteremia proceed to develop the manifestations of sepsis, a separation into distinct diagnostic categories is not always possible. Bacterial bloodstream infections may occur in isolation (primary) or in association with focal disease (secondary). This section focuses on primary infections.

Bacteremia

Background

In areas without widespread use of multivalent conjugate pneumococcal vaccine *Streptococcus pneumoniae* causes 70% to 90% of primary occult bacteremias. Since the introduction of a heptavalent conjugate pneumococcal vaccine in the United States (Prevnar®) there has been a substantial decrease (approximately 70% to 80%) in cases of invasive pneumococcal infections including bacteremia among children. As a result other bacteria now represent an increasing proportion of bactermias including *Salmonella*, *Neisseria meningitidis*, group A streptococcus, group B streptococcus, *Staphylococcus aureus*, and, rarely in the developed countries at present, *Haemophilus influenzae* or other pathogens. Table 92.1 summarizes the isolates in prospective studies of bacteremia, published primarily prior to the widespread administration of highly effective conjugated vaccines to children in the first 6 months of life, directed against Hib and *S. pneumoniae*. Subsequently, the isolation of these two pathogens has declined markedly, particularly for the former, which has been virtually eradicated in the United States.

Occult bacteremia occurs with predictable regularity among febrile children younger than 2 to 3 years. In a report of patients from the post–*H. influenzae* type b era, Lee and Harper noted a rate of bacteremia of 1.57% overall and 1.45% for *S. pneumoniae*, the peak incidence occurring in children 6 to 12 months of age. More recent reports describe an incidence of 0.5% to 1%.

Pathophysiology

A continuum of disease exists, starting with colonization of the host and then progressing to occult bacteremia if bacteria have the opportunity to gain access to the bloodstream. Occult bacteremia may have one of four outcomes: (i) spontaneous resolution, (ii) sepsis, (iii) focal infection, or (iv) sepsis and focal infection. Clearly, pathogens such as *N. meningitidis* and *H. influenzae* have a greater tendency than *S. pneumoniae* to produce sepsis or invasive disease. Other than the specific organism, factors have not yet been completely defined that determine which children become colonized, which colonized children become bacteremic, and which bacteremic children improve without therapy.

Exposure to carriers (asymptomatic colonized) plays an essential role in the community process, accounting for the increased incidence of asymptomatic carriage and disease among household contacts of patients with infections caused by *N. meningitidis* or *H. influenzae*. A concurrent viral infection may increase the likelihood of bacteremia in a colonized

[a]Analysis limited to children with an initial diagnosis of fever of unknown origin, upper respiratory infections, otitis media, or pneumonia.

child by disrupting mucosal barriers to invasion. Pathogen-specific bactericidal antibodies in the serum have been shown to protect carriers against the development of sustained bacteremia for several bacterial pathogens; however, some persons without such antibodies do not progress beyond colonization.

Clinical Manifestations

By definition, occult bacteremia causes few symptoms and signs. The complaints are usually those of malaise or an upper respiratory infection (URI). Fever, without evidence of a source, may be the only physical finding, or the patient may have a minor focus of infection, such as otitis media (OM).

McCarthy et al. attempted to define the history and observation variables useful in assessing febrile children. Observation of behavior (playfulness, alertness, and consolability) had the strongest correlation with the overall assessment; however, 9 of 21 children subsequently shown to have serious illnesses were not initially categorized as being moderately or severely ill. A subsequent study by Baker et al. found that this observational scale did not predict serious illness accurately in young infants, and Teach and Fleisher noted a similar lack of success in older children with occult bacteremia. Examining the overall assessment of experienced pediatricians, as opposed to a specific scoring system, Waskerwitz Berkelhammer described a sensitivity of 47%, a specificity of 83%, and a positive predictive value of 14%. Taken together, these studies indicate that abnormal clinical assessments in the evaluation of the otherwise well-appearing febrile child will increase the risk for bacteremia but with poor sensitivity and specificity.

Children 3 to 24 months of age who appear well with a fever at or above 39°C (102.2°F) have a higher incidence of bacteremia than those with low-grade fever [38°C to 38.9°C (100.4°F to 102°F)], but further elevations of the temperature above the 39°C (102.2°F) mark only minimally increase the likelihood of bacteremia. Torrey et al. tested whether the initial overall assessment of the response to an antipyretic drug administered in the ED could distinguish febrile children with bacteremia from those with viral infections. Neither the clinical evaluation nor the magnitude of the decrease in temperature was predictive for the presence or absence of organisms in the bloodstream. Additional studies have confirmed that the response to antipyresis does not correlate with the presence of bacterial infection.

The white blood cell (WBC) count is usually elevated in children with *S. pneumoniae* bacteremia. For all pathogens, Jaffe and Fleisher found the sensitivity of the WBC count among children 3 to 36 months of age with a temperature greater than 39°C (102.2°F) to be 92% at 10,000 per mm^3 or more, 65% at 15,000 per mm^3 or more, and 38% at 20,000 per mm^3 or more. Limiting their analysis to pneumococcal bacteremia among a similar group of highly febrile infants and toddlers, Kuppermann et al. reported that 8.2% of highly febrile infants and toddlers with a WBC count of 20,000 per mm^3 or more had occult pneumococcal bacteremia. Lee and Harper demonstrated that the risk of bacteremia was greater among the more highly febrile patients with leukocytosis

TABLE 92.2

PROPORTION OF PATIENTS WITH BACTEREMIA, DEPENDING ON WHITE BLOOD CELL (WBC) COUNT AND TEMPERATURE, 1993–1996

	Temperature (°C)[a]					
WBC (1,000/mm^3)	39.0–39.4	39.5–39.9	40.0–40.4	40.5–40.9	≥41	Row total
0–4.99	0	0	0	0	0	0
5–9.99	0	0.2	0.1	0	0	0.1
10–14.99	0.1	0.5	0.3	1.6	1.8	0.5
15–19.99	2.0	2.2	5.3	4.5	5.4	3.5
20–24.99	5.4	4.1	8.1	11.7	6.1	6.8
≥25	14.2	13.0	5.3	8.7	13.6	10.8

[a]For Fahrenheit equivalents, multiply by 9, divide by 5, and add 32.
Modified from Lee GM, Harper MB. Risk of bacteremia for febrile young children in the posthaemophilus influenzae type b era. *Arch Pediatr Adolesc Med* 1998;152:624–628.

(Table 92.2) and noted an incidence in the range of 10% among those with significant elevations.

A shift to the left in the differential count and signs of toxicity on the peripheral smear are seen more often in bacteremic children than in those with viral infections, but neither serves to reliably distinguish the two groups. Although the erythrocyte sedimentation rate (ESR), the C-reactive protein (CRP), and other acute phase reactants (e.g., procalcitonin) are usually elevated in patients with bacteremia, these tests provide minimal, if any, additional information.

Management

A discussion on the management of bacteremia must address three issues: (i) evaluation for bacteremia in the febrile child with a seemingly trivial febrile illness, (ii) treatment of the child with suspected bacteremia but no signs of sepsis or focal disease, and (iii) therapy of proven bacteremia.

(i) Evaluation for bacteremia in the febrile child with a seemingly trivial febrile illness: the appropriate evaluation takes into consideration the likelihood of bacteremia. Children between 3 and 24 months of age with a fever of 39°C (102.2°F) or higher and who have abnormal clinical assessments or who have not received immunizations against Hib and *S. pneumoniae* will be at somewhat increased risk for bacteremia. In these cases it may be useful to obtain a WBC count, differential, and blood culture to supplement clinical judgement in the early identification of bacteremia. Among children with low-grade fevers, no abnormal clinical assessments, and at least three immunizations each for Hib and *S. pneumoniae* or among those with an age above 24 months, the physician can rely more firmly on clinical judgment.

(ii) Treatment of the child with suspected bacteremia but no signs of sepsis or focal disease: there is no doubt that children known to be bacteremic need appropriate antibiotic therapy. The decision about whether to treat children who are identified to be at increased risk for occult bacteremia hinges in large part on the balance between the unnecessary administration of antimicrobial therapy to many children without bacteremia and the prevention of serious complications among the children with bacteremia. Because diagnosis based on clinical and laboratory findings at the time of the visit has limited accuracy, physicians must choose between two alternatives, neither of which is completely satisfactory. Presumptive treatment is advocated by many, but not all, for patients 3 to 24 months of age with a fever 39°C (102.2°F) or higher and who are at higher-than-average risk (e.g., more irritable or lethargic than the usual child with a fever; WBC count of 15,000 to 20,000 per mm^3 or more, not immunized against Hib and *S. pneumoniae*). For this group, a single intramuscular dose of ceftriaxone (50 mg per kg) has been demonstrated to be effective for eradicating bacteremia and reducing the incidence of subsequent focal complications. In managing highly febrile, young children not believed to be at higher risk, observation at home suffices.

(iii) Therapy of proven bacteremia: the management of patients with proven bacteremia is determined by the pathogen identified and the clinical signs and symptoms of the child at the time. If a penicillin-susceptible *S. pneumoniae* is isolated, the clinical findings at the time of clinical follow-up determine the subsequent treatment. Children no longer with fever and without any evidence of a serious infection on examination (e.g., meningitis, pneumonia, cellulitis) should receive oral amoxicillin 80 mg per kg per day for 10 days; those with continued fever [38.5°C (101.2°F) or higher] or clinical toxicity will generally merit specific testing for a serious focal infection (lumbar puncture, chest radiograph) and initial intravenous (IV) antibiotic therapy in most cases. Children returning after a blood culture has grown other pathogens (*S. pneumoniae* with reduced susceptibility to penicillin, *H. influenzae, N. meningitides,* or *S. aureus*) are most often managed with parenteral antibiotics in the hospital because even those who remain well and afebrile appear to have some potential for persistent bacteremia and/or the continued evolution of focal infections. However, some studies have suggested that selected afebrile and well-appearing children with a prior blood culture yielding penicillin-resistant *S. pneumoniae, N. meningitidis,* or *H. influenzae* may be managed with outpatient therapy, such as ceftriaxone (50 mg per kg), pending the results of repeat cultures. The diagnostic evaluation for primary or secondary focal infections is directed by signs, symptoms, and pathogen.

Sepsis

Background

The terminology used to describe children with inflammatory responses has evolved to allow better precision in predicting risk, comparing outcomes and performing research interventions. Currently proposed terminology includes (i) systemic inflammatory response syndrome (SIRS), which simply requires fever or leukocytosis and either tachycardia or tachypnea; (ii) infection, which is defined when there is an identified pathogen or clinical syndrome associated with a high probability of infection; (iii) sepsis defined as SIRS with infection; (iv) severe sepsis, which is sepsis plus cardiac or acute respiratory dysfunction or two or more other organ dysfunctions; and (v) septic shock, which is cardiovascular dysfunction with sepsis.

The etiology of sepsis, severe sepsis, and septic shock varies with age in the otherwise healthy child. During the first 2 months of life, group B streptococcus and *Escherichia coli* are the most common isolates. The group B streptococci cause more than 10,000 cases of neonatal disease yearly in the United States. At Yale, Gladstone et al. reviewed a decade of neonatal sepsis, from 1979 to 1988, and compared the findings with earlier reports from the same institution. Among 270 infants with sepsis, they isolated group B streptococcus from 64, *E. coli* from 46, *Klebsiella pneumoniae* from 18, and *H. influenzae* from 8. Analysis of the trend showed a steady level of infection for the group B streptococcus, compared with the prior decade, and a slight decrease in incidence for *E. coli.* More recent reports have noted a downward trend in early-onset group B streptococcus sepsis following the introduction of strategies for prophylaxis based on maternal screening, but Pena et al. observed a steady incidence in late-onset disease in Boston from 1982 to 1996.

N. meningitidis and *S. pneumoniae* infect the newborn only occasionally, but within 2 to 3 months of birth, they emerge as the most common causes of sepsis in children. In areas without widespread use of conjugate Hib vaccines, *H. influenzae* will remain a prominent cause. Group A streptococcus, *S. aureus,* and *Salmonellae* represent an increasingly important proportion of cases where conjugate vaccines are commonly used and are more commonly associated with focal infections.

For pediatric patients the highest risk period for severe sepsis is the first month of life. The overall mortality among children with severe sepsis is 10% regardless of age. Certain conditions impose an increased susceptibility to sepsis on children. In the United States approximately half of all cases occur among children with underlying conditions. These include low birth weight neonates, neoplasia, immunodeficiency syndromes, immunosuppressive therapy, asplenia, sickle cell disease, and the presence of indwelling devices, such as central venous catheters, which bypass typical anatomic and immune barriers. Patients with any of these predisposing factors and fever pose a particularly urgent problem for the emergency physician. Some centers have established protocols to target these high-risk children for specific goal-directed testing and empiric treatment. Unfortunately sepsis, severe sepsis, or septic shock may be the presenting feature that leads to the diagnosis of the underlying condition and, therefore, the increased risk will not be known at that visit. The hemoglobinopathies pose a particularly urgent problem because of their relative frequency and the fact that overwhelming sepsis may occur in the young infant before the initial clinical manifestation of the underlying hematologic disease.

Pathophysiology

As discussed under occult bacteremia, the first step toward sepsis occurs with colonization of the host by potentially pathogenic bacteria. The site of colonization is usually the pharynx in older children but may be the umbilicus or bowel in the neonate. Among immunosuppressed children, organisms that reside in the gastrointestinal tract often invade the bloodstream.

After entry into the bloodstream, bacteria increase in number. As some of the organisms are lysed, toxic products, such as endotoxin, are released into the circulation. These products interact with host proteins and bind to receptors on cells of the immune system, as well as endothelia. Activation of the host cells follows, releasing a series of inflammatory mediators into the circulation. The initial cascade includes tumor necrosis factor (TNF), interleukin-1, and interleukin-6. Subsequently, additional interleukins and prostaglandins assume an important role.

Not every child with bacteremia develops the clinical manifestations of sepsis, severe sepis, or septic shock. A multitude of pathogen and host-specific factors are involved. The intrinsic virulence of the pathogen determines, in part, whether the bacteremia resolves spontaneously. *N. meningitidis* bacteremia results in sepsis or a focal infection in 50% to 75% of children, whereas those infected with *Salmonella* more commonly remain febrile but otherwise asymptomatic. Host factors also assume an important role in clearing circulating bacteria. The young child, particularly younger than 2 years, has a greater tendency to become seriously ill.

Clinical Manifestations

The duration of the history in a child with sepsis varies. Even though some children are febrile for several days during a preceding bacteremia, others develop a sudden dramatic illness. The interval between the initial fever and death may be less than 12 hours in fulminant meningococcemia (Fig. 92.1).

FIGURE 92.1 Sepsis secondary to infection with *Neisseria meningitidis*. Note diffuse purpuric lesions in this critically ill child.

While the pace varies, children typically progress from malaise to profound lethargy and, finally, to obtundation. Although fever is the cardinal sign of infection, children younger than 2 to 3 months may remain afebrile with sepsis; hypothermia is common in the first 2 weeks of life.

A marked tachycardia occurs early in the course of the disease, at times exceeding 200 beats per minute (bpm) in the first 3 months of life, 175 bpm between 4 months and 2 years of age, and 150 bpm in the older child. Unfortunately, many children with fevers from minor infections, particularly when stressed by entry into a medical environment, may manifest pulse rates in a similar range. Hypotension and tachypnea develop as the illness evolves. The skin becomes cold and poorly perfused; in addition, petechiae and purpura may appear, particularly with *N. meningitidis*. Last, unexplained extremity pain in a febrile child represents a somewhat unusual, but well-described, feature of early sepsis.

The hemoglobin and hematocrit are usually normal, falling occasionally from hemolysis as seen with disseminated intravascular coagulation (DIC). Leukocytosis often accompanies sepsis, but leukopenia may be seen with severe sepsis or septic shock, especially among infants. The WBC count differential is frequently shifted to the left with metamyelocytes and band forms in the peripheral blood. As the infection progresses, the platelet count decreases. It is distinctly unusual to have evidence of cutaneous hemorrhage from sepsis without thrombocytopenia. Similarly, the prothrombin time (PT), partial thromboplastin time (PTT), and fibrin degradation products rise with the ongoing consumption of the clotting factors. The electrolytes reflect a metabolic acidosis in advanced disease, and occasionally, mild hyponatremia occurs; the blood urea nitrogen (BUN) is usually normal but may rise in the face of preceding dehydration. Although rarely performed, Gram stain of a petechial scraping may show the etiologic agent in one-third of cases. Hypoglycemia and hypcalcemia may occur.

Management

The initial therapy for severe sepsis and septic shock is directed at the preservation of vital functions, but every effort must be made in parallel to obtain the appropriate diagnostic studies (Table 92.3). Blood should be drawn for culture, complete blood cell (CBC) count, platelet count, PT, PTT, electrolytes, BUN, arterial blood gas (ABG) analysis, serum aspartate aminotransferase (AST), and serum alanine aminotransferase (ALT) in conjunction with establishing venous access.

In adults, goal-directed therapy with rapid reassessment of those targeted goals with timeframes for stepwise interventions has been associated with improved outcomes. As initial therapy, normal saline, with or without 5% dextrose, is administered as one, two, or three rapidly infused 20 mL per kg boluses, based on initial condition and the response. The unstable patient may require central venous, arterial, and urinary catheters, although in some settings these interventions may be performed following admission to the hospital. Deterioration often occurs after antibiotic administration because of sudden lysis of organisms, resulting in massive endotoxemia and release of cytokines, particularly TNF. Thus, preparations should be made for appropriate venous access and blood pressure monitoring when antimicrobials are given. The initial laboratory studies, the response to the saline, and the measurements of the intravascular status determine the type and quantity of the subsequent fluids and the need for vasopressors (see Chapter 3).

TABLE 92.3

IMMEDIATE MANAGEMENT OF SEPSIS

1. Insure adequate ventilation and cardiac function.
2. Obtain laboratory studies (simultaneously with step 3): CBC count, platelet count, PT, PTT, electrolytes, BUN, creatinine, glucose, ABG, blood culture, fibrin degradation products, AST, ALT.
3. Initiate hemodynamic monitoring and support: peripheral venous access; urinary catheter; central venous and arterial catheters (as indicated); cardiorespiratory monitors; normal saline, starting at 20 mL/kg.
4. Administer drugs and other therapeutic agents:
   Antibiotics: <2 mo: ampicillin (50 mg/kg) and gentamicin (2.5 mg/kg); consider vancomycin
   >2 mo: ceftriaxone (50 mg/kg) or cefotaxime (50 mg/kg); consider vancomycin if MRSA a concern;
   Sodium bicarbonate (pH <7.0) 1–2 mEq/kg
   Glucose (serum glucose <50 mg/dL) 0.25–1 g/kg
   Packed red blood cells (Hgb <10 g/dL) 10 mL/kg
   Platelet concentrates (platelet count <50,000/mm^3) 0.2 unit/kg
   Fresh-frozen plasma (elevated PT/PTT) 10 mL/kg

CBC, complete blood cell; PT, prothrombin time; PTT, partial thromboplastin time; BUN, blood urea nitrogen; ABG, arterial blood gas; AST, aspartate aminotransferase; ALT, alanine aminotransferase.

For full-term infants younger than 2 months, ampicillin (200 mg per kg per day) and gentamicin (7.5 mg per kg per day) are administered; the use of cefotaxime (150 mg per kg per day) or vancomycin (40 mg per kg per day) should be considered based on the suspected source and sites of infection and the severity of illness. Dosages need to be decreased for premature infants in the first month of life and term infants in the first week (Tables 92.4A and 92.4B). Doses may need to be increased if meningitis is suspected. Cefotaxime (200 mg per kg per day) or ceftriaxone (100 mg per kg per day) alone provides effective monotherapy for the child older than 2 months who appears well but may have early sepsis. Vancomycin (40 mg per kg per day) should be added for patients who are critically ill or at particular risk of infection with penicillin-resistant *S. pneumoniae,* as in the case, for example, of a patient with sickle cell anemia who is taking daily prophylactic penicillin. Vancomycin should also be used in the patient with a focus that is likely due to *S. aureus* until the isolate is determined not to be MRSA. Children with allergies to penicillins and cephalosporins may be managed with vancomycin and an aminoglycoside but if there is concern for CNS involvement a quinolone, an aztreonam, or an infectious diseases consultation should be considered. Various other antibiotics play a role, particularly in special populations, such as those with immunocompromise, central venous catheters, or recent hospitalizations. Examples include linezolid for resistant *S. aureus* or broad-spectrum agents, such as ceftazidime or piperacillin/tazobactam (Zosyn®), for children with neutropenia. Corticosteroid therapy is not routinely recommended for sepsis, but divergent opinions exist.

TABLE 92.4A

INTRAVENOUS ANTIBIOTIC DOSING FOR NEWBORN INFANTS BASED ON AGE AND WEIGHT [TOTAL DAILY DOSE (mg/kg/day) AND DOSING INTERVAL]

	Weight <2,000 g		Weight >2,000 g		
Antibiotic	**0–7 day**	**8–28 day**	**0–7 day**	**8–28 day**	**>28 day**
Ampicillin	100 mg q12h	150 mg q8h	150 mg q8h	200 mg q6h	200 mg q6h
Cefotaxime	100 mg q12h	150 mg q8h	100 mg q12h	150 mg q8h	150 mg q8h
Ceftriaxone	50 mg qd	50 mg qd	50 mg qd	75 mg qd	100 mg qd

Blood components are given as indicated by the results of the initial hematologic studies. If the hemoglobin is lower than 10 g per dL, packed red cells are administered at 10 mL per kg. Thrombocytopenia (less than 50,000 per mm^3) is corrected with platelet concentrates at 0.2 units per kg and decreased clotting factors with fresh-frozen plasma 10 mL per kg. For the child with hypoglycemia (glucose less than 50 mg per dL), glucose should be given at a dose of 0.25 to 1 g per kg, usually as a 10 or 25% solution. Heparin plays no role in the initial emergency care of the child with sepsis but may be useful subsequently to treat severe thrombotic episodes. Specific inhibitors of endotoxin and cytokines, such as bacterial polysaccharide-inhibiting protein, are under investigation but have not been demonstrated to be effective as of yet. Similarly, activated protein C (drotrecogin alpha), which proved effective as adjunctive therapy for adults, is not currently recommended for children.

CENTRAL NERVOUS SYSTEM INFECTIONS

Three important infectious syndromes involve the CNS: meningitis, encephalitis, and intracranial abscess. Because encephalitis and intracranial abscess usually confront the emergency physician as problems in the differential diagnosis of various neurologic manifestations, they are discussed as neurologic emergencies in Chapter 96.

Meningitis, an inflammation of the membranes lining the CNS, results from an infection or irritation on a noninfectious basis. Inflammation of the meninges produces a pleocytosis in the cerebrospinal fluid (CSF), allowing, in most cases, for the diagnosis of meningitis by examination of this readily accessible material. However, organisms may occasionally infect the meninges without eliciting a cellular reaction, either because sufficient time has not elapsed for a leukocyte response, because the pathogen is of low virulence, or the host is unable to respond (most commonly due to neutropenia).

In the ED setting, most cases of meningitis result from a viral or bacterial infection of the CNS, rather than from unusual inflammatory or neoplastic conditions. Table 92.5 lists the common etiologies. The most important initial task that confronts the emergency physician is the identification of children with bacterial meningitis, which is a life-threatening infection. The sine qua non for the definitive diagnosis of meningitis is examination of the CSF. Routine studies performed on this fluid should include cell count with differential, glucose, protein, Gram stain, and bacterial culture. In selected cases, additional studies, such as latex agglutination; acid-fast stain; India ink preparation; polymerase chain reaction (PCR) tests; serologic testing for Lyme disease and/or syphilis; cryptococcal antigen; and cultures for anaerobic bacteria, mycoplasma, mycobacteria, and fungi are indicated. Values of various parameters of the CSF are presented for healthy persons and for those with viral and bacterial meningitis (Table 92.6).

The CSF ordinarily contains no red blood cells. The presence of blood indicates either contamination from a traumatic lumbar puncture or hemorrhage in the CNS. If the density of the red cells is constant from the first to the last tube collected, the cells are crenated, or the fluid is xanthochromic (from lysed red cells), the likelihood of CNS hemorrhage is greater. The presence of WBCs is also abnormal. In the immediate neonatal period infants may have up to 29 WBCs per mm^3 in the CSF but older children should certainly have fewer than 5 to 10 WBCs per mm^3 in the CSF. More than this indicates inflammation of the meninges. Again, if CSF is obtained early in the course of illness before an inflammatory reaction has been invoked there may not be an evident CSF pleocytosis. Thus, a child with fewer than 10 cells per mm^3 in the CSF will occasionally later develop the clinical and laboratory manifestations of meningitis or have a pathogen isolated from culture.

In viral infections of the CNS, the WBC count in the CSF usually ranges from 10 to 1,000 per mm^3. Occasionally, a WBC count as high as 2,500 per mm^3 may be seen. A

predominance of mononuclear cells is usually present, although neutrophils may be in the majority. Bacterial meningitis evokes an intense infiltration of leukocytes, with an eventual marked predominance of neutrophils. The cell count will depend on when in the course of illness lumbar puncture is performed and on the host response but is frequently 1,000 to 20,000 per mm^3, and occasionally even higher.

The CSF glucose is normally one-half to two-thirds of the serum glucose. Equilibration between the serum and CSF glucose levels has been estimated to require at least 30 minutes. Thus, a rapid decrease in the serum glucose may obscure a wide variance from the CSF level, whereas a sudden elevation may lead to a falsely large discrepancy. Because the stress of a lumbar puncture produces hyperglycemia, a serum glucose for comparison with the CSF level should be obtained before this procedure is attempted. In viral meningitis, the CSF glucose, usually in the normal range, may be as low as 30 mg per dL. The glucose in bacterial meningitis often falls below 30 mg per dL. Hypoglycorrhachia, accompanying an elevated protein level and a mild mononuclear pleocytosis should arouse a suspicion of tuberculous meningitis. A normal CSF protein is less than 40 mg per dL in the child and 170 mg per dL in a newborn. Although the protein is minimally elevated in viral meningitis, the level in bacterial meningitis is often 100 mg per dL or greater. Additional studies, such as latex agglutination, may rarely be helpful in distinguishing bacterial from viral meningitis.

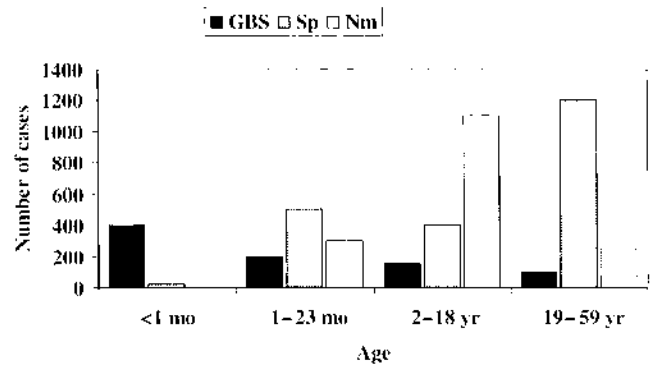

FIGURE 92.2 Projected cases of meningitis by age and organism, excluding *Escherichia coli*. GBS, group B streptococcus; Sp, *Streptococcus pneumoniae;* Nm, *Neisseria meningitidis*. (Modified from Schuchat A, Robinson K, Wagner JD, et al. Bacterial meningitis in the United States in 1995. *N Engl J Med* 1997;337:970–976.)

Bacterial Meningitis

Background

Almost any bacteria can cause meningitis at least occasionally; however, more than 90% of the cases in immunocompetent children result from infections with five organisms*: S. pneumoniae, N. meningitidis, E. coli,* group B streptococcus, and, less frequently, *H. influenzae*. The most common organism varies with the age of the child (Fig. 92.2). In the first month of life, *E. coli* and group B streptococcus are usually isolated; *Listeria monocytogenes*, a gram-positive rod, accounts for 1% to 3% of the cases. Between 30 and 60 days of age, group B streptococcus continues to be recovered frequently, followed by *S. pneumoniae* and *N. meningitidis; H. influenzae* occurs rarely. After the first 2 months of life, *S. pneumoniae* and *N. meningitidis* cause the majority of meningeal infections; *H. influenzae* remains a consideration primarily among children not immunized with conjugated Hib vaccine. *Salmonella,* an uncommon etiologic agent in the United States, should be suspected in the first few months of life if meningitis occurs in association with gastroenteritis.

Meningitis was formerly a relatively common life-threatening infection of children, but the incidence of this disease has

declined significantly since the introduction of conjugated vaccines against Hib and pneumococci. Schuchat et al. performed an active population-based surveillance of meningitis (excluding disease caused by gram-negative enteric rods) during 1995 from all the acute care hospitals in four states with a population of more than 10 million and described the attack rates for the various pathogens by age (Table 92.7). Based on their findings, they projected the total number of cases of bacterial meningitis during 1995 in the United States, as shown in Fig. 92.2, of particular note estimating that only 948 cases occurred in children from 1 to 23 months of age. The conjugated vaccine against *S. pneumoniae* introduced after the study by Schuchat et al. has further reduced the incidence of meningitis in childhood.

Pathophysiology

Microorganisms gain access to the CNS through two potential pathways. Most commonly in children, a preceding bacteremia leads to hematogenous seeding of the meninges. Alternatively, direct extension may occur from a purulent parameningeal focus.

Colonization of the nasopharynx sets the stage for the subsequent development of meningitis in most bacterial CNS infections in the older child. In the infant, who is susceptible to infection with gram-negative enteric organisms, the urinary tract or bowel is often the source of the pathogen. A small percentage of the children colonized with a potential pathogen will develop bacteremia, but most will clear the pathogens from their bloodstream spontaneously; more than 80% of cases of bacteremia with *S. pneumoniae* resolve without leading to local infection. The bacteremia causing meningitis may be transient as only about half of patients with meningitis presumed secondary to bacteremia have positive blood cultures at the time of the diagnosis of meningitis.

Although a less common predecessor to meningitis, purulent collections contiguous to the CNS may also produce such infections. Sinusitis is the most common offender. Organisms also may invade the meninges on occasion directly from the middle ear. However, meningitis following OM usually results from bacteremia, unless a congenital or posttraumatic fistula in the temporal bone provides access to the CSF. Children with cochlear implants suffer a higher than expected incidence of meningitis with encapsulated bacteria.

Clinical Manifestations

The signs and symptoms of meningitis vary with the child's age (Table 92.8). Particularly in the first 2 to 3 months of life, the clinician must maintain a high index of suspicion for this disease. In addition, it should be kept in mind that partial treatment with antibiotics may obscure the typical findings.

Before 2 to 3 months of age, the history is usually that of irritability, an altered sleep pattern, vomiting, and decreased oral intake. In particular, paradoxical irritability points to the diagnosis of meningitis. Irritability in the infant without inflammation of the meninges is generally alleviated by maternal fondling; however, in the child with meningitis, any

TABLE 92.8

SIGNS AND SYMPTOMS OF MENINGITIS

		Signs	
Age	Symptom	Early	Late
0–3 mo	Paradoxical irritability Altered sleep pattern Vomiting Lethargy	Lethargy Irritability Fever Hypothermia (<1 mo)	Bulging fontanel Shock
4–24 mo	Irritability Altered sleep pattern Lethargy	Fever Irritability	Nuchal rigidity Coma Shock
>24 mo	Headache Neck pain Lethargy	Fever Nuchal rigidity Irritability	Coma Shock

handling, even directed toward soothing the infant, may increase irritability by its effect on the inflamed meninges. The amount of time spent sleeping may either increase because of obtundation or decrease from irritability. Bulging of the fontanel, an almost certain sign of meningitis in the febrile, ill-appearing infant, is a late finding.

Vomiting is often a prominent feature of the presentation of infants with meningitis, but when emesis occurs in isolation, particularly in the absence of fever, it more likely points to pyloric stenosis or other disorders of the GI tract.

As the child ages past 3 months, the symptoms gradually become more specific for involvement of the CNS. A change in the level of activity is almost always noticeable. However, it is only in the child older than 2 years that meningitis manifests reliably with complaints of headache, neck stiffness, and photophobia.

The physical examination in the young infant rarely provides specific corroboration, even when the history suggests meningitis. Fever may be absent in these children, despite the presence of bacterial infection. Any child younger than 2 to 3 months who is brought to the ED with a documented temperature of 38.0°C to 38.5°C (100.4°F to 101.2°F) or higher should be considered at risk for meningitis. The physical signs are sufficiently elusive that many experts caution that one should not rely exclusively on the examination to rule out meningeal infection. In several studies, 5% to 10% of these young infants had meningitis (although mostly aseptic), despite being judged clinically well by experienced pediatric residents.

After 2 to 3 months of age, increasing, but not absolute, reliance can be placed on the physical findings; fever is typically noted. Specific evidence of meningeal irritation is often present, including nuchal rigidity (Fig. 92.3) and, less often, Kernig and Brudzinski signs. When a lumbar puncture fails to confirm the diagnosis of meningitis, despite the presence of meningeal signs, other conditions must be pursued that can mimic the findings on physical examination. Conditions capable of producing the findings typical of meningismus (irritation of the meninges without pleocytosis in the CSF) include severe pharyngitis, retropharyngeal abscess, cervical adenitis, arthritis or osteomyelitis of the cervical spine, upper lobe pneumonia, subarachnoid hemorrhage, pyelonephritis, and tetanus.

Seizures are a presenting complaint for 20% of children with bacterial meningitis. Many of these are focal, recurrent, or prolonged seizures. Most clinicians advise that children younger than 6 months with a first-time febrile seizure should routinely have lumbar puncture performed to discern the presence of CNS infection, unless there are specific contraindications or an alternative diagnosis is readily apparent. The occurrence of a seizure in a febrile child older than 6 months presents more of a dilemma for the clinician. Febrile seizures are common, affecting 3% to 5% of children, and underlie most of these episodes. Because of the difficulty of establishing a clinical diagnosis of meningitis in the 6 to 24 month age child, a lumbar puncture should be considered in these children with a first febrile seizure and a lumbar puncture performed if there is a specific clinical concern for meningitis. In the older child or in the case of recurrent febrile seizures, the management is typically guided by the physical findings and the evolution of the illness over the ensuing 12 to 24 hours.

The child eventually manifesting bacterial meningitis often has had one or two visits to a clinician earlier in the course of illness with diagnoses typically of viral infection, fever or OM. By the time these patients come to the ED, the presenting complaints, signs, or symptoms are often much more notable (Table 92.9). Lethargy, somnolence, severe sepsis or septic shock, seizures, and hyponatremia occur at any age, whereas apnea and hypoglycemia predominantly affect infants younger than 3 months. Although sterile subdural effusions and, rarely, empyemas usually occur later in the disease, they merit consideration in the infant with signs of herniation and a bulging fontanel.

Management

Bacterial meningitis is a medical emergency that requires the timely institution of therapy (Table 92.10). With appropriate treatment, mortality hovers around 5%. Antibiotics should be given intravenously (although intramuscular ceftriaxone is an

FIGURE 92.3 Child with meningitis who demonstrates ill appearance and nuchal rigidity. **A:** Patient lying supine with neck in neutral position. **B:** Pain grimace and resistance (lifting of shoulders) upon attempted flexion of the neck.

acceptable alternative when IV access is not available) at the completion of the lumbar puncture. Although several studies have shown the average elapsed time between arrival in the ED and delivery of antibiotics averages 2 to 3 hours, no modification in outcome has been demonstrated with temporal differences in antibiotic administration within a range of a few hours. Nonetheless, every effort should be made to act as promptly as circumstances allow. After initial stabilization, a few, but not the majority of children, require intensive monitoring or further therapy in an intensive care unit setting. If meningitis is suspected but attempts to obtain CSF are unsuccessful or deferred because of thrombocytopenia, hypotension, respiratory distress, or concern for intracranial mass or herniation, this should not delay antibiotic administration.

The otherwise healthy child's age determines the spectrum of microorganisms causing meningitis and the selection of antibiotic therapy (Tables 92.7 and 92.10). In the first 30 days of life, the most likely organisms include the gram-negative enteric rods, such as *E. coli,* and group B streptococcus. The enteric pathogens should be treated initially with a third-generation cephalosporin and an aminoglycoside antibiotic; penicillin or ampicillin effectively treats the group B streptococcus. Ampicillin and a third-generation cephalosporin (ceftriaxone or cefotaxime) or an aminoglycoside (gentamicin) thus provide coverage for the most common pathogens in the first month of life. The spectrum of these antibiotics also includes less common organisms in the neonate, such as *S. pneumoniae, N. meningitidis*, and *L. monocytogenes*. *Salmonella* is a somewhat unusual cause of meningitis in the United States but may be isolated in 1% to 2% of such infections. Increasingly, this organism is resistant to ampicillin. Thus, the isolation or strongly suspected presence of *Salmonella* from the GI tract dictates the inclusion of a cephalosporin (cefotaxime or ceftriaxone). Meropenem (60 to 120 mg per kg per day) offers an alternative to cephalosporins for children with simple rashes to penicillins and cephalosporins but for more severe anaphylactoid type reactions a quinolone and infectious diseases consultation should be considered.

Between 30 and 60 days of age, group B streptococcus remains the predominant pathogen, but the gram-negative enteric bacilli decrease in frequency. *S. pneumoniae* and *N. meningitidis* occur sporadically, as does *H. influenzae,* because these children are too young to be immunized against Hib and *S. pneumoniae*. The usual antibiotic combination is vancomycin (60 mg per kg per day in four divided doses) to cover penicillin-resistant pneumococci, plus either ceftriaxone or cefotaxime (Table 92.10).

After the first 2 months, the predominant pathogens that cause meningitis are *S. pneumoniae* and *N. meningitidis*. *H. influenzae,* formerly responsible for most CNS infections in children, has become exceedingly rare. As for the child between 30 and 60 days of age, initial antibiotic therapy includes vancomycin and either ceftriaxone or cefotaxime (Table 92.10). Meropenem (60 to 120 mg per kg per day) offers an alternative to cephalosporins for children with simple rashes to penicillins and cephalosporins but for more severe anaphylactoid type reactions vancomycin (60 mg per kg per day in four divided doses), a quinolone (moxifloxacin, if gram-positive organism, or ciprofloxacin, if gram-negative organism) and infectious diseases consultation should be considered.

The CSF Gram stain will be positive for an organism in approximately two-thirds (40% to 90%) of cases of bacterial meningitis and the results of Gram stain should be used to add additional antimicrobial therapy when appropriate. It is generally prudent to await culture confirmation before antibiotic coverage is narrowed.

In addition to the antibiotic administration aimed at the eradication of the offending organism, supportive therapy for complications (Tables 92.9 and 92.10) is an essential ingredient in the care of the child with meningitis. Recommended laboratory studies on every patient include a CBC count, electrolytes, BUN, PT and PTT, glucose, and blood culture. A rapid assessment should be made about the adequacy of ventilation. The CNS edema that accompanies inflammation of the meninges may produce obtundation and hypoventilation. Apneic episodes can occur in the infant. Thus, oxygen, intubation, and assisted ventilation may all be required. Bacteremia, which usually accompanies meningitis, may lead to septic

TABLE 92.10

IMMEDIATE MANAGEMENT OF BACTERIAL MENINGITIS

1. Insure adequate ventilation and cardiac function.
2. Obtain laboratory studies (simultaneously with step 3):
   Cerebrospinal fluid: cell count, glucose, protein, Gram stain, culture, latex agglutination (as indicated)
   Blood: complete blood cell count, platelet count, prothrombin time, partial thromboplastin time, electrolytes, blood urea nitrogen, creatinine, glucose, blood culture
3. Initiate hemodynamic monitoring and support.
   Achieve venous access; use cardiorespiratory monitors.
4. Administer drugs.
   Treat septic shock, if present.
   If >1 month consider dexamethasone (0.15 mg/kg) before or shortly after antibiotic administration if *S. pneumoniae* or *H. influenzae* type b likely
   Antibiotics: <1 mo: ampicillin (50 kg) and cefotaxime (50 mg/kg)
   >1 mo: vancomycin (15/mg) and either ceftriaxone (50 mg/kg) or cefotaxime (75 mg/kg)[a]
   Glucose (if serum glucose <50 mg/dL) 0.25–1 g/kg
   Treat acidosis and coagulopathy, if present.

[a]Meropenem (25–30 mg/kg) may be used in place of cephalosporins for children with simple rash to those agents. If anaphylactoid reaction to cephalosporins or penicillins then vancomycin (60 mg per kg per day in four divided doses), a quinolone, and infectious diseases consultation should be considered.

shock. This condition demands vigorous fluid resuscitation with normal saline. The response to an initial bolus of 20 mL per kg saline determines the need for further therapy, such as the use of vasopressor agents (see Chapter 3). The urgency to provide adequate perfusion to the vital organs by expanding the intravascular volume takes precedence over concerns about edema in the CNS.

Hyponatremia often accompanies meningitis, resulting from water retention because of inappropriate secretion of antidiuretic hormone (SIADH). Occasionally, the oral administration of hypotonic solutions by the parents during the preceding prodromal illness may produce fluid overload and a low serum sodium (Na). If the child is believed to have seizures on the basis of acute hyponatremia, the physician may give 3% NaCl (see Chapter 100) 5 mL/kg over 15 minutes until seizure abates remainder to be infused over 1 hour. A repeat dose may be required.

After the correction of dehydration or shock, the rate of fluid administration to the child with meningitis should generally not exceed maintenance requirements (see Chapter 100). Generally, D51/2NS (dextrose and half normal saline) is used for this purpose. Failure of the serum Na to rise in the hyponatremic child mandates further restriction on hydration. The ongoing measurement of patient weight and serum electrolytes and urine specific gravity and electrolytes can be used to evaluate the need for fluid restriction.

Hypoglycemia occurs as a reaction to septicemia and stress. It is a more common concomitant of meningitis in the first 3 months of life. If the blood glucose is less than 50 mg per dL, glucose, usually as a 10–25% solution, should be given at a dosage of 0.25 to 1 g per kg. This bolus is followed by an infusion of 5% glucose and monitoring of the response. Occasionally, 10% glucose will be necessary to maintain an acceptable serum level.

Seizures occur in 20% of children with bacterial meningitis and, occasionally, in those with viral infections of the CNS, such as meningoencephalitis due to herpes simplex virus (HSV). One should always be suspicious of derangement of the glucose or sodium as a cause of convulsive activity. However, most seizures are caused by irritation of the brain from the infectious process. They are controlled in the usual fashion with diazepam or lorazepam, fosphenytoin, and phenobarbital (see Chapters 69 and 96).

Subdural effusion and, less often, empyema occur in 20% to 40% of young children with meningitis but usually appear later in the course and remain asymptomatic. In the rare case of an infant with herniation caused by a subdural collection, percutaneous drainage relieves the pressure on the brain and produces significant improvement.

Occasional children with meningitis manifest signs of increased intracranial pressure (ICP), which requires appropriate supportive therapy. Although a few preliminary studies have suggested that measures directed specifically at lowering elevated ICP may be beneficial, this approach is not part of standard therapy.

Some studies have found that dexamethasone at a dosage of 0.15 mg per kg per dose given every 6 hours to children older than 2 months mitigates the sequelae of bacterial meningitis, particularly sensorineural hearing loss. The mechanism of action has been postulated to involve inhibition of cytokine production in the CSF. Although many clinicians choose to administer dexamethasone to patients beyond the first 2 months of life in whom the diagnosis of bacterial meningitis appears highly likely, contradictory evidence exists in the literature and expert panels have withheld a definitive endorsement. If the decision is made in favor of administration, the drug should be given before or shortly after antibiotic administration, when possible, because it appears to lose its theoretical benefit after an interval or more than 4 hours.

Aseptic Meningitis

Background

The aseptic meningitis syndrome is defined here as an inflammation of the meninges that occurs in the absence of bacterial growth on routine culture media. A child whose initial CSF findings suggest an aseptic meningitis may turn out to have a purulent infection because bacteria do not always elicit a marked polymorphonuclear leukocytosis early in the course of the disease. In addition, bacteria with unusual growth requirements, inhibited by subtherapeutic concentrations of antibiotics, or sequestered in pockets adjacent to but not directly communicating with the CSF, may produce an aseptic meningitis syndrome. Last, rare patients diagnosed initially with aseptic meningitis progress over time to develop clinical signs of encephalitis.

Both infectious and noninfectious diseases cause the aseptic meningitis syndrome (Table 92.11). By far, the most common

Kawasaki disease (? infectious)

cause is viral meningitis; however, the clinician should be alert to Lyme disease in endemic regions and to unusual pathogens in patients who are immunocompromised or who show atypical clinical features. Despite underreporting, the Centers for Disease Control and Prevention (CDC) notes about 5,000 cases annually in the United States.

Aseptic meningitis occurs throughout the year. Because the incidence of enteroviral infections, which are responsible for a large number of the cases, peaks in the summer in temperate regions, outbreaks of aseptic meningitis are more often seen in the warm months.

Pathophysiology

The multiple causes of aseptic meningitis syndrome produce inflammation of the meninges by different mechanisms. Even among the viral infections, the pathogenesis varies considerably. Some viruses lead to an immune reaction in the CNS, whereas others invade the neural tissue directly. Access to the meninges is usually hematogenous but may be achieved by ascension along peripheral nerves.

Clinical Manifestations

The signs and symptoms of aseptic meningitis resemble those of bacterial infections of the CNS but are not usually as severe. The infant shows only lethargy and irritability, whereas the older child complains of a headache, photophobia, and stiff neck. Vomiting may occur and may be persistent. There is often a history of a concomitant upper respiratory or GI viral illness. Fever usually occurs. The infant may appear toxic, but the older child may remain remarkably well. Nuchal rigidity in a patient who is alert and conversant suggests aseptic, rather than bacterial, meningitis. Shining a flashlight in the eyes often elicits photophobia. The fontanel of the infant generally maintains a normal configuration but may bulge rarely. Aside from occasional positive Kernig and Brudzinski signs, the neurologic examination often shows no abnormalities. An altered level of consciousness or focal neurologic deficit points to meningoencephalitis rather than aseptic meningitis (see Chapter 96).

Management

In addition to the routine CSF studies, children with aseptic meningitis usually require a CBC count, electrolytes, and a BUN. In regions where Lyme disease is endemic, consideration should be give to serologic testing for Borrelia. Most patients need no further tests, but in atypical situations, consideration should always be given to nonviral causes that may mandate additional diagnostic steps or specific therapy. If tuberculosis is suspected based on family contacts, a low CSF glucose with lymphocytic predominance, or pulmonary findings, then a Mantoux test and chest radiograph are useful for confirmation. In endemic areas, serologic studies for Lyme disease and antibiotic therapy may be indicated based on exposure history and time of year. A computed tomography (CT) scan provides essential information about patients with symptoms or signs of a parameningeal infection, HSV encephalitis, or CNS tumors and hemorrhages. Immunosuppressed patients develop infections with a wide variety of unusual bacteria, fungi, and parasites that can be identified in many cases with appropriate examination and culture of the CSF (India ink and acid-fast stains, cryptococcal antigen testing, fungal and mycobacterial cultures). In particular when dealing with infants in the first month of life, the physician must remain alert to the possibility of a HSV infection and consider both obtaining a PCR for HSV and initiating acyclovir therapy (60 mg per kg per day IV in three divided doses).

Therapy for the common viral infections does not currently extend beyond supportive care. Dehydration from prolonged emesis may necessitate IV fluid administration. After any deficit has been corrected, the rate should be set to provide 75% to 100% of the daily maintenance requirement to avoid overhydration and the possible aggravation of cerebral edema in the child who develops an encephalitic component.

Because the CSF findings in aseptic meningitis overlap those in bacterial infections, hospital admission is usually warranted until the CSF culture results are available. However, the experienced clinician may choose to follow the older child as an outpatient if the family is reliable and nonviral causes (e.g., Lyme Disease, tuberculosis, cryptococcosis) are clinically unlikely. Generally, to qualify for discharge with aseptic meningitis, a patient must have all CSF parameters pointing away from bacterial infection, for example, less than 500 cells per mm^3, less than 50% polymorphonuclear leukocytes, protein less than 100 mg per dL, and glucose greater than 30 mg per dL.

UPPER RESPIRATORY TRACT INFECTIONS

Infections in children involve the upper respiratory tract more often than any other region of the body. Included in this category are nasopharyngitis (common cold), stomatitis, pharyngitis, sinusitis, otitis, peritonsillar abscess, retropharyngeal and parapharyngeal abscesses, laryngotracheobronchitis (croup), and epiglottitis. The most common causative organism varies between sites as does the diagnostic and therapeutic approach. As a result it is useful to divide these infections into specific anatomic diagnoses to guide the clinician in further management.

Nasopharyngitis

Nasopharyngitis (URI), or the common cold, is a viral illness of the upper respiratory tract in children. The most commonly isolated organisms are the rhinoviruses and coronaviruses. Prospective family studies have shown that five or six episodes occur yearly during childhood. The illness is characterized by a fever lower than 39°C (102.2°F) and coryza. There may be a mild conjunctivitis and infection of the pharynx. Although the tympanic membranes may show a dull appearance and decreased mobility, the characteristic features of acute purulent OM (erythema, loss of the landmarks, and bulging) are absent. Therapy is limited to a recommendation for rest, adequate hydration, and antipyretic agents. Neither antibiotic nor decongestant therapy prevent secondary bacterial infections such as acute purulent OM. The use of antiviral agents or immunomodulatory therapy is not recommended.

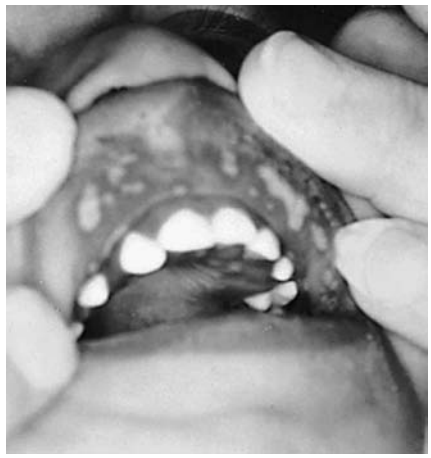

FIGURE 92.4 Lesions of herpetic stomatitis.

Stomatitis

Stomatitis, an infection of the mouth, is caused by herpes simplex and the coxsackieviruses at any age and by *Candida albicans* ("thrush") in the infant (see Chapters 122 and 123) or in the immunosuppressed child. Viral infections cause vesicular lesions initially (Fig. 92.4) and ulcerations and plaques subsequently. Some coxsackieviruses may involve the hands and feet (Fig. 92.5A) as well as the mouth (coxsackievirus hand-foot-mouth syndrome), and herpetic stomatitis may be complicated by spread of infection to the digits, which is called herpetic whitlow (Fig. 92.5B). For otherwise healthy patients, treatment is limited to systemic antipyretic and analgesic drugs and the local application of topical analgesics, such as 2% viscous Xylocaine® (do not exceed 3 mg/kg/dose) or the combination of Maalox® and diphenhydramine. IV or oral acyclovir, oral valacyclovir or oral famciclovir minimally shorten the course of disease in immunocompetent patients with stomatitis due to HSV if started within the first 24 hours of onset but should not be used routinely. Unless adequate hydration is ensured (typically the admitted patient receiving parenteral fluids) there is an increased risk of renal toxicity with these drugs. Therapy with one of these agents is recommended for HSV stomatitis in immunosuppressed patients but again hydration must be ensured.

C. albicans produces white plaques on the mucosa that bleed if scraped. Nystatin swish and swallow suspension (200,000 units four times daily) leads to a prompt resolution of this condition. Oral fluconazole is also an effective treatment but is not routinely indicated for the immunocompetent host.

Pharyngitis

Pharyngitis (see Chapter 71) is an infection of the throat (including the tonsils). In the immunocompetent child, several viruses, perhaps *Mycoplasma pneumoniae*, *Chlamydophyla pneumoniae*, and *Arcanobacterium haemolyticum*, and only a few bacteria cause pharyngitis. Common viral isolates include the adenoviruses, influenza viruses, enteroviruses (including coxsackievirus), parainfluenza viruses, and the Epstein-Barr virus (EBV). Although many bacteria may cause pharyngitis, only three organisms (group A streptococci, *Corynebacterium diphtheriae*, and *Neisseria gonorrhoeae*) have well-defined roles. Of these, only group A streptococcal infections have relevance to most clinical situations in children.

Pharyngitis is a common infection in children. Moffet et al. reported that 128 of 230 visits to an infirmary by youngsters of school age at a children's home were for pharyngeal infections. Group A streptococcus causes almost 50% of such infections between 5 and 15 years of age but is uncommon in the first 3 years of life. In one study of 50 children younger than 3 years old with exudative pharyngitis, only 7 had illness from group A streptococci.

For practical purposes, isolated pharyngitis can be considered as streptococcal (bacterial) or nonstreptococcal (viral).

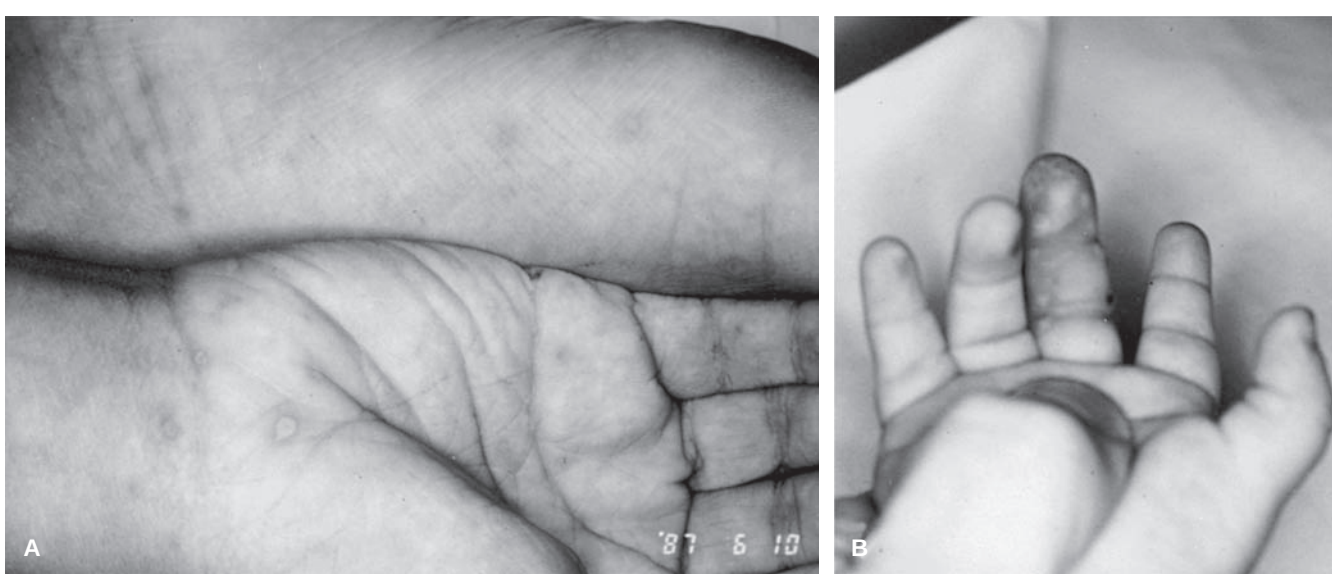

FIGURE 92.5 **A:** Vesicles in coxsackievirus hand-foot-mouth syndrome. **B:** Herpetic whitlow.

FIGURE 92.6 Examination of the pharynx in a child with streptococcal infection shows enlarged, erythematous tonsils with exudate.

Because the symptoms of the two types overlap, the physician can reliably distinguish the more important streptococcal infections only with the aid of the laboratory. However, certain clinical features favor a bacterial cause. Group A streptococcal pharyngitis is more likely to have an abrupt onset with fever and sore throat; whereas cough and coryza are uncommon. Examination of the pharynx reveals an erythematous pharyngeal mucosa, enlarged tonsils and exudate (Fig. 92.6) occasionally with petechiae on the posterior palate. In addition, the anterior cervical lymph nodes often become enlarged and tender.

Although unusual, complications may occur with bacterial pharyngitis; both suppurative and nonsuppurative sequelae can result from streptococcal infections. The latter category includes acute rheumatic fever and glomerulonephritis. Viral pharyngitis resolves spontaneously in 2 to 5 days with the exception of EBV, as discussed under the "Infectious Mononucleosis" section.

In the ambulatory setting, a tonsillar swab for antigen detection by latex agglutination or optical immunoassay should be obtained from children with pharyngeal inflammation and those who complain of sore throat, unless the diagnosis of a generalized viral syndrome can be confidently established on clinical grounds. If the test for antigen is positive the child is treated with penicillin. Although a single intramuscular injection of benzathine penicillin (600,000 units if less than 28 kg and 1.2 million units if 28 kg or more) obviates all problems with compliance, oral penicillin VK (250 mg per dose for children and 500 mg per dose for adolescents, given two to three times per day) prescribed for 10 days serves as standard therapy. Amoxicillin (40 mg per kg per day, given in two divided doses) may be used in place of penicillin but offers no advantage except possibly improved taste in the liquid preparation. Erythromycin (40 mg per kg per day) is used for penicillin-allergic children; azithromycin for 5 days (12 mg per kg once daily for 5 days, maximum single dose 500 mg) represents a more expensive alternative. Unlike the penicillins, resistance to macrolides may occur with group A streptococci and the rates of resistance, while generally low, may be high in some areas. Antipyretic agents, fluids, and adequate rest should be recommended. Among children with pharyngitis suggestive of streptococcal disease for which antigen detection is negative or unavailable, a throat culture is indicated. While awaiting the results of culture, one may choose to treat presumptively children with severe pharyngitis characteristic of streptococcal disease and those unable to reliably return for follow-up. Because antibiotics shorten the course of acute course of streptococcal pharyngitis only minimally, there is no reason to give these drugs hastily before confirming a bacterial cause. The prevention of nonsuppurative complications is generally accomplished even if treatment awaits confirmation by culture. Institution of a liquid diet and acetaminophen provide some symptomatic relief. In selected circumstances special culture methods should be employed, e.g. when *N. gonorrhoeae,* group C or group G streptococci are considered. *N. gonorrhoeae* should be considered in the sexually active adolescent and group C and group G streptococci may be considered in local outbreaks of pharyngitis where group A streptococci is known not to be the cause.

Otitis Media

Background

Otitis media refers to suppuration and inflammation within the middle ear. The disease can be further classified according to the associated clinical symptoms, specific otoscopic findings, duration, and occurrence of complications. Currently, the disease is divided into two broad categories (Table 92.12): acute otitis media (AOM) and otitis media with effusion (OME). AOM (formerly called acute purulent otitis media) is caused by an acute bacterial (or occasionally viral) infection, has a sudden onset, and usually causes symptoms. However, OME (formerly called serous otitis media) is not primarily bacterial in origin, has a more gradual onset, and often remains asymptomatic. A great deal of overlap exists between these two entities, such that clinical differentiation at a single

TABLE 92.12

CLASSIFICATION OF OTITIS MEDIA

Type	Duration	Bacteriology	Tympanum	Signs and symptoms
Acute otitis media	Days to weeks	Isolates in 70%	Erythematous or purulent, bulging	Fever (30%), earache (older child), irritability
Otitis media with effusion	Weeks to months	Occasional isolates	Dull, retracted, fluid level	Asymptomatic, decreased hearing, fullness

point in time may not be possible. The bacterial flora of middle ear infections varies somewhat with age. Although gram-negative enteric bacilli and *S. aureus* cause 15% to 20% of AOM during the first month of life, *S. pneumoniae, H. influenzae,* and *Branhamella catarrhalis* predominate at all ages, even in the neonate. *S. pneumoniae* can be recovered from about 40% and *H. influenzae* and *B. catarrhalis* each from 20% of children with AOM between 1 month and 10 years of age. Among older children and adolescents, *H. influenzae* decreases in frequency but remains a significant pathogen. More than 90% of the *H. influenzae* that cause AOM are nontypeable,. Most *H. influenzae* and *Moraxella catarrhalis* are resistant to ampicillin and thus penicillin and amoxicillin. Among pneumococci, the incidence of penicillin resistance varies geographically and continues to evolve; at present, on average, 10% to 30% of these organisms exhibit decreased susceptibility to beta lactam antibiotics.

AOM concerns the emergency physician to a far greater extent than OME. It is the most common bacterial infection in children, affecting an estimated 9 million children annually. Howie et al. found at least one episode of OM in two-thirds of 2-year-old children in their practice, and one in seven children had more than six episodes. Teele et al. reported an average of 0.4 to 1.2 episodes of OM annually among children from birth to age 7 years. AOM is more common in the winter in temperate climates. This is presumably related to the higher incidence of URIs during the colder months.

Pathophysiology

Any discussion of the pathophysiology of OM provokes great controversy among pediatricians and otolaryngologists alike. However, it appears that abnormal function of the eustachian tube contributes to the development of OM in most cases. Possible mechanisms for obstruction of the eustachian tube include hypertrophied nasopharyngeal lymphoid tissue or intrinsic abnormalities of the various components of this structure. Whatever the cause, blockage impairs ventilation of the middle ear, leading to an accumulation of fluid behind the tympanic membrane. This effusion then provides a fertile environment for the proliferation of bacteria from the heavily colonized nasopharynx.

Clinical Manifestations

Studies by Howie, Paradise, Klein, and others showed the variable spectrum of OM. An infection in the middle ear may produce no symptoms, being detected only on examination, or it may cause obvious localizing pain. In the young child, the initial manifestation is often not otologic but rather fever, irritability, or diarrhea. Children older than the age of 3 years generally, but not invariably, complain of pain in the ear. Less common symptoms include vertigo and hearing impairment.

Fever occurs in 25% to 35% of children with AOM. The diagnosis of AOM rests in the usual clinical settings on the accurate interpretation of the otoscopic findings, a skill gained only by experience with the pneumatic otoscope (Fig. 92.7). If cerumen obscures the tympanic membrane, a sufficient quantity must be cleared to allow adequate visualization. Either a blunt curette or an apparatus for irrigation adequately removes such material in most cases.

The tympanic membrane in AOM typically bulges out at the examiner as a result of the positive pressure generated by the production of purulent material in the middle ear cavity. Although the drum is sometimes red, it may appear white or yellow because of the exudate behind it. A convex contour of the drum secondary to an effusion in the child suspected of having AOM is sufficient to make this diagnosis, regardless of the color of the membrane. The diffuse injection of the normal tympanum, which is often exaggerated by crying, should not be confused with the intense erythema of infection.

Difficulty arises in differentiating AOM from OME and in diagnosing "early" AOM, particularly in the child with a preexisting middle ear effusion. The tympanic membrane has decreased mobility in both AOM and OME; however, it is usually retracted in the latter condition. During the course of a single examination, the physician may be unable to differentiate with any certainty; in such cases, it is safest to assume a bacterial cause.

The WBC count, not indicated in a routine case, usually falls within the normal range or shows a mild leukocytosis, when obtained. Tympanocentesis, when performed, yields an organism in 60% to 70% of cases. Blood cultures are not more or less likely to reveal a pathogen among children with AOM compared to children with comparable fever without AOM. Acute complications occur only occasionally with AOM, subsequent to the advent of effective antibiotics. Local suppuration may involve the mastoids and rarely leads to meningitis, epidural or subdural abscess or brain abscess. Perforations of the tympanic membrane generally heal spontaneously (see Chapter 110). A child with OM in the first year or two of life may develop dehydration from vomiting and diarrhea associated with the infection.

Management

Uncomplicated AOM in the child older than 1 month should be treated with oral antibiotic therapy on an outpatient basis. Amoxicillin (90 mg per kg per day in two or three divided doses for 10 days) is the drug of choice in the United States. The most reasonable alternatives include (i) high concentration amoxicillin with clavulanic acid in a 14:1 formulation (90 mg per kg per day of amoxicillin in two divided doses for 10 days); (ii) cefdinir [14 mg per kg per day (maximum single dose 600 mg) given once daily for 10 days]; (iii) azithromycin [30 mg per kg (maximum 1,500 mg) as a single dose]; and (iv) ceftriaxone (50 mg per kg intramuscularly as a single dose). Cefuroxime axetil (30 mg per kg per day in two divided doses for 10 days) is an additional choice. Cephalosporins and azithromycin can be used in children with a history of penicillin allergy, but the latter agent has not been extensively studied. Intramuscular ceftriaxone has an advantage in children with persistent vomiting and perhaps in those at high risk of occult bacteremia, and also obviates the issue of compliance in high-risk social situations. Whether the course of therapy must be 10 days (except for single-dose ceftriaxone and azithromycin) or can be shortened is controversial. Most authorities believe antibiotics administered for 5 days are sufficient in children older than 2 years with uncomplicated AOM but prefer the longer course in infants. Antihistamines and decongestants have not hastened the resolution of AOM in published studies and are thus not indicated. It should not be forgotten that there is often pain associated with AOM and, therefore, the use of analgesics should be considered as well.

If AOM persists during therapy with amoxicillin or recurs within 2 days of its discontinuance, ampicillin-resistant

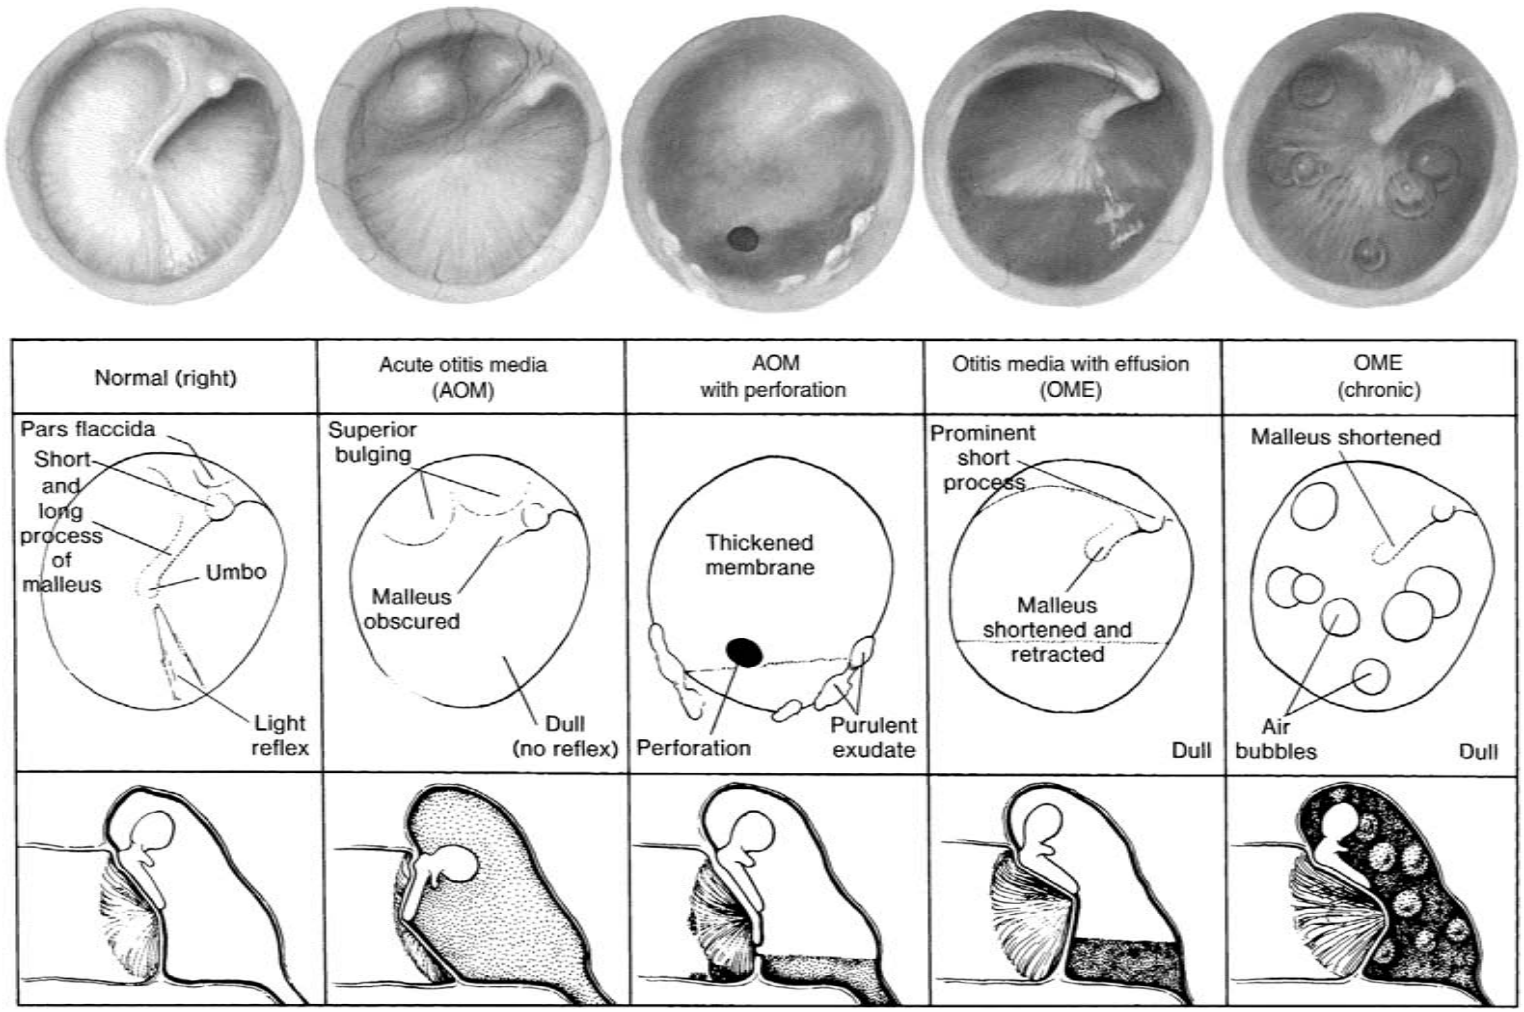

FIGURE 92.7 Appearance of the tympanic membrane in different types of otitis media.

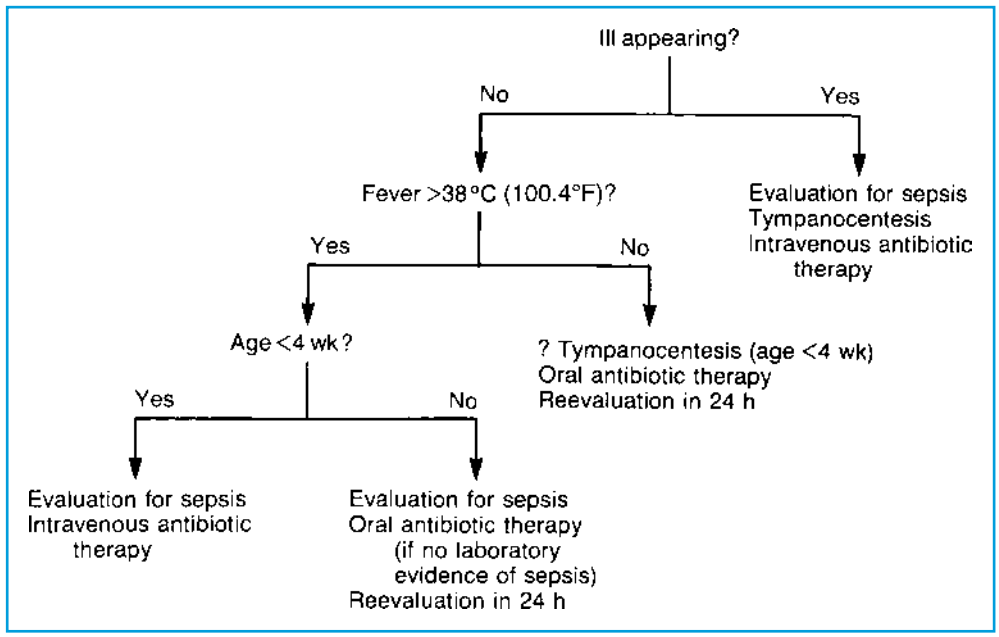

FIGURE 92.8 Diagnostic approach for the management of acute otitis media in the very young infant.

organisms are likely the cause of the infection if compliance with medication is assured. The alternatives to amoxicillin represent reasonable agents for a second course, and no compelling data favor any particular regimen. Failure of such a second course of antibiotics to eradicate the infection necessitates a third course of antibiotic therapy and merits consideration of a tympanocentesis for culture.

The management of AOM in the first month of life has provoked controversy because of (i) the occurrence of gram-negative enteric bacilli and *S. aureus* in middle ear infections in these children, and (ii) the decreased ability of the neonate to resist infection (Fig. 92.8). If a child younger than 1 month presents with fever or irritability and is found to have OM, in the opinion of many, admission for IV antibiotic therapy provides the safest course pending the outcome of cultures of the blood, urine, and CSF. Afebrile infants in the first month of life may be treated as outpatients with the usual oral antibiotics used for older patients and with careful follow-up.

Infants between 4 and 12 weeks of age with OM can be managed as outpatients because *S. pneumoniae, H. influenzae,* and *B. catarrhalis* are the predominant organisms. However, other sources of infection, including meningitis, must be excluded in the febrile child before attributing the source of a temperature elevation to OM alone.

Otitis Externa

Otitis externa (OE), or swimmer's ear, is an infection of the auditory canal and external surface of the tympanic membrane that spares the middle ear. Multiple organisms, particularly *Pseudomonas aeruginosa,* play a role in this disease. There is usually a history of recent swimming, but occasional cases are seen in children whose only submersion occurs during normal bathing. The first symptom is itching of the ear canal. The child complains subsequently of an earache that may be unilateral or bilateral, and purulent material often drains from the ear. Fever is never present unless cellulitis or another illness is associated. Unlike AOM, pulling on the ear lobe to straighten the canal in preparation for otoscopic examination elicits marked tenderness. A cheesy white or gray-green exudate fills the canal in more than 50% of patients, often obscuring the tympanum.

OE is at times confused with AOM. Although both may cause earache (see Chapter 54), the signs and symptoms usually make an exact diagnosis possible. Occasionally, the physician cannot distinguish OE from AOM with perforation and must treat for both disorders.

Treatment consists of removing the inflammatory debris from the ear canal, eliminating pathogenic bacteria, providing symptomatic relief, and controlling predisposing factors. Usually, dry mopping of the exudate with a cotton-tipped wire applicator cleanses the canal adequately; occasionally, gentle suction is also necessary. The patient should be given commercially available otic drops and a mild analgesic, such as aspirin or acetaminophen. Acetic acid solutions (Otic-Domeboro® or Vosol®) and the combination antibiotic–corticosteroid preparations (Cortisporin®, Lidosporin®), four drops instilled four times daily, or fluoroquinolines (ofloxacin and ciprofloxacin) are effective. The fluoroquinolines are more expensive but offer the advantages of fewer local allergic reactions and once daily administration. In cases with known or suspected perforations, suspensions (but not solutions) are preferred. For the occasional case of a patient with an edematous canal and thick exudate, a wick of cotton or gauze should be inserted 10 to 12 mm into the canal after cleansing to facilitate entry of the medications. All patients should be instructed to avoid swimming or to wear appropriately fitted earplugs until cured.

Children who return without improvement after initial therapy should be examined to be certain they have OE. If this diagnosis is confirmed, the canal should be cleansed again and an alternate medication prescribed. The occurrence of a local

cellulitis or adenitis requires the addition of an antistaphylococcal antibiotic, such as dicloxacillin (50 mg per kg per day) or cephalexin (100 mg per kg per day). Trimethoprim-sulfamethoxazole should be substituted if MRSA is common in the geographic area. Failure to respond to a second course of therapy or severe local inflammation (necrotizing OE) is an indication for referral to a specialist.

Sinusitis

Background

Sinusitis is an inflammation of the paranasal sinuses: maxillary, ethmoid, frontal, or sphenoid. The ethmoid and maxillary sinuses are present at birth, but the frontal and sphenoid do not become aerated until 4 or 7 years of age. Either an acute or a chronic infection may occur, each characterized by a different but overlapping group of symptoms. Among 2,613 patients seen in an office practice, Breese and Disney made this diagnosis in only 6 (0.23%), which may speak to its rarity or difficulty in ascertaining the diagnosis.

Wald et al. studied the bacteriology of sinusitis in children using cultures of material obtained by antral puncture. They recovered 47 organisms from 30 children: 17, *S. pneumoniae;* 11, nontypeable *H. influenzae;* 9, *M. catarrhalis;* 2, *Streptococcus viridans;* 7, group A streptococcus; and 1, *Moraxella* species. Hamory et al. found a similar spectrum of pathogens in adults with maxillary sinusitis. Although anaerobic organisms and *S. aureus* have been reported occasionally, they do not play a role in most of these infections seen in children. *H. influenzae* type b formerly caused ethmoiditis and periorbital cellulitis with great frequency but now occurs rarely.

Pathophysiology

Infection of the sinuses arises in a fashion similar to that described for AOM. Organisms ascend from the nasopharynx and cause disease if the mucosal barrier of the sinus or the normal pattern of drainage has been altered.

Clinical Manifestations

The presentation of acute sinusitis varies in some respects with the child's age. Usually, the infection follows a viral URI. Two features that distinguish sinusitis from a viral URI include persistent (longer than 10 days) and/or severe [temperature greater than 39°C (102.2°F) beyond 3 days] symptoms. Cough occurs in 75% of the patients. Unlike adolescents, young children do not often complain of a headache or facial pain. A fever is noted in about half of children with sinusitis. Nasal discharge occurs in almost all these infections and is often the symptom that prompts a visit. The area of the face that overlies the sinus swells in 10% to 20% of the patients with maxillary disease, and periorbital or orbital edema and cellulitis even more commonly accompany ethmoiditis.

The child with chronic sinusitis complains only of persistent cough (often worse when lying down) and rhinorrhea. Fever, headache, and facial pain are unusual. Recurrent wheezing may occur in children who suffer from underlying asthma. Often, abnormal findings are not seen on examination.

The WBC count, performed only occasionally, is normal in 60% to 80% of children with sinusitis. In 10% to 30% of these infections, transillumination of the sinuses shows a discrepancy between the two sides, but this is not sufficiently reliable to diagnose or exclude infection in the sinuses. Plain radiographs are abnormal in almost every child with sinusitis (Fig. 92.9); there may be an air–fluid level, complete opacification, or mucosal thickening (greater than 4 mm). Of 60 sinuses in 30 children evaluated radiographically by Wald et al., 4 were normal, 38 showed complete opacification, 15 showed mucosal thickening, and 3 showed an air–fluid level. Hamory et al. obtained radiographs on 43 patients with 58 episodes of sinusitis. Eighteen had an air–fluid level, 18 had opacification, 12 had mucosal thickening, and 10 had no abnormalities. A CT scan is more sensitive for diagnosis than plain radiograph but is not needed in routine cases. Unfortunately sinuses may be opacified with simple viral upper respiratory tract infections and, therefore, an abnormal radiographic study may be seen without bacterial sinusitis.

Although sinusitis usually responds to oral antibiotic therapy, serious complications occasionally result from the local spread of the suppuration. These include orbital infection, brain abscess, epidural or subdural empyema, and cavernous sinus thrombosis. Proptosis and paralysis of the extraocular muscles point to the accumulation of purulent material within

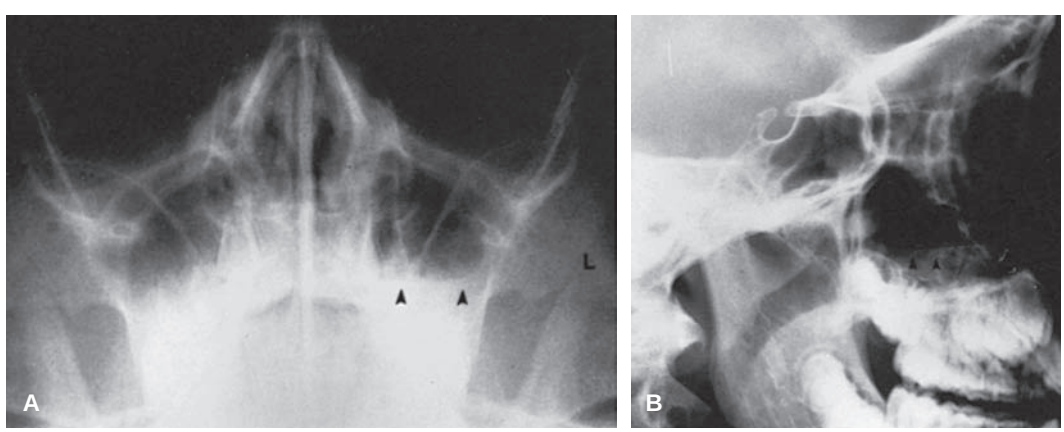

FIGURE 92.9 Anteroposterior (**A**) and lateral (**B**) radiographs show an air–fluid level in the left maxillary sinus *(arrowheads)* and mucoperiosteal thickening on the right side.

the orbit. After intracranial extension, the child appears toxic and usually has a detectable neurologic deficit.

Management

Children suspected of having acute sinusitis with severe symptoms or an uncertain clinical picture should have a radiograph evaluation of their sinuses. Among this group of patients clinically believed to be at risk for an infection, any abnormality (air–fluid level, opacification, or mucosal thickening) suffices to confirm the diagnosis. Afebrile children with chronic sinusitis diagnosed on the basis of persistent nasal discharge need no laboratory or radiographic evaluation. Possible indications for antral puncture and aspiration of the sinus include (i) associated life-threatening infection, (ii) immunocompromise, (iii) persistent illness despite therapy, and (iv) unusually severe disease. Amoxicillin (90 mg per kg per day divided into two or three daily doses) effectively treats the common pathogens, *S. pneumoniae* and nontypeable *H. influenzae,* in most cases. Current recommendations call for antibiotic therapy for 10 days although patients with chronic symptoms or underlying risk factors may require 14 to 21 days of therapy. Alternative drugs for penicillin-allergic children and those with recurrent disease are the same as for OM. Children with acute sinusitis require admission if they appear ill, have facial swelling and tenderness, or develop any complications.

Peritonsillar Abscess

A peritonsillar abscess, or "quinsy," results from the accumulation of purulent material within the tonsillar fossa. Adolescents develop this condition more often than younger children. Group A streptococci, various anaerobic organisms, and occasionally *S. aureus* are isolated from these lesions, which are unusual when compared to the frequency of uncomplicated tonsillopharyngitis.

The complaints of trismus and difficulty in speaking separate a peritonsillar abscess from the far more common pharyngitis. The voice sounds muffled, and the child drools profusely. Both tonsils may swell, but the enlargement of one is typically much more pronounced. Usually, the abscessed tonsil becomes sufficiently large to push the uvula to the opposite side of the pharynx, and the examiner may be able to palpate a fluctuant mass intraorally. The WBC count is often elevated but not needed for diagnosis.

All children with a peritonsillar abscess should have the lesion drained in the ED or, if admitted, after admission to the hospital followed by treatment with antibiotics. Amoxicillin (40 mg per kg per day divided into three daily doses) or amoxicillin-clavunate (40 mg per kg per day of amoxicillin component divided into three daily doses) are common oral selections. Ampicillin-sulbactam (200 mg per kg per day IV divided into four daily doses) or clindamycin (30 mg per kg per day IV divided into four daily doses) represent typical initial therapy. In the unusual case of a child with respiratory compromise, aspiration or drainage of the abscess can be life saving. This is accomplished by using an 18-gauge needle mounted on a 10-mL syringe or with a scalpel (see Chapter 123).

Cervical Lymphadenitis

Background

Cervical lymphadenitis is a bacterial infection of the lymph nodes in the neck. This condition must be distinguished from lymphadenopathy, an enlargement of one or more lymph nodes that occurs with viral infections, or as a reaction to bacterial disease in structures that drain to the nodes.

S. aureus and group A streptococci are the cause of acute suppurative lymphadenitis in most children with an identifiable pathogen. Of 74 children with this condition, Barton and Feigin isolated *S. aureus* from 27 (36%) and group A streptococci from 19 (26%). Other organisms that play a role in more chronic cases include mycobacteria and *Bartonella henselae* [cat-scratch disease (CSD)]. Rare causes include *Yersinia pestis* (plague), gram-negative bacilli, *H. influenzae* type b, *Francisella tularensis, Actinomyces,* and *Nocardia.*

Pathophysiology

The causative organisms in cervical adenitis initially colonize the nares or pharynx, or less commonly are inoculated transcutaneously. Dental abscesses may also be a source of pathogens. Regardless of whether they produce a local infection at the portal of entry, the bacteria can spread to the lymph nodes in the neck. If not contained by the immune system, they proliferate within the node and evoke an inflammatory response.

Clinical Manifestations

The child with cervical lymphadenitis is usually noted to have swelling in the neck. If sufficiently old, he or she will complain of pain. Fever occurs only occasionally, more often in children younger than 1 year. The infected node may vary in size from 2 cm to more than 10 cm. Initially, it has a firm consistency, but fluctuance (Fig. 92.10) develops in about 25% of the infected nodes. The skin overlying the node becomes erythematous, and there may be associated edema.

The WBC count is usually normal but may be elevated in the younger, febrile child. Aspiration of the node often identifies the organism by both Gram stain and culture, even if fluctuance is

FIGURE 92.10 Lymphadenitis in the inferior cervical chain. The node appears fluctuant.

not appreciated. Children with infections from *Mycobacterium tuberculosis* usually react to the standard purified protein derivative (PPD-S) skin test and may have changes compatible with tuberculosis seen on chest radiograph.

Complications of bacterial adenitis are unusual. Organisms such as *S. aureus* and group A streptococci can spread locally if unchecked. A draining sinus tract may develop in untreated children with atypical mycobacterial adenitis. Recurrence of infection suggests a local anatomic abnormality (e.g., branchial cleft cyst) or immunocompromising conditions such as chronic granulomatous disease.

Management

Figure 92.11 outlines the management of the child with cervical lymphadenitis. Children with cervical adenitis who are otherwise healthy should receive an antibiotic effective against *S. aureus* and the group A streptococci. Agents such as dicloxacillin (50 mg per kg per day) and cephalexin (50 mg per kg per day) have activity against both organisms. In more severe infections, oxacillin (100 to 200 mg per kg per day in four divided doses) can be administered intravenously. If the node is fluctuant, aspiration provides useful etiologic information and speeds the rate of resolution. All children with lymphadenitis should have a PPD skin test and be followed until the infection subsides. Clindamycin (15 to 25 mg per kg per day in three divided doses PO or 30 mg per kg per day IV) or vancomycin (40 mg per kg per day in four divided doses IV) offers alternatives in the face of penicillin and/or cephalosporin allergy or in geographic areas where coverage for methicillin-resistant *S. aureus* (MRSA) must be considered.

Children younger than 3 months and those who appear toxic or who have developed a draining sinus are best managed in the hospital. A failure to improve with oral antibiotic therapy or a positive skin test for tuberculosis necessitates subsequent hospitalization.

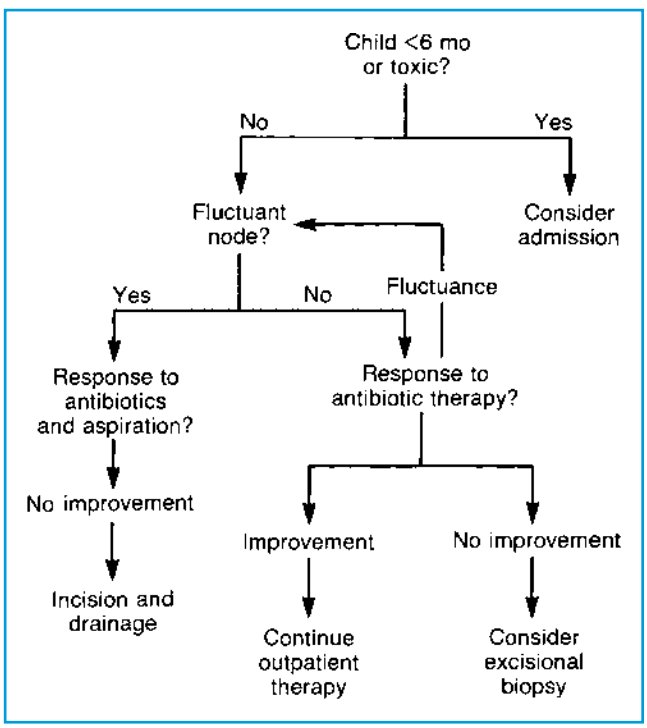

FIGURE 92.11 Diagnostic approach for the management of the child with presumed bacterial lymphadenitis.

Retropharyngeal and Lateral Pharyngeal Abscess

A retropharyngeal abscess fills the potential space between the anterior border of the cervical vertebrae and the posterior wall of the esophagus. The usual pathogens are group A streptococci, anaerobic organisms, and occasionally *S. aureus*. These infections occur most often in children younger than 4 years. A lateral pharyngeal (or parapharyngeal) abscess occurs in the deep soft-tissue space of the neck, but not in the midline, and is less common than a retropharyngeal infection.

The child with a retropharyngeal abscess may develop a clinical picture similar to that seen with epiglottitis, with a change in voice, high fever and a toxic appearance, but the onset is less abrupt; as purulent material collects, the fluctuant mass obstructs the larynx and esophagus, leading to stridor and drooling. Findings in less acute presentations include sore throat, neck pain, especially with movement of the neck from side to side, cervical lymphadenopathy, and, less commonly, torticollis. Inflammation surrounding the abscess may lead to meningismus; thus, this diagnosis should be considered in the child with nuchal rigidity but no pleocytosis in the CSF.

Although a retropharyngeal infection can rarely be seen as a midline swelling on examination of the pharynx, it is usually difficult to observe this finding in the uncooperative child. If the diagnosis is suspected and the airway is not threatened, a lateral neck radiograph or CT scan should be obtained. The radiograph shows an increase in the width of the soft tissues anterior to the vertebrae and, on occasion, an air–fluid level. In the child without retropharyngeal infection, the width of the retropharyngeal space is less than the width of the adjacent vertebral body in the young child at the upper cervical vertebrae (C2, C3) if the examination is performed with the neck properly extended. For children approaching school age and beyond the width of this space is typically less than half of the adjacent vertebral body at the mid cervical spine if the neck is properly extended.

A lateral pharyngeal abscess causes virtually identical symptoms to an infection in the retropharyngeal area. One important difference is that a lateral pharyngeal abscess, which is not well visualized by radiograph, requires a CT scan for confirmation. If sedation is to be given to facilitate CT imaging then consideration should be given to the possible need to secure the airway.

A retropharyngeal or lateral pharyngeal abscess poses a risk to the patency of the airway. All children with this infection should have careful monitoring in the ED and then be hospitalized in consultation with an otolaryngologist. Unless the airway is in immediate jeopardy, IV access should be secured and treatment given with either clindamycin (30 mg per kg per day in four divided doses) or ampicillin/sulbactam (ampicillin 200 mg per kg day in four divided doses). In the event of respiratory compromise, intubation or, less commonly, tracheotomy becomes necessary. Patients with smaller abscesses or phlegmon may be treated with antibiotic therapy alone; those with larger collections or persistent fever despite

therapy will require drainage, either transcutaneously with ultrasound guidance or at surgery.

Laryngotracheobronchitis (Croup)

Background

Croup, or laryngotracheobronchitis, is a viral infection that involves the larynx and may extend into the trachea and bronchi. It is a common infection, with thousands of cases of croup to every one of epiglottitis. Although most children with croup are treated as outpatients, some develop more pronounced respiratory distress and require hospitalization. Hoekelman reported that 3 (1.2%) of 246 healthy term infants in a pediatric practice developed croup during their first year of life. This infection is the most common cause for stridor in the febrile child (see Chapter 72).

Parainfluenza virus can be recovered from about 60% of children with croup. Additional causes of the disease are influenza, adenoviruses, measles, and respiratory syncytial virus (RSV). Bacteria play no role.

Croup occurs more commonly in the winter months. Children between the ages of 6 months and 3 years are most often affected. The diagnosis of croup in a child older than 3 years should arouse the suspicion of an underlying anatomic abnormality or foreign body.

Pathophysiology

The viral pathogens that eventually produce croup invade the epithelium of the pharynx initially. Spread occurs downward to the larynx and occasionally further along the respiratory tract. The infection causes endothelial damage, production of mucus, loss of ciliary function, and edema. Erythema and swelling of the vocal cords and the subglottic larynx are present. A fibrinous exudate partially occludes the lumen of the trachea.

Clinical Manifestations

Croup begins insidiously with the onset of fever and coryza. During the next 1 to 2 days, the infection spreads farther along the airway, producing signs of upper respiratory obstruction. Inspiratory stridor develops at this stage of the illness, and a barking cough is heard. The child may be unable to maintain adequate oral intake.

Although the severity of croup varies, most children appear mildly to moderately ill in contrast to the toxic patients with epiglottitis or retropharyngeal abscess. The fever usually ranges from 38°C to 39°C (100.4°F to 102.2°F). Tachycardia and tachypnea are evident, but the respirations rarely exceed 40 breaths per minute. Suprasternal and subcostal retractions often accompany croup. On auscultation of the chest, the examiner may hear either stridor alone in mild disease or rhonchi and wheezes with more extensive involvement of the respiratory epithelium. Cyanosis occurs only in the minority of children with severe croup.

Ancillary studies are indicated only occasionally. The WBC count is generally normal or mildly low; lymphocytosis may occur as with other viral infections. The lateral and anteroposterior neck radiographs may show subglottic narrowing ("steeple" sign) from soft-tissue edema in severe disease. However, most of the radiographic studies of the airway are normal or disclose only ballooning of the hypopharynx. Rather than confirm the diagnosis of croup, radiographic examination more often excludes other illness such as epiglottitis or retropharyngeal abscess. Although rarely indicated, analysis of ABG levels, which are normal in mild cases, may show hypoxia and/or hypercarbia, as respiratory fatigue ensues.

Both dehydration and upper airway obstruction may complicate croup. Because of the respiratory distress and the toxicity associated with a febrile illness, the ability to maintain normal hydration will decrease in some children. Dehydration then occurs in the face of increased fluid losses through the pulmonary and cutaneous routes.

Occasionally, a child with croup develops significant upper airway obstruction. Signs suggestive of impending respiratory failure include (i) hypotonicity, (ii) marked retractions, (iii) decreased or absent inspiratory breath sounds, (iv) depressed level of consciousness, (v) tachycardia out of proportion to the fever, and (vi) cyanosis. Although an ABG is not needed in the evaluation of children with mild croup, this study may play a role in deciding on the therapy in more severe cases. Respiratory failure is defined as a partial pressure of arterial carbon dioxide ($PaCO_2$) of 60 mm Hg or higher or a partial pressure of arterial oxygen (PaO_2) of less than 50 mm Hg in 100% oxygen. However, significant respiratory compromise is present in croup when the $PaCO_2$ rises over 45 mm Hg and the PaO_2 falls to less than 70 mm Hg in room air.

Management

Croup is usually apparent from the history and physical examination. Soft-tissue radiographs of the neck are needed only if the diagnosis is uncertain. Although visualization of the posterior pharynx/epiglottis is not advised routinely when epiglottitis is suspected, this examination may be performed to confirm the absence of tonsillar infection or an obviously enlarged epiglottis in cases in which one is confident that the diagnosis is croup.

Many children with croup are never taken to seek medical attention. Of those who come to the ED, most can be managed as outpatients. Clear indications for admission are dehydration and/or significant respiratory compromise. If any of the signs of respiratory failure are noted, hospitalization becomes necessary. Use of a scoring system may be helpful in deciding on disposition (Table 92.13). Neck radiographs and an ABG may be obtained in cases in which the clinical picture is inconclusive. In addition, the physician should consider the social milieu of the family. Hospitalization provides the safest course for the child when there is a concern about the ability of the family to return reasonably promptly with worsening symptoms.

Mist therapy serves as one of the traditional remedies for croup, but more recent studies have been unable to demonstrate the effectiveness of this modality. Because the viral origin of this disease has been well established, antibiotics play no role.

Racemic epinephrine, or L-epinephrine, is indicated for children with moderate to severe croup who will be hospitalized or for whom admission is being considered. The dose is 0.25 mL of racemic epinephrine, mixed with 3 to 5 mL of saline, delivered by nebulization. If a response is noted and discharge to home is contemplated, the child should be observed for at least 2 hours to be certain that the respiratory symptoms do not recur.

TABLE 92.13

SCORING SYSTEM FOR ASSESSING SEVERITY OF CROUP

	Croup Score			
	0	1	2	3
Stridor	None	Only with agitation	Mild at rest	Severe at rest
Retraction	None	Mild	Moderate	Severe
Air entry	Normal	Mild decrease	Moderate decrease	Marked decrease
Color	Normal	Not applicable	Not applicable	Cyanotic
Level of consciousness	Normal	Restless when disturbed	Restless when undisturbed	Lethargic

Croup Severity[a]		
Score	**Degree**	**Management**
All severity scores	Mild to severe	Most patients in the ED with croup should receive a single oral or intramuscular dose of 0.6 mg/kg dexamethasone (max 10 mg)
4	Mild	Outpatient—mist therapy
5–6	Mild to moderate	Outpatient if child improves in emergency department after mist, is older than 6 mo, and has a reliable family
7–8	Moderate	Admitted—racemic epinephrine
≥9	Severe	Admitted—racemic epinephrine, oxygen, intensive care unit

[a]Any one category with score of 3 leads to classification as severe disease.
Modified from Taussig LM, Castro O, Beaudry PH, et al. Treatment of laryngotracheobronchitis (croup): use of intermittent positive pressure breathing and racemic epinephrine. *Am J Dis Child* 1975;129:790–793.

Corticosteroids have long been mentioned as potential aids to the treatment of croup, but the early controlled studies on these agents failed to substantiate the early anecdotal successes. Subsequently, Leipzig et al. found dexamethasone effective in a controlled study in 1979, and a meta-analysis of the literature in 1989 supported the use of corticosteroids for hospitalized patients.

Therapy should be tailored to the severity of illness. In rare cases with inadequate gas exchange, management of the airway, at times with endotracheal intubation, takes precedence; tracheal edema may make passage of a tube with the usual diameter impossible, and the physician should be prepared with one a size smaller than typically expected. Patients in the ED who have concerning upper airway obstruction should receive prompt therapy with epinephrine by nebulization and parenteral dexamethasone at 0.6 mg per kg (maximum 10 mg). Patients with impending respiratory failure should receive epinephrine IM 0.01 mL/kg of the 1:1000 concentration (maximum 0.3 mL). For children with moderately severe croup, while hospitalization is being arranged, should also receive epinephrine by nebulization and parenteral (intramuscular or IV) or oral dexamethasone therapy. Patients with mild to moderate croup may be managed with an initial trial of mist, which has never been shown to have any efficacy, and either oral or intramuscular dexamethasone. Last, the majority of patients, who are only very mildly ill, require only instructions for antipyresis, oral hydration, and observation at home.

Epiglottitis

Background

Epiglottitis, or supraglottitis, is a life-threatening bacterial infection of the epiglottis and the surrounding structures. Rarely, trauma such as thermal injury to the epiglottis may cause swelling and clinical findings similar to those seen with infection.

Before the advent of a vaccine against Hib, epiglottitis occurred with regularity in children, accounting for 1 of every 1,000 pediatric admissions in the United States. It is now a rare disease in the pediatric population. Occasional cases are caused by the group A streptococcus. Although more common in the winter months, epiglottitis may occur throughout the year. The peak incidence during an era of greater prevalence fell between the ages of 3 and 7 years; however, infants and adults with epiglottitis have been well described.

Pathophysiology

The pharynx of normal children is often colonized with potentially pathogenic microorganisms such as *H. influenzae* and *S. pneumoniae*. Occasionally, these bacteria penetrate the mucosal barrier and invade the bloodstream. During the course of bacteremia, focal infection may occur at several sites, including the epiglottis and surrounding structures. Infection causes inflammatory edema, beginning on the lingual surface of the epiglottis, where the submucosa is loosely attached. The swelling progresses rapidly to involve the aryepiglottic folds, the arytenoids, and finally, the entire supraglottic larynx. Tightly bound epithelium on the vocal cords halts the spread at this level. The tremendous reduction in the caliber of the airway results in turbulent air flow on inspiration, appearing clinically as stridor.

Two possible mechanisms may explain the sudden respiratory arrest that can sometimes complicate this disease. The swollen epiglottis may be drawn into the glottis, acting like a plug to obstruct the flow of air, but this seems unlikely because the edematous, inflamed tissues of the supraglottic region become relatively tense. More likely, aspiration of oropharyngeal secretions occludes an already narrowed laryngeal inlet.

TABLE 92.14

EPIGLOTTITIS AND CROUP: A COMPARISON

	Epiglottitis	Croup
Anatomy	Supraglottic	Subglottic
Etiology	Bacterial (formerly *H. influenzae*)	Viral: parainfluenza
Age range	3–7 yr, adults	0.5–3 yr
Onset	6–24 h	24–72 h
Toxicity	Marked	Mild to moderate
Drooling	Frequent	Absent
Cough	Unusual	Frequent
Hoarseness	Unusual	Frequent
White blood cell count	Leukocytosis	Normal

Clinical Manifestations

Epiglottitis has an abrupt onset. The duration of illness before presentation is often as short as 6 hours and rarely exceeds 24 hours. Generally, parents first note the onset of fever. Shortly thereafter, the child develops stridor and labored respirations. As the disease progresses, the supraglottic edema interferes with the ability to swallow secretions; thus, drooling is a complaint in 60% to 70% of cases. Among children with epiglottitis, 50% complain of a sore throat. Aphonia, hoarseness, and cough are uncommon. Although both croup and epiglottitis manifest with stridor in a febrile child, the examiner can usually differentiate these two illnesses on the basis of the clinical features (Table 92.14).

The anxious appearance of most children with epiglottitis strikes the examiner immediately (Fig. 92.12). To maximize air entry, these children assume a sitting position with their jaws thrust forward. Cyanosis may occur in the later stages of the illness. The temperature, almost always elevated, often reaches a level of 40°C (104°F). Tachycardia is a constant feature. Although the patients are universally tachypneic, the respiratory rate rarely exceeds 40 breaths per minute. Stridor can be heard without a stethoscope, but auscultation of the lungs reveals no other adventitious sounds. Marked retractions are seen, predominantly involving the suprasternal and subcostal musculature.

As discussed under the "Management" section, rigorous attempts to visualize the epiglottis are hazardous and should

FIGURE 92.12 A 3-year-old girl with epiglottitis has an anxious appearance, assumes the "sniffing" position (**B**), and prefers to remain sitting (**A**).

FIGURE 92.13 A swollen, erythematous epiglottis after endotracheal intubation of a child with epiglottitis.

be avoided in the child with suspected epiglottitis. However, the examiner may view the pharynx without the use of a tongue depressor. The mucosa is seen to be erythematous, and pooled secretions are present in about half the children. Occasionally, a swollen, cherry red epiglottis (Fig. 92.13) protrudes above the base of the tongue and is visible without instrumentation.

Collection of laboratory specimens is usually delayed until the airway has been secured. The WBC count is elevated in most children with epiglottitis. Reports in the literature, addressing children with infections due to *H. influenzae* type b, describe a leukocytosis in the range of 15,000 to 25,000 per mm^3 and positive blood cultures in 80% to 90% of cases.

A lateral neck radiograph is pathognomonic of epiglottitis. There are three characteristic features: (i) a swollen epiglottis, (ii) thickened aryepiglottic folds, and (iii) obliteration of the vallecula (Fig. 92.14). The normal epiglottis has a thin, curved silhouette that has been likened to a bent finger, convex on one side and concave on the other. As a result of inflammatory edema from infection, it swells and assumes a configuration that is convex on both sides. This has been called the "thumb sign." The airway below the level of the vocal cords appears normal on the lateral neck radiograph of a child with epiglottitis.

The most serious complication of epiglottitis is sudden respiratory obstruction. This may occur unpredictably at any point in the illness, before seeking medical attention, in the ED, or after hospitalization. Although a child with minimal respiratory distress may occasionally have a total obstruction, marked retractions and labored breathing should serve as warning of an impending airway catastrophe. An additional complication of this illness is extraepiglottic spread of the infection. During the course of the bacteremia, seeding may involve the meninges, lungs, pericardium, synovial membranes, and soft tissues. Thus, the initial examination should attempt to elicit signs of infection at these additional sites.

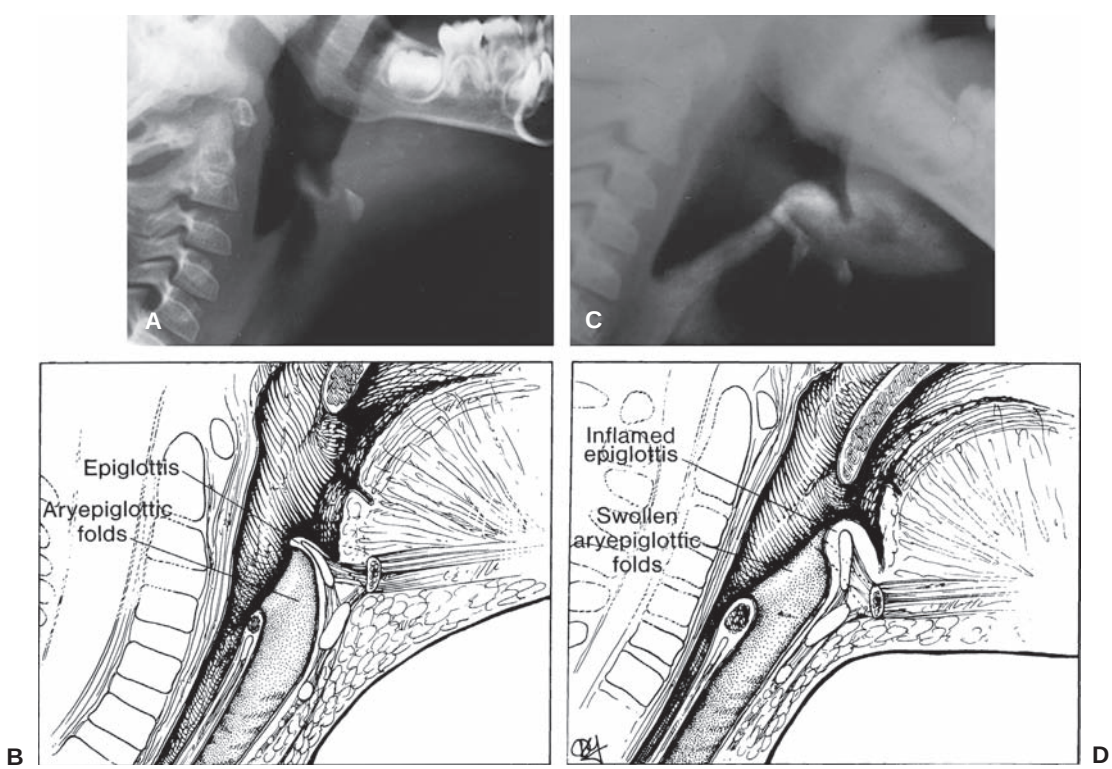

FIGURE 92.14 Appearance of the lateral neck region in a normal child (**A** and **B**) and a child with epiglottitis (**C** and **D**).

Management

When a child is suspected of having epiglottitis, the thrust of the management plan is to make a definitive diagnosis and institute therapy before the onset of airway obstruction. The major pitfall in this process is the vigorous examination of the posterior pharynx without having considered the possibility of supraglottic infection. Such manipulation may rarely initiate laryngeal obstruction in a small number of children with epiglottitis.

The initial steps in management are based on the degree of respiratory distress and the likelihood of epiglottitis, as judged from the clinical features (Fig. 92.15). Some children with epiglottitis have total or nearly total airway obstruction as the initial presentation of their disease. In this situation, treatment precedes any diagnostic evaluation and steps to maintain an adequate exchange of air are taken (see Chapters 1 and 5).

The majority of children, however, manifest lesser degrees of stridor and respiratory compromise with fever. The clinician must decide whether the constellation of historical and physical features points to croup or epiglottitis. In most children with stridor, the history will favor croup, which is the more common of the two diseases. The child will not appear toxic or show signs of air hunger. In such situations, a lateral neck radiograph is not indicated. Rather, the pharynx may be visualized directly with a tongue depressor to confirm the absence of a swollen, inflamed epiglottis.

When the findings weigh in favor of epiglottitis, however, further examination should be postponed and immediate preparation should be made for the insertion of an artificial airway; this includes collecting the necessary equipment and summoning additional personnel as needed. Anesthesiologists and otorhinolaryngologists alike, if available, should be involved in the care of children with epiglottitis, in addition to the staff in the ED. Following the appropriate preparations, a physician should accompany the child to the radiology department for a lateral neck radiograph, or a portable radiograph may be obtained. An IV infusion using a plastic cannula may be started in the cooperative patient. However, if the child becomes agitated or the procedure lengthy, the radiograph must be obtained quickly, assuming the airway has not been compromised, rather than persisting with attempts to gain IV access. The lateral neck radiograph either confirms or disproves the clinical diagnosis. If epiglottitis is verified radiographically, a skilled physician next performs endotracheal intubation, most often in the operating suite. If intubation is not possible, a surgical approach to the airway is necessary (Table 92.15).

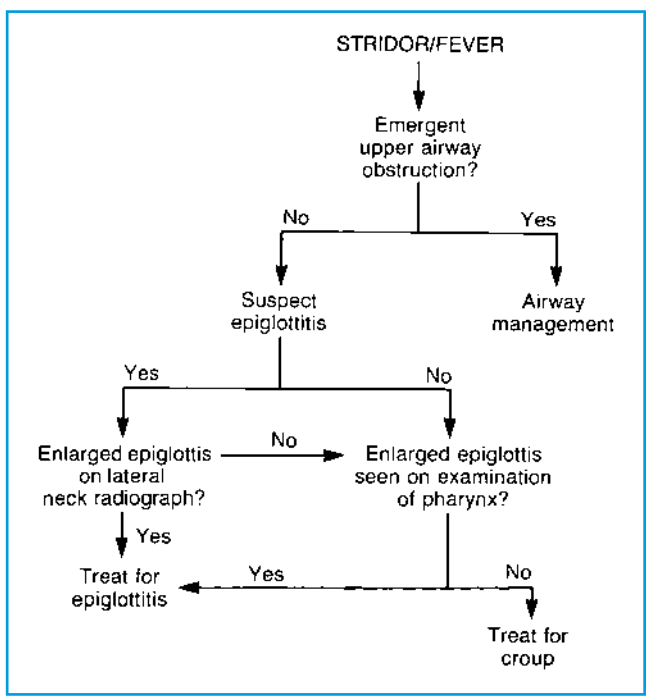

FIGURE 92.15 Diagnostic approach to the child with suspected epiglottitis.

TABLE 92.15

IMMEDIATE MANAGEMENT OF EPIGLOTTITIS

Insure adequate ventilation
Gain peripheral venous access, if tolerated by the child
Endotracheal intubation (or tracheostomy), providing bag-mask ventilation as needed
Defer laboratory studies until airway is secured

A review of the mortality statistics in epiglottitis emphasizes the importance of an artificial airway in the management of this illness. Rapkin described a fatal outcome in 20% of the children treated with antibiotics and observation alone. In 1978, Cantrell et al. summarized 749 cases of epiglottitis. The mortality varied with the method of airway management as follows: tracheostomy, 3 deaths in 348 children (0.86%); endotracheal intubation, 2 in 216 (0.92%); no artificial airway, 13 in 214 (6.1%).

Ceftriaxone (100 mg per kg per day in one or two divided doses) and cefotaxime (200 mg per kg per day in four divided doses) provide appropriate antibacterial coverage. Vancomycin (45 mg per kg per day in three divided doses) and aztreonam (120 mg per kg per day in three divided doses) offers an alternative for patients allergic to penicillins or cephalosporins. Steroids have not been shown to play a role in epiglottitis.

Bacterial Tracheitis

Infections of the trachea, presumed to be bacterial, were originally described in the period from 1920 to 1940. Although an uncommon and, in the past, occasionally disputed entity, increasing reports of bacterial tracheitis confirm that this disease represents an occasional concern. The etiologic agents are *S. aureus* and *H. influenzae* type b, the latter occurring rarely at this point in time. Patients may range from infants to young children.

Clinical Manifestations

Published reports indicate that the signs and symptoms of bacterial tracheitis mimic those of acute epiglottitis but with a somewhat slower onset. The fever is usually greater than 39°C (102.2°F), and the patients are stridorous. Toxicity and respiratory distress occur as a rule. On radiograph, there is tracheal narrowing, and a pseudomembrane may be visible within the tracheal lumen; the supraglottic area is normal.

Management

Children with bacterial tracheitis are often diagnosed initially as having severe viral croup or epiglottitis. Their management is as outlined for these conditions. The first priority is to secure an adequate airway. If bacterial tracheitis is suspected on the basis of a lateral neck radiograph or the findings at laryngoscopy, intravenous antibiotic therapy should be initiated with vancomycin (45 mg per kg per day in three divided doses) and ceftriaxone (100 mg per kg per day in one or two divided doses) or ampicillin–sulbactam (200 mg per kg per day of ampicillin in four divided doses). Aztreonam (120 mg per kg per day in three divided doses) offers an alternative for penicillin-allergic patients. Admission to an ICU is essential.

LOWER RESPIRATORY TRACT INFECTIONS

The most common lower respiratory tract infections in children include bronchiolitis and pneumonia, which may be caused by various bacteria or viruses, *Chlamydia trachomatis, M. pneumoniae, or C. pneumoniae*. Approximately 1 of 50 children in the United States has pneumonia annually. In a 12-year study of approximately 125,000 patients enrolled in the Group Health Cooperative of Puget Sound, the incidence of childhood pneumonia from all causes averaged 19 per 1,000 per year. Occasional episodes of pertussis and pulmonary tuberculosis are also seen. More recently described agents are rare but can be remarkably severe and include *Hantavirus*, which occurs in patients with exposure to rodents; the coronavirus causing severe acute respiratory syndrome (SARS), and influenza.

Pneumonia is an inflammation of the lung tissue that may follow a noninfectious or an infectious insult. In the ED, the febrile child with an acute onset of pneumonia almost always has an infection. The causative organisms in pneumonia vary according to the age of the child (Table 92.16). Although viral agents account for 60% to 90% of pneumonia, bacteria, particularly *S. pneumoniae*, play a major role. *M. pneumoniae* increases in frequency after 4 years of age. Unusual causes of pneumonia in the immunocompetent child include *Legionella pneumophilia* (Legionnaires' disease), *M. tuberculosis, Hantavirus*, coronavirus (SARS), rickettsia (Q fever), fungi, and protozoa. Children with neoplasms, HIV, and other forms of immunocompromise show susceptibility to a variety of unusual pathogens, including *Pneumocystis carinii, Candida, and Aspergillus species* (see Chapters 93 and 97).

TABLE 92.16

LOWER RESPIRATORY TRACT INFECTIONS

Age	Infecting organism
<3 wk	Bacteria Group B streptococcus Gram-negative bacilli (*E. coli*, Klebsiella) *S. aureus* Viruses (CMV, rubella, herpes, RSV)
3 wk–3 mo	*Chlamydia trachomatis* Viruses (RSV, parainfluenza, adenovirus, influenza) Bacteria *S. pneumoniae* *S. aureus* *H. influenzae*
3 mo–5 yr	Viruses (RSV, parainfluenza, adenovirus, influenza) Bacteria *S. pneumoniae* *S. aureus* *H. influenzae*
5 yr–19 yr	Viruses (adenovirus, influenza) Bacteria *S. pneumoniae* *M. pneumoniae*

Bacterial Pneumonia

Background

Bacterial pneumonia is an inflammation of the pulmonary parenchyma caused by a bacterial pathogen. In the first weeks of life, the group B streptococcus and gram-negative bacilli cause most such infections (Table 92.16). Between 2 weeks and 2 months of age, viruses and *C. trachomatis* are most common but group B streptococcus and *S. pneumoniae* are the cause of many cases requiring hospitalization. Among the bacteria, *S. pneumoniae* predominates at every age beyond the newborn period. *H. influenzae* type b formerly ranked second to pneumococcus in children 2 months to 3 years of age but now occurs rarely in countries utilizing the conjugate Hib vaccine. *S. aureus* causes a severe, rapidly progressive but uncommon pneumonia in young children; 60% of these infections occur in the first year of life. Group A streptococcus is also uncommon but may also be severe, *N. meningitidis* has been described rarely, and anaerobic bacteria play a role primarily following aspiration.

Definitive studies on the relative frequency of the various pathogens have not been performed in a randomly selected outpatient population of children. Because an organism is not usually recovered from the blood, establishing an etiologic diagnosis requires recovery of the pathogen from either pleural fluid or the pulmonary parenchyma. However, pleural effusion accompanies only a minority of bacterial pneumonias, and a percutaneous or transtracheal aspiration of the lung, although safe, cannot be justified on children who are sufficiently well to be managed as outpatients. Thus, the data collected on hospitalized children or those with more severe infections must be extrapolated to estimate the spectrum of pathogens in uncomplicated bacterial pneumonia.

Pathophysiology

In most pneumonias, the pathophysiology remains unknown. Pathogens reach the lung, either by hematogenous dissemination or by aspiration. In *H. influenzae* type b pneumonia, the organism can be recovered from the bloodstream in 90% of children, often 1 to 2 days before the appearance of the infiltrate. This suggests that bacteremia precedes the pulmonary infection. However, bacteremia is found in only 5% of pediatric pulmonary infections with *S. pneumoniae* at the time of

diagnosis. Thus, aspiration must play a greater role in the pathogenesis of infections with this organism or else the preceding bacteremia resolves before the development of pneumonia.

Following invasion of the pulmonary tissue by bacteria, an acute inflammatory reaction ensues. There is an exudation of fluid and polymorphonuclear leukocytes, followed by the deposition of fibrin. Several days later, macrophages appear in the alveoli. The accumulation of fluid in a lobe of the lung leads to the characteristic lobar consolidation seen on the chest radiograph.

Clinical Manifestations

Bacterial pneumonia generally has an abrupt onset with fever, often accompanied by chills. A cough is a common but nonspecific complaint. The young child reacts to bacterial infection in the chest with lethargy and/or a decreased appetite. Occasionally, pleuritic involvement produces pain with respiratory effort.

The observation of the child at rest before the examination often provides the key to the diagnosis of pneumonia. Tachypnea out of proportion to the fever is sometimes the only sign, particularly in the first year of life. The infant who breathes at a normal rate, to the contrary, is much less likely to have a bacterial infection of the lung. A hasty effort at auscultation that disturbs the quiet infant obscures this finding.

Fever is almost universally present, ranging from 38.5°C to 41°C (101.2°F to 105.8°F). Grunting respirations in a young child should arouse a strong suspicion of pneumonia. Localized findings, more often seen in the child older than 1 year, include inspiratory rales, decreased breath sounds (sometimes the only abnormality), and less often, dullness to percussion. Gastric dilation may accompany pneumonia. Patients with lower-lobe pneumonia may present with abdominal pain; occasionally, the abdominal findings in pulmonary infections mimic appendicitis. With upper lobe pneumonia, the pain may radiate to the neck, causing meningismus; the diagnosis of pneumonia must, therefore, be considered in the child with nuchal rigidity and normal CSF.

In the ED, a chest radiograph often assists in the management of a child suspected of having bacterial pneumonia. Although a patient who is dehydrated with pneumonia occasionally may not have an infiltrate, the radiographic evaluation confirms or denies the diagnosis of bacterial pneumonia in most cases. This is important in a clinical setting not conducive to continuity of care. In addition, the radiograph may provide information on the disease process. A lobar consolidation is assumed to be of bacterial origin, needing treatment with antibiotics (Fig. 92.16), whereas a minimal, diffuse interstitial infiltrate in a previously healthy toddler suggests a viral infection that can be managed with symptomatic therapy or, in an adolescent, *M. pneumoniae*, calling for treatment with erythromycin or azithromycin. Bilateral involvement, pleural effusion, and pneumatoceles point to more severe disease.

Further laboratory studies are obtained only on specific indications. A WBC count may be helpful in differentiating viral from bacterial disease or in assessing the likelihood of bacteremia in the young child; the count often exceeds 15,000 per mm^3 and occasionally rises above 30,000 per mm^3 with bacterial invasion of the pulmonary parenchyma or the bloodstream. An elevated CRP correlates with the bacteremia and lobar infiltrates more closely than the WBC count but is rarely needed. A blood culture can be helpful when positive.

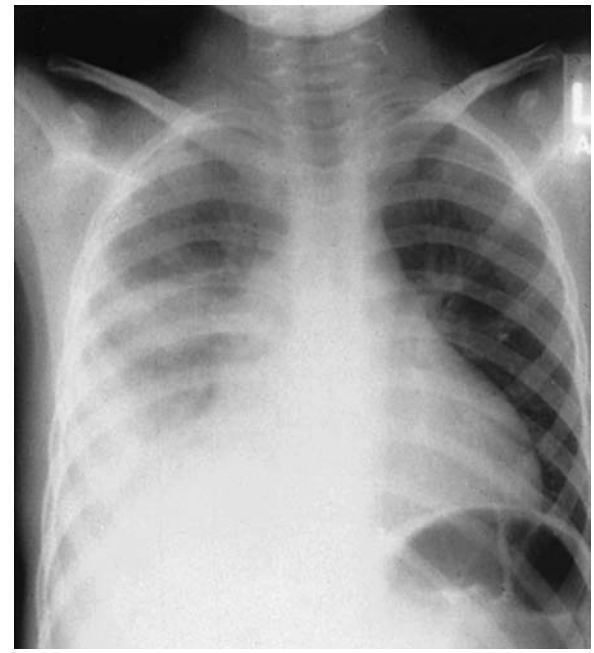

FIGURE 92.16 Radiograph showing lobar consolidation and pleural effusion in a child with bacterial pneumonia.

The most common complication of pneumonia is dehydration, particularly in young children. Electrolytes and a BUN are useful in assessing the degree of fluid loss in a child who appears ill or exhibits dry skin and/or mucosa. Rarely, extensive pulmonary involvement compromises ventilation, leading to respiratory failure. ABGs should be considered for any child with significant respiratory distress or transcutaneous oxygen saturation below 90%. A pleural effusion accumulates in many infections with *S. aureus* and *H. influenzae*, less often with *S. pneumoniae*. Bacteremia may result in additional foci of infection, including meningitis, pericarditis, epiglottitis, and septic arthritis.

Management

The large majority of healthy children with pneumonia respond to outpatient antibiotic therapy.

Because most of the bacterial pneumonias are caused by *S. pneumoniae*, amoxicillin (90 mg per kg per day given orally in three divided doses) has been the mainstay of therapy. Ceftriaxone (50 mg per kg) may be administered intramuscularly at the time of diagnosis, especially if there is any concern about oral intake during the first 24 hours. Alternatively, macrolides, including erythromycin (40 mg per kg per day in four divided doses) or azithromycin (10 mg per kg as a single dose on the first day and 5 mg per kg as a single dose on days 2 to 5), may be used in penicillin-allergic children or when mycoplasmal infection is suspected on the basis of age or radiographic findings.

Supportive therapy includes antipyretics and adequate hydration. Antitussives have no place in the treatment of pneumonia. Ill children should return within 24 to 48 hours for a second evaluation; patients who do not clinically improve and become afebrile should be evaluated carefully for admission to the hospital.

TABLE 92.17

INDICATIONS FOR ADMISSION IN CHILDREN WITH PNEUMONIA

Age <1 yr (lobar infiltrate)	Failure to respond to antibiotic therapy within 24–48 h
Respiratory compromise	Dehydration
Pleural effusion	
Pneumatocele	

Any child who appears to be toxic (on the basis of the physician's clinical judgment) or is immunocompromised should be hospitalized. Firmer, but not unarguable, indications for admission are listed in Table 92.17. The child younger than 1 year, as well as those who are older, do not tolerate bacterial pneumonia. In addition, potentially serious infections with *S. aureus* and *H. influenzae* type b occur more often in the first year of life. The radiographic detection of a pleural effusion or pneumatocele also suggests a pathogen other than *S. pneumoniae*. Whenever *S. aureus* is likely, coverage for MRSA should be strongly considered (e.g., clindamycin 30 mg per kg per day in three divided doses or, in severely ill patients, vancomycin 45 mg per kg per day in three divided doses per day). Effusions should be cultured by thoracentesis (see Procedures in Section VII), when possible, which requires subsequent observation of the child in the hospital. Although a persistent elevation of the temperature is well described in children with pneumococcal pneumonias that subsequently respond to penicillin, failure of the fever to defervesce within 24 to 48 hours after the administration of antibiotics suggests a greater likelihood of more virulent pathogens or a viral etiology.

Viral Pneumonia

Background

A number of viruses are able to infect the lungs of children and adolescents. Respiratory syncytial and parainfluenza viruses are the most common isolates, particularly in the first year of life. Other viruses, including influenza, adenoviruses, enteroviruses, rhinoviruses, measles, varicella, rubella, herpes simplex, cytomegalovirus, EBV (rare), metapneumovirus, coronavirus (SARS), and *Hantavirus*, can cause pneumonia. Pulmonary disease complicates infections with influenza and varicella more often in the adolescent. The annual incidence of viral pneumonia peaks in the first 5 years of life at 40 per 1,000, and then declines with advancing age.

Pathophysiology

Most viruses that cause pneumonia initially invade the epithelium of the upper respiratory tract and spread locally to the lungs. The infection evokes an inflammatory response that consists primarily of mononuclear cells. After infection, the epithelial cells slough into the airway and obstruct the bronchi, producing the hyperinflation characteristically seen on chest radiograph.

A few viruses may reach the lungs by hematogenous dissemination. These include measles, varicella, rubella, cytomegalovirus, herpes simplex, and EBV.

Clinical Manifestations

Viral pneumonia generally has its onset over a 2- to 4-day period, being more gradual than with bacterial infection. Cough, coryza, and low-grade fever commonly occur. Particularly with RSV infections in the first 3 months of life, an apneic spell may be the first sign to draw attention to the illness.

Fever in viral pneumonia is usually lower than 39°C (102.2°F). As with bacterial infections, tachypnea in the undisturbed child may be the only physical finding. Rales are often audible diffusely throughout the chest, and wheezing may also be present. With more severe disease, the child shows signs of respiratory failure: grunting, cyanosis, and changes in mental status.

The WBC count varies widely in viral pneumonia. Although leukocytosis over 15,000 per mm^3 may occur in some cases, such elevated counts should arouse suspicion of bacterial disease.

The radiographic examination provides useful clues to the type of pathogen that causes a pneumonia but can never confirm a viral infection or rule out a bacterial cause. Most typically, the radiograph in a child with viral pneumonia shows bilateral air trapping and peribronchial thickening. A diffuse increase in the interstitial markings is also commonly seen. However, the findings can vary from barely detectable increases in volume to segmental infiltrates. Decubitus films occasionally detect small effusions. Because of the limitations in obtaining reliable cultures for bacteria, it is safest to presume a bacterial cause in the child with clinical evidence of pneumonia and a lobar infiltrate, a pleural effusion, a temperature greater than 39°C (102.2°F), or signs of clinical toxicity. Particularly in a dehydrated child, the chest radiograph may fail to show a lobar consolidation early in the course of a bacterial pneumonia.

Most viral pneumonias resolve without specific therapy. Potential complications include dehydration, apnea, and local progression of the infection. Apnea may occur in the first 3 months of life.

Occasional patients initially appear to have an uncomplicated viral pneumonia and then go on to develop systemic manifestations. This picture of marked deterioration suggests pathogens such as *Hantavirus* or coronavirus (SARS).

Management

The physician must attempt to make an etiologic diagnosis in pneumonia on the basis of the clinical and radiographic findings without the benefit of definitive laboratory tests. A WBC count should be obtained if there is uncertainty about the likely cause. In such cases, a leukocytosis over 15,000 per mm^3 would weigh against a viral infection. In individuals with signs of systemic involvement for whom less common pathogens are being considered, a more extensive laboratory evaluation is merited.

If an uncomplicated viral pneumonia is strongly suspected, no specific therapy need be given. An example of such a situation would be a well-hydrated 5-year-old child with a gradual onset of cough, a temperature of 38°C (100.4°F), scattered bilateral rales, WBC count of 8,000 per mm^3 with predominantly lymphocytes, and the finding of hyperaeration on chest radiograph. Treatment in this case could be limited to antipyresis and hydration with a follow-up visit in 24 hours.

Because the infant younger than 3 months may become apneic during the course of viral pneumonia, these young children may benefit from observation in the hospital.

Mycoplasma Pneumonia

Background

M. pneumoniae is one of the most common causes of pneumonia among children older than 5 years. In younger children, infections with this organism are often limited to the upper respiratory tract or, occasionally, to the bronchial tree, although one study has implicated this organism as a common cause of pneumonia in children as young as 18 months. By the end of adolescence, 90% of the population has antibodies to *M. pneumoniae*.

Pathophysiology

The initial infection with *M. pneumoniae* occurs on the surface of the respiratory epithelium. Destruction of these cells causes them to slough into the lumen of the bronchi. The infection evokes an inflammatory response, primarily by mononuclear leukocytes.

Clinical Manifestations

Pneumonia caused by *M. pneumoniae* begins insidiously with fever, myalgias, headache, and malaise. After 3 to 5 days, the child develops a nonproductive cough, hoarseness, sore throat, and in one-quarter of cases, chest pain. Fever is almost invariably present and may reach a level of 40°C (104°F). Children seldom develop much respiratory distress, with the exception of those who are younger than 5 years old or also have sickle cell anemia or an immunodeficiency. Rales are heard in 75% of these infections, often bilaterally. The pharynx may appear inflamed, and some investigators have noted ear infections, particularly bullous myringitis, in association with pneumonia caused by *M. pneumoniae*. In 10% of patients, a maculopapular or, less often, a vesicular rash occurs; rarely, erythema multiforme, urticaria, or petechiae are seen.

The total WBC count is often normal in infections with this pathogen. A cold agglutinin titer of 1:32 or higher is found in most patients with lobar infiltrates from an *M. pneumoniae* infection but may also occur, although less often, with viral and bacterial illnesses. While not routinely indicated, the organism may be recovered from oropharyngeal specimens by culture or PCR. Alternatively antibody titers in acute and convalescent sera may be used to confirm the diagnosis. The radiographic findings show considerable variation. Between 10% and 25% of children will have lobar consolidation. Scattered segmental infiltrates, interstitial disease, and combinations of all these patterns may be seen. Pleural effusions occur in 5% of cases.

Numerous complications are described in association with *M. pneumoniae* infections, but they occur rarely. These include hemolytic anemia, arthritis, encephalitis, meningitis, and neuropathy.

Management

The diagnosis of mycoplasmal pneumonia is presumptively based on the clinical and radiographic findings and, in unusual cases, on the cold agglutinin titer or specific serologic testing. An older child or adolescent with the gradual onset of a mild bilateral pneumonia should be treated for this infection. However, a lobar infiltrate in a 5-year-old child is usually assumed to be of bacterial origin regardless of the level of the cold agglutinins. The results of cultures and specific serologic assays entail too great a delay to be useful to the clinician in the ED. Erythromycin (40 mg per kg per day in three to four divided doses) or azithromycin (10 mg per kg as a single dose on day 1, followed by 5 mg per kg daily as a single dose for four additional days) provide effective therapy for *M. pneumoniae* infections. The response is more pronounced in the older child with lobar disease than in the younger child with a diffuse infiltrate.

Chlamydia trachomatis Pneumonia

Background

C. trachomatis is the most commonly recovered pathogen from children with afebrile pneumonias between 4 and 12 weeks of age.

Pathophysiology

Among infants born to pregnant women with vaginal colonization by *C. trachomatis*, one-third to one-half acquire the organism. These infants are at risk for the subsequent development of pneumonitis. Pathologic examination in chlamydial pneumonitis shows a mononuclear consolidation with occasional eosinophils and neutrophils and marked necrotic changes in the bronchioles.

Clinical Manifestations

Infancy. Infants with chlamydial pneumonia usually have a dry staccato cough that may resemble the paroxysms seen in pertussis but is usually less prolonged. In 50% of cases, conjunctivitis precedes the onset of respiratory symptoms. Pneumonia with this organism only rarely produces a fever. Mild retractions, hyperresonance, and diffuse rales are noted on examination of the chest. Hyperaeration of the lungs depresses the liver, allowing the edge to be palpated 1 to 2 mm below the right costal margin. Because of the increased work of breathing these infants may not gain weight as expected.

Although the WBC count is usually in the normal range, the eosinophil count rises slightly (400 per mm^3, or 5% to 10%) in 75% of these patients. Elevated immunoglobulin levels, although nonspecific, often occur with chlamydial infections, but seldom with viral illnesses. Mild hypoxemia is common. The chest radiograph shows hyperaeration of the lungs and a diffuse increase in the interstitial markings. Lobar consolidations and pleural diffusions are not seen.

Although usually a mild illness, chlamydial pneumonia may be complicated by the occurrence of mucous plugging of the bronchi, apnea, and severe impairment of oxygenation. It is impossible to predict which infants with an initially mild course will have a stormy one.

Management

Because of the difficulty in making a definitive etiologic diagnosis and the potential for complications, young infants with

presumed chlamydial pneumonia should be considered for admission to the hospital. Azithromycin (10 mg per kg on day 1 and 5 mg per kg per day as a single daily dose for four additional doses) may shorten the course and should be given.

Chlamydophyla Pneumonia

Two species of *Chlamydophyla* cause pneumonia: *Chlamydia psittaci* and *Chlamydia pneumoniae* (TWAR). Psittacosis, a severe pneumonia caused by *C. psittaci*, is rare but should be suspected in patients with unusual avian exposures. *C. pneumoniae* causes pneumonia primarily in children older than 5 years. In a study from Seattle, the attack rate for this agent was approximately 0.5 to 1 case per 1,000 children (5 to 14 years old) per year, compared with 4 to 5 cases per 1,000 for *M. pneumoniae*.

Pathophysiology

C. pneumoniae spreads within families, day care centers, and schools.

Clinical Manifestations

The spectrum of infection ranges from asymptomatic to severe. Most children have seroconversion as evidence of infection that did not require any medical intervention. Adolescents are more likely to have signs of pneumonia than younger children, who may have clinical findings confined to the upper respiratory tract. Pneumonia is often preceded by sore throat and hoarseness, usually with a brief fever. By the time pneumonia has developed, the fever often resolves. Patients usually have a cough and scattered rales on auscultation. As for the clinical syndrome, the chest radiograph picture resembles that seen with *M. pneumoniae,* consisting of subsegmental lesions rather than lobar consolidation. Leukocytosis is not seen. No specific diagnostic testing is routinely available.

Management

C. pneumoniae infections in older children respond to therapy with macrolide antibiotics, including erythromycin (40 mg per kg per day in three to four divided doses) or azithromycin (10 mg per kg as a single dose on day 1, followed by 5 mg per kg daily as a single dose for 4 additional days).

Bronchiolitis

Background

Bronchiolitis is a pulmonary infection of young children characterized by wheezing. RSV causes most of these illnesses, but other viruses, particularly parainfluenza, influenza, and metapneumovirus may also cause bronchiolitis. In addition, *M. pneumoniae* has been reported as a rare cause of bronchiolitis.

The epidemiology of bronchiolitis primarily follows the pattern of its principal pathogen, RSV. Most of these infections occur in the winter and affect children between 2 and 8 months of age. Although some authorities do not accept the diagnosis of bronchiolitis after the age of 1 year, others believe that the disease occurs until the second birthday.

Pathophysiology

RSV, the most common cause of bronchiolitis, invades the epithelial cells of the nasopharynx and spreads to the mucosa of the lower respiratory tract by cell-to-cell transfer. The infection causes death of the cells that line the bronchi, which then slough into the lumen. The production of mucus increases, and mononuclear cells infiltrate the area. Clumps of necrotic epithelium and mucus initially decrease the diameter of the bronchi, causing turbulent air flow, particularly on expiration when the luminal diameter normally decreases. Eventually, plugging of the bronchi produces hyperinflation and atelectasis.

Clinical Manifestations

Bronchiolitis begins as a URI with cough and coryza. Over 2 to 5 days, signs of respiratory distress appear. The parents can often hear the child wheezing. Fever occurs in two-thirds of children with bronchiolitis. They often appear ill on overall assessment. The respiratory rate climbs to at least 40 breaths per minute and may reach 80 to 100 breaths per minute. Nasal flaring and retractions of the intercostal and supraclavicular muscles are noted and increase as the disease progresses. In bronchiolitis and other lower respiratory tract infections, the intercostal retractions are more pronounced than the supraclavicular, the opposite of the findings in croup and epiglottitis. Wheezes and a prolonged expiratory phase are heard in all children with bronchiolitis, at times without a stethoscope, and rales are usually minimal. As the ventilatory muscles fatigue, the child will have grunting respirations; only in the most severe cases does cyanosis occur.

The total WBC count in bronchiolitis is most often normal. Usually, the chest radiograph shows only hyperaerated lungs and peribronchial cuffing, but there may occasionally be areas of atelectasis. If respiratory failure supervenes, the Pa_{O_2} decreases and carbon dioxide is retained.

The complications of bronchiolitis include apnea, dehydration, respiratory failure, and rarely, bacterial superinfection. Pneumothorax and pneumomediastinum are rarely seen. The increased respiratory effort in bronchiolitis may prevent an infant from maintaining an adequate oral intake. Careful attention should be paid to the details of fluid balance when taking a history. Of infants with bronchiolitis, 10% to 20% develop significant respiratory compromise. Cyanosis (or an oxygen saturation less than 91%), decreased inspiratory breath sounds, and lethargy on examination point to ventilatory failure. Bacterial superinfection is uncommon in the early stages of the illness, occurring occasionally in hospitalized infants. However, lobar consolidation seen on the chest radiograph suggests a potential bacterial pneumonia, although areas of atelectasis may be confused with infiltrates.

Apnea has been a particular concern to pediatricians and emergency physicians because it has been considered to be unpredictable. In a more recent study by Willwerth and colleagues, 19 of 691 (2.7%) infants hospitalized with bronchiolitis developed apnea, but all had one of three high-risk criteria: full-term birth and age younger than 1 month; preterm birth (less than 37 weeks) and less than 48 weeks postconception; or report of a suspected apneic episode at home.

Management

In the management of children with suspected bronchiolitis in the ED, a chest radiograph should be considered to help exclude other entities such as lobar pneumonia or a foreign body. Pulse oximetry provides an estimate of the degree of hypoxia. A WBC count, ABG, and/or electrolytes are obtained only if the diagnosis is uncertain or the clinical picture suggests that complications have occurred.

Children with bronchiolitis may benefit from nebulized bronchodilators, although most recent studies suggest minimal, if any, efficacy from albuterol, salbutamol, or epinephrine. For the child with moderate to severe distress, a trial of nebulized broncholidators is reasonable, starting at 0.1 to 0.3 of a 0.5% solution of albuterol or using 3 to 4 mL of 1:1,000 epinephrine and reassessing after three treatments spaced 20 minutes apart. Patients who show a favorable response to nebulized therapy are candidates to receive further nebulized treatments. Oral albuterol solution has no proven efficacy.

Corticosteroids are not indicated for the treatment of patients with bronchiolitis. In general, it is difficult to differentiate asthma from bronchiolitis during the first 2 years of life; thus, corticosteroids may be given occasionally to some children who may have bronchiolitis or asthma, in accordance with the guidelines for the latter disease.

For the patient who does not respond to nebulized bronchodilator agents, therapy is limited to antipyretics, the encouragement of adequate oral intake, and reevaluation after 24 to 48 hours. Dehydration, secondary bacterial infection, and significant respiratory distress necessitate admission to the hospital. Although not validated in infants with bronchiolitis, a score of 4 or more on the asthma scale (see Chapter 82) suggests significant respiratory compromise. A transcutaneous oxygen saturation less than 91% to 93% or an arterial Pa_{O_2} less than 70 mm Hg in room air at sea level also suggests a need for hospitalization. In addition, children with underlying cardiac or pulmonary disease and those with high-risk factors for apnea should be considered for admission.

Pertussis

Background

Pertussis, or whooping cough, is an infection of the respiratory tract caused by *Bordetella pertussis*. Occasionally, a similar clinical syndrome is caused by *Bordetella parapertussis*, the adenoviruses, or *C. trachomatis*. Usually, young children most often contract pertussis, but the incidence in adolescents has increased more recently. Although vaccination has contributed to the significant decrease in the frequency of this disease, several thousand cases occur yearly in the United States among unvaccinated children and, to a lesser degree, among those who have received vaccine.

Pathophysiology

Following inhalation, *B. pertussis* organisms attach to the epithelial cells of the respiratory tract. Multiplication of the bacteria leads to infiltration of the mucosa with polymorphonuclear leukocytes and lymphocytes. Inflammatory debris in the lumen of the bronchi and peribronchial lymphoid hyperplasia obstruct the smaller airways, causing atelectasis.

Clinical Manifestations

Although pertussis can be divided into three stages for discussion, a clinically distinct syndrome does not evolve until the disease has progressed to the second stage. Initially, the symptoms mimic a viral URI. This first stage (catarrhal), characterized by a mild cough, conjunctivitis, and coryza, lasts for 1 to 2 weeks. An increasingly severe cough heralds the onset of the second stage (paroxysmal), which continues for 2 to 4 weeks. After a prolonged spasm of coughing often involving 10 or more coughs in succession, the sudden inflow of air produces the characteristic whoop (young infants lack the ability to generate sufficient negative inspiratory pressure and may, therefore, not whoop). Vomiting often occurs after such an episode. When not coughing, the child has a remarkably normal physical examination, except for an occasional subconjunctival hemorrhage. During the third stage (convalescent), the intensity of the cough wanes. At times, pertussis may present as a chronic cough without other signs of infection (see Chapter 15).

The WBC count in children usually reaches a level of 20,000 to 50,000 per mm^3 with a marked lymphocytosis, but such changes are not often seen in infants younger than 3 to 6 months. Although a chest radiograph occasionally shows the characteristic "shaggy" right heart border, more often the lung fields appear clear. *B. pertussis* can be identified by PCR of nasopharyngeal secretions, or less commonly, recovered by culture of this material if the specimen is obtained in the first or early second phase of the illness.

The fatality rate for pertussis is approximately 1% for patients in the first month of life and 0.3% for those between age 2 and 12 months. Complications often occur during a bout of pertussis. The most immediately life-threatening complication is complete obstruction of the airway by a mucous plug, leading to respiratory arrest. Although secondary bacterial pneumonia has a more insidious onset, it occurs in 25% of children with pertussis and accounts for 90% of the fatalities. Seizures are seen in 3% of patients, and encephalitis in 1%. Sudden increases in intrathoracic pressure can cause intracranial hemorrhages, rupture of the diaphragm, and rectal prolapse.

Management

The initial diagnosis of pertussis rests on clinical grounds. Children with an unmistakable paroxysmal cough followed by a whoop should be assumed to have the disease. When the clinical picture is unclear, a WBC count and chest radiograph may be useful. The radiograph helps eliminate other causes of a severe cough (e.g., foreign body, bacterial pneumonia, cystic fibrosis, tuberculosis), and the WBC count provides confirmatory evidence if a leukocytosis with marked lymphocytosis is found. Because of the grave risk of complications, all children younger than 3 to 6 months diagnosed firmly as having pertussis should be considered for observation in the hospital. While paroxysms typically resolve spontaneously, the younger child may have cyanosis and bradycardia at the end of paroxysms and seem to benefit from gentle stimulation often given as pats on the back. Older children who show signs of respiratory compromise, such as cyanosis during paroxysms of coughing, or who develop complications also require admission. Treatment includes erythromycin (40 mg per kg per day for 14 days) or azithromycin (10 mg per kg as a single dose on day 1, followed by 5 mg per kg per day as a single dose on days 2 to 5),

maintenance of adequate hydration, and a level of respiratory support appropriate to the severity of the disease. Household and other close contacts require chemoprophylaxis with erythromycin (40 mg per kg per day for 14 days) or azithromycin (10 mg per kg per day for 5 days). Children younger than 7 years who are unimmunized or have received fewer than four doses of pertussis vaccine should have their pertussis immunization initiated or continued as soon as possible after exposure. Children who are fully immunized for age but have received only three doses require a fourth dose. Those who have had four doses need a booster unless the last dose has been within 3 years or they are older than 6 years. DT_aP is preferred. For adolescents and adults requiring a tetanus booster, one should be given as Tdap to ensure adequate protection against pertussis.

Tuberculosis

Background

In the United States, tuberculosis is caused almost exclusively by *M. tuberculosis* and occurs in childhood in several clinical forms. Although currently an unusual infection in developed countries the disease should be kept in mind as an occasional, treatable cause of morbidity and mortality. At particular risk are children in urban, low-income areas and recent immigrants from underdeveloped countries. In addition, the emergency physician must be concerned about tuberculosis when either the patient or close contacts are infected with HIV (see Chapter 93).

Pathophysiology

Tubercle bacilli enter the body through the respiratory tract, producing an initial focus in the lungs. This lesion usually remains subclinical but may progress locally, resulting in a primary tuberculous pneumonia. During the primary infection, the organisms can disseminate hematogenously. Such spread may remain quiescent or, in a young child, may lead to miliary tuberculosis. Seeding of various organs occurs and may produce focal infections, a particularly serious concern with meningeal involvement.

Usually, the immune system limits the initial infection. However, reactivation of these foci may cause disease years later at any site involved during dissemination. Pulmonary lesions reactivate to produce tuberculous pneumonia in adults and adolescents much more often than in children.

Clinical Findings

Most infections by *M. tuberculosis* in children never cause any significant symptoms. Among the many possible clinical presentations, three stand out as particular concerns to the emergency physician: primary pneumonia, miliary tuberculosis, and meningitis. Pneumonia is by far the most common. Of note, these infections may develop despite prior vaccination against tuberculosis with Bacillus Calmette-Guerin vaccine.

The onset of primary tuberculosis pneumonia resembles that of bacterial infections of the lungs. It begins with fever and tachypnea; rales and an area of dullness are found on examination of the chest. The WBC count may be elevated with a shift to the left, and the chest radiograph shows a lobar consolidation, often accompanied by hilar adenopathy and less often by pleural effusion or cavitation. Although the primary pneumonia often resolves spontaneously, the child occasionally follows a downhill course caused by local progression. In addition to the epidemiologic risks described, clinical findings that should arouse a suspicion of tuberculous pneumonia in the child otherwise believed to have a bacterial infection of the lung include pleural effusion, cavitation, toxicity, and a failure to respond to antibiotic therapy.

Miliary tuberculosis begins with an abrupt rise in temperature but a paucity of other physical findings; it may mimic sepsis. Subsequently, respiratory symptoms and enlargement of the liver, spleen, and superficial lymph nodes occur. The WBC count is usually in the range of 15,000 per mm^3. Although the chest radiograph initially shows no lesions, a diffuse mottling of the lung fields appears 1 to 3 weeks after the fever. Miliary tuberculosis is a consideration in a child with a persistent fever and hepatosplenomegaly.

Tuberculous meningitis comes on insidiously with a low-grade fever, apathy, and in 50% of patients, vomiting. After 1 to 2 weeks of nonspecific illness, neurologic signs appear, including cranial nerve deficits, drowsiness and nuchal rigidity; if untreated, the child lapses into coma. The CSF shows a mononuclear pleocytosis, an elevated protein concentration, and eventually, a low glucose level. A CSF glucose level greater than 30 mg per dL would be distinctly unusual in a child with tuberculosis meningitis. Cranial CT imaging with contrast will typically reveal evidence of a basilar meningitis.

Management

A child suspected of having pneumonic, meningeal, or miliary tuberculosis should be admitted to the hospital for evaluation and possible chemotherapy. Among inner-city populations, where the risk of tuberculosis is greatest, the routine placement of a tuberculous skin test (Mantoux test) in children with lobar pneumonia should be considered. The Mantoux test must be interpreted in accordance with the child's age and the presence of risk factors (Table 92.18). Current treatment for tuberculosis

TABLE 92.18

DEFINITION OF POSITIVE CRITERIA FOR THE STANDARD MANTOUX SKIN TEST (5 TUBERCULIN UNITS OF PPD) IN CHILDREN[a]

Induration >5 mm
Children in close contact with known or suspected cases of active tuberculosis, if adequate and timely treatment cannot be verified
Children suspected to have tuberculosis based on a consistent chest radiograph or clinical findings
Children immunosuppressed on the basis of therapy or disease
Induration >10 mm
Children <4 years
Children with chronic illness, including lymphoma, diabetes mellitus, renal failure, and malnutrition
Children born in or traveling to regions of the world with a high prevalence of tuberculosis or exposed to adults likely to be infected
Induration >15 mm
Children ≥4 years without any risk factors

[a]Applies regardless of previous BCG vaccination.
Modified from Committee on Infectious Diseases. *2006 RedBook*. Elk Grove Village, IL: American Academy of Pediatrics, 2006.

consists of two to four or more drugs (isoniazid, rifampin, pyrazinamide, ethambutol, streptomycin, capreomycin, ciprofloxacin, cycloserine, ethionamide, kanamycin, ofloxacin, paraaminosalicylic acid) for a minimum of 6 months.

Hantavirus

The *hantavirus* pulmonary syndrome was described in 1994 among 17 adults, of whom 13 died with severe pneumonia and hypotension. In a subsequent series, 8 of 100 patients were 16 years old or younger. Rodents serve as the reservoir for the hantaviruses, of which several varieties infect humans. The syndrome begins with fever, cough, and myalgias, followed shortly thereafter by tachypnea, tachycardia, dyspnea, and finally, hypotension. A marked leukocytosis is common along with thrombocytopenia and elevated clotting studies. The initial chest radiograph shows an interstitial more often than an alveolar infiltrate, with changes starting or becoming bilateral in the majority of cases.

Pleural effusions occur in about one-fourth of the patients. The diagnosis should be considered when a severe pneumonia occurs in combination with systemic deterioration and can be confirmed subsequently by specific viral serology. Treatment is supportive.

Severe Acute Respiratory Syndrome

SARS affects predominantly adults, although a few cases have occurred in patients younger than 15 years. It is caused by a coronavirus and has an incubation period that typically ranges from 2 to 7 days. The illness begins generally with a prodrome of fever, which may be accompanied by headache, malaise, and myalgias. Some patients have mild respiratory syndromes and occasionally diarrhea is noted. After 3 to 7 days, a lower respiratory phase ensues with cough and then dyspnea, which may progress to hypoxemia and respiratory failure. Chest radiographs may either be normal or show focal interstitial infiltrates. Although the CBC count is usually normal initially, approximately 50% of patients develop leucopenia and thrombocytopenia at the peak of the respiratory illness. Elevated creatinine kinase (CK) levels and hepatic transaminases occur commonly. Treatment is primarily supportive. Although efficacy is unproven, ribavirin may be considered in patients with significant respiratory symptomatology.

GASTROINTESTINAL INFECTIONS

Gastroenteritis is an inflammation of the alimentary tract that, in its acute form, is overwhelmingly infectious in origin. Viruses are the organisms most commonly found in children with diarrhea in the United States and can be isolated from 30% to 40% of patients. In 10% to 15% of patients, bacteria are recovered, including *Salmonella, Shigella, Campylobacter, Yersinia*, and pathogenic *E. coli*; *Aeromonas hydrophila* and vibrio species, such as *Plesiomonas shigelloides*, are occasional pathogens. *Clostridium difficile*, which elaborates a toxin, may cause colitis, particularly after the use of antibiotics. Parasitic infestations rarely lead to diarrhea in developed countries. *Giardia lamblia* and *Cryptosporidium* should be considered, particularly in outbreaks in day care centers, and *Entamoeba histolytica*, among immigrants or travelers from tropical areas; cryptosporidiosis also commonly affects patients with HIV. Current diagnostic techniques are unable to identify an etiologic agent in most of the remaining episodes.

In the United States, GI infections rank second in frequency to respiratory tract infections during childhood. An estimated 30,000,000 children with gastroenteritis receive treatment at home each year, 3,000,000 visit a physician, and 200,000 require hospitalization. Approximately 12% of all hospitalizations of children 1 month through 4 years of age include diarrhea among one of the top three positions on the list of discharge diagnoses. Almost 400 children die annually in the United States from infections of the GI tract.

Viral hepatitis is covered in Chapter 89. Bacterial infections of the liver and bacterial cholangitis, almost exclusively abscesses, are rare in otherwise healthy children; more commonly, they complicate either an anatomic malformation or an immunosuppressive condition, or they affect the neonate.

Because calculi in the bile ducts rarely occur before adolescence, cholecystitis occurs much less often in children than in adults. Occasionally, episodes are seen in teenagers or children predisposed to stone formation, as in the chronic hemolytic anemias. Less commonly, salmonellosis, leptospirosis, Kawasaki disease, or drug therapy produces acalculous cholecystitis.

In childhood, peritonitis almost invariably reflects an intraabdominal catastrophe that requires surgical intervention. However, the accumulation of ascitic fluid in children with diseases such as nephrosis and cirrhosis allows the development of a primary infection of the peritoneum.

Viral Gastroenteritis

Background

Viral gastroenteritis occurs primarily in two forms caused by different pathogens. The human calciviruses (norovirus and sapovirus) produce an illness characterized by an explosive onset and vomiting, more severe than the diarrhea that accompanies it. The symptoms are self-limiting, resolving in 2 to 3 days. Infections occur in epidemics, most often in the winter, and affect predominantly school-age children. Rotavirus, however, produces a prolonged diarrheal illness of varying severity. It occurs more often in young children, although older family members may be affected. Other viruses, including enteroviruses, coronaviruses, and adenoviruses, may play a role in gastroenteritis.

Viral gastroenteritis is common. Among U.S. families, it trails only the common cold in frequency. Rotaviruses are the most commonly isolated pathogens, particularly among children who develop dehydration. Viral infections of the GI tract cause considerable loss of time from school and occasionally require treatment in the hospital.

Pathophysiology

Rotaviruses invade the intestinal epithelial cells, where they can be visualized by electron microscopy. The histology of the mucosal layer is disturbed during the active infection and for 3 to 8 weeks afterward. Functional abnormalities accompany the morphologic changes, including depressions of disaccharidase levels. Although calcivirus may invade the mucosal lining

of the intestine, they have not been detected intracellularly. Histologic changes occur and persist for 2 weeks, and disaccharidase levels decline during the infection.

Clinical Findings

Children with viral gastroenteritis develop diarrhea and/or vomiting. The numbers of stools may vary from 2 or 3 to 15 or 20 daily. Most commonly, there are 6 to 8 bowel movements in a 24-hour period; the stools range from semisolid in consistency to watery. Although hematochezia may occasionally occur in viral infections, the presence of blood in the stool should suggest a bacterial gastroenteritis. Vomiting may accompany diarrhea or be the sole manifestation of a viral gastroenteritis. The daily frequency of emesis varies in the same range as for diarrhea. After forceful emesis, streaks of blood may be present in the vomitus. Many children with viral gastroenteritis older than the age of 2 or 3 years complain of crampy abdominal pain. Parents may relate a history of decreased oral intake and, in more severe cases, oliguria.

Children with viral gastroenteritis are usually febrile, occasionally highly so. However, in the child older than 3 years, a temperature higher than 39°C (102.2°F) may suggest a bacterial enteritis. Tachycardia, hypotension, and lethargy may reflect dehydration in moderate to severe episodes. Whereas the respiratory rate is usually normal, tachypnea occurs when acidosis and/or dehydration are present. The abdomen is soft and nondistended in most cases. Although the child may perceive palpation as uncomfortable, this maneuver does not elicit localized or rebound tenderness. Auscultation reveals hyperactive bowel sounds. The skin turgor is decreased and the mucous membranes are dry, when gastroenteritis leads to clinically detectable dehydration (see Chapters 17, 18, and 100).

No laboratory studies are indicated in the uncomplicated case of gastroenteritis. The CBC count, electrolytes, and BUN usually fall within the normal range. If oral intake fails to keep pace with the efflux of fluids from the alimentary tract, dehydration occurs. The sodium, usually normal, may drop as low as 110 mEq per L or rise to 170 mEq per L, and the bicarbonate is often low. With mild dehydration, the serum bicarbonate hovers just below the normal level at 18 to 20 mEq per L; however, values of 10 to 12 mEq per L may be found in the face of prolonged diarrhea. The BUN reflects the state of hydration and the adequacy of the recent intake of protein. It may climb rarely as high as 50 to 60 mg per dL in children who lose 10% to 15% of their body weight, although mild elevations (20 to 30 mg per dL) occur more commonly. In a child who has been maintained on clear liquids, however, the BUN will not accurately indicate the degree of dehydration because urea arises as a breakdown product during protein metabolism. Although the hemoglobin and WBC count are usually normal in the child with viral gastroenteritis, hemoconcentration may occur with dehydration.

Management

Uncomplicated viral gastroenteritis usually remits in 2 to 5 days and does not require treatment in the hospital. All children should be weighed, preferably with minimal clothing, to provide a baseline for follow-up. The vomiting will generally respond to a brief cessation of oral intake. After 2 to 4 hours of abstinence, the diet should be resumed gradually. The diarrhea may persist for several days, but hydration can usually be maintained orally after the vomiting has subsided.

Current recommendations for oral therapy emphasize the use of appropriately balanced glucose and electrolyte solutions, as well as the early reintroduction of feedings. Generally, rehydration is initiated, particularly in infants younger than 1 year, with a solution that contains 75 to 90 mEq per L sodium in a ratio with glucose of 1:1 (e.g., Rehydralyte®). Older children often tolerate juices and sodas. Some studies have advocated the use of glucose polymers (e.g., Ricelyte®) instead of glucose as a means to reduce diarrhea, but significant advantages have yet to be demonstrated for these products. Preparation at home of fluids that contain salt notoriously leads to errors, and this procedure is to be condemned. Similarly, the physician should avoid the use of boiled skim milk, a hypertonic solution that may produce hypernatremia.

The antiemetic ondansetron may be helpful in selected children coming to the ED for care. By providing some improved ability of the child to tolerate oral intake, there may be more opportunity to manage these children as outpatients. Ondansetron can be administered orally, as an orally disintegrating tablet or intravenously (0.15 mg per kg, maximum 8 mg, as a single dose or an age based regimen [see drug formulary section]) to improve the ability of the child to maintain hydration. Trimethobenzamide (Tigan®) appears to be ineffective as an antiemetic in children. The phenothiazine compounds reduce emesis somewhat, but they occasionally produce adverse side effects, such as extrapyramidal reactions or oculogyric crises that limit their usefulness. Antidiarrheal medications to reduce stool output are not commonly used in children, as some of these drugs may carry significant risks to infants, especially those with bacterial enteritis. Loperamide (0.5 mg per kg per day) has been shown to reduce the severity of diarrhea in conjunction with oral rehydration therapy, but is indicated only for unusually severe or prolonged cases of gastroenteritis after excluding a cause that would respond to specific therapy. Although administration of the combination of diphenoxylate and atropine (Lomotil®) may be successful in adults, toxic reactions in children limit its usefulness. A few studies have suggested a small benefit from bismuth subsalicylate (Pepto-Bismol®), but this agent is not recommended for routine cases.

Dehydration is the only significant complication of viral gastroenteritis. If the physician suspects that a child has developed more than 5% to 10% dehydration, electrolytes and a BUN should be obtained. These tests establish the degree of acidosis and the presence of hyponatremia or hypernatremia.

Most children with gastroenteritis tolerate oral rehydration. In underdeveloped countries, even patients with severe dehydration are often managed successfully by using the oral route. However, in the ED, treatment for children with moderate to severe dehydration is usually initiated intravenously. As a rule, all patients with dehydration estimated to be greater than 10%, and many cases falling in the range of 5% to 10%, receive IV fluids.

When IV therapy is chosen, a bolus of fluid, such as 10 to 20 mL per kg normal saline or normal saline with 5% dextrose, may be administered over 1 hour, or more rapidly if needed (see Chapter 3). As some children with moderate to severe dehydration develop mild hypoglycemia, it is reasonable to perform a rapid test of serum glucose and administer a bolus of dextrose (0.5 to 1 g per kg) or use glucose-containing solutions, when indicated. If rehydration is achieved and the child is capable of subsequent oral intake, treatment may be continued at home (as in the milder cases).

Children who are more than 5% dehydrated or have alterations in the serum sodium (less than 130 mEq per L or more than 145 mEq per L) may require hospitalization. IV therapy should be started in the ED, particularly if there is evidence of vascular instability (see Chapters 3, 17, 18, and 100).

Bacterial Gastroenteritis

Background

Five bacterial pathogens commonly produce gastroenteritis: *Salmonella, Shigella, Yersinia, Campylobacter,* and pathogenic *E. coli.* Together, these organisms cause 10% to 15% of the diarrheal illnesses seen in children coming to the ED (Fig. 92.17). In underdeveloped countries and occasionally in the United States, *Vibrio* species must also be considered. In addition, *A. hydrophila* has been associated occasionally with diarrheal illnesses in children. *C. difficile* causes toxin-associated colitis, particularly in patients who receive antibiotics.

Salmonella, Shigella, Yersinia, and *Campylobacter* do not normally inhabit the alimentary tract. Thus, recovery of one of these organisms suffices for the diagnosis of gastroenteritis. *E. coli*, however, is part of the normal bowel flora, only occasionally assuming a pathogenic role. Serotyping is useful for detecting *E. coli* O157, which along with related strains is capable of inducing hemolytic uremic syndrome, but identification of other disease-producing strains is not readily available to the clinician.

Pathophysiology

Salmonella species gain access to the small intestine following ingestion. Gastric acid is usually lethal to the organism, but large numbers of bacteria may overcome this defense mechanism. Patients with gastrectomies (or taking agents that inhibit the production of gastric acid) are more susceptible to *Salmonella* infection than those with an intact, normally functioning stomach. *Salmonella* can penetrate the epithelial layer to the level of the lamina propria and evoke a leukocyte response. Generally, the infection extends no further, but bacteremia may occur, especially in young children. Several species, notably *Salmonella choleraesuis* and *Salmonella typhi,* readily enter the circulation through the lymphatics. *Salmonella* produce diarrhea by multiple mechanisms. Several toxins have been identified; in addition, prostaglandins that stimulate the active secretion of fluids and electrolytes may be released.

Certain *Shigella* attach to binding sites on the surface of the intestinal mucosal cells. The organisms penetrate the cells and proliferate within them. Intraepithelial multiplication destroys the cell and produces mucosal ulcerations. Invasion of the epithelium evokes an intense inflammatory response. At the base of the ulcerated lesions, erosion of blood vessels may lead to bleeding. Other species of *Shigella* elaborate exotoxins that can produce diarrhea. These toxins result in increased secretion of fluid and electrolytes by the intestinal mucosa.

Although the pathophysiology of infection from *Yersinia enterocolitica* has not been completely elucidated, clues are available from animal models and occasional pathologic specimens. The organisms are believed to produce terminal ileitis; inflammatory changes and ulcerations have been visualized with endoscopy. The infection elicits a neutrophilic response, particularly around the Peyer's patches. It then extends to the mesenteric lymph nodes, which are destroyed by microabscess formation and may enlarge considerably. Occasionally, further dissemination occurs with involvement of the liver and spleen.

Campylobacter utilize mobility and chemotaxis to navigate the gastrointestinal epithelial surface, appear to produce adhesins and cytotoxins and possess the ability to survive within macrophages, monocytes, and epithelial cells but predominantly within vacuoles. At present the mechanism by which diarrhea results is not known. Mesenteric lymphadenitis and ileocolitis are common. Extraintestinal complications or bloodstream invasion is rare among patients with intact humoral immunity and phagocytosis.

E. coli may produce diarrhea on the basis of several characteristics. Disease-producing strains have been classified as enteropathogenic, enterotoxic, enteroinvasive, enteroaggregative, enteroadherent, and enterohemorrhagic. The risk of developing hemolytic uremic syndrome after infection with *E. coli* O157 is estimated to be 10% to 15% in children.

Clinical Manifestations

Signs and Symptoms. A careful epidemiologic history often provides a clue to the diagnosis of Salmonella infections. Foodborne outbreaks usually occur in the summer. After an

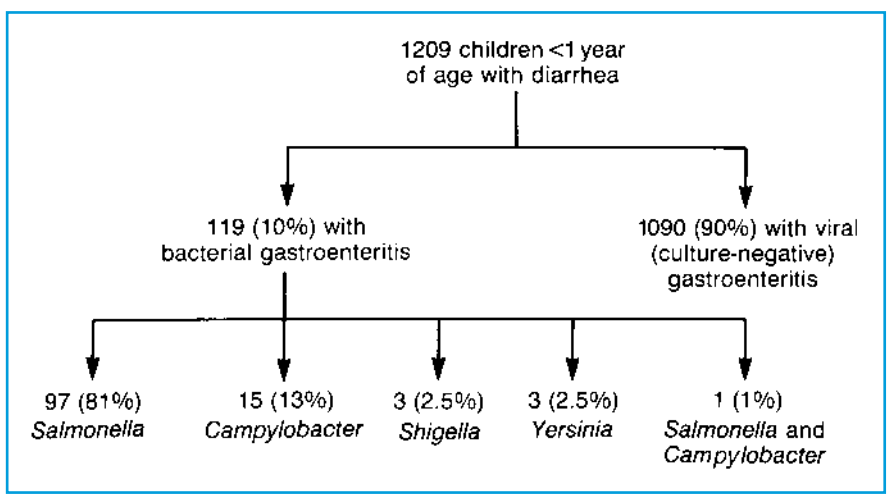

FIGURE 92.17 Etiology of gastroenteritis among consecutively cultured infants younger than 1 year in an urban emergency department. (Reprinted from Torrey S, Fleisher G, Jaffe D. Incidence of *Salmonella* bacteremia in infants with *Salmonella* gastroenteritis. *J Pediatr* 1986; 108:718, with permission.)

incubation period of 8 to 48 hours, the child experiences crampy abdominal pain and nausea. The stools are watery and may contain blood, but this is not the rule. Fever is noted in most children. Unless protracted diarrhea has led to clinically apparent dehydration, the physical examination is unremarkable. Abdominal tenderness and distension are occasional findings. The leukocyte count is usually 10,000 to 15,000 per mm^3. Methylene blue staining of the stool may show the presence of polymorphonuclear leukocytes but not in sheets as seen with *Shigella*. A single rectal swab leads to isolation of *Salmonella* from more than 90% of children with this infection.

Shigella may cause an asymptomatic infection, mild gastroenteritis, or bacillary dysentery. Mild illnesses are more common. Children affected in this way complain of frequent watery stools but few constitutional symptoms. The temperature remains normal in many cases, and the physical examination is unremarkable.

Bacillary dysentery from *Shigella* begins suddenly with fever and abdominal pain. Diarrhea begins shortly thereafter. The stools, which may average 10 to 12 daily, contain mucus and blood, and tenesmus is common. Children with this form of shigellosis have a fever, often in the range of 39°C to 40°C (102.2°F to 104°F). Palpation of the abdomen often elicits diffuse tenderness but no evidence of peritoneal irritation.

Occasionally, a *Shigella* infection may produce CNS irritation because of the release of toxin before the onset of diarrhea. Thus, shigellosis must be considered in the differential diagnosis of meningismus in the absence of a pleocytosis in the CSF. A seizure may actually be the first manifestation of the illness.

Certain laboratory abnormalities strongly suggest *Shigella* as the cause of gastroenteritis. The leukocyte count often shows many band forms that exceed the mature neutrophils in number. One study described this phenomenon in 85% of 123 children between the ages of 2 months and 8 years with shigellosis. The total WBC count may show a leukopenia or a leukocytosis but most commonly hovers in the normal range. Because *Shigella* invades the intestinal mucosa, this infection elicits a profound inflammatory response. The exudation of white cells leads to the finding of sheets of neutrophils in the stool after methylene blue staining. A single rectal swab suffices for the isolation of *Shigella* from most children with this illness. Children with gastroenteritis caused by *Y. enterocolitica* usually have an abrupt onset of diarrhea. The stools are often watery and may contain blood, but vomiting generally remains inconsequential. Patients with this illness often complain of severe abdominal pain, sometimes before the onset of diarrhea. Delorme et al. noted this symptom in 6 of the 35 children studied, half of whom were 1 to 5 years old. In an epidemic in a school in New York State, 37 of 38 patients had abdominal pain; the potential severity of the abdominal pain in this disease is illustrated by the fact that 16 patients in this outbreak mistakenly underwent an appendectomy.

Gastrointestinal infection with *Y. enterocolitica* usually elicits a febrile response. The mean temperature in the young adolescents reported by Black et al. was 38.7°C (101.6°F), with a range of 37.2°C to 40°C (99°F to 104°F); it exceeded 37.8°C (100°F) in more than 95% of patients. Younger children appear to develop a fever less often. The abdominal examination is usually benign, but palpation produces marked tenderness in the subset of patients with mesenteric adenitis. Arthritis and skin rashes occur in 5% to 10% of patients with this disease.

The mean WBC count in children with yersiniosis is usually normal, although leukocytosis with a shift to the left occurs occasionally. The electrolytes and BUN are normal except in the face of dehydration. Examination of stool stained with methylene blue reveals polymorphonuclear neutrophils. The organism can be recovered from stool culture but requires enrichment techniques. Although a single specimen is diagnostic in 70% to 80% of illnesses, a second sample should be obtained in the face of a previous negative culture when the clinical suspicion of disease remains strong.

Campylobacter enteritis is characterized by the abrupt onset of fever and abdominal pain, followed shortly by diarrhea. The temperature often remains normal in children younger than 3 months old, but ranges up to 40°C (104°F) in the older child. Vomiting occurs uncommonly and resolves rapidly. Two-thirds of children complain of abdominal pain, which may be severe. The number of stools varies from 2 to 20 daily; they are watery and contain blood in at least 50% of cases. The physical examination is generally unremarkable. Although the abdominal pain occasionally simulates appendicitis, palpation of the abdomen elicits minimal tenderness. Signs of dehydration are found only rarely.

The WBC count in *Campylobacter* enteritis usually remains below 12,000 per mm^3, the highest being 22,500 per mm^3 in one study; on occasion, there may be a shift to the left. The electrolytes and BUN are usually normal. Maki et al. found fecal leukocytes in four of five patients with enteritis caused by *Campylobacter*. The organism is not often isolated from the blood but can be recovered easily from the stool by using appropriate media. When available, phase contrast microscopy can demonstrate the organism in fresh stool specimens.

The clinical picture of diarrhea caused by *E. coli* varies. This organism is suspected most often in the setting of a specific outbreak.

In general, features suggestive of a bacterial rather than a viral gastroenteritis include (i) more than ten stools per day or diarrhea lasting for more than 4 days, (ii) blood in the stool, (iii) fever of 39.5°C (103°F) or higher, (iv) clinical toxicity, and (v) polymorphonuclear leukocytes in the stool. The presence of these findings enhances the likelihood that a bacterial pathogen is involved, although a viral gastroenteritis is not necessarily ruled out.

Complications. The complications of *Salmonella* gastroenteritis include dehydration and spread of infection beyond the confines of the GI tract. During bacteremia, focal infections, including meningitis, osteomyelitis, and endocarditis, may develop. However, most episodes of bacteremia terminate spontaneously, except perhaps in neonates and children with hemoglobinopathies. Dehydration is diagnosed on the basis of the clinical findings: dry mucous membranes, decreased skin turgor, tachycardia, and hypotension. Although the electrolytes are most often normal, both hyponatremia and hypernatremia may occur.

Bacteremia is most common in young children. In a study by Hyams et al., 25% of hospitalized patients with *Salmonella* gastroenteritis had the organism recovered from their blood. However, Torrey et al. noted an incidence of only 6% in an ambulatory population. Although a high fever

usually accompanies spread to the circulation, the physical examination is often devoid of any signs of serious illness. In addition, infants in the first 3 months of life often remain afebrile in the face of bacteremia. The WBC count is greater than 15,000 per mm^3 in 80% to 90% with bacteremia, and culture of the blood leads to recovery of the organism.

Enteric fever also occurs from the dissemination of certain serotypes of *Salmonella;* if *S. typhi* is isolated, the illness is called typhoid fever. The disease is characterized by chills and fever, often rising in a steplike pattern to 40°C (104°F). Diarrhea does not necessarily precede or coexist with the systemic illness. A relative bradycardia in relation to the height of the temperature is a hallmark of enteric fever. Splenomegaly and a macular rash, or rose spots, are detectable in 20% to 30% of patients. Leukopenia characterizes the hematologic picture. Both blood and stool cultures may be negative.

Invasion of the bloodstream may lead to various focal diseases. Meningitis most commonly affects the youngest children. The features are identical to those observed in CNS infections with other purulent organisms. Children with sickle cell hemoglobinopathies have a peculiar predilection for bone and joint involvement. Endocarditis is less commonly seen.

The complications of shigellosis include dehydration, bacteremia, seizures, and colonic perforation. Dehydration often accompanies dysenteric infections and is diagnosed on the basis of the usual clinical findings. Bacteremia and perforation are both rare, occurring in far fewer than 1% of GI infections.

Most episodes of gastroenteritis with *Yersinia* are self-limiting, resolving before dehydration develops. Appendicitis occasionally results from obstruction of the appendiceal lumen by swollen lymphoid tissue. The incidence is unknown, but 5 of 38 patients in the aforementioned New York State epidemic underwent removal of appendices that were suppurative. Bacteremia and focal infection follow gastroenteritis almost exclusively in the compromised host, particularly in association with thalassemia.

Campylobacter infections occasionally lead to dehydration, but less often than is seen with the other bacterial pathogens in the GI tract. Rarely, bacteremic or focal infections occur.

Management

Salmonella gastroenteritis is usually a self-limiting illness. In most cases, the disease is not sufficiently distinct or severe enough to suggest to the clinician the need for a diagnostic evaluation. However, serious complications occur on occasion in very young infants and in children with sickle cell hemoglobinopathies.

The treatment of *Salmonella* gastroenteritis should be directed toward the maintenance of adequate hydration. As with viral infections, limitation of the diet to electrolyte solutions ("clear liquids") suffices in most children. Antibiotic therapy neither ameliorates the course of the gastroenteritis nor eradicates the organism from the intestinal tract in the immunocompetent host. In fact, several studies have suggested prolonged carriage after the administration of antibiotics.

Potential indications for admission of a child with diarrhea suspected or proved to be caused by *Salmonella* species are (i) dehydration not responsive to treatment, (ii) focal infection or bacteremia/sepsis, (iii) age younger than 3 months or temperature higher than 39°C (102.2°F) in a child younger than 12 months (unless blood culture is known to be sterile), (iv) sickle cell anemia, or (v) immunosuppressive conditions such as HIV. If bacteremia is suspected, IV therapy with ceftriaxone (50 mg per kg per day in one daily dose) or cefotaxime (100 mg per kg per day in two divided doses) should be initiated. Fluoroquinolones (ciprofloxacin, ofloxacin) or azithromycin provides an alternative for cephalosporin-allergic patients. When oral therapy is indicated trimethoprim-sulfamethoxazole (8 mg per kg per day of trimethoprim in two divided doses) is the drug of choice for susceptible strains.

Shigellosis stands alone as the only form of bacterial gastroenteritis for which antibiotics have proved efficacious. Antimicrobial therapy shortens the course of the illness and the duration of excretion of the organisms in the stool. Treatment alleviates the symptoms and signs of the gastroenteritis and limits its transmission of the disease. Trimethoprim-sulfamethoxazole (8 mg of trimethoprim and 40 mg of sulfamethoxazole per kilogram per day) is the initial drug of choice while the results of sensitivity tests are pending. Fluoroquinolones and ceftriaxone are alternatives.

Supportive therapy is an important aspect of the management of shigellosis. The initial oral intake should be limited to solutions with physiologic concentrations of glucose and electrolytes. As the diarrhea begins to abate, solid foods can be added. Dietary manipulation leads to resolution of the disease in some children before the isolation of the organism. Antibiotic therapy may be omitted in such cases, unless there is a particular concern about spread in a closed population.

As with other varieties of infectious gastroenteritis, most medications designed to provide symptomatic relief from diarrhea have no demonstrated efficacy. In particular, paregoric or combinations of diphenoxylate and atropine (Lomotil®) are contraindicated. Dupont and Hornick showed that diarrhea persisted longer in infected volunteers treated with antibiotics and diphenoxylate/atropine than with those who received only antibiotics.

Most episodes of shigellosis can be handled on an outpatient basis. Potential indications for admission include (i) age 6 months or younger, (ii) dehydration, and (iii) bacteremia (rare). Before the definitive diagnosis of shigellosis, particularly with significant bleeding, hospitalization may be required because of a concern about noninfectious entities such as a Meckel's diverticulum.

Most children with yersiniosis can be treated as outpatients. Initially, the diet may be limited to electrolyte solutions (clear liquids). Although *Y. enterocolitica* is usually sensitive in vitro to tetracycline, chloramphenicol, colistin, gentamicin, and kanamycin, current studies have demonstrated no benefit from antibiotic therapy of uncomplicated gastroenteritis. However, persistent diarrhea may respond to antimicrobial treatment. Suspected or proven sepsis merits IV administration of antibiotics such as gentamicin (5 to 7.5 mg per kg per day in one to three divided doses, beyond the neonatal period). Potential indications for admission include dehydration, severe abdominal pain suggesting appendicitis, and underlying diseases such as thalassemia.

Campylobacter enteritis is a self-limited but prolonged illness; diarrhea persists for more than 1 week in one-third of children. These organisms exhibit almost universal sensitivity to erythromycin, which can be given orally at a dosage of 40 mg per kg per day; ciprofloxacin is an alternative for adolescents. However, antimicrobial therapy has not proved to decrease the duration of diarrhea.

Antibiotic-associated Colitis

Background

Children who take antibiotics often develop diarrhea, which varies from mild to severe. For most of the mild cases, no specific diagnosis is established. A small subset of patients, usually with more severe illnesses, manifest pseudomembranous colitis, caused by *C. difficile*. Although antibiotics are the most important precipitating factor for pseudomembranous colitis, the disease was recognized in the preantibiotic era and still occurs occasionally in the absence of prior antibiotic therapy. Almost every antibiotic has been reported to be associated with pseudomembranous colitis. Clindamycin, lincomycin, and the broad-spectrum β-lactam agents in particular predispose to overgrowth of *C. difficile,* but because these drugs are rarely used for children on an outpatient basis, widely prescribed medications, such as amoxicillin, are more often implicated in the pediatric age group.

Pathophysiology

C. difficile, the etiologic agent in pseudomembranous colitis, is a gram-positive anaerobic bacillus that may be part of the normal intestinal flora, particularly during the first year of life. Even a short course of antibiotic therapy may lead to overgrowth of this organism. Colitis results from toxin production by *C. difficile* within the intestinal lumen; the two major toxins are known as A and B. These toxins attack the membranes or microfilaments of cells and produce hemorrhage, necrosis, and inflammation.

Clinical Manifestations

Colitis with *C. difficile* varies widely in severity. Typically, profuse watery or mucoid diarrhea begins after several days of antibiotic therapy. Many older children complain of crampy abdominal pain. On examination, the usual findings include fever and diffuse abdominal tenderness. Often, the WBC count rises above 15,000 per mm^3. The stool may be guaiac-positive or frankly bloody; leukocytes are found on smears from approximately 50% of patients. An etiologic diagnosis requires the identification of *C. difficile* toxin in the stool; recovery of the organism on culture is suggestive but not sufficient.

If *C. difficile* colitis goes unrecognized and untreated, complications, including toxic megacolon, perforation, and peritonitis, may develop. Case fatality rates as high as 10% to 20% were described before the introduction of specific treatments.

Management

The treatment for children with colitis caused by *C. difficile* depends on the severity of the disease. Mild cases respond to cessation of antibiotic treatment and supportive therapy with fluids and electrolytes. In particular, children seen with a small amount of diarrhea on oral antibiotics for a minor infection, and in whom the suspicion of pseudomembranous colitis is low, do not need an extensive diagnostic investigation or institution of specific antimicrobial therapy.

Patients with more severe or persistent antibiotic-associated diarrhea should be evaluated for *C. difficile* with a test for toxin in the stool. Oral metronidazole (30 mg per kg per day in four divided doses) or oral vancomycin (40 mg per kg per day, with a usual maximum of 125 mg per dose, in four divided doses) is prescribed most commonly. Although used with some success in the past, cholestyramine does not have the same efficacy as oral antibiotics, but it may be tried in patients who fail treatment with vancomycin and metronidazole. Antidiarrheal agents should be avoided. When possible, the precipitating antibiotic should be discontinued, but cessation is not essential once specific therapy has been initiated. Children with more pronounced clinical illnesses, particularly those receiving antibiotic therapy, may merit hospitalization.

Gastritis

Background

Gastritis is an inflammation of the lining of the stomach. Most cases are noninfectious; however, *Helicobacter pylori*, a gram-negative rod that is capable of surviving in the acid milieu of the stomach, is the cause in some patients. Infection rates with this organism are low in young children but increase in adolescence. Chronic infection with *H. pylori* is associated with peptic ulcer and gastric carcinoma.

Clinical Manifestations

Gastritis caused by *H. pylori* manifests in older children and adolescents with persistent epigastric pain, nausea, and vomiting. Often, the stool will test positive for blood. More severe cases are characterized by hematemesis. In younger children and infants unable to verbalize or localize pain reliably, irritability may be the primary manifestation.

H. pylori can be diagnosed by culture of gastric tissue obtained at biopsy, breath testing, serology, and stool antigen assays. Only serology and stool assay have applicability in the setting of the ED. Sensitivity for these two tests has been reported to range from 80% to 95%, with greater accuracy being observed in older children; specificity hovers around 90%.

Management

In most cases, the clinician cannot diagnose *H. pylori* infection in the ED with sufficient certainty to warrant the initiation of treatment with antibiotics. Effective therapies require two or three drugs, an inhibitor of acid secretion along with one or two antibiotics, administered for 10 to 14 days. For adolescents, a frequently used regimen includes omeprazole (20 mg twice daily), clarithromycin (500 mg twice daily), and amoxicillin (1 g twice daily) for 10 days.

SKIN, SOFT-TISSUE, AND BONE INFECTIONS

The major infections of the skin, soft tissues, and bones include impetigo, cutaneous abscesses, lymphadenitis, cellulitis, fasciitis, pyomyositis, septic arthritis, and osteomyelitis. Additionally mastitis and omphalitis occur in the neonate. Chapter 117 deals with cutaneous abscesses. Among the disorders in this group, impetigo and cellulitis are both common complaints in the ED. Although children with bone and joint infections are seen only occasionally, the differential diagnosis of several common complaints (e.g., fever, limp) often includes these conditions. Thus, the emergency physician who deals

FIGURE 92.18 Bullous impetigo.

with children should be familiar with such infections, particularly because a prolonged delay in the institution of therapy can result in appreciable morbidity.

Impetigo

Background

Impetigo is a bacterial infection of the skin confined to the epidermis. A deeper variety of impetigo, ecthyma, also involves the dermis. Pustules larger than 1 cm in diameter (Fig. 92.18) characterize bullous impetigo. Impetigo is a common infection in children, particularly during the summer months. It occurs in epidemics during the warm weather in confined populations of children.

Any strain of group A streptococcus, including nephritogenic varieties, can infect the skin and cause impetigo. *S. aureus,* the primary agent in bullous impetigo is a common cause of nonbullous impetigo as well.

Pathophysiology

The intact epidermis forms a relatively impervious barrier to bacteria. However, a breach in the integument, even if too small to be noticed by the patient or parents, may allow the entry of pathogens and the development of impetigo. In streptococcal infections, toxins, such as streptolysins, elaborated by the organism, promote local spread of the process. Different toxins produced by *S. aureus* lead to the accumulation of purulent material and the evolution of bullae.

Clinical Manifestations

Impetigo is more common in young children, particularly those younger than 6 years. Typically, a parent will bring a child to the ED complaining of sores on the body. No systemic ailments, such as fever or malaise, are associated. Physical examination shows a healthy child with a normal temperature. The lesions usually ooze serous fluid but may be bullous or crusted as well (Fig. 92.18). Surrounding erythema is minimal, and the regional lymph nodes often do not enlarge noticeably.

Laboratory studies are not routinely obtained in children with impetigo. Cultures of the lesions, performed only if there is any doubt about the diagnosis, will yield group A streptococci or *S. aureus* in most cases. The WBC count is normal.

The complications of impetigo include spread of the infection locally and remote nonsuppurative disease. Occasionally, impetigo may progress to cellulitis. If the lesions are caused by nephritogenic streptococci, glomerulonephritis may develop 7 to 14 days later. The attack rate for glomerulonephritis has been as high as 1% in certain epidemics, but the incidence is far less in the usual clinical setting.

Management

A single course of antibiotic therapy cures impetigo in 95% of children. Erythromycin (40 mg per kg per day in four divided doses) provides effective oral treatment for the usual pathogens. Other acceptable oral drugs include dicloxacillin (50 mg per kg per day) or cephalexin (50 mg per kg per day). For cases of impetigo due to MRSA, trimethoprim-sulfamethoxazole (8 mg per kg per day of TMP) or clindamycin (30 mg per kg per day) may be prescribed. Mupirocin (Bactroban®) applied locally is able to eradicate most cases of impetigo, particularly if the disease is limited in distribution. Combination topical and systemic therapy is unnecessary. Vigorous scrubbing does not hasten the resolution, and routine cleanliness is sufficient. Even when systemic antibiotic therapy eliminates the infection, the incidence of glomerulonephritis has not been demonstrated to decrease.

Lymphadenitis

Lymph nodes in any region of the body may become infected. Regardless of the site of involvement, the same considerations apply as discussed under cervical lymphadenitis. *S. aureus* and group A streptococci are the most common pathogens. The finding of inguinal or axillary adenitis should prompt a meticulous search for a portal of entry for bacteria on the extremities. Locating an impetiginous lesion or other breech in the integument provides reassurance that the lymph node enlargement is caused by infection rather than by neoplasm. History should be requested regarding a cat scratch or bite as a possible etiologic focus. Particularly in the adolescent, inguinal adenitis suggests a need to look for sexually transmitted pathogens. The child with lymphadenitis should be treated with antibiotic therapy and drainage with culture, if fluctuation occurs. Dicloxacillin (50 mg per kg per day) and cephalexin (50 mg per kg per day) are effective against the usual pathogens except for community acquired MRSA where clindamycin or the addition of trimethoprim sulfamethoxasole should be used.

Cellulitis

Background

Cellulitis is an infection of the skin and subcutaneous tissues. Any anatomic area may be involved, but the body can be divided, for etiologic considerations, into two regions: (i) the face and (ii) the scalp, neck, trunk, and extremities.

Facial cellulitis includes buccal, periorbital, and less often, orbital lesions. Before the introduction of a vaccine against Hib, *H. influenzae* type b caused 50% of these infections. At present, the organisms involved most commonly are *S. aureus*, group A streptococci, and *S. pneumoniae*. Bacteremia is present in 90% of the cases of disease caused by *S. pneumoniae* and *H. influenzae* type b. Alternatively, a dental abscess may serve as the source for an apparent cellulitis, in which case treatment relies almost exclusively on drainage of the abscess.

S. aureus causes most nonfacial cellulitis and has been reported to be recovered from 70% of extremity lesions with an identifiable origin, either as the sole pathogen or in combination with group A streptococci. Nonfacial cellulitis very rarely results from infection with *H. influenzae,* although when this organism is involved, as with facial lesions, it usually invades the bloodstream.

Cellulitis occasionally occurs among immunosuppressed patients. In these cases, unusual organisms, including *P. aeruginosa*, gram-negative enteric rods, and anaerobic bacteria, must be considered. Even when initial examination suggests minimal inflammation, an extensive infection may exist, because neutropenia often masks the depth of the lesion.

Cellulitis is a common infection that is more often seen in temperate climates when the weather is warm. Precise statistics on the incidence of cellulitis are not available; however, in one study during the summer months, this infection accounted for approximately 1 of every 500 visits to the ED of a children's hospital.

Pathogenesis

Cellulitis follows either hematogenous dissemination of a pathogenic organism or local invasion.

Surgical or traumatic wounds may serve as a portal of entry for bacteria. This is the route by which *S. aureus* and group A streptococci usually gain access to the subcutaneous tissue; subsequently, toxins produced by these organisms allow for local spread. Alternatively, invasion of the bloodstream may precede the appearance of cellulitis. The periorbital and facial lesions seen occasionally with *H. influenzae* and *S. pneumoniae* follow a bacteremia, and these organisms often are recovered from the blood. *S. aureus* and group A streptococcus are less often spread by this mechanism.

Clinical Manifestations

The child with cellulitis develops a local inflammatory response (Fig. 92.19) at the site of infection with erythema, edema, warmth, pain, and, when an extremity is involved, limitation of motion. There may be a history of a prior wound or insect bite. Facial infections are more common during the first 5 years of life. Fever is unusual, except in bacteremic infections or when the lesions are extensive. Only 10% to 20% of children with cellulitis manifest a fever. The lesion itself is erythematous and tender, and may be indurated but is not fluctuant; red streaks may radiate proximally along the course of the lymphatic drainage. The regional lymph nodes usually enlarge in response to the infection.

With cellulitis caused by *S. aureus* or group A streptococci, the WBC count is normal in most children. More extensive lesions or bacteremia, seen only occasionally with these organisms, evoke a leukocytosis. A culture obtained from the central area of the cellulitis by needle aspiration or biopsy will yield a pathogen in 50% of cases, even though cultures of the blood usually remain sterile.

FIGURE 92.19 Infant with buccal cellulitis caused by *Haemophilus influenzae*.

Bacteremia accompanies cellulitis caused by *H. influenzae* or *S. pneumoniae;* these organisms are isolated from the blood in 90% of infected patients. The WBC count is greater than 15,000 per m^3 as a rule, usually with a shift to the left.

The complications of cellulitis, although uncommon, include local and metastatic spread of infection. The organisms may invade deeper tissues, producing septic arthritis or osteomyelitis. During the course of bacteremia with *H. influenzae, S. pneumoniae*, or rarely other organisms, there may be involvement of the meninges, pericardium, epiglottis, or synovial membranes. Multifocal areas of cellulitis should arouse a suspicion of hematogenous dissemination. Occasionally, cellulitis provides a clue to an infection that originates in deeper anatomic structures. As an example, a lesion on the abdominal wall may be a sign of peritonitis.

Management

Most children with nonfacial cellulitis can receive antibiotic therapy as outpatients, as long as bacteremic disease is unlikely (Fig. 92.20). Because *S. aureus* and group A streptococci are most commonly isolated, treatment should be directed at these organisms. Acceptable alternatives include a semisynthetic penicillin, such as dicloxacillin (50 mg per kg per day), cephalexin (50 mg per kg per day), or amoxicillin–clavulanic acid (50 mg per kg per day of amoxicillin); even methicillin-susceptible *S. aureus* will generally be resistant to penicillin and ampicillin. In areas where community-acquired MRSA are common the use of clindamycin or a combination of a semisynthetic penicillin, such as dicloxacillin, or cephalexin and trimethoprim-sulfamethoxazole may be needed. A CBC count, blood culture, and aspirate culture are not necessary in afebrile patients.

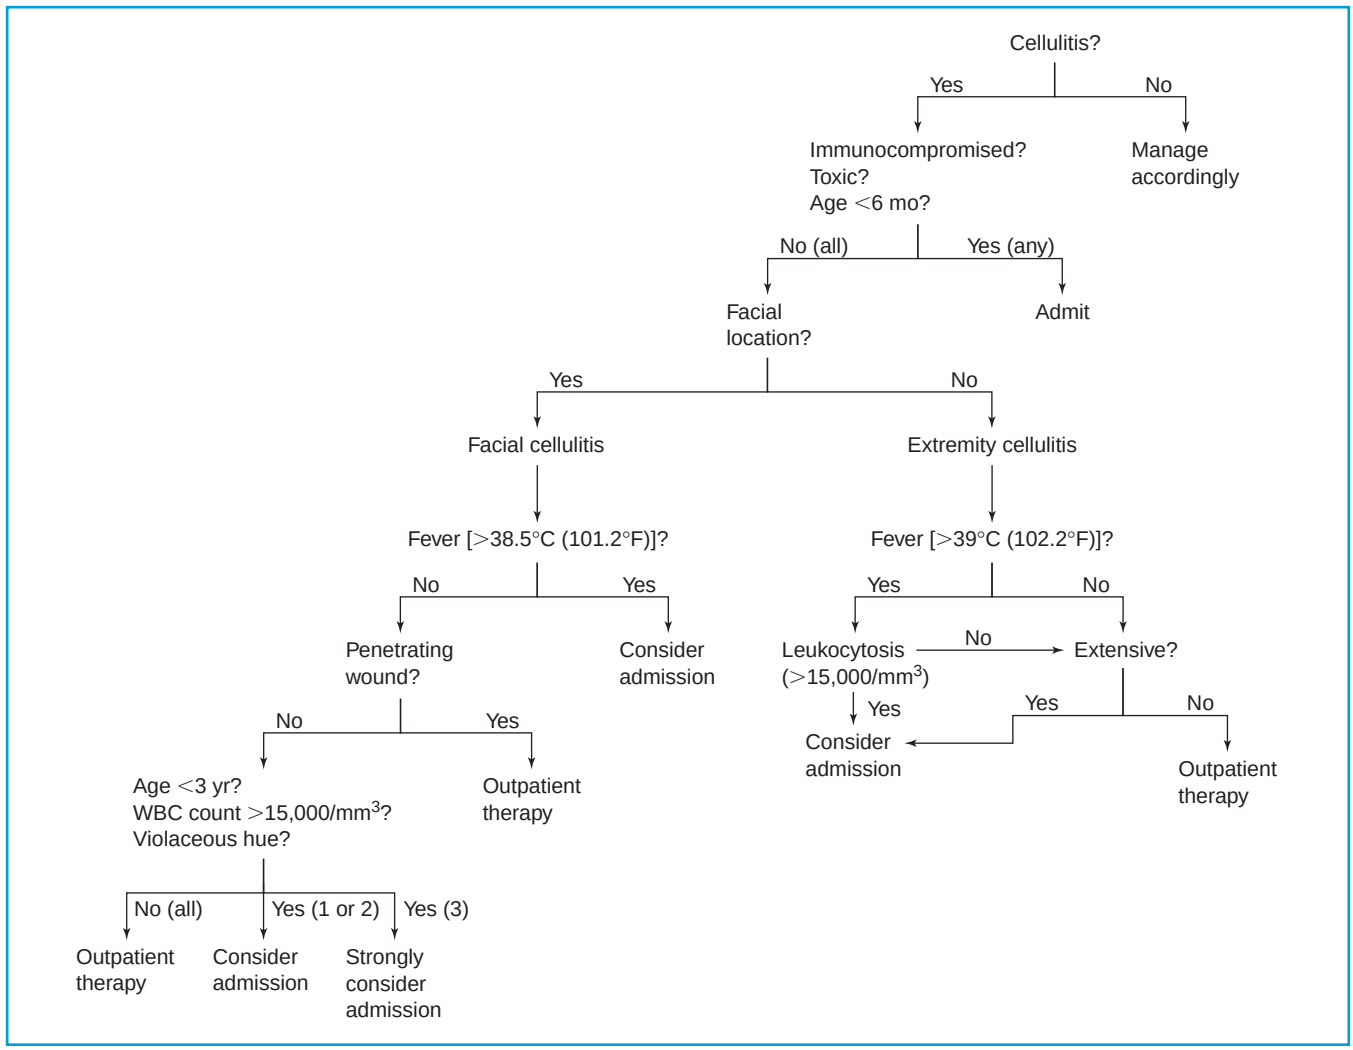

FIGURE 92.20 Diagnostic approach for the management of the child with soft-tissue swelling and possible cellulitis. WBC, white blood cell.

If a child with a nonfacial cellulitis has a high fever [39°C (102.2°F) or higher], the likelihood of a bacteremic infection or lymphangitic spread remains low but increases. A WBC count and culture of the blood should be obtained, along with consideration of a culture from the lesion. In cases in which the patient is well-appearing, little evidence of lymphangitic spread is seen and the WBC count is below 15,000 per mm^3, antibiotic therapy is given as described for afebrile children, with a plan to have the patient reevaluated the following day. An ill-appearing patient, rapid spread, or a leukocytosis in association with a fever of 39°C (102.2°F) or higher should result in strong consideration for IV treatment, usually on an inpatient basis, with oxacillin (100 to 200 mg per kg per day in four divided doses) or cefazolin (100 mg per kg per day in three divided doses). Where rates of MRSA are high, intravenous clindamycin (40 mg per kg per day in four divided doses) or vancomycin (45 mg per kg per day in three divided doses) may be needed. For children not immunized against Hib, consider therapy with cefotaxime (200 mg per kg per day in four divided doses), ceftriaxone (100 mg per kg per day in a single dose), or ampicillin sulbactam acid (200 mg per kg per day of ampicillin in four divided doses). Children allergic to penicillins and cephalosporins can be given clindamycin (40 mg per kg per day in four divided doses). When *H. influenzae* type b is a concern a quinolone or aztreonam should be added.

Children with facial cellulitis and fever are particularly likely to be bacteremic, in most cases with *S. pneumoniae* or, less commonly, *H. influenzae* type b, and are at risk for local complications. Thus, most should receive IV therapy as listed previously. Those who are afebrile may be managed as outpatients if they do not have risk factors for bacteremic disease—age younger than 3 years, spontaneous cellulitis without a preceding wound, and violaceous discoloration (Fig. 92.20).

Fasciitis

Background

Fasciitis is a deep soft-tissue infection. Unlike cellulitis, it involves the fascial and muscle layers, as well as the skin and subcutaneous tissues, but it does not extend per se to the bones or joints. Terms used to refer to this condition include *necrotizing*

fasciitis, acute streptococcal hemolytic gangrene, Meleney synergistic gangrene, and *necrotizing erysipelas*. In more recent years, the most common cause, by far, has been group A streptococci; other etiologic agents include *S. aureus* and anaerobic organisms. Until the widespread use of varicella vaccine most cases of fasciitis would occur as a complication of varicella.

Clinical Manifestations

As occurs with cellulitis, the child with fasciitis develops a local inflammatory response at the site of infection, characterized by erythema, edema, warmth, pain, and limitation of motion. Fever occurs in almost every case, often exceeding 39°C (102.2°F). In contrast to the usual patient with cellulitis, those with fasciitis generally experience more pain and may appear toxic with a marked tachycardia and, occasionally, hypotension. The local lesion is often described by the family as progressing rapidly and generally exhibits noticeable induration and erythema. Particularly, in the presence of varicelliform lesions, the physician should maintain a high index of suspicion for fasciitis, as opposed to cellulitis, in children with extensive local disease, high fever, and any degree of prostration. The WBC count generally reflects a leukocytosis, and blood cultures yield an organism in most cases.

Management

A confirmed case of well-established necrotizing fascutis should be considered an emergency.

The first priorities include supportive therapy for signs of sepsis and initiation of antibiotics, followed promptly by surgical consultation. Appropriate antimicrobial therapy includes a penicillin (penicillin G 500,000 units per kg per day in four divided doses) and clindamycin (40 mg per kg per day in four divided doses) intravenously. The use of vancomycin should be considered in areas with community acquired MRSA. In some cases, the surgical consultant will elect to incise and/or debride the lesions.

Omphalitis

Background

Omphalitis is an infection of the umbilical cord and surrounding tissues. Although formerly an important cause of neonatal mortality, the disease is now rare in developed countries because of advances in antisepsis and local care of the umbilical cord stump. Home delivery and low birth weight represent risk factors. When infection occurs, the usual pathogen is *S. aureus*; group B streptococci, *Streptococccus pyogenes* (group A streptococci), and gram-negative enteric rods may also be isolated. Children are at risk during the first 2 weeks of life.

Pathophysiology

After ligation at delivery, the umbilical stump undergoes necrosis as a result of interruption of its blood supply. Bacterial colonization follows soon after birth. In rare cases, because of colonization by virulent bacteria or ill-defined host factors, colonizing organisms may invade the umbilical cord stump and surrounding tissues. The initial infection is cellulitis, but peritonitis, liver abscess, and/or sepsis may ensue in short order.

Clinical Findings

Omphalitis is characterized first by drainage and later by erythema around the umbilical cord stump. Late in the course of infection, infants manifest the signs of sepsis, including lethargy, irritability, and hypothermia or hyperthermia. Laboratory studies are normal early in the course. Because a small amount of drainage and patchy erythema can occur in the absence of infection, the diagnosis of omphalitis may be difficult. There are no definite clinical criteria for early infections, and laboratory tests are not helpful. The findings suggestive of omphalitis are (i) purulent, foul-smelling drainage from the umbilical cord with any erythema of the anterior abdomen; or (ii) any drainage with erythema that completely encircles the umbilicus. Induration and erythema of the anterior abdomen wall are definite indicators of infection.

Management

If there is drainage, the material should be sent for culture and Gram stain. Infants who appear toxic, have induration and erythema of the abdominal wall, or show signs clearly suggestive of omphalitis (purulence and patchy erythema or light drainage plus circumferential erythema) should be presumed to have a significant infection and require IV antibiotic agents. Appropriate therapy is oxacillin (100 to 200 mg per kg per day in four divided doses) and gentamicin (7.5 mg per kg per day in three divided doses for term infants). The addition of vancomycin should be considered for coverage of MRSA. In some cases, minimal drainage or erythema may be present, but the findings are not sufficient for the diagnosis of omphalitis. The parents of these infants should be instructed to swab the cord after each diaper change and to observe the child for any changes in activity or feeding. Reexamination in 24 hours is advisable if the problem has not resolved.

Neonatal Mastitis

Background

Mastitis is an infection of the breast tissue that affects prepubertal children only during the first 2 to 5 weeks of life. In most cases, *S. aureus* is the usual offending organism, although 5% to 10% of the infections are caused by gram-negative enteric bacteria. Girls are affected twice as commonly as boys.

Pathophysiology

Maternal hormones cross the placenta during gestation and stimulate hypertrophy of neonatal breast buds in both males and females. Usually, the enlargement subsides within 2 weeks. In occasional cases, bacteria are able to invade the hypertrophied glandular tissue, leading to abscess formation. Manipulation of the breast to excrete "witch's milk" may be a predisposing factor.

Clinical Manifestations

The primary finding in neonatal mastitis is a warm, erythematous, enlarged breast bud (Fig. 92.21). With disease progression, purulent drainage from the nipple may occur and there is tenderness to palpation. Only 25% of infants are febrile or appear ill. Mastitis in the infant must be distinguished from physiologic hypertrophy, which resolves spontaneously. The

FIGURE 92.21 A 2-week-old infant with mastitis, characterized by erythema and induration.

normal breast bud that enlarges in response to stimulation by maternal hormones is neither red nor tender; if any drainage is present, the material is milky white, rather than yellow, and does not contain polymorphonuclear leukocytes or bacteria on Gram stain. Culture of the purulent drainage yields the pathogen in most cases, but the blood is usually sterile. Because these infections are well localized, the WBC count is usually in the normal range.

Management

Occasionally, an infant will appear septic and require appropriate supportive therapy, as described earlier in this chapter. The remainder will nonetheless require IV antibiotics, pending the results of cultures. Oxacillin (100 to 200 mg per kg per day in four divided doses) and gentamicin (7.5 mg per kg per day in three divided doses) provide appropriate coverage for the expected pathogens. The addition of vancomycin should be considered for coverage of MRSA. Incision and drainage is advisable in the case of local fluctulance, with careful attention to avoiding injury to the developing breast bud, which is already at risk of damage from the infectious process and may lead to cosmetic issues of the breast first noted at adolescence.

Septic Arthritis

Background

Septic arthritis is defined as a bacterial infection within a joint space. The incidence of this infection is low at an estimated 5 per 100,000 children per year for pyogenic bacteria. As opposed to adults, children who develop septic arthritis are generally otherwise healthy. Boys are affected twice as often as girls.

The bacterial cause of septic arthritis varies with age. During the first 2 months of life, group B streptococcus and *S. aureus* predominate. Gram-negative enteric bacilli, *Candida* species, and *N. gonorrhoeae* are seen sporadically.

Between 3 months and adolescence, *S. aureus* emerges as the single most common pathogen, being isolated from 80% to 90% of children with septic arthritis. The incidence of disease caused by *H. influenzae* type b has declined significantly since the introduction of the conjugated vaccine, but this organism remains a concern in children in this age range who have not been immunized against this pathogen. Group A streptococci and *S. pneumoniae* cause occasional cases.

The incidence of gonococcal arthritis in teenagers has varied in different reports, depending on the prevalence of sexual activity in the population studied. In most studies, *N. gonorrhoeae* has been the most common cause of septic arthritis among adolescents, trailed closely by *S. aureus*.

Many other organisms occasionally invade the joint space, some only in special circumstances. *P. aeruginosa* shows a peculiar predilection for septic arthritis after trauma as is seen in the foot after puncture wounds. In the child with sickle cell anemia, *Salmonella* species may cause septic arthritis. With the exception of Kingella, the gram-negative bacilli are almost never recovered from previously healthy children but are seen in immunosuppressed patients. *M. tuberculosis* is a rare causative agent but may be isolated at any age. In endemic areas, Lyme arthritis merits consideration.

Pathophysiology

Septic arthritis generally results from the hematogenous dissemination of an organism, into either the joint or the bony metaphysis. Except in circumstances of osteomyelitis, trauma, or recent surgery, it is rare for pediatric patients to have the pathogen gain access to the joint by direct inoculation or spread from a contiguous site of infection as is seen in adults. Although many children have a history of recent trauma, the role played by injury remains unknown. In gonococcal arthritis, the initial site of infection may be the genitals, pharynx, or rectum. Dissemination from the cervix follows menstruation when shedding of the organism is highest.

Bacteria in the joint space evoke an inflammatory response with an infiltration of neutrophils. The accumulation of purulent material distends the joint capsule, producing the physical and radiographic findings. *S. aureus* septic arthritis is associated with long-term joint morbidity in approximately 25% of patients.

Clinical Features

Infection within a joint produces pain and limitation of motion. Thus, the site of the arthritis determines the specific complaint. Ninety percent of children have a monoarticular arthritis that involves the lower extremity (hip, knee, and ankle). Thus, limp (see Chapter 42) is the most common initial manifestation. If a joint in the arm is involved, mobility of the upper extremity will be decreased (see Chapter 35).

With infections in deeper joints, the pain may radiate to contiguous anatomic structures. Children with a septic hip often complain of an ache at the knee, and sacroiliac arthritis may mimic appendicitis, pelvic neoplasm, or UTIs. Although the duration of symptoms in septic arthritis is less than 3 days in more than 50% of children with these conditions, the delay in diagnosis may reach 3 to 4 weeks with sacroiliac arthritis.

The findings are often vague in the first 6 months of life. Pyoarthritis may cause paradoxical irritability and an increase in crying on being fondled, as seen with meningitis. The infant with a septic hip usually lies quietly, holding the leg abducted and externally rotated.

Of children with septic arthritis, 60% to 70% have a temperature of 38.5°C (101.2°F) or higher. The absence of fever occurs most commonly in the adolescent with a gonococcal infection or in the neonate. Infants with infections caused by

H. influenzae, rare since the advent of the conjugated vaccine, almost invariably have high fever. An erythematous swelling may surround a superficial joint that is infected. Although a temperature difference exists between the affected and unaffected sites, it can be difficult to discern in the febrile child. Inflammation within the joint distends the capsule and produces pain with movement. If a child allows the physician to manipulate an extremity through a full range of motion, septic arthritis is unlikely.

The ESR and CRP are the most consistently abnormal laboratory study. Molteni observed an elevated ESR in 32 of 37 (86%) children with septic arthritis; the median value was 50 mm. The peripheral WBC count usually varies from less than 5,000 to more than 20,000 per mm^3. Although a leukocytosis with a shift to the left commonly occurs, as many as 20% of children will have a WBC count less than 10,000 per mm^3. If septic arthritis is diagnosed early, a radiograph of the joint will not show any pathologic changes. The first radiographic alteration to be noted is edema of the adjacent soft tissues, which is not pathognomonic of inflammation in the joint. Later, distension of the capsule becomes visible, and bony destruction may be seen late in the course of the infection.

The thickness of the tissues that surround the hip joint makes the detection of an effusion difficult by physical examination. A radiograph of the hip should generally be obtained if infection in this joint is possible. Early in the course, the tendon of the obturator internus is displaced as the muscle passes over the distended hip capsule. Continued accumulation of an inflammatory exudate forces the femoral head laterally and upward, disrupting the arc formed by the femoral head and the pelvis (Shenton's line). The hip may actually dislocate with intraarticular infection in the young infant, but this is an unusual radiographic finding in older children. Ultrasound examination is useful for the detection of an effusion not apparent on radiograph and to direct diagnostic aspiration.

No constellation of laboratory and radiographic results can rule out the diagnosis of septic arthritis; an analysis of the joint fluid is mandatory if the index of suspicion is high (see Procedures in Section VII). Infection causes an infiltration of polymorphonuclear leukocytes into the joint space. Although intraarticular WBC counts greater than 100,000 per mm^3 are traditionally associated with infection, a lesser cellular response is often noted. Nelson found a WBC count in the joint fluid of less than 25,000 per mm^3 in 9 (34%) of 31 children with proven bacterial arthritis. The joint fluid glucose is reduced to less than 40 mg per dL in only 25% to 50% of patients, but the Gram stain of the synovial fluid shows organisms in 75%. In part because inflammatory exudates have bacteriostatic properties, cultures of joint fluid yield an organism in only 60% of cases. A pathogen is recovered from the bloodstream in 40% of children with septic arthritis, more commonly if *H. influenzae* type b or *S. pneumoniae* is the cause of the disease.

The complications of septic arthritis include both local and distant spread of the infection. Osteomyelitis often accompanies joint infections in the first year of life because of the location of the metaphysis within the joint capsule. During the process of hematogenous dissemination, bacteria may invade sites other than the joint. Simultaneous infections may occur in the meninges, pericardium, or the soft tissues; these are particularly common with *H. influenzae*. Lyme arthritis is an important consideration in areas where it is endemic.

Management

Septic arthritis demands prompt management; in particular, infection in the hip joint should be considered particularly urgent. Pressure generated by purulent material within the joint space can compromise the vascular supply of the femoral head, leading to necrosis and eventual loss of normal ambulation. The initial treatment is aimed at relieving the pressure within the joint and controlling the infection. At the time of the diagnostic aspiration, as much purulent fluid as possible should be removed. Prompt surgical intervention is typically advocated for septic arthritis of the hip.

Joint fluid should be sent for Gram stain and culture, blood should be sent for routine aerobic culture, and in endemic areas blood testing for Lyme should also be performed routinely. With the widespread emergence of community-acquired MRSA, some now advocate routine nasal culture for MRSA, which, if positive, supports the need to provide coverage for MRSA if *S. aureus* is suspected.

All children with septic arthritis require admission to the hospital for IV antibiotic therapy. Because *S. aureus* is common at all ages, the addition of clindamycin, trimethoprim-sulfamethoxazole, or vancomycin (in children who appear ill) to the suggested regimens below should be considered for coverage of MRSA where these organisms are prevalent. Otherwise, the initial choice of antimicrobials depends on the child's age and the Gram stain. If no organisms are apparent on examination of the joint fluid, presumptive antibiotic therapy is determined by the age of the patient. For infants 2 months of age or younger, the usual therapy is oxacillin 100 to 200 mg per kg per day in four divided doses and gentamicin 7.5 mg per kg per day in three divided doses. In children older than 2 months to younger than 3 years, choices include oxacillin 100 to 200 mg per kg per day in four divided doses or, for children not fully immunized against Hib, either cefotaxime 200 mg per kg per day in four divided doses or ampicillin/sulbactam 200 mg per kg per day of ampicillin in four divided doses. In cases of penicillin allergy, clindamycin 40 mg per kg per day in four divided doses with the possible addition of aztreonam 120 mg per kg per day in three divided doses if Kingella or Hib are suspected. For children between 3 and 12 years of age, oxacillin 100 to 200 mg per kg per day up to a maximum of 6 g per day suffices as a single agent, with clindamycin available with penicillin allergy. Adolescents at risk for gonococcal infections require ceftriaxone, 50 to 100 mg per kg per day once daily.

Osteomyelitis

Background

Osteomyelitis is an infection of the bone; a variant, discitis, affects the intervertebral disc space. An estimated 1 in 10,000 children per year develop osteomyelitis. Approximately 10 children with bone infections were admitted yearly to the pediatric service at Parkland Memorial Hospital in Dallas between 1959 and 1973.

S. aureus causes osteomyelitis in most cases, regardless of age. During the neonatal period, group B streptococcus is the second most common isolate; *N. gonorrhoeae* and gram-negative enteric bacilli are also found. Group A streptococcus

causes 5% to 10% of osteomyelitis in children. Other pathogens are recovered rarely, including *S. pneumoniae, H. influenzae, Y. enterocolitica, Brucella* species, anaerobic organisms, *M. tuberculosis*, and *Actinomyces* species.

P. aeruginosa may infect the bones of the foot after a puncture wound. In children with sickle cell hemoglobinopathies, *Salmonella* species account for almost half the cases of osteomyelitis. Unusual pathogens may be recovered from immunocompromised children.

Pathophysiology

In most children with osteomyelitis, bacteria reach the bone through the bloodstream. Occasional infections follow the direct inoculation of pathogens or spread from a contiguous focus. During hematogenous dissemination, organisms lodge in the sinusoidal vessels of the metaphysis at the site of sludging or thrombosis. Bacterial proliferation evokes an inflammatory exudate. Within the confined space of the bone, the pressure generated by the accumulation of purulent material can necrose the cortex and elevate or rupture the periosteum. If the metaphysis is contained within the joint capsule, as at the hip, septic arthritis may ensue.

Clinical Features

Osteomyelitis causes bone pain as the infection progresses. The site of the osteomyelitis determines the presentation of the disease. In 90% of cases, a single bone is involved. The femur and tibia are the most common bones infected, making limp (see Chapter 42) a common presentation. In a study of 100 consecutive children with a limp seen at the ED of The Children's Hospital of Philadelphia, osteomyelitis was diagnosed in 2%. Osteomyelitis affects the bones of the upper extremity in 25% of cases. These children complain of pain on motion of their upper extremities (see Chapter 35).

The multiplicity of bones that may be involved leads to a wide spectrum of chief complaints. Vertebral osteomyelitis manifests as backache, torticollis, or stiff neck, and involvement of the mandible causes painful mastication. Infection of the pelvis is particularly elusive and may masquerade as appendicitis, septic hip, neoplasm, or UTI. Infants with osteomyelitis localize the symptoms less well than older children. Initially, irritability may be the only complaint.

Fever exceeds 38.5°C (101.2°F) in 70% to 80% of children with osteomyelitis. The infant with a long bone infection often manifests pseudoparalysis, an unwillingness to move the extremity. Movement may also be decreased in the older child, but to a lesser degree. Point tenderness is seen commonly in osteomyelitis; however, it is found in other conditions, such as trauma, may be difficult to discern in the struggling infant, and does not always occur early in the course of the infection. Percussion of a bone at a point remote from the site of an osteomyelitis may elicit pain in the area of infection.

When purulent material ruptures through the cortex, diffuse local erythema and edema appear. This finding occurs often in infants, but late in the course, and is confined primarily to children in the first 3 years of life (before the cortex thickens sufficiently to contain the inflammatory exudate). Weissburg et al. noted swelling of the extremity in 14 of 17 patients with osteomyelitis who were younger than 1 month.

The ESR or CRP provides a useful screening test for osteomyelitis because bony infection almost always leads to an elevation. Nelson found an ESR less than 15 mm per hour in only 4 of 88 children with osteomyelitis, and the mean value was 70 mm per hour. Although the WBC count may reach a level of 20,000 per mm^3, it falls within the normal range in two-thirds of cases. Cultures from the blood yield an organism in 50% and from the bone in 60% of children with osteomyelitis.

If osteomyelitis is suspected, radiographs of the affected area should always be obtained, even though they are often normal early in the course. The first change, noted after 3 to 4 days, is deep soft-tissue swelling seen as a subtle shift of the lucent deep-muscle plane away from the bone. Within 3 to 10 days, the muscles swell and obliterate the lucent planes that usually separate them radiographically. Visualization of osseous destruction requires the loss of 40% of the bony matrix in an area at least 1 cm in diameter. This amount of demineralization occurs only after 10 to 14 days of infection. At this stage, lytic lesions and periosteal elevation are apparent on the radiograph (Fig. 92.22).

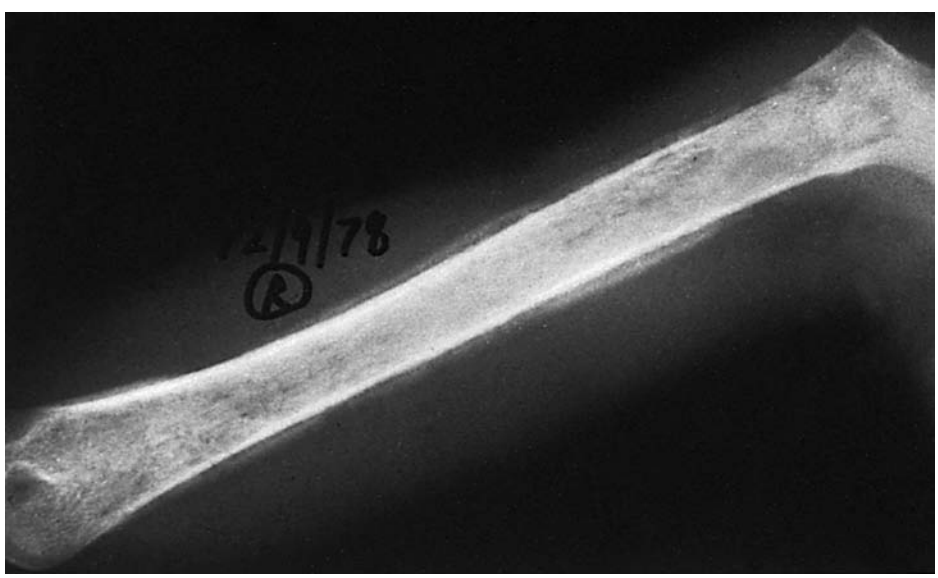

FIGURE 92.22 Radiograph showing lytic lesions and periosteal elevation with osteomyelitis.

Radionuclide scanning provides a useful diagnostic tool for the clinician. Uptake of compounds such as technetium is seen at sites of increased osteoblast activity, which occurs in an infection before sufficient bony destruction has occurred to be seen on conventional radiographs. If scintigraphy is available, the patient who is strongly suspected of having osteomyelitis despite a normal radiograph should have this study. However, the absence of increased uptake does not preclude bony infection. Some patients will have decreased uptake because the accumulation of purulent material lessens the flow of blood to the site; occasionally, in children, the scan may be entirely normal early in the course. When scintigraphy is not diagnostic and clinical suspicion persists, magnetic resonance imaging (MRI) is useful, although some authorities prefer MRI as an initial alternative to a technetium scan. MRI should be used routinely in suspected spinal or pelvic osteomyelitis as associated abscesses are common or pose specific risk.

The complications of osteomyelitis include the spread of infection, either locally or to remote sites, chronic infection, and irreparable bony destruction.

Management

Children strongly suspected or known to have osteomyelitis require admission to the hospital for initial IV antibiotic therapy. Those with a low likelihood of bony infection should have a blood culture obtained and can be reevaluated in 24 hours at which time a technetium scan or MRI can be performed if the clinical findings are not definitive. The emergency physician should withhold antibiotics until the orthopedic surgeon has been contacted about culturing the bone at the site of infection. Infants should subsequently receive oxacillin (100 to 200 mg per kg per day in four divided doses) and gentamicin (7.5 mg per kg per day in three divided doses); older children can be treated with either oxacillin or, in the case of penicillin allergy, clindamycin (40 mg per kg per day in three to four divided doses) alone. The addition of clindamycin, trimethoprim-sulfamethoxazole, or vancomycin (in children who appear ill) should be considered for coverage of MRSA in areas where MRSA are prevalent.

GENITOURINARY INFECTIONS

UTIs in the child are discussed in this section and in Chapter 53. Chapter 93 addresses the range of sexually transmitted diseases, including HIV, and Chapter 90 focuses on issues in the female.

Urinary Tract Infection

Background

Infections occur along the urinary tract from the tip of the urethra to the renal parenchyma. Clinical syndromes that may accompany infections include urethritis, cystitis, and pyelonephritis. *Bacteriuria* refers to the presence of bacteria in the urine, arising from any site in the urinary tract, with or without symptoms. Significant bacteriuria describes the presence of bacteria in sufficient quantity such that infection is more likely than contamination or colonization. Significant bacteriuria may be asymptomatic, and the clinical syndromes mentioned previously may occur in the absence of infection. Because cystitis and pyelonephritis may coexist or be difficult to distinguish clinically and share a similar etiology, they are discussed together, using the generic term *urinary tract infection.*

The predominant pathogen isolated in UTIs is *E. coli,* which is recovered in 90% of cases. Next in frequency are other members of the *Enterobacteriaceae* family, including *Enterobacter* and *Klebsiella.* Among the gram-positive organisms, enterococci are seen at all ages, staphylococcal species (*Staphylococcus saprophyticus*) occur most often in adolescents, and group B streptococci are recovered primarily in infants and during pregnancy. *P. aeruginosa, C. albicans*, and a number of other bacteria and fungi infect patients with immunocompromise, anatomic obstruction, or indwelling catheters. Cystitis may be caused, in addition, by adenoviruses. *S. aureus* is not a common pathogen unless there is bacteremia, urinary tract abnormality, or indwelling hardware.

The frequency of infections of the urinary tract varies by age, gender, and race. Overall, infections occur commonly in neonates, decrease in frequency during childhood, and then rise in incidence after puberty in sexually active females. Males are more commonly infected than females in the first 6 months of life, in part because of a higher incidence of congenital urinary tract anomalies, but they rarely acquire infections beyond this period unless uncircumcised and then these infections are uncommon beyond a year of age. Females have a rather high incidence of symptomatic infection between 6 months and 2 years of age and of asymptomatic bacteriuria throughout childhood. Bachur and Harper (Table 92.19) recently described an incidence of UTI that decreased from 6.9% in febrile infants younger than 1 month to 0.8% in children between 18 and 24 months of age.

Pathophysiology

Bacteria may invade the urinary tract by ascension or hematogenously. In most cases, the organisms colonize the urethral area and ascend to the bladder. The higher incidence of UTI in girls is often attributed to the shorter female urethra. Hematogenous spread to the kidney may occur at times in neonates but rarely thereafter.

Those organisms that cause UTIs have certain distinct properties. In comparison to other gram-negative rods, the few strains of *E. coli* that are most commonly recovered from the urine share recognized virulence factors, including increased adherence to uroepithelial cells and higher quantities of K antigen.

Children with UTIs have a higher incidence of genitourinary anomalies than the general population, although in most infections, no anatomic or functional abnormalities are identified. Lesions that obstruct the flow of urine and/or predispose to incomplete emptying of the bladder contribute to an increased risk of infection. Additional host factors that play a role include an alkaline urinary pH and glucosuria.

Clinical Manifestations

The manifestations of UTIs vary with age, being particularly nonspecific in infancy. During a neonatal onset, a septic appearance (see Chapter 70) or fever is often the only finding. UTIs in infants may also cause vomiting, diarrhea, irritability, and, reportedly, meningismus.

Beyond 2 to 3 years of age, symptoms more often point to the urinary tract. For all practical purposes, strict differentiation

TABLE 92.19

PREVALENCE OF URINARY TRACT INFECTIONS IN FEBRILE CHILDREN YOUNGER THAN 24 MONTHS

Age (mo)	Prevalence (%)	Females: Prevalence (%)	Males: Prevalence %
0–1	6.9	5.1	8.5
>1–3	5.5	5.9	5.3
>3–6	3.6	5.1	2.5
>6–9	2.1	3.7	0.8
>9–12	1.4	2.3	0.7
>12–18	0.8	1.4	0.4
>18–24	0.8	1.4	0.3

Modified from Bachur R, Harper M. Reliability of the urinalysis for predicting urinary tract infections in young febrile children. *Arch Pediatr Adolesc Med* 2001;155:60–65.

between upper and lower tract disease in children is not feasible for the clinician in most cases, and children who are febrile [greater than or equal to 38.5°C (101.2°F)] should be assumed to have pyelonephritis. However, some patients will have typical syndromes that localize disease to the upper or lower tract. Typically, children with cystitis appear relatively well and complain of dysuria and suprapubic pain. On examination, they have a lower-grade fever and tenderness on the suprapubic area. In contrast, patients with pyelonephritis may be toxic and usually have additional symptoms, including vomiting and flank pain. The physician is often able to elicit tenderness to percussion in the costovertebral area, either unilaterally or bilaterally.

The mainstays of diagnosis are the urinalysis and culture of the urine, both of which require the clinician to make an interpretation that is influenced by the method of collection and processing, as well as the clinical syndrome exhibited by the patient.

Urine is analyzed directly using both a chemical reagent strip (dipstick) and microscopy, looking most specifically, in regard to infection, for the presence of leukocyte esterase, nitrites, WBCs, and bacteria. Either spun or unspun urine may be studied through the microscope, with or without the aid of a Gram stain. Spinning should be done in accordance with a standardized protocol. When a clean urine specimen is centrifuged at 2,000 rpm for 5 minutes and examined under high power, each leukocyte [per high power field (hpf)] represents 5 to 10 cells per mm^3, with 10 to 50 WBC per mm^3 (5 to 10 per hpf) being the upper limit of normal. One organism per high-power field seen on Gram stain of a spun specimen correlates with a colony count of 10^5 organisms or more.

In interpreting a urine culture in children, the physician must keep in mind that the guidelines for positivity were developed based on data in adults and that the significance of colony counts applies most explicitly to voided specimens. Given these caveats, it is generally accepted that a colony count of greater than 10^5 on a single sample indicates a probability of infection of greater than or equal to 80% to 90% for a specimen obtained by suprapubic aspiration, transurethral catheterization, or clean void technique. Table 92.20 presents more specific guidelines.

TABLE 92.20

CRITERIA FOR DIAGNOSIS OF AN INITIAL URINARY TRACT INFECTION BY CULTURE

Method of collection	Colony count (pure culture)	Probability of infection
Suprapubic aspiration	Gram-negative rods: any Gram-postive cocci: $\geq 10^3$	99%
Transurethral catheterization	$\geq 10^5$ 10^4–10^5 10^3–10^4 $\leq 10^3$	95% Infection likely Suspicious: repeat Infection unlikely
Clean void: boy	$\geq 10^4$	Infection likely
Clean void: girl	3 specimens $\geq 10^5$ 2 specimens $\geq 10^5$ 1 specimen $\geq 10^5$ 5×10^4–10^5 10^4–5×10^4 $<10^4$	95% 90% 80% Suspicious; repeat Symptomatic: suspicious; repeat Asymptomatic: infection unlikely Infection unlikely

Modified from American Academy of Pediatrics. Practice parameter: the diagnosis, treatment, and evaluation of the initial urinary tract infection in febrile infants and young children. *Pediatrics* 1999;103:843–852.

In general, a single negative finding on one parameter of the urinalysis does not exclude a UTI. Taken together, however, negative testing for both leukocyte esterase and nitrites by dipstick alone, or even more so in combination with a microscopic examination that shows the absence of pyuria, makes the diagnosis of a UTI (as opposed to asymptomatic bacteriuria) in a male infant older than 6 months or a female older than 2 years highly unlikely. A schema for the use of urinalysis and urine culture is presented in Fig. 92.23. As illustrated for selected children who are somewhat older but not yet toilet trained, in the absence of a high likelihood of UTI a priori, the urinalysis may be collected using a bag. However, if the urinalysis is positive, a specimen for culture should preferably be obtained by catheterization or suprapubic aspiration.

Bacteremia accompanies UTIs primarily during the first 6 to 12 months of life. In the very young infant, bacteremia may be present in the absence of fever and should be suspected in any child during the first year of life with a temperature greater than or equal to 39°C (102.2°F) or higher. Indications for a CBC count and blood culture with a suspected UTI include (i)

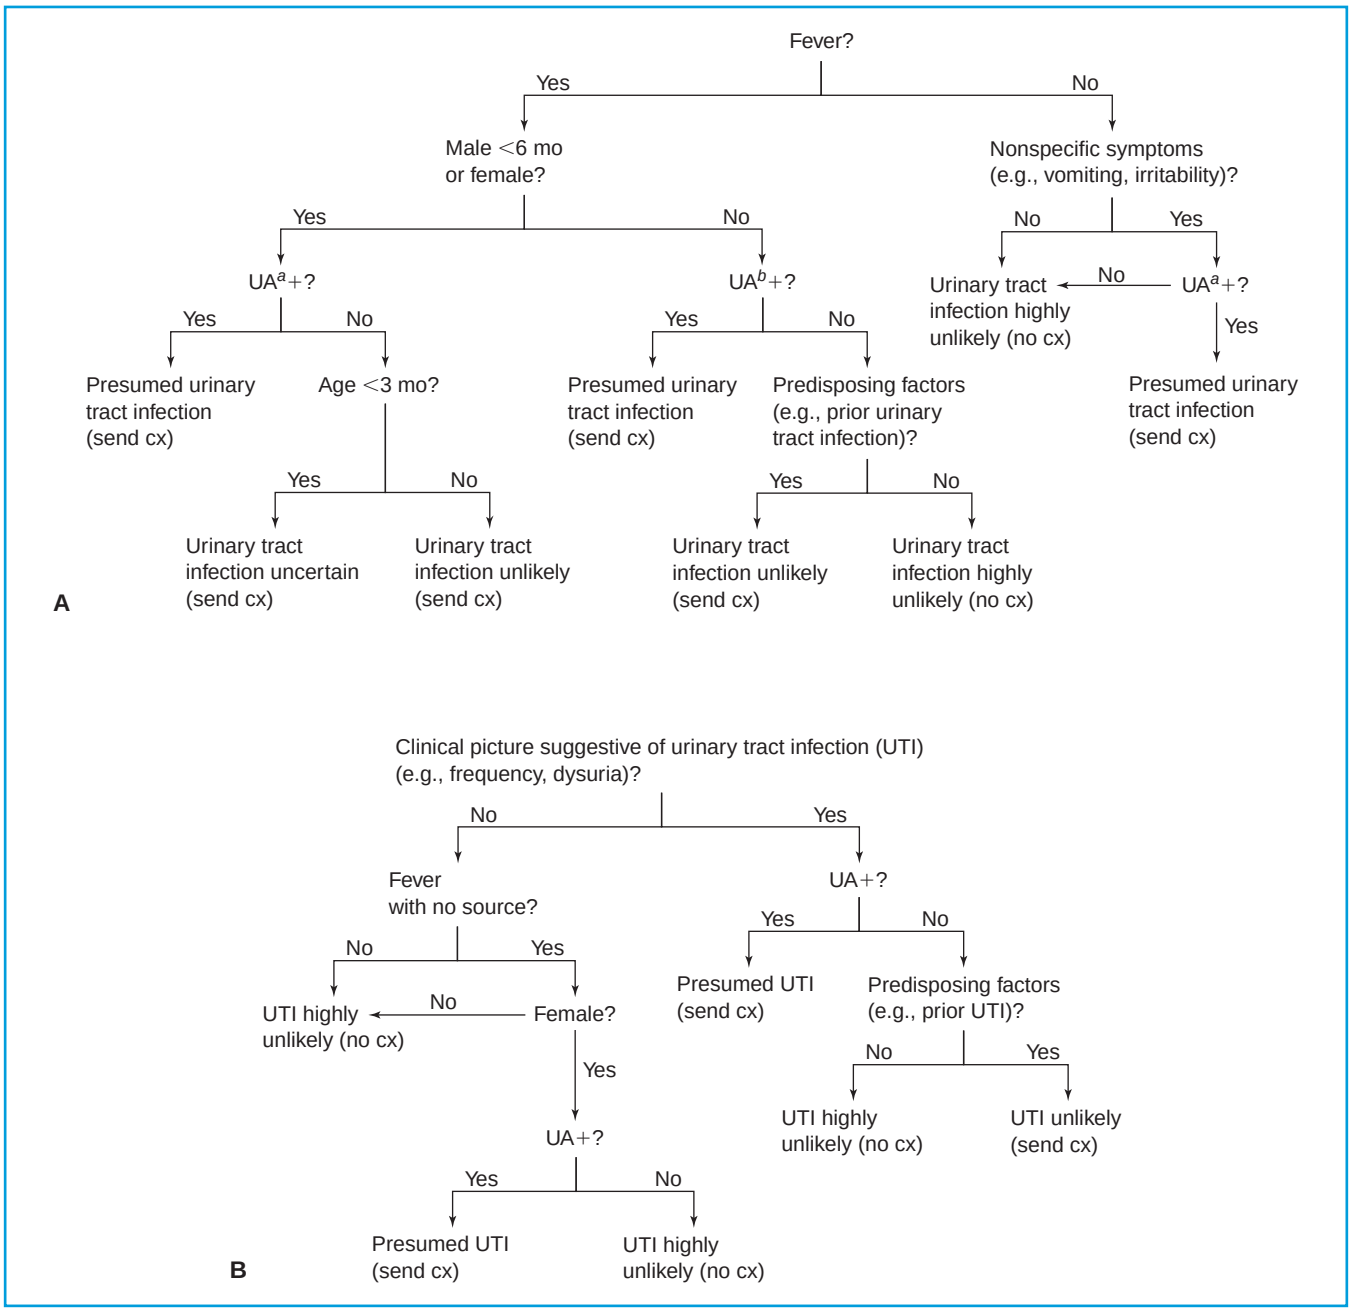

FIGURE 92.23 Diagnostic approach to infants and children with fever, symptoms specifically suggestive of urinary tract infection (UTI), and/or nonspecific symptoms and signs compatible with UTI. Use of urinalysis (UA) and culture (cx) in the diagnosis of UTI (**A**) in children age 2 years or younger and (**B**) in those older than 2 years. [a]UA obtained by catheterization or suprapubic aspiration. [b]UA (only) may be obtained using a urine collection bag.

signs of clinical toxicity (extreme tachycardia, low blood pressure, shaking chills); (ii) age younger than 3 months; and (iii) age 3 months to 1 year and temperature greater than or equal to 39°C (102.2°F). Children with dehydration or likely pyelonephritis (as opposed to cystitis) require measurement of electrolytes, BUN, and creatinine.

Management

When the diagnosis of UTI has been established as a result of earlier urine culture or is presumed based on the clinical syndrome and findings on urinalysis, antibiotic therapy is indicated. The clinician may choose to await the results of culture before prescribing antibiotic therapy, when the combination of clinical symptomatology and urinalysis is suggestive but not strongly presumptive. If available, the results of susceptibility testing should guide the selection of antimicrobial agent. In all other cases, an antibiotic is chosen to cover the most likely pathogens.

Most patients respond to oral antibiotic therapy. Indications for IV administration of antibiotics include (i) clinical toxicity; (ii) age younger than 2 months; (ii) vomiting, refusal to drink, or other factors making the delivery of oral medications unreliable; (iv) adverse anatomic factors, such as an obstruction to urinary flow; and (v) a known positive culture for a pathogen not susceptible to oral agents.

For ill-appearing patients, IV ampicillin (200 mg per kg per day in four divided doses) plus gentamicin (5 to 7.5 mg per kg per day in a single dose, adjusted for gestation age and weight; Table 92.4) are given. Cefotaxime (150 mg per kg per day divided into three 50 mg per kg daily IV doses) provides an alternative. Options for oral therapy in children, given for a 7- to 10-day course, include cefdinir (14 mg per kg per day as a single dose), cefixime (8 mg per kg per day as a single dose), or trimethoprim-sulfamethoxazole (8 mg per kg per day of trimethoprim in two divided doses), if the regional prevalence of resistance to this antibiotic is low. Fluoroquinolones, such as ciprofloxacin (500 mg twice daily), offer an alternative for adolescents. As 20% to 30% of the strains of *E. coli* demonstrate resistance to ampicillin, the physician should not choose this drug or amoxicillin for oral therapy, unless local patterns of susceptibility dictate otherwise.

SPECIFIC INFECTIONS

Viral Syndrome

The term *nonspecific viral syndrome* is used to refer to a generalized illness, presumed clinically to be caused by a virus and characterized by malaise and, usually, fever. Numerous agents, including influenza, enteroviruses, and herpesvirus (roseola), have been implicated. Nonspecific viral syndromes and viral URIs account for most of the febrile visits made by children to the ED.

Usually, a viral syndrome begins with malaise and fever. The temperature varies from 37°C (98.6°F) to more than 40°C (104°F), greater elevations occurring particularly in children younger than 2 years. Children who are older and able to verbalize their discomfort complain of diffuse aching, especially with influenza. There may be a cough or occasional bout of emesis. Signs of mild inflammation may be seen in the upper respiratory tract.

The physician arrives at a diagnosis of a nonspecific viral syndrome by excluding other diseases on the basis of the history and physical examination. Particularly in children younger than 6 months and/or not fully immunized against bacterial pathogens, a WBC count may help the physician determine whether the young child with a high fever is at risk for occult bacteremia (see "Bacteremia" section). Treatment is limited to antipyresis with acetaminophen (15 mg per kg per dose, maximum 4000 mg per day) or ibuprofen (10 mg per kg per dose, maximum 800 per dose), for patients who do not respond to acetaminophen, and the maintenance of an adequate oral intake. Antibiotics will not prevent secondary bacterial infections and are not to be prescribed routinely. Generally, parents should seek further care for their children if fever persists for more than 48 hours, although additional testing or therapy will only occasionally be needed. When fever persists for more than 5 days in infants and young children, at least passing consideration should be given to occult bacterial infections, such as UTI, and to Kawasaki disease.

Influenza

Influenza viruses A and B produce annual outbreaks of disease during the winter months that involve 10% to 40% of healthy children during each cycle. Infection may produce a generalized viral syndrome, predominant respiratory symptomatology, or less commonly, other syndromes, including a sepsislike picture in young infants, croup, bronchiolitis, pneumonia, diffuse myositis, and rarely Reye's syndrome (usually following the administration of aspirin). Older children with influenza classically manifest sudden onset of fever, chills, malaise, headache, a nonproductive cough, and diffuse myalgia. Some may develop nasal congestion, sore throat, and occasionally conjunctivitis. Myositis may be sufficiently severe as to cause an inability/refusal to walk and tenderness of palpation of the muscles, particularly in the calf.

Influenza may be diagnosed on the basis of rapid testing of nasopharyngeal material for antigen, viral culture of the nasopharynx, or the collection of acute and convalescent sera for serology. With myositis, serum CPK levels may be elevated. In the ambulatory setting, the rapid tests have the greatest utility, although sensitivity is only in the 50% to 70% range. Specific therapy is available for some strains of influenza but is generally reserved for (i) patients with underlying conditions, such as chronic lung disease or immunosuppression, that place them at risk for prolonged or severe infection; (ii) healthy children with unusually severe illness; and (iii) individuals with special social or family situations for which ongoing illness would be detrimental; (iv) circumstances where there are newly circulating strains with increased rates of morbidity or mortality (e.g., H1N1 flu, avian flu). The specific antivirals recommended (e.g., oseltamivir, zanamivir, rimantidine) will depend on the susceptibility of circulating strains. The CDC posts regular updates regarding influenza activity and treatment recommendations at http://www.cdc.gov/flu. Vaccination and chemoprophylaxis are occasionally advised in the acute care setting, and standard references are available with specific indications and dosage schedules.

Erythema Infectiosum (Fifth Disease)

Erythema infectiosum, or fifth disease, is an exanthematous illness of childhood caused by parvovirus B19. It occurs most

commonly between 2 and 12 years of age. The appearance of a rash marks the onset of the disease; fever or other prodromal symptoms are uncommon. The rash involves the face initially, conferring on the child a "slapped-cheek" appearance. Maculopapular lesions erupt 24 hours later, initially on the upper portion of the extremities, and they then spread both proximally and distally. Fading of the central portion of the lesions gives a lacelike appearance to the rash. Adolescents in particular may develop arthralgia or arthritis, and patients with chronic hemolytic anemias, such as sickle cell disease, are at risk for aplastic crisis. During pregnancy, infection with parvovirus B19 causes fetal hydrops in approximately 10% of cases. There is no specific therapy in the normal host, but immunocompromised patients may benefit from IV gamma globulin.

Infectious Mononucleosis

Background

Infectious mononucleosis (IM) is a disease characterized by malaise, fever, pharyngitis, lymphadenopathy, and splenomegaly. In 1968, Henle and Henle identified EBV as the cause of this illness. EBV infections are common, but usually relatively asymptomatic, during the first years of life. In children, sporadic infections occur, and IM is occasionally diagnosed. By late adolescence, 50% to 90% of all people are seropositive. In lower socioeconomic groups infections are most common in the preschool age where infections are typically mild. Children in higher socioeconomic groups are commonly infected in adolescence and young adulthood; half of these will experience the clinical manifestations of IM.

Pathophysiology

EBV is shed in oropharyngeal secretions, which represent the major source of infectious virus. The virus infects B lymphocytes that may spread to the various lymphoid tissues in the body. The atypical lymphocytes seen in the circulation represent activated, EBV-specific cytotoxic (CD8)-suppressor T lymphocytes, which destroy the infected B cells and limit the production of virus. Natural killer lymphocytes also play a role and together these changes result in a transient general depression of cellular immunity.

Clinical Manifestations

IM begins insidiously with fever and malaise. Three-fourths of children with this illness complain of a sore throat. Although a child may recover from IM in 7 to 10 days, the symptoms usually last for 2 to 4 weeks. This persistence of symptoms separates the patient with IM from those with pharyngitis caused by group A streptococci or other viruses. Occasionally, the onset resembles that of infectious hepatitis.

The symptomatic child with IM is febrile in 90% of cases at presentation. The fever often persists for several days and low-grade fevers may persist for 2 weeks or more. Enlarged lymph nodes are uniformly palpable. Although the lymphadenopathy may be limited to the cervical region, involvement of the axillary and inguinal areas is common. Pharyngitis caused by any pathogen produces an increase in the size of the anterior cervical nodes, but EBV characteristically affects the posterior cervical and submental glands as well (Fig. 92.24). In 75% of cases, the pharynx is inflamed, often with an exudate. The spleen enlarges in 60% of children typically in the second week of illness and the hepatomegaly occurs in 25%. Some elevation of liver transaminases (AST and ALT) occur in 80%. Periorbital edema and a diffuse maculopapular rash are seen occasionally.

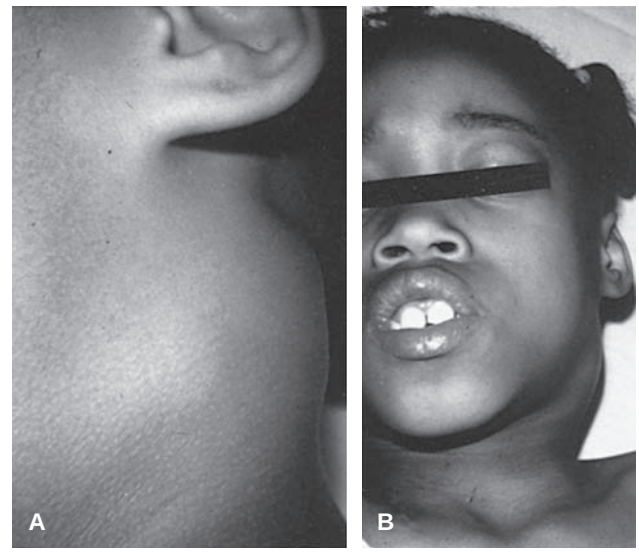

FIGURE 92.24 Posterior cervical adenopathy in a child with infectious mononucleosis. **A:** Close-up of posterior adenopathy. **B:** Anterior and posterior cervical node enlargement.

The hemoglobin and hematocrit are normal in the uncomplicated disease. Although the total WBC count does not often increase much beyond 15,000 per mm^3, levels up to 30,000 per mm^3 are seen in 10% to 15% of children. A higher leukocyte count casts some doubt on the diagnosis of IM. There is an absolute lymphocytosis with many atypical mononuclear cells; however, 16% of children presenting with IM in one series had fewer than 10% atypical lymphocytes, and 50% had fewer than 20% of such cells. The mainstay for the diagnosis of IM in the adult is the heterophil antibody test, but these antibodies reach levels detectable by routine assays in only 50% of young children. Confirmation of a heterophil-negative case of IM is typically by EBV-specific serologic assays. Serum PCR tests for EBV are available and may be useful in selected circumstances.

The most worrisome complications of IM in the immunocompetent host for the emergency physician are splenic rupture and airway obstruction. Even minor trauma can cause a rent in the capsule of the enlarged spleen seen in IM; these children manifest the usual signs of intraperitoneal hemorrhage. Occasionally, massive lymphoid hyperplasia of the tonsils occludes the airway, leading to stridor and retractions. The site of narrowing is easily visualized on examination. Less common complications include encephalitis, pneumonia, myocarditis, hemolytic anemia, and thrombocytopenia.

Patients with immunosuppression related to transplantation (visceral, liver, kidney, lung, cardiac, stem cell) receiving agents such as antithymocyte globulin, cyclosporine, and tacrolimus are at risk for EBV-related posttransplant lymphoproliferative disorders (PTLD). Patients with AIDS may experience EBV related lymphocytic interstitial pneumonitis (LIP),

lymphoma. EBV is also associated with the development of X-linked lymphoproliferative syndrome and infection-associated hemophagocytic syndrome (HLH). These latter entities occur among patients with specific defects in regulating EBV proliferation and/or the immunologic response to infection.

Management

A WBC count and heterophil antibody titer usually suffice for the confirmation of the clinical diagnosis. EBV-specific antibodies are indicated only for heterophil-negative cases. Specific therapy is not available. Adequate rest and nutrition should be maintained, and antipyretic agents will increase the child's comfort. Children with airway compromise can be treated with oral corticosteroids, which will almost always dramatically shrink the enlarged tonsils. Prednisone is given at 2 mg per kg for the first few days and tapered, once improvement has occurred, over 5 to 7 days. Antivirals such as acyclovir or ganciclovir do not have demonstrated efficacy in immunocompetent hosts. Consultation with an infectious diseases specialist should be considered for management of EBV infection or its complications in the immunocompromised host.

Measles (Rubeola)

Background

Measles is a disease caused by a specific myxovirus and is characterized by fever, cough, coryza, conjunctivitis, and rash. Since the widespread introduction of effective vaccines, the incidence of this disease has decreased significantly. In 2001, just over 100 cases were reported to the CDC.

Pathophysiology

Measles virus enters the body through the upper respiratory tract, where local replication is believed to occur. A transient viremia ensues, and virus spreads to the reticuloendothelial system. A secondary viremia then follows, producing the clinical disease.

Clinical Findings

Fever and malaise herald the onset of measles. During the course of the illness, the temperature often rises to 40°C (104°F). Within 24 hours, coryza, conjunctivitis, and cough develop. Koplik's spots appear on the buccal mucosa by the third day of fever. These are seen as fine white spots on an erythematous background and have been likened to grains of sand. The rash erupts on the fourth or fifth day. The exanthem is maculopapular in appearance and begins on the face and neck. The lesions are heaviest on the upper portion of the body, often coalescing. As the rash advances down the trunk, the prodromal findings (cough, coryza, conjunctivitis) and the Koplik's spots resolve. The rash involves the extremities on its third day but has already begun to fade on the face. A leukopenia and lymphopenia accompanies uncomplicated measles. Specific antibodies, initially absent from the serum, reach detectable levels 2 weeks after the onset of illness.

Complications, which are unusual, fall into two categories: (i) extension of the viral infection and (ii) secondary bacterial infection. The virus itself may produce inflammation of the lower respiratory mucosa, leading to laryngotracheitis, bronchitis, and/or pneumonia. Encephalitis occurs in 1 of every 1,000 cases of measles; this is a debilitating illness with a mortality rate of 15%. Thrombocytopenia and corneal ulcerations are rarely seen. Lymphoid hyperplasia in the bowel can occlude the lumen of the appendix, leading to inflammation of this organ; histologic examination of surgically removed tissue confirms the diagnosis of measles on the basis of the characteristic giant cells. Acute purulent OM is the most common bacterial complication of measles, and cervical adenitis occasionally occurs. Pneumonia, although usually viral, may have a bacterial etiology.

Management

Clinical clues, gathered from the history and physical examination, suffice for the diagnosis of measles by the experienced clinician. However, most U.S. physicians are no longer familiar with this disease. As a result, and for epidemiologic purposes, serologic studies are used to confirm the cause, particularly among the first few children seen in sporadic outbreaks. Ordinarily, acute and convalescent titers drawn 1 to 2 weeks apart are used for a determination, but a single specimen positive for measles-specific IgM antibodies is sufficient.

Measles runs a self-limited course. Bed rest and antipyretic therapy help keep the child comfortable. Antitussives, antihistamines, and topical ophthalmic preparations have no role. Prophylaxis against secondary bacterial infections with antibiotics is not warranted. Children with uncomplicated measles or superficial secondary infections such as otitis and cervical adenitis can be treated as outpatients. Hospitalization is required when significantly severe laryngotracheobronchitis is evident, as discussed earlier in this chapter. Lower respiratory tract or CNS involvement necessitates admission to the hospital.

Measles is a preventable disease. Otherwise healthy, susceptible contacts should receive intramuscular immune serum globulin, 0.25 mL per kg; the dose is increased to 0.5 mL per kg for immunocompromised patients. Unless the patient is younger than 6 months or immunocompromised, vaccine is also indicated within 72 hours of exposure (see Appendix D).

Roseola

Roseola infantum, or exanthem subitum, is a common, self-limiting, viral infection of infants caused in most cases by human herpesvirus 6; and only occasionally by human herpesvirus 7. The child, usually younger than 3 years, presents with a high fever, ranging up to 40.5°C (104.9°F), and a paucity of physical findings. Mild irritability may occur, half have some URI, mild pharyngeal erythema and may have red tympanic membranes. There is typically no bulbar conjunctivitis but some mild palpebral redness may be seen. A bulging fontanelle is seen in 25% of young infants and neurologic complications can be seen (most commonly seizure). After 2 to 4 days of illness, the fever drops precipitously and a rash appears. The lesions are discrete, pink maculopapules, 2 to 3 mm in diameter. They fade with pressure and do not coalesce. The exanthem appears on the trunk initially and spreads outward. Roseola resolves without complications other than an occasional febrile convulsion. The diagnosis of roseola is made on the basis of the clinical course, often in retrospect. If a WBC count is obtained, it is typically low for age. CSF when

obtained is typically normal. Specific testing is not typically warranted. Treatment is symptomatic and generally limited to antipyretic agents except in cases of reactivation in severely immunocompromised patients.

Rubella

Background

Rubella is a childhood infection caused by a specific togavirus. Before the advent of vaccination, epidemics occurred every 6 to 9 years; 488,796 cases were reported to the CDC in the United States in 1964, the year of the last outbreak in this country. In contrast, the CDC reported only 18 cases in 2002. Rubella traditionally affects children 5 to 9 years of age. The initial site of inoculation is the upper respiratory tract, where local replication occurs. A viremia ensues, disseminating the virus to the skin.

Clinical Manifestations

Only 10% of children experience prodromal symptoms such as fever, malaise, cough, and mild conjunctivitis. However, these complaints are often voiced by the adolescent. The rash begins on the face and spreads downward, reaching the extremities by the end of the second day. The lesions are pink maculopapules that may coalesce. The lymph nodes in the postauricular, suboccipital, and posterior cervical chains enlarge and become somewhat tender. During the first 2 days of illness, the temperature usually rises, but remains less than 39°C (102.2°F). The WBC count often decreases in rubella, and a few atypical lymphocytes may appear. A fourfold rise in specific antibodies occurs after 10 to 14 days.

Complications of rubella are rare in children but include encephalitis, thrombocytopenia, and arthritis or arthralgia. Painful and/or swollen joints often occur in adolescents. Encephalitis has an incidence of 1 in 6,000 cases of rubella and usually resolves spontaneously.

Management

Rubella is difficult to diagnose clinically because of its rare occurrence and the plethora of exanthems that have a similar appearance. Situations that require a definite etiologic diagnosis, such as pregnancy in an adolescent, demand serologic confirmation. Children with rubella can be managed as outpatients with antipyretic therapy. Only the rare child with encephalitis or thrombocytopenia requires admission to the hospital.

Varicella/Zoster

Background

Herpesvirus varicellae causes two clinical illnesses, varicella (chickenpox) and zoster (shingles). Varicella occurs during a primary infection, and zoster occurs after a reactivation of latent virus.

With introduction of a vaccine in 1995, varicella has become a relatively uncommon infection in children but cases continue to be seen with the CDC reporting approximately 10,000 cases in 2008. Varicella is highly contagious: Almost 90% of susceptible household contacts of an index case develop the disease. By adolescence, serologic surveys have shown a seropositive rate of 70% to 80%. Zoster, however, affects adults predominantly. More than 60% of cases occur in persons older than 45 years.

Pathophysiology

The virus typically enters the body on inhalation of virus exhales by patients with chickenpox or contact with skin lesions of patients with varicella or shingles. The virus is then thought to spread to regional lymph nodes and cause a primary viremia infecting cells of the reticuloendothelials cells of the liver and it is the secondary viremia that causes the skin lesions seen in primary infection. During an episode of varicella, the virus invades sensory nerve endings and ascends to the dorsal root ganglion where it becomes latent. Zoster follows reactivation of the latent virus.

Clinical Findings

Varicella. A mild prodrome that lasts 1 to 3 days often precedes the exanthem of varicella; however, the first sign of illness may be the rash. Most children develop fever, usually less than 39.5°C (103.1°F) and may complain of malaise. The fever usually has subsided within 24 hours of the appearance of the skin lesions. Recurrence of significant fever should serve as a warning sign for suspicion of complications. Lesions erupt initially on the upper trunk, neck, or face and spread centripetally. Pruritus is universal.

The abnormal findings on physical examination are limited to the elevated temperature and the skin and mucous membrane lesions. Initially, the exanthem consists of erythematous papules that evolve into vesicles and then pustules over 6 to 8 hours (Fig. 92.25). The early vesicles have a diameter of 2 to 4 mm and a "dewdrop-like" appearance. Because new lesions erupt in crops for 2 to 4 days, papules, vesicles, and pustules are usually seen together. An exanthem involves the mucosa of the oropharynx and, occasionally, the vagina. The severity of the cutaneous manifestations varies widely, and there may be from 1 to more than 1,000 lesions.

Previously vaccinated children may experience breakthrough varicella infection following exposure to wild-type virus. The illness is usually mild without much fever and typically few skin lesions that may remain maculopapular rather than becoming vesicular. Because of its atypical presentation diagnosis frequently depends on an exposure history. Not all cases of breakthrough varicella are mild and a minority of patients will have clinical features similar to those occurring in unvaccinated patients. These children, especially if immunocompromised, should be considered for treatment as they would if unvaccinated.

There are few laboratory derangements in varicella. The WBC count occasionally shows a leukocytosis, and the AST and ALT may be mildly elevated. In adolescents, the chest radiograph reveals an interstitial infiltrate in 5% to 10% of patients, even though there may be no respiratory symptoms.

Varicella runs a self-limited course in most cases but is occasionally a more serious illness. Fleisher et al. reviewed 96 children hospitalized with complications of this disease during a 5-year period at The Children's Hospital of Philadelphia. Of the group, 81 were immunocompetent children older than 1 month; they experienced complications, including encephalitis (20),

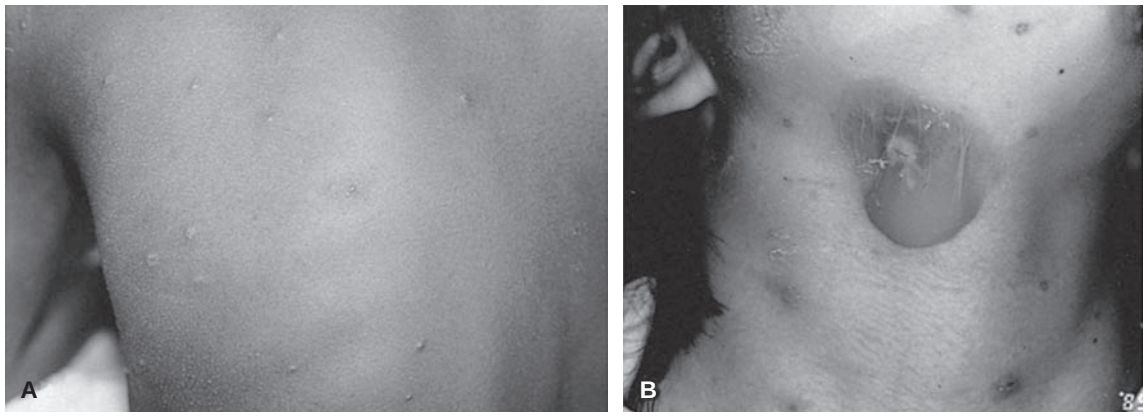

FIGURE 92.25 **A:** Typical lesions of varicella. **B:** Bullous varicella.

pneumonia (5), hepatitis (8), bacterial superinfection (22), Reye's syndrome (17), unusual cutaneous manifestations (5), medication overdoses (5), exacerbation of an underlying disease (2), and dehydration (1). Simultaneous streptococcal pharyngitis can also occur.

Encephalitis takes two forms: (i) a diffuse cerebritis with coma and seizures, and (ii) a cerebellitis with ataxia. Both varieties may occur before, during, or after the cutaneous eruption. Because bacterial meningitis can also complicate varicella, an analysis of the CSF should be considered even if viral encephalitis is suspected. There will often be a mild pleocytosis (10 to 300 cells) and a slight elevation of the protein (40 to 80 mg per dL). If the encephalopathy is believed to be related to Reye's syndrome, a serum ammonia should be obtained.

Starting in approximately 1990, a number of authors reported an increasing incidence of group A streptococcal complications with varicella, including primarily sepsis and necrotizing fasciitis. The diagnosis of streptococcal sepsis should be considered in patients who appear toxic, remain febrile for 5 days or more, or develop a fever after being afebrile for more than 48 hours.

Zoster. Zoster appears suddenly in most children without any warning symptoms (pain or pruritus). The lesions are grouped vesicles on an erythematous base in a dermatomal distribution. In 15% to 20% of cases, extradermatomal cutaneous dissemination is seen. However, spread to the viscera does not occur in the immunocompetent child. If the eruption follows the ophthalmic branch of the trigeminal nerve, the cornea may be involved. The appearance of vesicles on the tip of the nose should evoke a suspicion of ocular involvement that can be best seen after fluorescein staining of the eye. Zoster in childhood occurs most commonly among children who had varicella in the first 1 to 2 years of life; it may affect vaccinated patients.

Management

Visual inspection suffices for the diagnosis of varicella; no laboratory studies are indicated. Acetaminophen is given to control the fever, and antihistaminic drugs provide some relief from the pruritus. Aspirin is contraindicated because of an association with Reye's syndrome. Although some investigators have speculated about a relationship between the use of ibuprofen and the development of fasciitis, this remains unproven. Diphenhydramine (5 mg per kg per day), hydroxyzine (2 mg per kg per day), or other antihistamines may be used to decrease pruritus. The child is excluded from attending school for 1 week after the eruption of the first lesion.

Immunosuppressed children with varicella should be treated with acyclovir (30 mg per kg per day IV in three divided doses per day), or oral famciclovir, or oral valacyclovir (note the doses are higher than required for HSV infections, with the exception of HSV encephalitis). Complications that mandate admission to the hospital for immunocompetent patients include fasciitis, Reye's syndrome, pneumonia, and encephalitis, except in the mildest cases. Superficial bacterial infections such as impetigo, cellulitis (if fasciitis is believed to be unlikely), and adenitis can be treated with oral antibiotic therapy such as dicloxacillin, cephalexin, clindamycin, and/or trimethoprim sulfamethoxazole as discussed previously in this chapter. Children with deeper bacterial infections (i.e., septic arthritis) should receive IV antimicrobials.

For immunocompetent children, oral acyclovir (80 mg per kg per day in four divided doses) given within 24 hours of the onset of the rash reduces the duration of fever and the number and duration of skin lesions. Indications for use have not been formalized, but consideration is warranted for patients who are at some risk for a particularly severe course: infants younger than 6 months old, adolescents (older than 12 years), children receiving long-term aspirin therapy or being treated with oral/inhaled steroid, patients with chronic cutaneous (e.g., atopic dermatitis) or pulmonary (e.g., cystic fibrosis) disorders, and those with fever above 40°C (104°F) and a large number of lesions noted as early as the first day of the eruption (particularly if case follows a household contact). Oral acyclovir should be considered for the pregnant adolescent, but its use remains controversial in this situation.

Zoster (or shingles) is typically treated with oral famciclovir or valacyclovir in adults with the primary goal of reducing postherpetic neuralgia. Postzoster pain syndromes are, fortunately, uncommon in children and efficacy has not been demonstrated in this group. Antipruritic and antipyretic agents provide symptomatic relief. Immunocompromised children should be treated with acyclovir, famciclovir or valacyclovir with the goal to prevent dissemination and shorten the

duration of new lesion formation. Ocular involvement merits consultation with an ophthalmologist.

Anyone likely to experience a severe episode of varicella should receive prophylaxis after a significant exposure to a patient contagious for varicella-zoster virus (household or close contact for more than 1 hour in a closed environment). Varicella-zoster immunoglobulin, one vial (125 units) per 10 kg, is indicated for susceptible normal adults, pregnant women, and immunocompromised children. Newborns whose mothers have had onset of varicella within 5 days before or 2 days after delivery should receive 125 units, as soon as possible (see Appendix D).

MISCELLANEOUS INFECTIONS

Babesiosis

Babesia species, particularly *Babesia microti*, are protozoa, transmitted by the bite of an *Ixodes* tick, which also serves as a vector in Lyme disease. Cases of this infection have been reported with increasing frequency along both coasts and in the upper Midwest. The majority of infected children are asymptomatic or experience only mild symptoms. However, the clinical picture of babesiosis can resemble that of malaria and is characterized by anorexia; malaise; fatigue; and intermittent chills, sweats, and fevers (Fig. 92.26) as high as 40°C (104°F). Other than an elevated temperature, physical findings are absent or limited to mild hepatosplenomegaly. Patients with asplenia are susceptible to severe, or even life-threatening, disease, especially with *Babesia divergens* (more often seen in Europe). Laboratory findings include hemolytic anemia with reticulocytosis, a normal or slightly decreased leukocyte count, mild thrombocytopenia, and elevated liver enzymes. Microscopic examination of a peripheral smear confirms the presence of intracellular and extracellular ring forms, similar to those of *Plasmodium falciparum*. The degree of parasitemia is generally less than 20% in patients with functional spleens but can exceed 85% in asplenic patients. Specific serologic assays are also available, but the results are often delayed for several weeks and do not distinguish between acute infection and asymptomatic seropositivity. Therapy is reserved for patients with symptomatic infections or a predisposition to severe disease. The treatment of choice is clindamycin (30 mg per kg per day in three divided doses) plus quinine (25 to 30 mg per kg per day in three divided doses) orally or atovaquone (40 mg per kg per day in two divided doses) plus azithromycin (12 mg per kg once daily) orally for 7 days. The latter combination (atovaquone and azithromycin) is associated with fewer adverse reactions.

Botulism

Background

Botulism is a paralytic illness produced by neurotoxins elaborated by *Clostridium botulinum*. The disease may result from the ingestion of preformed toxin or from the elaboration of toxin by organisms in a wound or in the GI tract. Of particular concern to the physician who cares for children is infantile botulism caused by toxin formed in the intestines. In the United States, the CDC reports approximately 100 cases of infantile and 20 cases of foodborne botulism annually.

During growth, *C. botulinum* releases neurotoxins that are the most potent poisons known on a weight basis. They interfere with neurotransmission at peripheral cholinergic synapses by blocking the release of acetylcholine.

Clinical Manifestations

Botulism from the ingestion of toxin, which affects children and adolescents, as opposed to infants, causes vomiting in 50% of cases. The patients complain of weakness and a dry

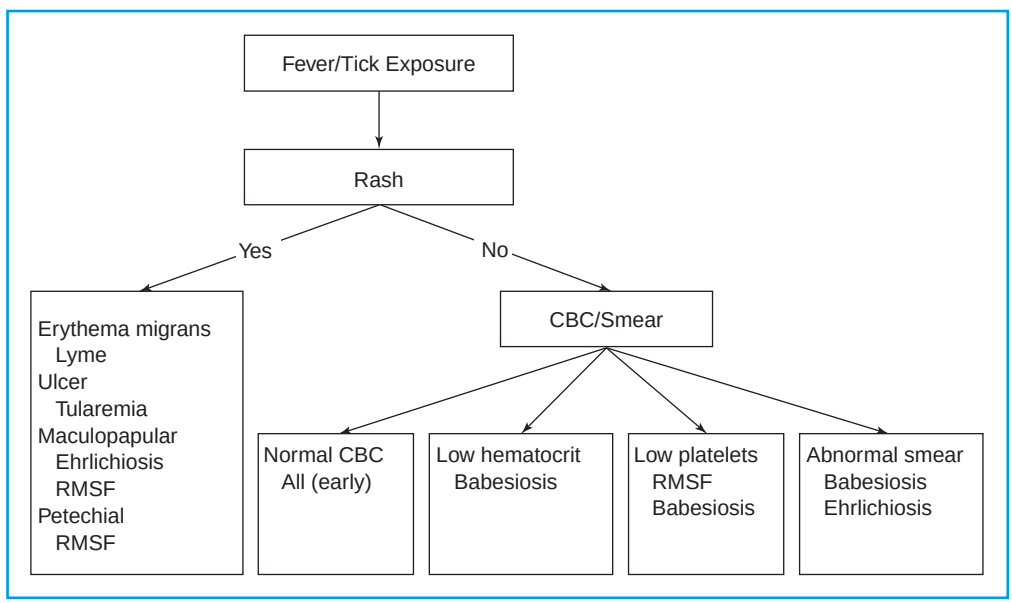

FIGURE 92.26 Approach to the febrile child with an exposure to ticks. CBC count, complete blood cell count; RMSF, Rocky Mountain spotted fever.

mouth; constipation and urinary retention may occur. Paralysis is noted within 3 days, usually affecting the cranial nerves first and then the extremities. The patients are alert and afebrile. Abnormalities of the neurologic examination include ptosis, extraocular palsies, fixed dilated pupils, symmetric weakness, and hyporeflexia. Both the ileus and urinary retention seen in this disease may lead to abdominal distension.

Infantile botulism occurs in children in the first 6 months of life who are otherwise healthy. The duration of symptoms before hospitalization ranges from 1 to 20 days. Breastfed, Caucasian infants from middle-class families are primarily affected. Constipation is the first symptom of the disease but may not be sufficiently severe to draw attention to any underlying illness. After several days, mild lethargy, weakness, and a decreased appetite are noted. Occasionally, the onset of lethargy and weakness may be so precipitous as to resemble bacterial sepsis or meningitis.

On examination, the infant is quiet, with little discernible movement, and has a weak cry. Fever is not a part of this syndrome. The child sucks on a nipple with difficulty and may be unable to swallow. The absence of a gag reflex, profound hypotonia, and hyporeflexia in infantile botulism helps distinguish this illness from bacterial sepsis.

The WBC count is normal in botulism. Organisms may be recovered by anaerobic culture techniques from the GI tract in infantile or wound botulism, but identification of the toxins requires the specialized facilities of the public health department. Children with botulism have an electromyogram that shows a characteristic pattern of brief duration, small amplitude, overly abundant motor unit action potentials (BSAP).

Respiratory failure is a potential life-threatening complication in botulism of any variety, and ventilatory support is often required. The profound bulbar weakness in infantile botulism often prevents an adequate fluid intake; dehydration occurs frequently.

Management

Because no test is immediately available to diagnose infantile botulism, the initial evaluation of these infants aims at excluding other causes of lethargy and weakness such as sepsis, poliomyelitis, myasthenia gravis, neuropathy, and drug ingestion. A lumbar puncture is often performed in the ED to rule out meningitis. Electrolytes and a BUN are useful to assess hydration.

The children all require admission to the hospital (Table 92.21). Monitoring of pulse and respiratory rate should start in the ED. An IV line should be started for the administration of fluids to correct dehydration and in anticipation of a possible respiratory arrest. Neither antibiotics nor antitoxin ameliorate the course of infantile botulism. Because they may potentiate the neuromuscular blockade, aminoglycoside antibiotics should be avoided when treating for possible sepsis when there is a concomitant concern for botulism.

Children with foodborne and wound botulism also require admission to the hospital. All children suspected clinically of having botulism should be treated with a single dose of human botulism immune globulin IV (BIG-IV or BabyBIG) while awaiting confirmation by testing. Such treatment has been documented to substantially reduce length of stay, need for mechanical ventilation, and the need for parenteral nutrition or nasogastric feeds. However, because of the notable expense and difficulty obtaining of this therapy, consultation with a *toxicologist or infectious diseases specialist* is typically warranted. Information on obtaining the drug is available at http://www.infantbotulism.org/

TABLE 92.21

INFANTILE BOTULISM: IMMEDIATE MANAGEMENT

Ensure adequate ventilation.	Achieve venous access and maintain hydration.
Administer oxygen, as indicated.	Obtain laboratory studies.
Initiate cardiorespiratory monitoring.	Administer botulism immune globulin (BIG) as soon as available

Cat-scratch Disease

CSD is an infection caused by *B. henselae*. Approximately 80% of cases occur in patients younger than 20 years. Traditionally, this disorder has been thought of primarily as an infection of regional lymph nodes (typical CSD), but the spectrum of the disease has been expanded to include infections of other organ systems by *B. henselae* (atypical CSD). In addition, this same agent causes severe infections (bacillary angiomatosis and peliosis hepatis) in patients with HIV (see Chapter 93).

More than 90% of children with typical CSD have a history of exposure to cats. The most complete form of the illness begins with the appearance of a pustule at the site contact, 7 to 10 days after exposure. Lymphadenopathy follows within 1 to 6 weeks. The regional nodes enlarge and become mildly to moderately tender on palpation. In one-third of cases, the glands become fluctuant. The epitrochlear, axillary, inguinal, and cervical nodes are commonly affected.

Manifestations of atypical CSD include encephalitis, aseptic meningitis, neuroretinitis (blindness and stellate macular lesions of the retina), Parinaud's syndrome (conjunctivitis and preauricular adenitis), hepatitis, osteolytic lesions, and fever of unknown origin.

In typical cases with a history of exposure, particularly to a kitten, and characteristic lymph node enlargement, no specific diagnostic studies are needed. In atypical disease or with lymphadenopathy that is not characteristic, serologies should be sent.

Various antibiotics have been reported to have some efficacy for CSD, including rifampicin, TMP-SMZ, ciprofloxacin, and azithromycin. The only controlled study of patients with typical CSD found that azithromycin (10 mg per kg in a single dose on day 1, followed by 5 mg per kg once daily on days 2 through 5) shortened the duration of adenopathy. Although not definitive, some current authorities recommend this antibiotic at 12 mg per kg daily for 5 days. Nodes that persist and become fluctuant usually resolve after needle aspiration.

Ehrlichiosis and Anaplasmosis

Ehrlichia chaffeensis causes human monocytic ehrlichiosis and *Ehrlichia ewingii* can also cause disease. *Anaplasma phagocytophilum* causes a disease known as human granulocytic

anaplasmosis. These three infections are transmitted by a number of tick vectors. The disease they produce may resemble Rocky Mountain spotted fever (RMSF) with symptoms of fever, chills, malaise, myalgias, nausea and headache. Additional symptoms may include vomiting, diarrhea, cough, arthralgias and confusion. Unlike RMSF, rash may develop late in the illness and occurs in only 60% of patients with human monocytic ehrlichiosis and rarely with human granulocytic anaplasmosis. The infection may spread to involve the meninges or cause the typical complications of septic shock. Laboratory findings may include anemia, thrombocytopenia, leukopenia, lymphopenia, hyponatremia, and mildly elevated liver enzymes. Examination of the peripheral smear may show inclusions (morulae) in monocytes or granulocytes (depending on the species) but these not uniformly seen. A definitive diagnosis relies on serology, detection of Ehrlichia or anaplasma DNA by PCR, antigen detection by immunohistochemical methods, or isolation in cell culture any of which is available only from reference laboratories. The treatment of choice is doxycycline (3 mg per kg per day in two divided doses), even for children younger than 8 years; chloramphenicol (75 to 100 mg per kg per day in four divided doses) offers an alternative.

Malaria

Malaria is a protozoal infection that occurs in humans and is caused by four species: *P. falciparum, Plasmodium vivax, Plasmodium ovale*, and *Plasmodium malariae*. Although one of the most common infections in the world, malaria is rare in the United States; about 1,000 cases occur annually. This illness should be considered particularly in recent immigrants from tropical areas and in travelers, but there have been a handful of indigenously acquired cases since 1990, including transmission in the northeastern part of the country. At times, malaria may be fatal, particularly with infections from *P. falciparum*.

Pathophysiology

Plasmodia gain access to the bloodstream when a person is bitten by a female anopheline mosquito or, rarely, by transfusion or transplacentally. The sporozoites invade liver parenchymal cells that subsequently release merozoites. The merozoites enter the erythrocytes and eventually cause their destruction. Subsequent cycles of infection account for the recurrent nature of the illness.

Clinical Manifestations

Fever characterizes malarial infections. Although specific patterns may occur, chaotic elevations of the temperature are more common because of multiple broods of parasites. The typical attack starts with a chill and tachycardia. Within 1 hour, the fever rises to 40°C (104°F) or higher. A profuse diaphoresis follows and lasts for several hours. Hepatosplenomegaly is a common finding. The febrile episodes may be accompanied by hypotension and jaundice. Laboratory findings include anemia, leukocytosis, thrombocytopenia, and hyperbilirubinemia.

Complications of malaria resulting from *P. falciparum* include massive hemolysis (blackwater fever), renal failure, pulmonary edema, and cerebral dysfunction. Neurologic signs of cerebral malaria include decreased level of consciousness, behavioral changes, hallucinations, seizures, and rarely, focal signs. The CSF is usually normal.

Management

Malaria must be suspected in any febrile child recently in an endemic area and in febrile neonates born to women who are recent immigrants from such regions. Thick and thin blood smears should be performed and, if positive, will confirm the diagnosis. However, these smears may be negative in some infections and are often not easily interpreted except by experienced personnel. In such circumstances, a CBC count is helpful. Thrombocytopenia often occurs in children during febrile episodes; the platelet count usually falls in the range of 50,000 to 100,000 per mm^3.

Children with suspected or proven malaria from areas without resistant *P. falciparum* (representing only about 10% of the disease diagnosed in the United States and occurring at present only in the Middle East, Eastern Europe, Central America north of the Panama Canal, and Haiti/Dominican Republic) should be given chloroquine phosphate [initial dose is 10 mg per kg of base (maximum 600 mg), followed by 5 mg per kg at 6, 24, and 48 hours] plus either doxycycline [3 mg per kg per day (maximum 200 mg) once daily for 3 days] or a single dose of sulfadoxine-pyrimethamine (Fansidar®; younger than 1 year old, one-fourth tablet; 1 to 3 years, one-half tablet; 4 to 8 years, one tablet; 9 to 14 years, two tablets; older than 14 years, three tablets). Fansidar should not be used in patients with known sensitivity to sulfa drugs. (Updated information on the geographic prevalence of resistance is available from the CDC at www.CDC.gov.) Patients who are seriously ill or unable to take oral medication require IV quinidine, beginning with a loading dose of 10 mg per kg over 1 hour, followed by a continuous infusion of 0.02 mg per kg per minute, with cardiac monitoring. Uncomplicated infections with chloroquine-resistant *P. falciparum* can be treated with oral quinine sulfate (25 to 30 mg per kg per day in three divided doses) plus oral pyrimethamine-sulfadoxine, as previously discussed. An alternative regimen for chloroquine-resistant *P. falciparum* is atovaquone-proguanil (Malarone®), dosed once daily for 3 days according to weight (11 to 20 kg: one adult tablet; 21 to 30 kg: two adults tablets; 31 to 40 kg: three adult tablets; greater than 40 kg: four adult tablets).

Children with nonfalciparum malaria from any area can be treated with chloroquine, as previously discussed. For *P. vivax* and *P. ovale,* primaquine [0.6 mg base per kg per day (maximum 30 mg)] for 14 days is indicated after chloroquine for the prevention of relapse, in patients who are not G6PD deficient.

Parasitic Infestations of the Gastrointestinal Tract

A variety of parasites can infest the GI tract or invade the body via this route. These infestations may be asymptomatic, being detected on screening examination of the stool. In the ED, the diagnosis is usually entertained when a parent reports observing a worm (pinworm, *Enterobius vermicularis*) or in acute diarrheal diseases, particularly among patients who are immunosuppressed or recently in underdeveloped countries. Two pathogens deserve particular consideration in the United States among immunocompetent children. *Cryptosporidium parvum,* first reported as a cause of human disease in 1976 and well known as a pathogen in children with HIV, has been reported to be the responsible pathogen in 2% to 5% of cases

TABLE 92.22

PARASITIC DISEASES

Parasite	Disease	Clinical manifestations	Treatment (uncomplicated disease)
Ancylostoma braziliense	Cutaneous larval migrans	Serpiginous rash	Thiabendazole topically or 50 mg/kg/day in two divided doses
Ascaris lumbricoides	Ascariasis	Abdominal pain, passage of large (20 cm) worm	Mebendazole 100 mg twice daily for 3 days
Balantidium coli	Balantidiasis	Abdominal pain, vomiting, bloody diarrhea	Metronidazole 35–50 mg/kg/day in three divided doses
Cryptosporidium parvum	Cryptosporidiosis	Diarrhea	Nitrozoxanide 12–47 mo: 100 mg (5 mL) q12h for 3 days 4–11 yr: 200 mg q12h for 3 days
Entamoeba histolytica	Amebiasis	Abdominal pain, bloody diarrhea, extraintestinal abscesses	Metronidazole 35–50 mg/kg/day in three divided doses
Enterobius vermicularis	Enterobiasis (pinworms)	Perianal pruritus Observation of small (1 cm) worm	Mebendazole 100 mg once; repeat in 2 weeks
Giardia lamblia	Giardiasis	Diarrhea, malabsorption, abdominal pain	Furazolidone 8 mg/kg/day in four divided doses or metronidazole 15 mg/kg/day in three divided doses or nitrozoxanide 12–47 mo: 100 mg (5 mL) q12h for 3 days 4–11 yr: 200 mg q12h for 3 days
Necator americanus	Hookworm	Initial pedal rash, then diarrhea and eosinophilia, later anemia	Mebendazole 100 mg twice daily for 3 days
Taenia saginatum/solium	Taeniasis (adult)/ cysticercosis (larvae)	Diarrhea, tapeworm segment in stool, seizures (cysticercosis)	Taeniasis: praziquantel 10 mg/kg as a single dose Cysticercosis: praziquantel 100 mg/kg/day in three divided doses for 1 day then 50 mg/kg/day in 3 divided doses for 29 days. Seizure control and steroids should be considered.
Toxocara canis	Visceral larva migrans	Hepatosplenomegaly	Thiabendazole 50 mg/kg/day in two divided doses
Trichinella spiralis	Trichinosis	Abdominal pain, vomiting, myalgias, periorbital edema, eosinophilia	Mebendazole 300 mg three times daily

of nonspecific, watery diarrhea and has been implicated in several large, waterborne outbreaks, one affecting an estimated 400,000 persons in Milwaukee, Wisconsin, in 1993. *G. lamblia* is also a waterborne parasite that can survive even in running waters and has been described as a cause of diarrhea among campers and hikers who have ingested water from streams. Both cryptosporidiosis and giardiasis merit consideration in day care settings. Table 92.22 summarizes the clinical symptoms and treatment of GI parasites in children.

Rabies

Rabies is a viral infection of the brain that is almost invariably fatal. Although the actual disease is rare in the United States, potential exposure in the form of animal bites commonly occurs. Dogs bite 1 million to 2 million people per year, and 75% of the victims are children.

The decision whether to give prophylaxis for rabies is influenced by the species of animal, the condition of the animal, the ability to study the animal, the type of exposure, and the prevalence of rabies in the region (Fig. 92.27). The incidence of rabies in the area should be available from the local health department. If a sleeping or preverbal child has had close exposure to a bat in an area where rabies is endemic in this species, prophylaxis is indicated even in the absence of a visible bite wound because of the occurrence of several pediatric cases in this circumstance. When the physician determines that prophylaxis is necessary, human rabies immune globulin (HRIG) 20 units per kg and human diploid cell vaccine (HDCV) are used. After cleaning the wound, as much of the HRIG as possible is given locally and the remainder at a distant site. Vaccine must be given in the deltoid muscle (not the thigh or buttock) in a different extremity than that used for the HRIG (see "Practical Information" in Appendix D).

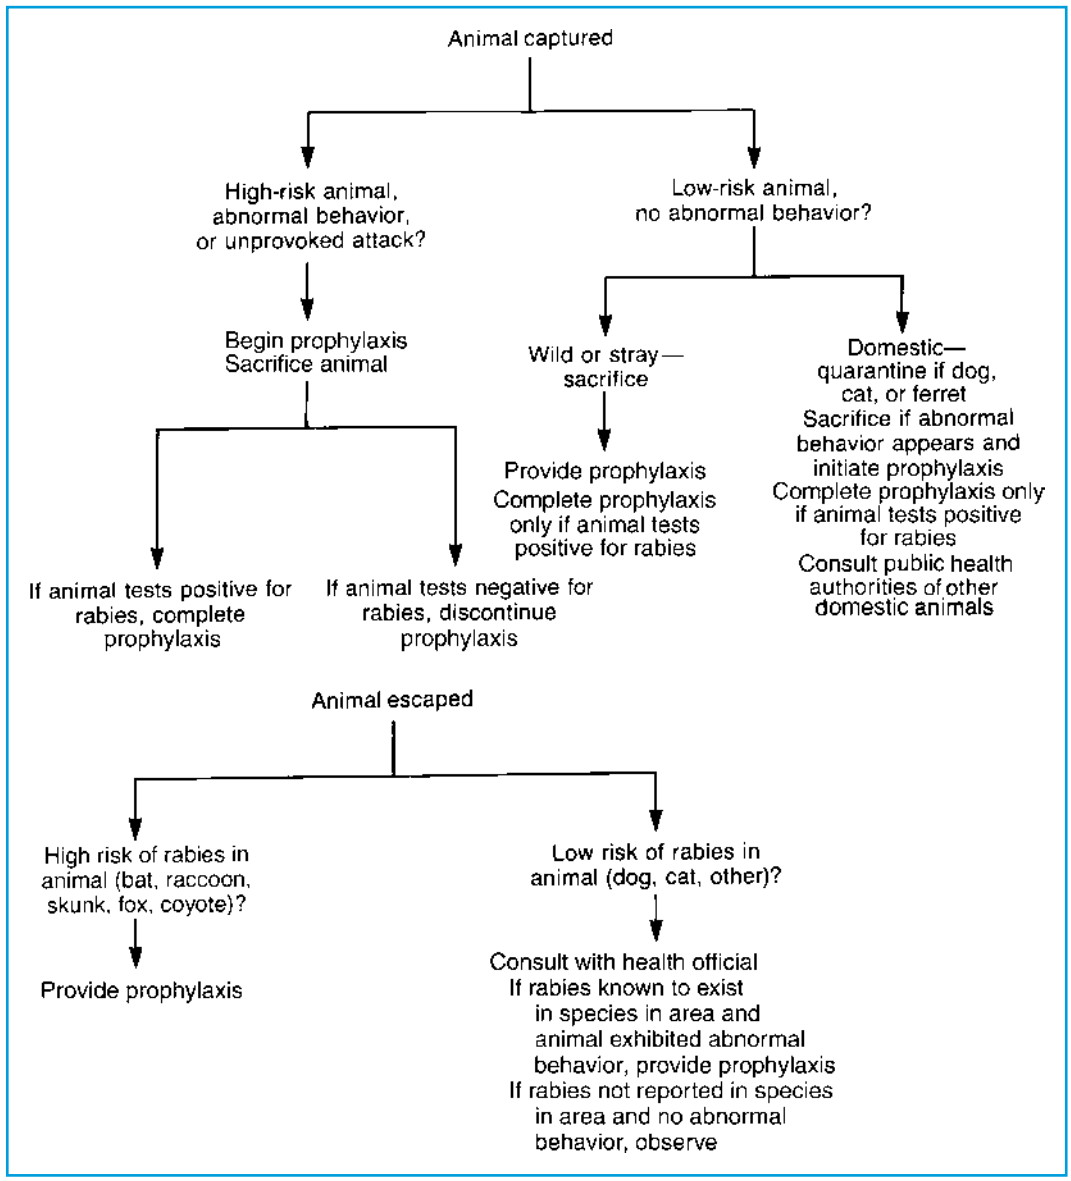

FIGURE 92.27 Diagnostic approach for the management of the child with a mammalian bite wound.

Rocky Mountain Spotted Fever

Background

RMSF is an infection caused by *Rickettsia rickettsii*. It is the most commonly occurring rickettsial disease in the United States. Ticks harbor the organism and transmit it to humans during blood sucking. Although the disease is named for the area of the country in which the causative agent was discovered, most cases of RMSF occur in the states along the eastern coast of the United States. The incidence of the disease peaks during the warmer months. It affects persons of all ages, but two-thirds of the victims are children and adolescents. Each year, approximately 1,000 cases are reported to the CDC.

Pathophysiology

Rickettsiae are inoculated during blood sucking by a tick and replicate locally. In animal models, the organisms disseminate hematogenously and invade the endothelial lining of the small blood vessels. The infection induces an inflammatory reaction in these cells that leads to swelling, necrosis, thrombosis, and finally, occlusion of the vascular lumina. The diffuse vasculitis underlies the widespread clinical manifestations that may involve almost every organ.

Clinical Manifestations

The incubation period of RMSF ranges from 2 to 10 days but usually lasts 1 week. The initial symptoms of headache and malaise are followed by fever (Fig. 92.28). The rash erupts on the third or fourth day of illness. In more than half the cases reviewed by Vianna and Hinman, the exanthem appeared first on the wrists and ankles and then spread inward toward the trunk. The initial lesions are maculopapular but become hemorrhagic in the ensuing 24 to 48 hours if the disease remains unchecked (Fig. 92.28).

FIGURE 92.28 Rocky Mountain spotted fever.

The findings on examination vary with the duration of the disease. Early in the course of the illness, the child remains alert. Conjunctivitis and a rash may be the only signs. Edema begins in the periorbital regions and involves the extremities as the vasculitis progresses. Mild splenomegaly is found in one-third of cases. Vomiting is common. Although the sensorium is clear initially, obtundation and, finally, coma develop after several days of illness.

The WBC count remains normal or rises slightly with RMSF. Thrombocytopenia occurs in 75% of patients during the first stages of the disease; later, DIC may develop with a prolonged PT and PTT, as well as elevated fibrin split products. Most patients have hyponatremia but no other electrolyte abnormalities. Bradford and Hawkins noted a decrease in the serum sodium among 88% of children. Immunofluorescent staining has been used to identify rickettsiae in the endothelial cells of dermal vessels from skin biopsies but is not routinely available for diagnosis. Even when myocarditis remains clinically silent, the electrocardiogram may show signs of cardiac dysfunction. The earliest changes consist of an elevation of the ST segment; later, the P-R interval may become prolonged and arrhythmias may occur. In some cases, mild increases in the CSF cell count and protein concentration are seen.

Complications of RMSF that demand immediate attention include shock and seizures. Vascular collapse occurs from the combination of endothelial damage and inadequate hydration in the vomiting, obtunded patient. Tachycardia, hypotension, and an impaired peripheral perfusion point to a decrease in the intravascular volume. Convulsions may occur in the comatose child with RMSF. Either hyponatremia or a cerebral vasculitis may underlie the seizure activity. Occasionally, the hemorrhagic diathesis needs immediate treatment in the ED. Myocarditis and nephritis are also seen.

Management

A CBC count, platelet count, electrolytes, PT, PTT, and serologic titers should be obtained on the child with suspected RMSF. These studies help pin down the diagnosis and influence the management. Because no routinely available test confirms the diagnosis of RMSF early in its course, treatment must be initiated presumptively. The mildly ill child with a fever, maculopapular exanthem, and a history of a tick bite can be treated as an outpatient. Although some authorities recommend chloramphenicol (50 mg per kg per day) as the drug of choice for patients younger than 8 years, most recommend tetracycline (50 mg per kg per day) of all ages. Fluoroquinolones offer an option but there is less experience with this antibiotic class. Admission is indicated when there is (i) clinical evidence of toxicity, (ii) encephalitis, (iii) thrombocytopenia (platelet count less than 150,000 per mm^3) or derangements in the clotting studies, and (iv) hyponatremia (Na less than 130 mEq per L). In the ED, an IV infusion should be started and sufficient fluids administered to maintain an adequate blood pressure (as discussed in Chapter 3). Tetracycline (50 mg per kg per day) or chloramphenicol (50 mg per kg per day) can be given alone if the illness is clearly believed to be RMSF; in practice, however, broader antibacterial coverage (e.g., chloramphenicol plus ampicillin or ceftriaxone) is often used because bacterial sepsis cannot be excluded.

Tetanus

Clinical tetanus is caused by the toxin produced by *Clostridium tetani*. The disease is rare in the United States (less than 50 cases annually) because of widespread use of the vaccine. Neonatal tetanus from infections of the umbilicus by the organism continues to be reported occasionally. However, the more common problem for the emergency physician is the use of prophylaxis after traumatic wounds. Both tetanus toxoid (0.5 mL) and human tetanus immunoglobulin (250 units) may be indicated, depending on the wound and the immunization history (Table 92.23). Tetanus-prone wounds include punctures, crush injuries, and injuries contaminated by animal excreta or those left untreated for more than 24 hours (see "Practical Information" in Appendix D).

Toxic Shock Syndrome

Background

Toxic shock syndrome (TSS) is characterized by severe, prolonged shock and is caused by a toxin produced by *S. aureus*. Todd et al. initially described this syndrome in seven children, ages 8 to 17 years, but most of the subsequently reported episodes have occurred in postpubertal females, often after a menstrual period. About 400 cases of TSS occur annually in the United States.

Colonization by a phage-group-1 toxin-producing staphylococcal strain sets the stage for the development of TSS. The enterotoxins of these organisms are pyrogenic and enhance the susceptibility to shock from endotoxins.

Clinical Manifestations

TSS begins suddenly with high fever, vomiting, and watery diarrhea. Pharyngitis, headache, and myalgias may also occur, and oliguria rapidly develops. Within 48 hours, the disease progresses to hypotensive shock. The patient has a fever, usually 39°C to 41°C (102.2°F to 105.8°F); a diffuse, erythematous

TABLE 92.23

GUIDELINES FOR TETANUS PROPHYLAXIS

Age	No. of primary immunizations	Years since last booster	Type of wound	Recommendation
<7 yr	<3	Irrelevant	Low risk	DT
			Tetanus prone	DT + TIG
	3 or more	<5	Any	No treatment
	3 or more	>5	Low risk	DT
>7 yr	<3	Irrelevant	Low risk	7–9 yr Td ≥10 yr Tdap
			Tetanus prone	As above but add TIG
	3 or more	10	Any	7–9 yr Td ≥10 yrs Tdap
	3 or more	5–10	Low risk	No treatment
			Tetanus prone	7–9 yr Td ≥10 yrs Tdap
	3 or more	<5	Any	No treatment

maculopapular rash; and hyperemia of the mucous membranes. Often, marked disorientation evolves.

The WBC count is elevated, with a shift to the left. Thrombocytopenia commonly occurs, being present in more than 75% of children reported by Todd et al. Most patients develop DIC and have an elevated PT and PTT. Additional abnormalities in the laboratory studies may include an elevated AST, ALT, BUN, creatinine, and creatinine phosphokinase. The serum calcium and phosphate may be decreased.

Management

The initial diagnosis of TSS rests on the constellation of clinical and laboratory findings. The following laboratory tests should be obtained from all children suspected of having this syndrome: CBC count, platelet count, PT, PTT, fibrin split products, electrolytes, BUN, creatinine, AST, ALT, and creatinine phosphokinase. Cultures of the blood, urine, stool, throat, and vagina serve to isolate *S. aureus* and to rule out other infectious causes of shock. A lumbar puncture is often required to exclude bacterial meningitis.

The management of TSS is the same as that for shock caused by other organisms (see Chapter 3). The physician should secure venous access with a plastic cannula and administer sufficient fluids to maintain an adequate blood pressure, beginning with 20 mL per kg of normal saline. Monitoring of the intravascular volume and urine output usually requires the placement of central venous and peripheral arterial lines and a urinary catheter. Broad-spectrum antibiotics (vancomycin and ceftriaxone) are indicated for patients who are hemodynamically unstable, while those who are less ill may have treatment limited to an antistaphylococcal agent (e.g., oxacillin or cefazolin). Many authorities recommend the addition of clindamycin, which inhibits the toxin.

CHAPTER 93 ■ INFECTIOUS DISEASE EMERGENCIES—SEXUALLY TRANSMITTED DISEASES

MARVIN B. HARPER, MD

Sexually transmitted diseases (STDs) are the most commonly reported infections in the United States and represent an important pediatric problem, particularly during infancy or adolescence. This chapter focuses on infections due to gonorrhea, chlamydia, syphilis, and human immunodeficiency virus (HIV). A myriad of social issues necessarily interpose themselves with regard to the management of these patients. Sexual abuse as a general topic is handled in Chapter 132, but the emergent antimicrobial postexposure prophylaxis of sexual assault is also discussed here. Issues of adolescent sexuality and pelvic inflammatory disease are discussed in Chapter 90. The pathogens causing STDs are described separately in this chapter, but the risk episodes leading to infection with these organisms, as well as the nature of the infections and their lesions, will commonly result in coinfections. Therefore, any patient identified as having one of these pathogens should be considered to possibly have infection with any or all the others.

GONORRHEA

Congenital

Background

The epidemiology of congenital infection depends entirely on the prevalence of gonorrhea among pregnant women and the prenatal care, testing, and treatment they receive. Infection occurs from infected mothers via ascending infection, possibly including chorioamnionitis, with ruptured membranes prior to delivery or during passage through the birth canal.

Clinical Manifestations

Among infants, the most common site for infection is the eye. This is not a commonly seen complication in the United States because of the success of neonatal ocular prophylaxis; however, no strategy is uniformly applied or completely effective and cases do occur. In the neonatal period, generally day of life 2 to 5, an initial simple conjunctivitis rapidly comes to develop a thick mucopurulent discharge (see color plate 127.7). Gram-stained smears of the exudates often reveal gram-negative intracellular diplococci, distinguishing gonococcal conjunctivitis from other causes.

Management

This infection must be treated promptly and aggressively because corneal ulceration and perforation may occur and iridocyclitis may also develop. The usual treatment is ceftriaxone 125 mg intramuscular (IM) and hospitalization commonly in consultation with an ophthalmologist. In addition to conjunctivitis, focal gonococcal infections or sepsis may occur as a result of direct inoculation (e.g., at scalp electrode site) or hematogenous seeding. Infants born to a mother with untreated gonorrhea should receive postexposure prophylaxis (PEP) with a single dose of parenteral ceftriaxone (50 mg per kg to a maximum of 125 mg) in an effort to prevent dissemination. Specific focal infections such as meningitis require therapy with intravenous (IV) penicillin. Testing and treatment of the infant and/or mother for chlamydia must also be considered.

Acquired

Background

Gonorrhea decreased in incidence by 75% from 1975 to 1996, but this rate has been steady at approximately 120 per 100,000 population in the United States since. It remains the second most commonly reported communicable disease. Rates are highest in the southeastern states, among minorities, and among adolescents of all racial and ethnic groups. The peak age incidence overall is in the 15- to 19-year age group.

Pathophysiology

Humans are the only host for this organism, which causes infections of mucous membranes, most often in the genitourinary tract. Infections of the conjunctivae, pharynx, and rectum occur less frequently than infections of the sites lined with a columnar epithelium, such as the urethra, prostate, or epididymis in males; and the urethra, Skene's and Bartholin's glands, cervix, and fallopian tubes in females. Because *Neisseria gonorrhoeae* cannot invade stratified squamous epithelium, the postpubertal vagina and the external genitalia are not infected, whereas these sites may be involved in prepubertal females. The incubation period is very short at 2 to 7 days.

Clinical Findings

The most common gonococcal infection of young children is vulvovaginitis, which usually occurs as a result of sexual abuse (see Chapter 132). In adolescence, the typical presentation is with urethritis or cervicitis, although some may have clinically asymptomatic disease. Prostatitis, epididymitis, and pelvic inflammatory disease are also relatively common. Approximately 1% of patients with gonococcal infections will develop disseminated disease. This disseminated gonococcal infection

TABLE 93.1

SUMMARY OF TREATMENT REGIMENS FOR LOWER GENITAL TRACT GONORRHEA AND CHLAMYDIAL INFECTION

Patient circumstance	Drug	Dose, route	Comments
Treatment for Gonorrhea			
In children <45 kg	Ceftriaxone	125 mg, IM	
In children >45 kg and adolescents	Ceftriaxone *or* cefixime *or* ciprofloxacin *or* ofloxacin	125 mg, IM 400 mg PO 500 mg PO 400 mg PO	Regimens other than ceftriaxone may not treat incubating syphilis
Penicillin allergy			
In children	Spectinomycin	40 mg/kg, IM	Maximum dose 2 g
In adolescents	Spectinomycin	2 g, IM	May not treat incubating syphilis
Treatment for Chlamydial Infection			
All ages	Azithromycin	20 mg/kg in a single dose to maximum 1 g	Single-dose regimen obviates compliance problems
Alternative for those ≥8 years of age	Doxycycline	100 mg PO bid for 7 d	
During pregnancy	Erythromycin base *or* erythromycin ethylsuccinate	500 mg PO qid for 7 d 800 mg PO qid for 7 d	Efficacy of this therapy to eradicate organism estimated 80%

usually presents with an inflammatory polyarthropathy and dermatitis (discrete papules and pustules, sometimes hemorrhagic), often with bacteremia. This phase may resolve spontaneously but is often followed by the development of a purulent arthritis (commonly the knee). When this disease is suspected, all mucosal sites (cervix, rectum, pharynx) should be cultured to improve the yield of the organism recovery from approximately 50% from blood or synovial fluid to at least 80% when mucosal sites are also cultured. Other manifestations of infection include gonococcal perihepatitis (Fitz-Hugh-Curtis syndrome), conjunctivitis, pharyngitis, proctitis, and pelvic inflammatory disease (see Chapter 90).

The diagnosis of gonorrhea relies primarily on culture from an infected site or antigen detection, either from the site or from a urine specimen. Newly introduced nucleic acid amplification tests have proven highly sensitive and specific; however, false-positive tests can occur, so these methods should not be used in low-risk populations or in legal cases where culture methods that can confirm *N. gonorrhoeae* are preferred. In addition, the nucleic acid amplification tests are not approved for testing from vaginal, rectal, or pharyngeal swabs although in preliminary reports they appear to have improved sensitivity as compared with that of culture. These tests can, however, conveniently be used on voided urine specimens from symptomatic sexually active adolescents seeking care for urethritis, epididymitis, cervicitis, or pelvic inflammatory disease.

Culture for *N. gonorrhoeae* requires the use of selective media and prompt placement into a CO_2-enriched environment, avoiding notable temperature changes and drying. It is also important to alert the microbiology laboratory of the specimen source because this will be important for distinguishing nonpathogenic *Neisseria* organisms, which can represent normal flora from *N. gonorrhoeae*.

Penicillin, tetracycline, and quinolone resistance are all reported problems with gonococcal infections in various parts of the world. However, in the United States, treatment with a single 50 mg per kg IM dose (maximum of 125 mg, regardless of age or weight) of ceftriaxone (Table 93.1) is effective for most mucosal forms of gonorrhea (higher or more prolonged doses are recommended for conjunctivitis, disseminated disease, arthritis, meningitis, and endocarditis). In the penicillin-allergic postpubertal patient, the use of fluoroquinolones is no longer recommended unless susceptibility has been confirmed in culture. Azithromycin as a single 2-g oral dose is an option but concerns about emerging resistance prevent its routine use. Only parenteral cephalosporins have been studied and can therefore be recommended for use in prepubertal children. Patients with documented gonococcal infections should be evaluated for other STDs (hepatitis B virus, syphilis, *Chlamydia trachomatis*, and HIV) and empirically treated for *C. trachomatis*. Sexual partners should also be evaluated.

SYPHILIS

The *Treponema pallidum* causes syphilis. This thin, slowly growing helical organism cannot be grown on artificial media. Natural host immunity can suppress but does not eradicate infection that, untreated, may persist for life.

Congenital Syphilis

Background

A sustained reduction in the incidence of congenital syphilis in the United States has occurred during the last decade, with 10.5 cases reported per 100,000 live births in 2007. Congenital infection occurs via transplacental transfer of spirochetes from the mother's bloodstream or during birth. Pregnant mothers with diagnosed syphilis should be treated as early as possible during gestation and evaluated for reinfection regularly to help prevent congenital transmission.

Clinical Manifestations

Clinical findings early in congenital syphilis can range from very profound (stillbirth) to initially asymptomatic. The rate and the severity of infection correlate with the staging in the mother. Women with untreated early syphilis are estimated to have a 40% rate of spontaneous abortion. The rate of transmission to the fetus is very high in maternal secondary syphilis but decreases for mothers with latent or tertiary syphilis. The most common neonatal symptoms include hepatosplenomegaly, jaundice (conjugated hyperbilirubinemia), bony changes seen on radiographs (osteochondritis or periostitis), rhinitis (snuffles), and rash (small red maculopapules that persist for 1 to 3 months). Less commonly, fever, lymphadenopathy, and nephritis or nephrosis may occur. A reactive cerebrospinal fluid (CSF) venereal disease research laboratory (VDRL), elevated CSF white blood cell (WBC) count, or elevated CSF protein are unfortunately not highly sensitive or specific for diagnosing congenital syphilis or the presence of treponemal organisms in the CSF. Late findings of congenital syphilis include changes in the teeth, bones, eyes (interstitial keratitis), hearing loss, and rarely neurosyphilis, which can be seen years or even decades after birth.

Diagnosis and Management

The diagnosis of the infant with congenital syphilis is made difficult by the frequent lack of symptoms initially and the presence of maternal IgG antibodies used in serologic testing (Table 93.2). Therefore, cautious management is recommended. Any infant whose mother has inadequately treated syphilis, or the infant with any symptoms consistent with congenital syphilis and positive serologic tests for syphilis, should be managed as a presumptive case. Definitive diagnosis can be made when spirochetes are identified by microscopic dark field or direct fluorescent antibody testing of the placenta or umbilical cord. Treatment of the newborn with syphilis is with penicillin G, either as 50,000 units per kg penicillin G procaine given intramuscularly once per day for 10 days or as aqueous penicillin G 50,000 units per kg per dose given intravenously every 12 hours during the first 7 days of life and dosed every 8 hours thereafter until 10 days of treatment is completed. If one or more days of therapy are missed, the treatment course is restarted.

TABLE 93.2

CRITERIA FOR DIAGNOSIS OF NEONATAL AND EARLY CONGENITAL SYPHILIS

I. Diagnostic Criteria
- A. Absolute
  1. *Treponema pallidium* seen by dark-field microscopy
- B. Major
  1. Condylomata
  2. Osteochondritis, perichondritis
  3. Snuffles
- C. Minor
  1. Fissures of lips
  2. Cutaneous lesions
  3. Mucous patches
  4. Hepatomegaly, splenomegaly
  5. Lymphadenopathy
  6. CNS signs
  7. Hemolytic anemia
  8. Elevated cell count or protein level in spinal fluid
- D. Serologic
  1. Reactive serologic test for syphilis
  2. Reactive immunoglobulin M (FTA-ABS) fluorescent treponemal antibody absorption test
  3. Nonreactive serologic test for syphilis
  4. Reactive serologic test for syphilis STS that does not revert to nonreactive within 4 mo
  5. Rising titer over 3 mo

II. Certainty of Diagnosis
- A. Definite: absolute clinical criterion
- B. Probable: any of the following: (i) serologic criterion 4 or 5; (ii) one major or two or more minor clinical criteria and serologic criterion 1 or 2; (iii) one major and one minor clinical criterion
- C. Possible: serologic criterion 1 or 2 with only one minor or no clinical criterion
- D. Unlikely: (i) serologic criterion 3; (ii) maternal history of adequate treatment for syphilis during pregnancy

CNS, central nervous system; STS, serologic test for syphilis.
Modified from Mascola L, Pelosi R, Blount JH, et al. Congenital syphilis revisited. *Am J Dis Child* 1985;139:575–580.

Acquired Syphilis

Background and Pathophysiology

The population rate of syphilis is low but rising, especially among males, in the last decade. In 2007, primary or secondary syphilis was diagnosed in 3 per 100,000 in the teen population with a peak incidence in the young adult male population of 15 per 100,000. Sporadic outbreaks among adolescents have been reported.

Acquisition is by direct contact with an ulcerative lesion of an infected individual. The incubation period to primary syphilis is 10 to 90 days.

Clinical Manifestations

Acquired syphilis infections are divided into three stages. Primary syphilis is characterized by the presence of a well-defined, rounded, firm, painless localized ulcer (chancre) at the site of acquisition, which is most commonly the genitalia (Fig. 93.1). This ulcer forms within weeks of infection (most commonly about 3 weeks) and persists for several weeks.

FIGURE 93.1 Chancre in an adolescent with serologically confirmed syphilis.

TABLE 93.3

TREATMENT RECOMMENDATIONS FOR SYPHILIS

Syphilis stage	Recommended treatment
Primary, secondary, or early latent (infection acquired within the previous year) syphilis	A single dose of 50,000 units/kg benzathine penicillin IM (maximum is the adult dose of 2.4 million units)
Late latent (>1 year since acquisition), latent syphilis of unknown duration, or tertiary syphilis	Three separate single doses given at 1-wk intervals of 50,000 units/kg benzathine penicillin IM (maximum single dose is the adult dose of 2.4 million units)
Neurosyphilis or congenital syphilis	Aqueous penicillin G 200,000–300,000 units/kg/day (to maximum adult dose of 24 million units total per day) as 50,000 units/kg/dose every 4 to 6 h for 10–14 day An alternative for adults: procaine penicillin G 24 million units given IM daily with probenicid 500 mg four times per day for 10–14 day
The penicillin-allergic nongravid adult may be treated with twice daily 100-mg oral doses of doxycycline daily for 14 days with primary, secondary, or early latent syphilis, and for 4 weeks with late latent or latent syphilis of unknown duration.	

Secondary syphilis occurs several weeks to months after the primary phase and is characterized by a diffuse rose pink rash that involves to include the palms and soles, generalized adenopathy, malaise, fever, headache, and pharyngitis. Condylomata lata (warts), splenomegaly, and mucocutaneous lesions may be seen. The rash in this stage may resemble pityriasis rosea. This phase generally resolves within 1 to 3 months.

Late syphilis is extremely uncommon in children because it is the manifestation of many years of infection that typically presents as neurosyphilis, cardiovascular disease (e.g., aortic aneurysm), or gummas.

It should be noted that the manifestations of syphilitic stages may not occur in the usual manner in immunocompromised patients. In particular, neurosyphilis can occur at any stage of infection among patients with HIV.

Diagnosis and Management

In primary syphilis, dark-field examination or a direct fluorescent antibody test for *T. pallidum* in exudates or tissue from the lesion can confirm the diagnosis. Specimens for testing should be obtained after washing the ulcer with saline and then by scraping and squeezing the lesion to express serum, which is sent for testing. Aspirated material from regional lymph nodes may also be sent. Serologic tests should also be sent, although the diagnosis may be missed if only a serum nontreponemal test (RPR, VDRL, or antiretroviral therapy) is ordered because it may be too early for reliable response. In this circumstance, the laboratory should perform a treponemal test (FTA-ABS or TP-PA), regardless of the nontreponemal result. Serologic tests of either type are reliably positive in later stages of syphilis. Confirmation of infection from serologic testing is best when both nontreponemal and treponemal tests are positive because false-positive test results can occur with each. Treponemal tests generally remain positive for life and are therefore not helpful in diagnosing reinfection. When neurosyphilis is suspected, CSF should be evaluated and sent for VDRL testing and for routine testing for CSF protein and cell count. Patients with documented syphilitic infections should also be evaluated for other STDs (hepatitis B virus, *N. gonorrhoeae*, *C. trachomatis*, and HIV).

The preferred treatment is always with penicillin G, unless the patient is allergic. The dose, dosage form, and the duration of therapy depend on the stage and form of the illness (Table 93.3). Oral forms of penicillin and combination forms of benzathine plus procaine penicillin are not considered acceptable alternatives to aqueous crystalline penicillin, aqueous procaine penicillin, or benzathine penicillin. Sexual partners will require clinical and serologic evaluation.

CHLAMYDIA

Congenital Chlamydia

Background

Pregnant women with an active chlamydia infection at the time of vaginal delivery have a 50% chance of transmitting the organism to the newborn. Transmission to infants born by cesarean section delivery with intact membranes is rare. Of infants colonized with *C. trachomatis*, it is estimated that 25% to 50% will develop conjunctivitis and 5% to 20%, pneumonia.

Clinical Manifestation

Infants exposed to chlamydia in the birth canal are likely to acquire infection at one of several sites. The best sources to culture are the conjunctivae, nasopharynx, rectum, and vagina. Symptoms depend on the site infected, and the timing of onset varies by site. Conjunctivitis will generally occur within the first 2 weeks of life (and is the most common identifiable cause of conjunctivitis at this age) and will last for 1 to 2 weeks but can, in some cases, when left untreated, persist for weeks or months. Approximately half of infants with conjunctivitis will have colonization of the nasopharynx. Nasopharyngeal colonization with chlamydia can persist for 2 to 3 years and will lead to pneumonia in one-third of cases. The pneumonia presents as nasal congestion, dry cough, and tachypnea without fever. Symptoms will appear within the first 4 months and most commonly in the second or third month of life. Rales and wheezing may be heard on auscultation of the

chest but are uncommon. Chest radiographs are nonspecific but often reveal hyperinflation and/or increased interstitial markings and infiltrates. Diagnostic testing should be performed, using culture methods from the nasopharynx and/or conjunctivae, to confirm the need for treatment of the infant as well as mother and her partner(s). Treatment of congenital chlamydia infections is with erythromycin base or ethylsuccinate 50 mg per kg per day orally divided into four doses daily for 14 days. Infants treated with erythromycin should be followed for signs and symptoms of pyloric stenosis because of a possible association of this condition with the use of erythromycin. Azithromycin 20 mg per kg per day for 3 days is an alternative to erythromycin in cases where the development of pyloric stenosis is of particular concern. It must be noted that even with appropriate dosing of erythromycin, there is a relapse rate of approximately 20%; therefore, follow-up should be arranged and a second course of therapy may be required. The addition of topical therapy for chlamydia conjunctivitis is not necessary or recommended.

Acquired Chlamydia

Background

There has been a large increase in the reported cases of chlamydia infections in the United States, with the Centers for Disease Control and Prevention (CDC) reporting a rate among women of 370 cases per 100,000 population in 2007. This is more than triple the reported incidence of gonorrhea. The highest reported rates are among adolescents with a prevalence of 4.8% among a nationally representative sample of 18 to 26 year olds. Recurrence within months of treatment is common.

Acquisition is by direct contact of mucous membranes with an infected source. This can include the pharynx, cervix, vagina, and rectum. The incubation period is generally at least 1 week.

Clinical Manifestations

Infected males can present with clinically evident urethritis, but most will be asymptomatic and do not seek care. Chlamydia infections account for a large proportion of nongonococcal urethritis in men. There is much variability in the clinical symptoms of males, but generally, cases of chlamydial urethritis are less purulent than gonococcal infections. However, testing will reveal more than 15 WBCs per high-powered field in the spun urine sediment of a first void urine sample. Overall, *C. trachomatis* causes 50% of epididymitis among men 15 to 34 years of age. Homosexual or bisexual males practicing anal receptive intercourse can present with a chlamydia proctitis.

Infected females can present with mucopurulent cervicitis, but most remain asymptomatic. Infections when left untreated can last for months or even years. Women can also develop acute or chronic pelvic inflammatory disease with the subsequent risks for infertility or ectopic pregnancy (see Chapter 90).

Diagnosis

When testing urethral (male), vaginal, or endocervical swab specimens or first void urine specimens, nucleic acid amplification tests are more sensitive than other diagnostic methods and are generally preferred over culture. False-positive tests can occur; therefore, in certain circumstances (e.g., evaluation for sexual abuse), it is advisable to obtain cultures or a second type of nonculture test. Although not Food and Drug Administration (FDA)-cleared for use, nucleic amplification testing is offered by some laboratories for testing of rectal swab specimens. Nucleic amplifications tests are not recommended for detection of *C. trachomatis* from the pharynx at this time. Patients with documented chlamydia infections should also be evaluated for other STDs (hepatitis B virus, syphilis, *N. gonorrhoeae*, and HIV).

Treatment of acquired *C. trachomatis* infections is with 20 mg per kg (maximum 1 g) of oral azithromycin given as a single dose (Table 93.1). Alternatives include doxycycline (100 mg orally twice per day for 7 days), ofloxacin (300 mg orally twice per day for 7 days), or levofloxacin (500 mg orally once per day for 7 days), but the age of the child and possibility of pregnancy must be considered. Sexual partners should also be evaluated.

The treatment of acute salpingitis and pelvic inflammatory disease is discussed elsewhere (see Chapter 90).

HERPES SIMPLEX VIRUS

Herpes simplex virus (HSV) can infect the genitals and other anatomic sites. Although the most common cause of genital ulceration seen among adolescents and adults at venereal disease clinics, this entity is unusual in prepubertal children.

Genital pain is a frequent complaint with infections caused by herpes simplex and may precede the appearance of the lesions. Characteristically, the virus produces grouped vesicles on an erythematous base (Fig. 93.2); however, erosion of the overlying skin often leaves only painful ulcers at the time of the first visit. Particularly with a primary infection, the inguinal lymph nodes enlarge. HSV-2 is nearly always the result of anogenital infection. HSV-1 most commonly causes oropharyngeal infections but is an increasing cause of anogenital infections as well. National data on seroprevalence suggest

FIGURE 93.2 Genital herpetic lesions in a young girl who was sexually abused. (Courtesy of Stephen Ludwig, MD)

a decrease in rates of HSV-2 to 17% in the years 1999 to 2004 from 21% a decade earlier. Fewer than one-fourth of patients seropositive for HSV-2 report having been diagnosed with genital herpes.

Visual inspection often suffices for the initial diagnosis in the adolescent presenting to the emergency department (ED). However, specific testing, typically by culture, to confirm the diagnosis as due to HSV-1 or HSV-2 is warranted as this impacts subsequent prognosis for recurrences and therefore impacts counseling. Cellular change as seen with a Tzanck smear (Chapter 85) positive for giant cells lends further weight to the clinical impression but has poor sensitivity for detection of disease; either immunofluorescent staining of a scraping from the base of a vesicle or a viral culture can also verify the diagnosis. In the setting of negative HSV cultures but clinical suspicion of HSV disease or known positive partner with HSV, it may be prudent to obtain type specific serologic testing that distinguishes between HSV-1 and HSV-2 antibody. In children, a culture should always be obtained because the disease is seen rarely and needs medicolegal confirmation. Serologic tests for syphilis and HIV and cultures for gonorrhea and chlamydia are appropriate to rule out coexisting sexually transmitted infections. Although it is occasionally spread by nonsexual contact, the physician must explore the possibility of sexual abuse when herpes genitalis occurs before puberty. Oral acyclovir therapy is indicated for primary infections; the dose is 80 mg per kg per day in four divided doses (or for postpubertal patients, 400 mg orally three times per day for 7 to 10 days). Alternatives include famciclovir 250 mg orally three times per day for 7 to 10 days or oral valacyclovir 1 g orally twice per day for 7 to 10 days.

HIV INFECTION

Epidemiology

HIV, the etiologic agent for acquired immunodeficiency syndrome (AIDS), has been present in humans for decades. As a worldwide problem, in 2007, the number of people living with HIV infection was estimated by the World Health Organization to be 33.2 million, of which 2 million were children younger than 15 years. It is estimated that more than 1,000 children are infected each day (370,000/year). In the United States, improved prenatal testing and perinatal treatment and blood product testing has made acquisition of infection rare with fewer than 200 newly acquired HIV infections per year among children younger than 13 years. Unfortunately, adolescents continue to be infected, with 19,200 new cases among 13- to 29-year-old adolescents and young adults in 2006. Eighty percent of new HIV infections among female population are acquired via heterosexual contact (20% by injection drug use). Males are more likely to acquire infection by male-to-male sexual contact (three quarters) with only 13% from heterosexual exposure.

Pathophysiology

HIV is a ribonucleic acid (RNA) retrovirus. After gaining entrance to the body, it binds to helper T lymphocytes, monocytes, macrophages, dendritic and glial cells, and intestinal endothelial cells and enters the cell. There, viral RNA is transcribed to deoxyribonucleic acid (DNA) by reverse transcriptase and is incorporated into the host cell DNA. The viral DNA may remain dormant for long periods but can be stimulated at any time to transcribe itself into messenger RNA, which, in turn, leads to protein synthesis, assembly, and release of virus and virus particles. Abnormalities develop in both the cellular and humoral immune systems as HIV replication continues. Most circulating cells showing HIV infection are CD4 helper lymphocytes, and the number of circulating CD4 lymphocytes has been shown to be a useful marker of risk for opportunistic infection; early in childhood, this is not reliably the case. Children often have an abnormal polyclonal activation of B cells that can result in notable hypergammaglobulinemia; however, these children do not respond with appropriate antibodies to new antigens and often produce autoantibodies.

The likelihood of acquiring infection depends on the amount of infectious virus in the body fluid and the extent of contact with that body fluid. The risk of perinatal acquisition increases with increasing maternal viral load and decreased maternal immunity. Viral load will depend on many factors but most importantly the use of antiretroviral therapy. Untreated, infected infants often have high levels of viremia; this is also common very early and late during the course of infection among affected individuals.

Blood and genital secretions (seminal, vaginal) are the most likely media to transmit HIV. Other fluids such as saliva, urine, sweat, amniotic fluid, synovial fluid, feces, and tears contain no virus or only low levels of virus and are not important sources of virus transmission. The likelihood of HIV infection after a single exposure to an HIV-positive source has been estimated to be less than 1% for most exposures (Table 93.4). Breast-feeding is also associated with an increased risk of transmission of HIV to the infant. Therefore, in areas such as the United States where alternatives to breast-feeding are safe, HIV-infected women should be counseled not to breast-feed.

TABLE 93.4

APPROXIMATE RISK OF HUMAN IMMUNODEFICIENCY VIRUS ACQUISITION AFTER A SINGLE EXPOSURE LISTED BY SOURCE

Exposure	Risk of infection (per 10,000)
Transfusion with positive blood unit	950
Intravenous drug use	67
Percutaneous exposure (needlestick)	30
Receptive anal intercourse	50
Receptive penile-vaginal intercourse	10
Insertive anal intercourse	10
Insertive penile-vagnial intercourse	5
Receptive oral sex	1
Insertive oral sex	0.5

Detection of virus can now be accomplished in commercial laboratories by culture, quantitative HIV RNA and HIV DNA polymerase chain reaction (PCR) techniques, and antigen testing. Commercially available quantitative HIV RNA PCR techniques allow detection of viral RNA to levels as low as 50 copies per milliliter.

Clinical Manifestations

Initial Presentation of Children with HIV

Most perinatally infected infants develop symptoms progressively over time, and although lymphadenopathy, hepatosplenomegaly, and failure to thrive are common clinical features, any organ system can be affected (Table 93.5). Many children show signs of abnormal humoral immune function such as recurrent or persistent bacterial infection. Children lack preexisting antibodies to bacterial pathogens at the time they are infected with the HIV virus, which makes them vulnerable to infection by these organisms. Some children show early defects in cellular immunity, exhibited by persistent candidiasis, chronic diarrhea, or opportunistic infections. Still others, especially with antiretroviral therapy, remain relatively asymptomatic for long periods (6% completely asymptomatic at 5 years).

Untreated, approximately 50% of infants infected perinatally will develop clinical signs or symptoms within the first 12 months of life. Among adolescents with acquired infection, the initial presentation may represent acute HIV infection. Within days to weeks of initial exposure to HIV, an acute syndrome occurs that almost always includes fever. Approximately 70% will have lymphadenopathy, pharyngitis, or a rash that can be a maculopapular (can involve palms and soles) or have mucocutaneous ulcerations. Almost 30% to 50% will experience myalgias, arthralgias, headache, nausea, vomiting, and/or diarrhea. Finally, 10% to 15% will have hepatosplenomegaly, weight loss, thrush, or neurologic signs or symptoms (e.g., meningoencephalitis or aseptic meningitis, peripheral neuropathy or radiculopathy, facial palsy, Guillain-Barré syndrome, brachial neuritis, cognitive impairment, or psychosis). During this acute phase, many patients also develop leukopenia and thrombocytopenia.

Although some patients with acute HIV infection will seek care, few are diagnosed with acute HIV unless a specific history of HIV exposure is given because of the common occurrence of these symptoms with other viruses. The diagnosis of acute HIV infection cannot be made with standard serologic tests [enzyme-linked immunosorbent assays (ELISAs) or Western blot] because these tests first become positive 3 to 4 weeks after acute infection. Early detection, when indicated, is possible through the use of plasma HIV RNA testing but should be confirmed within 2 to 4 months after the initial testing by ELISA and Western blot serology. Follow-up testing and counseling should be arranged.

TABLE 93.5

SIGNS AND SYMPTOMS OF HUMAN IMMUNODEFICIENCY VIRUS INFECTION IN CHILDREN

Lymphadenopathy	Recurrent fevers
Hepatomegaly	Splenomegaly
Failure to thrive	Chronic or recurrent diarrhea
Bacteremia	Wasting syndrome
Oral thrush	Developmental delay
Chronic or recurrent parotitis	Acquired microcephaly
Opportunistic infections	Spastic paresis

Fever

Background. The evaluation of the HIV-infected child with fever requires a careful history, thorough physical examination, and often, laboratory testing. Fever in HIV-infected children can represent simple childhood viral infections, but because of the humoral immunodeficiency of these children, they also commonly suffer from acute bacterial infections. Otitis media, sinusitis, pneumonia, adenitis, bacteremia, and skin and soft-tissue infections are common. In addition, opportunistic infections must be considered. It is important to inquire about any previous opportunistic infection or the use of prophylactic medications for the prevention of *Pneumocystis jiroveci* pneumonia (PCP), Mycobacterium avium intracellulare (MAI), or cytomegalovirus (CMV), because these may be markers for poor immune function. Some adolescents or parents may be able to provide a recent CD4 count, but laboratory data that reflect the status of the immune system are frequently unavailable to the emergency physician.

The clinical appearance of the patient is the starting point for determining ED management (Fig. 93.3). Identification of a focal source, particularly in the well-appearing children, plays a key role in determining management.

Evaluation of the Well-appearing, Febrile, HIV-positive Child. The HIV-infected child who appears well and does not have an obvious source of infection presents a more difficult problem than the child with an obvious localized infection. The first step is to decide on an appropriate evaluation. Several studies have demonstrated that HIV-positive children have an increased incidence of bacteremia. They are also more susceptible to serious viral infections such as disseminated CMV. However, it appears that serious bacterial, viral, or opportunistic infections are relatively uncommon among well-appearing HIV-positive children who present to the ED with fever.

Whenever a child with HIV infection presents with high-grade fever (temperature higher than 39°C or 102.2°F), a complete blood cell count (CBC) with differential and blood culture is recommended. If the child is still in diapers, a urine sample should be obtained for analysis and culture. Older children who are toilet-trained usually complain of dysuria or frequency if they have a urinary tract infection. If the child has any respiratory signs or symptoms, including isolated tachypnea, or if the CBC has an elevated leukocyte count with a shift to left, regardless of the presence of respiratory signs, pulse oximetry and a chest radiograph should be ordered. The WBC count is best evaluated in relation to baseline counts because many HIV-infected children have some degree of leukopenia. If it is known that the child is not leukopenic or the baseline is not available, a WBC count of 15,000 per mm^3 or more should be considered suggestive of bacterial infection. These patients may

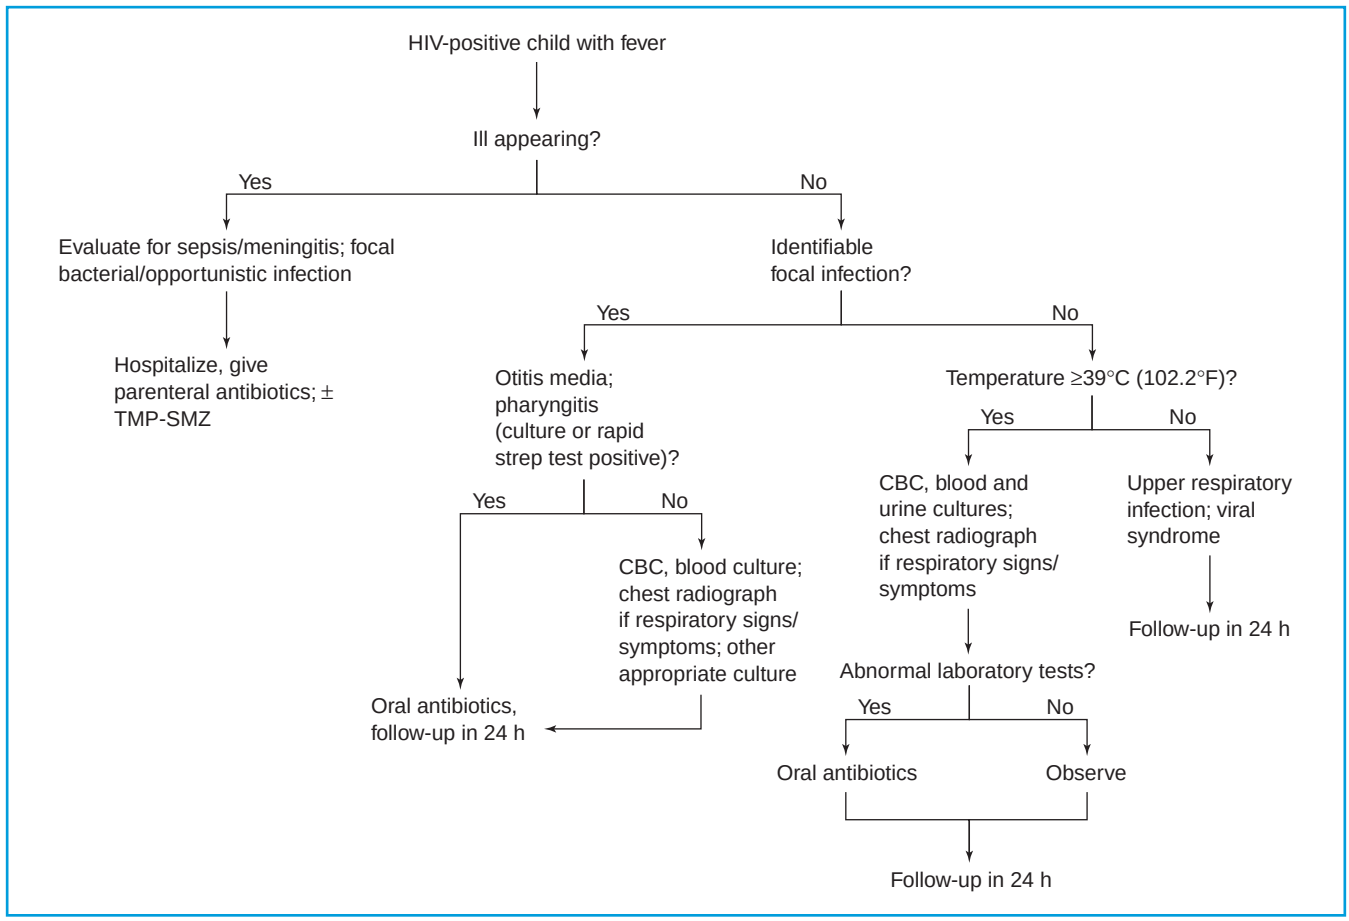

FIGURE 93.3 Evaluation of the HIV-positive child with fever. TMP-SMZ, trimethoprim–sulfamethoxazole; CBC, complete blood cell count. (Adapted from Dorfman D, Crain E, Bernstein L. Care of febrile children with HIV infection in the emergency department. *Pediatr Emerg Care* 1990;6:308.)

be started on empiric antibiotic treatment such as high-dose amoxicillin, amoxicillin-clavulanic acid (Augmentin®), or IM ceftriaxone (Rocephin®), pending the results of culture(s).

If the child appears well and the evaluation has not revealed a source for the fever that requires hospitalization, the child may be sent home (if the child's caregiver can be easily contacted and has the means to return if necessary) with instructions to return if symptoms worsen or if the patient develops lethargy or will not take adequate amounts of fluids. A follow-up evaluation by telephone or a revisit to the child's regular provider or the ED should be scheduled for the next day.

Evaluation of the Ill-appearing, Febrile, HIV-positive Child. HIV-positive patients with fever who appears ill should be treated like other ill-appearing, febrile children because they are likely to be infected with the same types of organisms that infect immunocompetent children. A lumbar puncture is indicated for those with meningismus, change in mental status, or an underlying abnormal mental status makes assessment difficult. If a child is believed to be so unstable that lumbar puncture is not safe, it can be delayed. In either case, the child should be started on parenteral broad-spectrum antimicrobials. Ceftriaxone (100 mg per kg per day divided every 12 hours) is an appropriate choice because it covers the organisms that most commonly cause sepsis in children. In young children, because of the possibility of PCP presenting with fever and ill appearance, trimethoprim-sulfamethoxazole (TMP-SMZ) (5 mg per kg per dose of trimethoprim every 6 hours) should be considered if there are respiratory symptoms, with or without a positive chest radiograph. Treatment for suspected PCP should not be delayed because of fear of interfering with the diagnostic workup. Fungal infections, with the exception of oral thrush, are uncommon in HIV-infected children. However, candidal sepsis should be considered in hospitalized patients who do not improve with antibiotics.

Evaluation of the HIV-positive Child with Persistent Fever. Chronic fever is common in HIV-infected children. It can have many causes, and the evaluation of children with fever of unknown origin is often difficult and not always revealing. The major focus of such an evaluation in the ED is to rule out acute bacterial infection. A careful history and physical examination should be followed by a CBC, urinalysis, chest and sinus films, and blood, urine, and stool cultures. Recurrent otitis media is commonly seen, and some children may have recurrent parotitis or sinusitis. If no source is recognized on examination and the initial testing is negative, more unusual infections need to be considered. Tuberculosis, although common among HIV-infected adults, is uncommon in children but may be more likely among adolescents. MAI may cause

chronic fevers in HIV-infected children. This pathogen is often associated with anemia secondary to bone marrow infiltration and can be cultured from blood, stool, and bone marrow. Numerous viruses can cause chronic infections associated with fever in these children. Epstein-Barr virus (EBV) and CMV are among the more common, with CMV often presenting with chronic hepatitis and bloody diarrhea. It may also cause pneumonia and retinitis. A blood buffy coat specimen can be sent for quantitative CMV-antigen detection. Most HIV-positive children with fever of unknown origin are hospitalized to facilitate the diagnostic process. The possibility of drug fever must also be considered.

Soft-tissue Infections

Clinical Manifestations. Cervical adenitis and cellulitis are common and may be accompanied by fever. Both cervical adenitis and cellulitis may be secondary to alterations in the child's immune status or may occur on a mechanical basis as a secondary infection of already-enlarged lymph nodes (in the case of cervical adenitis) or disruption of the normal skin by other lesions such as condylomata, molluscum, or vesicular and follicular eruptions. Acute bacterial adenitis in these patients is usually caused by *Staphylococcus aureus* or group A streptococci. *Bartonella*, the agent of cat-scratch disease, which can also cause bacillary angiomatosis and trench fever in these patients, should be considered.

Parotitis is a common soft-tissue infection that occurs in HIV-positive children who can have chronic enlargement of the parotid glands secondary to lymphocytic infiltration (Fig. 93.4). In these children, the parotid glands are enlarged and firm but nontender, and the overlying skin is not erythematous. With acute suppurative parotitis, these children develop fever, tenderness over the parotid, and purulent drainage from Stenson's duct. *S. aureus* is the most likely offending organism.

Management. If the child appears well and the infection is well circumscribed and does not impinge on a critical structure such as the airway, outpatient antibiotic therapy active against *S. aureus* and *Streptococcus pyogenes* (e.g., cephalexin 60 to 80 mg per kg per day, divided four times daily) is appropriate as long as it appears that the caregiver can adhere to the regimen and the child can be reevaluated within 24 to 48 hours. Coverage for community acquired methicillin resistant *S. aureus* may be warranted if the prevalence in the community is higher than 10% to 20%. In most cases, a blood culture should be obtained, particularly if the child has fever, has a history of an opportunistic infection, or does not appear well. In addition, the need for drainage of an infected lymph node (needle aspiration or surgical) must be considered. Children who are sent home must have close outpatient follow-up.

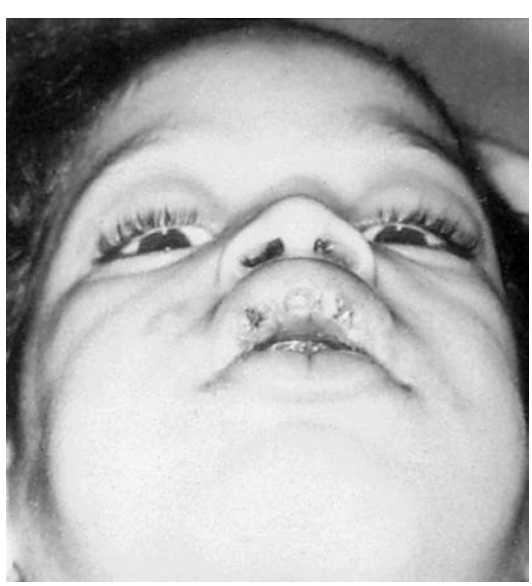

FIGURE 93.4 Chronic parotitis in an HIV-positive child. (Courtesy of Dr. A. Rubenstein.)

Pulmonary Manifestations

Just as respiratory complaints are common among immunocompetent children, so are respiratory conditions in patients and children with HIV infection. They deserve special attention, however, because they are the most common cause of mortality in these patients. Documentation of oxygenation by pulse oximetry or arterial blood gas, blood culture for bacterial pathogens, nasopharyngeal specimens for rapid viral diagnosis, and viral culture should all be considered in any HIV-positive patient with respiratory symptoms (Fig. 93.5). Chest radiographs should be obtained and can be helpful in determining the cause (Fig. 93.6). Decisions regarding sputum induction or bronchoscopy do not usually need to be made in the ED.

Pneumocystis jiroveci Pneumonia (formerly *Pneumocystis carinii* pneumonia)

Background. PCP is the most common serious opportunistic infection in HIV-infected children. Although PCP can occur at any age, in children, it develops most often between the ages of 2 and 8 months and may be the first presentation of HIV infection. Moreover, the first episode is often acute in onset and may be fatal.

For the most part, the results of immunologic studies are not available to the emergency physician. However, particularly relevant differences between adults and children should be noted in case the CD4 lymphocyte counts are known. Among adults, absolute CD4 lymphocyte counts are associated with the risk of acquiring PCP. In young children, CD4 counts cannot be used to exclude the risk of PCP. For indications for PCP prophylaxis (and prophylaxis of other infections complicating HIV), see Table 93.6.

Clinical manifestations. PCP presents as an acute or subacute illness. The infant or child typically is febrile, with marked tachypnea, wheezing, rhonchi, and diminished breath sounds. Rales are not usually part of the PCP picture, and cough may be absent. When coughing is present, it is typically dry and nonproductive. Over hours to days, the patient develops hypoxia and increased respiratory distress.

Management. When PCP is suspected, the physician should intervene to maintain the airway as necessary, obtain an arterial blood gas or room air pulse oximetry, and provide supplemental oxygen. A chest radiograph and a serum lactate dehydrogenase (LDH) evaluations should be ordered. The patient typically has a high (greater than 30 mm Hg) alveolar-arterial oxygen gradient and low oxygen saturation, and generally

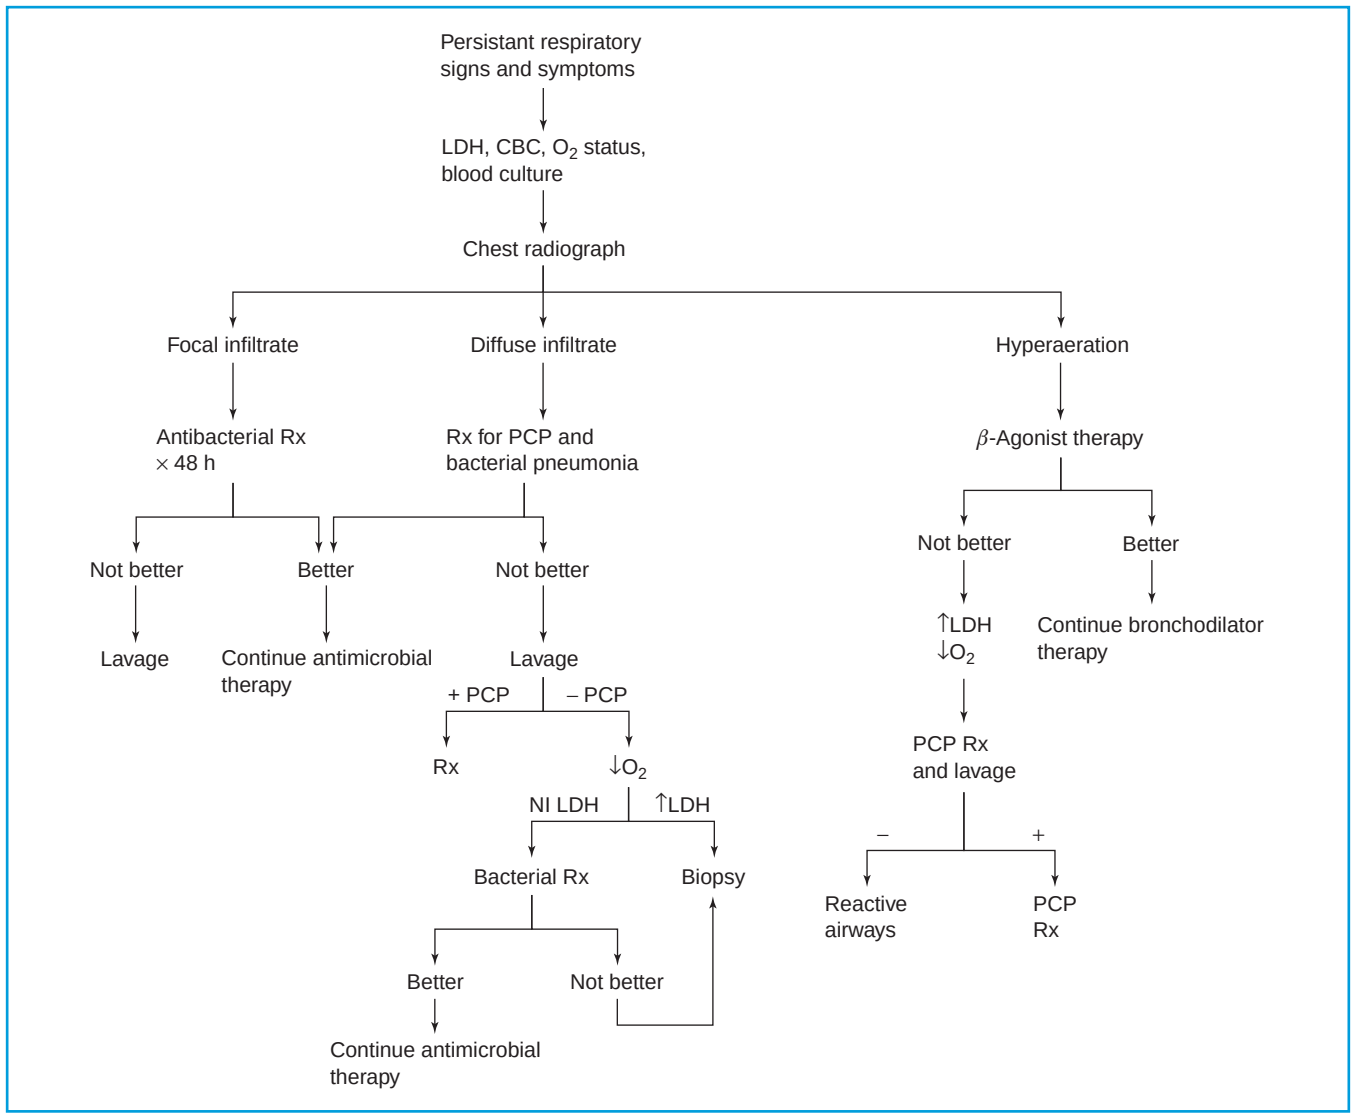

FIGURE 93.5 Evaluation of persistent respiratory signs and symptoms. LDH, lactate dehydrogenase; CBC, complete blood cell count; Rx, treatment; PCP, *Pneumocystis jiroveci* pneumonia. (Modified from Cunningham SJ, Crain EF, Bernstein LJ. Evaluations of the HIV-infected child with pulmonary signs and symptoms. *Pediatr Emerg Care* 1991;7:32–37.)

shows a marked (greater than 500 IU) elevation of the serum LDH. Radiographic findings typically consist of a diffuse interstitial ("ground glass") pattern, but infants may develop patchy infiltrates or complete opacification of the lung fields. Occasionally, however, the lung fields may be clear with hyperinflation suggestive of bronchiolitis, and in 5% to 10% of patients with PCP, the chest radiograph appears normal.

It is often difficult to make the diagnosis of PCP in the ED. If PCP is suspected on the basis of the history, physical examination, or the results of the laboratory investigation, it is appropriate to start IV TMP-SMZ at a dosage of 20 mg per kg per day of TMP divided every six hours. The child should be hospitalized for close observation and further evaluation as needed. In general, patients with PCP do not respond rapidly to antibiotic therapy. Patients intolerant of TMP-SMZ can be treated with pentamidine (4 mg per kg per day as a single daily dose) or atovaquone, but these should be considered second-line agents. Corticosteroid therapy in children with severe PCP improves survival and is generally recommended for patients with PaO_2 less than 70 mm Hg or an alveolar-arterial gradient of greater than 35 mm Hg. Patients suspected of having PCP should undergo bronchoalveolar lavage (BAL) although an induced sputum may be sufficient in older patients. Results of BAL may remain positive for 3 to 4 days after the initiation of TMP-SMZ therapy. Therefore, if PCP is suspected, appropriate therapy should be started immediately and not be withheld pending lavage.

Bacterial Pneumonia

Background and clinical manifestations. The HIV-positive child with bacterial pneumonia is most often infected with the usual pediatric organisms: *Streptococcus pneumoniae*, *Hemophilus influenzae*, group A streptococcus, and *Moraxella catarrhalis*. Hospitalized children or those with indwelling devices may be infected with gram-negative enteric organisms or *S. aureus*. In addition, these children often present with coinfection by respiratory viruses.

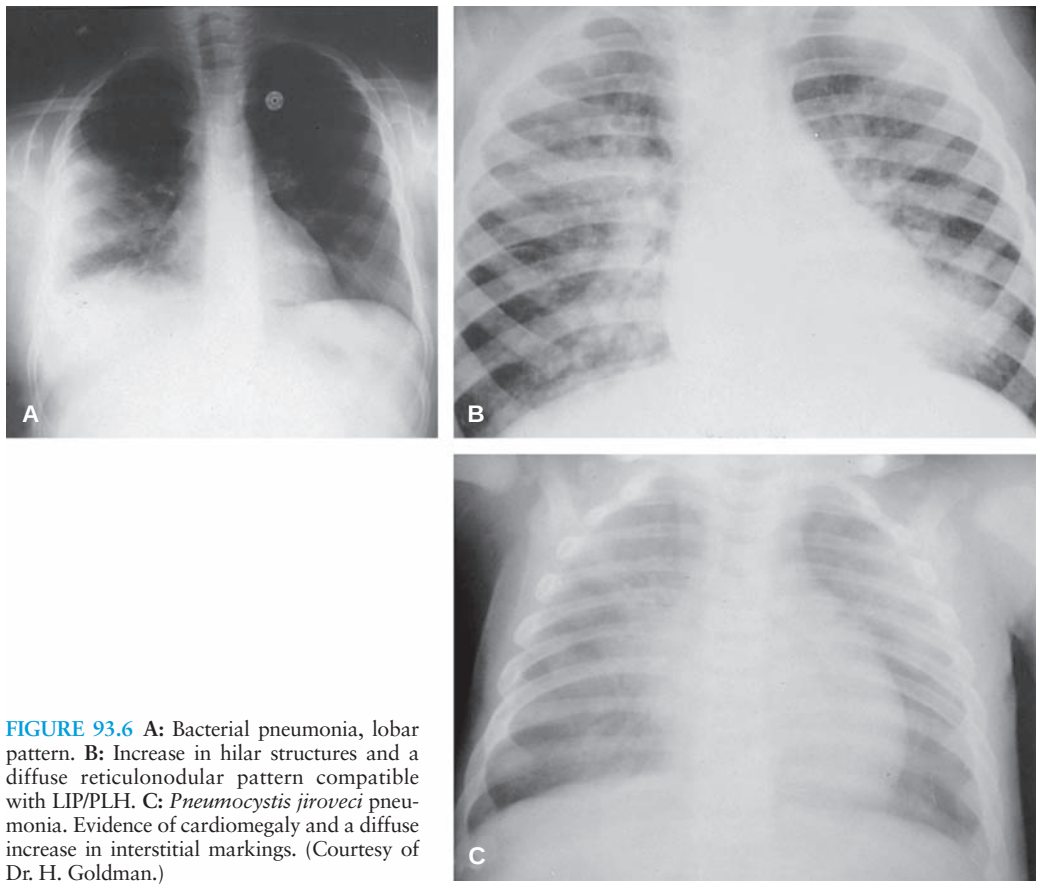

FIGURE 93.6 **A:** Bacterial pneumonia, lobar pattern. **B:** Increase in hilar structures and a diffuse reticulonodular pattern compatible with LIP/PLH. **C:** *Pneumocystis jiroveci* pneumonia. Evidence of cardiomegaly and a diffuse increase in interstitial markings. (Courtesy of Dr. H. Goldman.)

Management. A chest radiograph should be part of the evaluation of the HIV-positive child with fever of unknown origin or with respiratory signs or symptoms. The radiograph can help distinguish bacterial pneumonia (Fig. 93.6) from PCP or pulmonary lymphoid hyperplasia, and in fact, a chest radiograph compatible with bacterial pneumonia in an otherwise well-appearing child suggests that outpatient therapy may be possible if other criteria are met (Table 93.7).

The chest radiograph in bacterial pneumonia typically reveals a lobar or segmental infiltrate, and the peripheral WBC count is often more than 20,000 per mm^3. However, because many of these children are leukopenic when not infected, it may be difficult in the ED to determine what constitutes leukocytosis. For example, a child whose normal WBC count is 2,000 per mm^3 may mount a WBC of 8,000 to 10,000 per mm^3 in response to a bacterial infection, but this would go unnoticed without knowledge of the child's baseline. Because it is rare to be confident that pneumonia is not bacterial in origin, children with pulmonary signs and symptoms, especially associated with fever, are commonly given antimicrobial therapy against the common respiratory pathogens.

Other Pulmonary Infections. Other infections associated with respiratory signs and symptoms in HIV-positive children include viral illnesses, particularly, CMV pneumonia, *Mycobacterium tuberculosis*, and MAI. Except for *M. tuberculosis*, which is surprisingly rare in HIV-infected children as compared with adults, there has been little documentation of the frequency of the other infections. Adults and some children with environmental exposures have also had problems with coccidioidomycosis, blastomycosis, and histoplasmosis.

Wheezing.

Background and clinical manifestations. Reactive airway disease is the most likely diagnosis in an HIV-positive child with wheezing, with or without fever. If the wheezing is associated with rales, however, the physician needs to consider the possibility of PCP, lymphoid interstitial pneumonitis (LIP), acute pneumonia, or congestive heart failure. Congestive heart failure is rarely a presenting sign of HIV infection; instead, HIV-positive children with cardiomyopathy can develop congestive heart failure when under additional stress caused by an infection or fever. Physical examination may reveal the constellation of tachycardia, tachypnea, rales, and a palpable liver. However, these findings commonly occur in HIV-positive children without congestive heart failure.

Management. After a rapid but thorough physical examination to evaluate the degree of wheezing and air movement, the presence and location of retractions, and any other focus for fever, note whether the child responds to bronchodilator therapy. If so, reactive airway disease is the likely diagnosis, and the child can be treated accordingly. Pulse oximetry should be performed before the patient is discharged. Steroid therapy should be used as it would for an immunocompetent child with the same clinical findings.

TABLE 93.6

PROPHYLAXIS OF INFECTIONS IN HUMAN IMMUNODEFICIENCY VIRUS (HIV)-INFECTED PATIENTS[a]

Pathogen		Indication	Treatment
Pneumocystis jiroveci	Birth–4 wk	No prophylaxis	
	4–6 wk to 12 mo	Prophylaxis is recommended for all HIV-infected infants, as well as all HIV-exposed infants in the first year of life, until HIV infection can be reasonably excluded	Trimethoprim-sulfamethoxazole (TMP-SMZ) with secondary choices of dapsone, atovaquone, or pentamidine (aerosolized or IV)
	1–2 yr	Prophylaxis if CD4 count <750 cells/μL or <15%	
	2–5 yr	Prophylaxis if CD4 count <500 cells/μL or <15%	
	≥6 yr	Prophylaxis if CD4 count <200 cells/μL or <15%	
	Adult	Prophylaxis if CD4 count <200 cells/μL or <14%, or history of AIDS defining illness	
	Any age	Previous episode of *P. jiroveci* pneumonia Rapidly declining CD4 count	
Bacterial infections	Neutropenia		G-CSF or GM-CSF
	Recurrent invasive bacterial infections		IV immunoglobulin or antibiotic prophylaxis
Streptococcus pneumoniae	All patients unless already received vaccine as per schedule with good immune function at the time		Conjugate pneumococcal vaccine as per routine schedule
	>2 yr		23-Valent polysaccharide pneumococcal vaccine consider revaccination at 5-yr intervals
Influenza	>6 mo of age, on a yearly basis before influenza season (generally recommended)		Influenza vaccine, alternative rimantidine or amantadine
Varicella zoster virus (VZV)	Age >12 mo with good immunity		Live-attenuated varicella vaccine
	Significant exposure to varicella and no primary immunity (no documented history of chicken pox or shingles or, if available, negative VZV antibody)		Varicella zoster immunoglobulin; if within 96 hr, consider use of attenuated vaccine, consider preemptive acyclovir
Mycobacterium avium complex (MAC)	<1 yr: CD4 count <750 cells/μL 1–2 yr: CD4 count <500 cells/μL 2–6 yr: CD4 count <75 cells/μL ≥6 yr: CD4 count <50 cells/μL Any age: previous MAC disease		Clarithromycin, azithromycin, or rifabutin
Mycobacterium tuberculosis	Positive diagnostic test for latent tuberculosis (TB) infection without treatment or contact with case of active TB or history of inadequately treated TB		Recommendation varies according to likely antibiotic susceptibility
Herpes simplex	Very frequent or severe recurrences		Acyclovir, famciclovir, or valganciclovir
Candida	Frequent or severe recurrences; generally can discontinue when CD4+ count >200 cells/μL		Topical—nystatin, clotrimazole Oral—fluconazole, ketoconazole, itraconazole
Toxoplasma gondii	Positive IgG antibody to *Toxoplasma* and CD4 count <100 cells/μL		Primary prophylaxis—TMP-SMZ, dapsone with pyrimethamine, or atovaquone ± pyrimethamine
	Prior toxoplasmic encephalitis		Pyrimethamine plus sulfadiazine plus leucovorin, or pyrimethamine plus leukovorin
Cryptococcus neoformans	Documented cryptococcal disease; May discontinue if CD4+ >200 cells/μL for > 6 mo in response to antitretroviral therapy		Fluconazole or itraconazole
Coccidiodis immitis	Documented coccidiodal disease; or CD4+ count <250 cells/μL and Positive IgM or IgG serologic test		Fluconazole or itraconazole
Histoplasma capsulatum	Documented disease or live in highly endemic area and CD4 count <150 cells/μL		Itraconazole
Human papillomavirus (HPV)	Women aged 15–26 yr		HPV quadravalent vaccine
Hepatitis A	>2 yr old and high risk for exposure or chronic liver disease (e.g., hepatitis b or c)		Hepatitis A vaccine ×2
Hepatitis B	All susceptible patients		Hepatitis B vaccine ×3

Criteria for discontinuing prophylaxis among patients with immune reconstitution on antiretroviral therapy are not presented.
IV, intravenous; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor.
[a]It is assumed that patients will receive routine hepatitis B, diphtheria, pertussis, tetanus, haemophilus influenzae type b, polio, measles, mumps, and rubella vaccinations but have not yet received varicella vaccination.
Modified from CDC guidelines. *MMWR Morbid Mortal Wkly Rep* 51 (RR-8):1–60.

TABLE 93.7

GENERAL GUIDELINES FOR ELECTING OUTPATIENT THERAPY OF HUMAN IMMUNODEFICIENCY VIRUS-POSITIVE CHILDREN WITH PNEUMONIA

Age >6 mo
Able to tolerate oral fluids and medication
Absence of signs of respiratory distress (e.g., flaring or retractions)
Respiratory rate
<45 Respirations/min if age <2 yr
<30 Respirations/min if age >2 yr
Oxygen saturation ≥93%
Has not already worsened while receiving oral antibiotic
Close clinical follow-up available and patient able to return
Pneumocystis jiroveci pneumonia should be considered unlikely

If the child has a high fever [temperature higher than 39°C (102.2°F)], a chest radiograph should be obtained to look for an infiltrate or evidence of PCP or congestive heart failure. The febrile child with wheezing and rales or evidence of pneumonia on chest radiograph who otherwise appears well enough for outpatient therapy may be given oral amoxicillin (80 to 100 mg per kg per day) or IM ceftriaxone (50 mg per kg) in addition to bronchodilator therapy.

Children with clinical or radiographic evidence of PCP or congestive heart failure should be hospitalized. A first dose of IV TMP-SMZ should be given to infants suspected of having PCP, and congestive heart failure should be treated with afterload reducers and diuretics in addition to bronchodilators (see Chapter 84).

Lymphocytic Interstitial Pneumonitis

Background. LIP or pulmonary lymphoid hyperplasia is common among pediatric HIV-infected patients with pulmonary disease. It is believed to be an infiltrative lymphoproliferative disorder associated with HIV, EBP, and HTLV type 1 infections.

Clinical manifestations. LIP is an insidious condition that causes a slowly progressive hypoxia typically in children who are older than 1 year. Most children present to the ED with chronic cough, mild tachypnea, marked lymphadenopathy, and may have intermittent rales, occasional wheezing, and marked hypoxia and clubbing of the digits. Definitive diagnosis requires bronchoscopy with transbronchial biopsy or open lung biopsy.

Management. Rarely is intervention required to maintain the airway in children with LIP. Most HIV-positive children with a cough should undergo chest radiography. Chest radiography commonly reveals an interstitial nodular pattern that can be diagnostic. Occasionally, bronchiectasis develops, and these children may become superinfected with bacterial or viral pathogens and have fever. Fever is an important differentiating point in the management of HIV-positive children believed to have LIP. Therapy may be with highly active antiretroviral therapy (HAART), but in acute respiratory compromise, empiric corticosteroid therapy may be warranted. If the Pa_{O_2} is less than 65 mm Hg, LIP is treated with 1 to 2 mg per kg per day of prednisone to a maximum of 60 mg for 2 to 4 weeks and subsequently tapered as necessary to maintain the Pa_{O_2} above 70 mm Hg. If the patient is febrile, tuberculosis or MAI must be ruled out before beginning steroid therapy.

Gastrointestinal Manifestations

Chronic or recurrent oral thrush or esophageal candidiasis are common and can be treated with nystatin, clotrimazole, or fluconazole.

Diarrhea

Background. The gastrointestinal tract generally shows only subtle changes in histology in HIV infection unless there are secondary infections. In addition to the common causes of diarrhea that affect immunocompetent children, HIV-positive children are prone to parasitic (*Giardia*, *Microsporidium*, *Cryptosporidium*), chronic viral (CMV), mycobacterial, and serious bacterial infections of the gastrointestinal tract (Table 93.8). Malnutrition is a common problem in HIV infection and, in children, requires careful monitoring of growth parameters.

Clinical Manifestations and Management. The general evaluation of the child with diarrhea is described in Chapter 18. Because diarrhea has many potential etiologies in HIV-infected children, the physician should seek to identify the cause. A stool test for blood, a stool smear for polymorphonuclear leukocytes, and a stool culture (for *Salmonella*, *Shigella*, *Yersinia*, *Campylobacter*, *Escherichia coli*) should be obtained, with consideration given to sending stool for parasites and *Clostridium difficile* toxin. The child who is afebrile, appears to be well hydrated, and has no blood or leukocytes in the stool can be treated symptomatically with dietary management and close follow-up. If the child attends a day care program and is still in diapers, the parents/guardians should be instructed to keep the child home until the illness has resolved and the culture is tested negative.

In febrile children with gastroenteritis, although viral causes are still most common, *Salmonella* is the primary bacterial pathogen of concern and is a major cause of bacteremia in HIV-positive children. If there is blood or more than five leukocytes per high-power field on examination of the stool smear but the child has normal vital signs and looks well, he or she should be treated with TMP-SMZ and reevaluated the next day. Oral ampicillin is an alternative drug, but in many

TABLE 93.8

ORGANISMS ASSOCIATED WITH ACUTE DIARRHEA IN HUMAN IMMUNODEFICIENCY VIRUS-POSITIVE CHILDREN

Viral agents	*Shigella*
Rotavirus	*Escherichia coli*
Adenovirus	*Clostridium difficile*
Norwalk agent	*Giardia lamblia*
Cytomegalovirus	*Cryptosporidium*
Salmonella species	*Isospora*
Yersinia enterocolitica	*Microsporidia*
Campylobacter	

areas, 20% to 30% of *Salmonella* species are resistant to ampicillin. The child who appears dehydrated or ill should be admitted for IV hydration and parenteral antibiotic therapy.

If the patient remains symptomatic in the face of a negative stool culture and dietary management, a total of at least three stool specimens should be sent for ova and parasite evaluation and two samples tested for *C. difficile* toxin. If no cause is identified, endoscopy or colonoscopy should be considered, depending on the severity of symptoms.

Hematologic Manifestations

Hematologic abnormalities are common and can be the result of HIV infection itself (occurring early or late in the illness) or secondary to concomitant infections (mycobacteria, CMV, parvovirus B19, fungal infections), lymphoma, or medication toxicities. Anemia redominates, especially with zidovudine therapy; erythropoietin levels may be low, identifying patients likely to benefit from erythropoietin therapy. Nutritional deficiencies are frequent and may also contribute to the anemia. Neutropenia is common and may be accentuated by medications (e.g., zidovudine, ganciclovir, TMP-SMZ) but is generally mild. If necessary, granulocyte colony-stimulating factor or granulocyte—macrophage colony-stimulating factor can be given with improvement of the neutropenia. Thrombocytopenia is a typical part of the acute HIV infection and can persist or worsen over time. Improvement is often seen with antiviral therapy. If the thrombocytopenia is severe, it can generally be managed along the same lines as for non–HIV-infected patient with idiopathic thrombocytopenia (steroids, Rhogam®, or gamma globulin) (see Chapter 91).

Rash

Background and Clinical Manifestations. Of all the categories of dermatologic manifestations of HIV infection in children, seborrheic dermatitis and infections are by far the most common. Neoplasms with skin manifestations such as Kaposi's sarcoma are not often seen in children. Measles can be particularly severe in HIV-positive children. This illness may be associated with the characteristic clinical signs and symptoms of generalized rash, coryza, conjunctivitis, cough, and Koplik's spots, or it may occur without the typical rash. The HIV-infected child with measles must be evaluated carefully for signs of dehydration and respiratory distress. If the child is taking liquids well and breathing comfortably, he or she may be sent home with careful instructions to return for reevaluation if status worsens. All HIV-positive children who have been exposed to measles should receive gamma globulin (0.5 mL per kg with maximum of 15 mL given intramuscularly), regardless of whether they have been vaccinated against measles.

Varicella can also cause severe illness in the immunocompromised host. Varicella zoster immunoglobulin should be given to HIV-infected children after exposure to chicken pox (1 vial containing 125 units for each 10 kg of body weight with any opened vial used completely, maximal dose is five vials). Once clinical illness has started, these children should initially be treated with IV acyclovir (10 mg per kg every 8 hours). Children with local single dermatome zoster infection may be treated with oral acyclovir (20 mg per kg per dose given every 6 hours). These children must be followed closely to ensure the infection does not disseminate.

More than 10% of children infected with HIV will have thrombocytopenia associated with high levels of circulating immune complexes and antiplatelet antibodies that may manifest as petechiae or easy bruising. Patients with platelet count more than 50,000 per mm^3 should be considered for admission and treatment. Febrile or toxic-appearing HIV-positive children with petechiae must be considered to have septicemia (see Chapter 92). After a rapid assessment of the airway, breathing, and circulation, these patients should undergo a full evaluation for sepsis, including lumbar puncture, and they should receive parenteral antibiotics pending culture results.

Syphilis screening should be performed for any HIV-infected child whose syphilis serology at birth is unknown because women with HIV have a high rate of coinfection with syphilis.

Molluscum contagiosum is a viral infection of the skin that presents as single or grouped small, firm, skin-colored papules. The appearance of these papules over scattered areas of the body is common among immunocompromised patients. Finally, medication-related adverse reactions including rashes are common among HIV patients as well (Table 93.9).

Neurologic Manifestations

Background. Once transmitted to the central nervous system (CNS), a neurotropic HIV strain emerges. In the early 1980s, a progressive dementia was reported in adults with AIDS. A syndrome analogous to the adult AIDS dementia complex was described in HIV-infected children in 1985 and was called *AIDS encephalopathy*. As it turns out, AIDS encephalopathy is common and does not require other manifestations of full-blown AIDS. Untreated, a large proportion of children with HIV infection will have neurologic involvement, and the possibility of HIV infection should be considered in the differential diagnosis of developmental delay or loss of milestones. With treatment, the proportion with neurologic involvement decreases substantially to about 20%.

HIV-infected children are at increased risk of meningitis (including cryptococcal, although less commonly than in adults, and tuberculous meningitis), encephalitis (including that caused by *Toxoplasma*), stroke and cerebral infarcts, progressive multifocal leukoencephalopathy (caused by human polyomavirus JC), and a variety of vasculopathies.

Clinical Manifestations. Children with AIDS encephalopathy exhibit developmental delay or developmental regression, acquired microcephaly, and pyramidal tract signs. Although growth and development are often affected by any serious illness in a child, AIDS encephalopathy may occur in patients with no signs of opportunistic infections and few signs of immunodeficiency. It may manifest itself as a static, progressive, or indolent encephalopathy with periods of plateaus in cognitive and motor development. Static encephalopathy is defined by the presence of nonprogressive cognitive or motor deficits. Progressive encephalopathy usually begins within 2 months to 5 years after initial exposure to HIV. It is characterized initially by deterioration of play and progressive apathy. Developmental delay ensues, with loss of developmental milestones, including deficits in socially adaptive language and in fine and gross motor skills. As the condition progresses, there may be spastic diplegia and quadriparesis. Patients develop extrapyramidal and cerebellar signs, including rigidity,

TABLE 93.9

ADVERSE EFFECTS OF DRUGS USED IN TREATING HUMAN IMMUNODEFICIENCY VIRUS, PREVENTING OPPORTUNISTIC INFECTIONS, OR IN TREATING COMMONLY ACQUIRED INFECTIONS[a]

Adverse effect—drug(s)
Bone marrow suppression—amphotericin B, cidofovir, dapsone, enfuvirtide, foscarnet, flucytosine, ganciclovir, hydroxyurea, interferon alpha, linezolid, peginterferon alpha pyrimethamine, rifabutin, ribavirin, sulfadiazine, trimethoprim-sulfamethoxazole, trimetrexate, valganciclovir, zidovudine
Diarrhea—atovaquone, didanosine, clindamycin, nelfinavir, ritonavir, lopinavir/ritonavir, tenofovir
Hepatotoxicity—atovaquone, azitrhomycin, clarithromycin, fluconazole, isoniazid, itraconazole, ketoconazole, pyrazinamide, rifabutin, rifampin, trimethoprim-sulfamethoxazole, voriconazole, most antiretrovirals; hepatic failure can be seen with nevirapine.
Nephrotoxicity—acyclovir, adefovir, amphotericin B, cidofovir, foscarnet, indinavir, pentamidine, tenofovir
Ocular effects—didanosine, cidofovir, ethambutol, rifabutin, voriconazole
Pancreatitis—didanosine, lamivudine, pentamidine, ritonavir, stavudine, trimethoprim-sulfamethoxazole, zalcitabine
Peripheral neuropathy—didanosine, isoniazid, linezolid, stavudine, zalcitabine
Neurotoxicity—high-dose acyclovir, quinolones
Skin rash—abacavir, amprenavir, atovaquone, dapsone, delavirdine, efavirenz, nevirapine, primaquine, pyrimethamine, ribavirin, sulfadiazine, trimethoprim-sulfamethoxazole, voriconazole

[a]Adapted from *2001 USPHS/IDSA guidelines for the prevention of opportunistic infections in persons infected with human immunodeficiency virus and the guidelines for the use of antiretroviral agents in HIV-1-infected adults and adolescents*. For more related information see *Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*. http://aidsinfo.nih.gov/guidelines.

dystonic posturing, and ataxia. Seizures, although uncommon, may occur.

Another group of children present with indolent encephalopathy. These patients experience variable plateaus in their development during which there is little or no further cognitive growth. Either new milestones are not obtained or the rate of acquisition of new skills deviates from the norm and the child's initial rate of developmental progress. Many of these children may go on to develop the progressive form of AIDS encephalopathy.

Physical examination of the patient with AIDS encephalopathy often reveals microcephaly. Younger children will be hypotonic with persistence of the Moro or tonic neck reflexes after 4 months of age. Older children may have symmetric ankle clonus and extensor plantar responses. As the condition progresses, pyramidal signs of varying severity, including a pure spastic quadriparesis with signs of pseudobulbar palsy, dysphagia, and dysarthria, are seen. Ataxia may be seen in children old enough to walk.

Management. The diagnosis of AIDS encephalopathy involves obtaining a history suggestive of developmental delay or regression in an HIV-infected child. Management is more complicated when these children come to the ED with fever because it may be difficult to evaluate their mental status. Commonly, a lumbar puncture is necessary to rule out bacterial meningitis, unless the physician can be confident on a clinical basis that the child is behaving at baseline and that the fever is not secondary to CNS infection.

Cancers

Cancers have been seen less frequently in children than in adults. The most common malignancies of children with AIDS are non-Hodgkin's lymphomas. The next most common are leiomyomas and leiomyosarcomas in the gastrointestinal tract. These are associated with EBV infection. Some other malignancies have also been linked to specific viral infections. Kaposi's sarcoma is associated with human herpes virus-8 infection, some peripheral lymphomas and most primary to the brain contain EBV, and anal cancers and cervical carcinomas are linked with human papilloma virus infections.

Management of HIV

Overview of Anti-HIV Medications

Many effective anti-HIV medications are now available. At present, these can be divided into several general classes.

Entry inhibitors such as enfuvirtide (Fuzeon®) or maraviroc (Selzentry®) work by blocking the entry of the HIV virus into human cells.

Nucleoside (and nucleotide) reverse transcriptase inhibitors are nucleoside (nucleotide) analogs that compete with the viral reverse transcriptase and include abacavir (Ziagen®), apricitabine (in trials), didanosine (Videx®, ddI), emtricitabine (Emtriva®, FTC®), lamivudine (Epivir®, 3TC®), stavudine (Zerit®, d4T), tenofovir DF (Viread®), zidovudine (Retrovir®, AZT, ZDV), and combinations of the above medications: Combivir® (lamivudine and zidovudine), Trizivir® (abacavir, lamivudine, and zidovudine), and Epzicom® (abacavir and lamivudine).

Nonnucleoside reverse transcriptase inhibitors also block the viral reverse transcriptase enzyme and include delavirdine (Rescriptor®), efavirenz (Sustiva®), and nevirapine (Viramune®).

Protease inhibitors block protease enzymes responsible for cleaving viral proteins into functional units. Medications in this class include atazanavir (Reyataz®), darunavir (Prezista®), fosamprenavir (Lexiva®), indinavir (Crixivan®), lopinavir/ritonavir (Kaletra®), nelfinavir (Viracept®), ritonavir (Norvir®), saquinavir (Fortavase®, Invirase®), and tipranavir (Aptivus®). Because of poor tolerability at full dose, ritonavir is predominantly used in low dose to reduce the metabolic clearance and thus increase the levels of another concurrently given protease inhibitor.

Integrase inhibitors interfere with the ability of the integrase enzyme to insert the DNA, produced by reverse transcription of the virus RNA, into the human cell DNA. The first FDA-approved drug of this class is raltegravir (Intelence®) and trials are underway with a second in the class, elvitegravir.

Because HIV has the capacity to rapidly develop resistance to individual antiviral drugs, combination therapy using three to four agents has now become the treatment standard. As a result combinations of different classes of medications have been introduced to reduce the number of separate pills that must be taken simultaneously. Such medications include Atripla® (efavirenz, emtricitabine, and tenofovir) and Truvada® (emtricitabine and tenofovir).

Unfortunately, drug therapy does not eradicate infection. The efficacy of these antivirals in various tissues that may (i) harbor virus, (ii) be important in the spread of virus, or (iii) be important to symptomatology (e.g., lymph nodes, brain, testes, mucosal surfaces) is not always known. These drugs also commonly cause significant side effects and drug interactions that may bring patients to the ED for attention. These most often include rash, headache, nausea, diarrhea, pancreatitis, fatigue, anemia, granulocytopenia, peripheral neuropathy, renal stones, decreased absorption of other medications, and increased or decreased metabolism of other medications (Table 93.9). Significant advances have been made in drug therapy with the ability to monitor drug and quantitative viral levels in the clinical setting. In addition, these patients frequently require antimicrobials for treatment or prophylaxis against bacterial, fungal, mycobacterial, and viral infections, management of malignancies, neuropathic pain, and/or metabolic, hematologic, and endocrine derangements. All of these medications may result in important interactions or toxicities. The emergency physician must therefore also consider the patient's medications as a possible culprit for acute presentations in these patients.

Prevention of HIV Acquisition

Development of an effective and safe vaccine for the prevention of HIV is a high priority, but progress has been disappointing. Until such a vaccine is available, current strategies for postexposure prevention of HIV infection take advantage of the finding that it may take several hours after exposure (or possibly, in some cases, days) for HIV infection to become established. During this time, antiviral medications can be given to prevent the transmitted virus from causing an established infection. Prevention of perinatal acquisition through the use of anti-HIV medications during the last trimester of pregnancy and the first days or weeks of infancy has been successful in significantly reducing the risk of infection. The introduction of antiviral therapy has resulted in an impressive reduction in perinatally acquired HIV cases currently seen in the United States. Unfortunately, the cost of this treatment is prohibitive in the countries where 90% of HIV infections occur. The risks of acquisition from exposures to HIV are listed in Table 93.4.

Postexposure HIV Prophylaxis

Community Exposures: Consensual Sex and Needlesticks. Sexual contact is the most common means of transmitting HIV infection, and reducing exposure is the mainstay of public health efforts. Prophylaxis after sexual intercourse or sharing needles could potentially decrease transmission, although efficacy has not yet been demonstrated and is not likely to be practical where repeated exposure is likely. A patient with a significant exposure to HIV, such as receptive or penetrative anal or vaginal sex, receptive oral intercourse with ejaculation, or needle sharing involving a partner who is HIV positive or who is in a known risk group should be considered for PEP. The patient who has had an isolated high-risk episode of consensual sex with an individual known to have HIV in which safe sex practices were not followed (or failed, e.g., broken condom) should also be offered HIV prophylaxis and risk-reduction counseling.

Accidental community-acquired needlestick exposures also require attention. HIV has been detected and infectious virus has been recovered from syringes obtained from high-risk community sources. Most discarded syringes will not have any recoverable HIV, and if complete drying of the syringe has occurred, there will be no infectious HIV. Thus far, no report exists of transmission of HIV from a discarded syringe left in a public place. Therefore, the risk of transmission of HIV from an accidental needlestick from a needle/syringe found in a public place is likely very low. Prophylaxis should not be routinely recommended, but because the risk is not zero, careful discussion with the family should include the need for subsequent monitoring and testing of the patient. Voluntary sharing of needles among IV drug abusers would pose a substantially higher risk because immediate use of the needle would result in a greater likelihood of infectious virus being transmitted. A prophylaxis strategy in this situation would demand the patient discontinue ongoing exposures that carry a continued risk for acquiring HIV.

Health-care Worker Exposures. An increased risk for HIV infection after percutaneous or mucous membrane exposures to HIV-infected blood is associated with the quantity of blood, as indicated by visible contamination of the device with the patient's blood, its use directly in a vein or artery, or a deep injury to the health-care worker. It is likely to increase with a higher viral load in the patient's blood. Finally, the risk of acquiring HIV is decreased by an estimated 80% by the prompt postexposure use of effective antiretrovirals. Each health-care institution should have a system to evaluate their employees' occupational exposures and offer treatment. As of December 2002, the CDC was aware of 57 health-care workers who had documented seroconversion after occupational exposures and another 139 HIV-positive health-care workers who are likely to have acquired infection after an occupational exposure.

Sexual Assault

Evaluation of the victim of sexual assault is a multidisciplinary process and will involve medical, psychological, and legal issues (Table 93.10). Medical issues to consider include acute trauma care, postexposure pregnancy prophylaxis, and postexposure infection prophylaxis. The discussion that follows is limited to issues of infection prophylaxis. The most commonly acquired infections after sexual assault are chlamydia, gonorrhea, trichomoniasis, and bacterial vaginosis. Other less commonly acquired but important infections include HIV; hepatitis viruses A, B, and C; human papillomavirus condylomata

TABLE 93.10

ISSUES TO CONSIDER IN CASES OF SEXUAL ASSAULT

Medical
Obtain medical history
Evaluate and treat physical injuries: genital/nongenital (consider EUA)
Obtain cultures/serology/clinically indicated tests
–Culture: gonorrhea, chlamydia (sites based on contact), others as indicated
–Serology: RPR, HIV ELISA, hepatitis B surface antibody, hepatitis C antibody
–Clinically indicated tests: pregnancy, hematocrit, toxicology screen
Treat preexisting infection
Offer postcoital contraception (Plan B or Ovral®) if postpubertal
Evaluate risk for transmission of STDs
Consider and offer postexposure prophylaxis to postpubertal patients for bacterial infections
–Gonorrhea: ceftriaxone
–Chlamydia: azithromycin
–Bacterial vaginosis or *Trichomonas*: metronidazole (Flagyl®)
Consider antiviral prophylaxis
–Hepatitis B: vaccine
Less commonly indicated (see text)
–HIV: specific recommendations vary based patient age, local HIV resistance patterns and exposure risk for acquisition of infection but two or three drug regimens are typical.
Depending on injuries consider tetanus: vaccine ± tetanus immunoglobulin
Arrange medical follow-up within 1 wk if feasible
Provide and/or arrange counseling with very specific follow-up instructions
Recommend sexual abstinence until STD prophylaxis completed

Legal
Record events accurately
Document injuries; photo as indicated, clothes, semen, etc.
Collect forensic specimens
Preserve chain of evidence
Determine need to contact civil authorities (police, child protective services)

EUA, examination under anesthesia; STD, sexually transmitted disease; HIV, human immunodeficiency virus. See also: http://www.cdc.gov/std/treatment/ and http://www.aidsinfo.nih.gov/Guidelines/ under Guidelines > Nonoccupational Exposure Considerations, for the most up-to-date recommendations.

acuminata; syphilis; and herpes simplex. Finally, pubic lice, scabies, and sexually transmitted infections that are rare in developed countries will be seen occasionally or identified in follow-up. Depending on the form of the sexual assault and risk of acquiring infection, empiric PEP is generally discussed and offered. For patients without a contraindication, treatment with 1 g azithromycin for *C. trachomatis* prophylaxis, 125 mg IM ceftriaxone for gonorrhea prophylaxis, and 2 g metronidazole for bacterial vaginosis prophylaxis are offered. Hepatitis B vaccination with follow-up doses at 1 to 2 months and 4 to 6 months should be given if the victim has not previously been vaccinated and known to have an adequate response.

Generally, postexposure prophylaxis for HIV is not required but should be discussed in circumstances where the risk of transmission is high. The possibility of HIV transmission with such contacts should be discussed with the victim, the risk of transmission assessed, and PEP offered or recommended if appropriate. Risk increases with ejaculation without effective condom use, multiple assailants, injuries that involve blood, evidence to suggest illicit drug use on the part of the assailant(s), and/or threats or suggestions that the assailant(s) is HIV positive.

Treatment with antiretrovirals should be considered when the patient presents within 72 hours after a single event where there is exposure of vagina, rectum, mouth, or other mucous membrane with blood, semen, vaginal secretions, rectal secretions, breast milk, or any blood-contaminated fluid or percutaneous contact where bleeding is present. Exposures to urine, nasal secretions, saliva, sweat, or tears when not visibly blood-contaminated are not considered sufficient to warrant postexposure prophylaxis. The drug of choice will depend on local HIV susceptibility patterns and perhaps knowledge regarding the assailant, but as of this printing, the preferred regimens typically contain at least two and more often three drugs. Preferred regimens as per the CDC include: (i) Efavirenz® or Kaletra® (lopinavir/ritonavir); plus (ii) lamivudine or emtricitabine; plus (iii) zidovudine or tenofovir. An infectious diseases consultant can assist in drug selection. The decision regarding the use of postexposure prophylaxis for HIV should be made as early as possible, and discussion with the patient must include the limited data for efficacy and the potential toxicities and requirement for close outpatient follow-up.

When considered appropriate (Fig. 93.7), PEP should be instituted as quickly as possible after exposure. Most would limit PEP to exposures within 72 hours of exposure (preferably less than 24 hours). Patients receiving PEP should receive first doses of medication in the ED, if available, and need

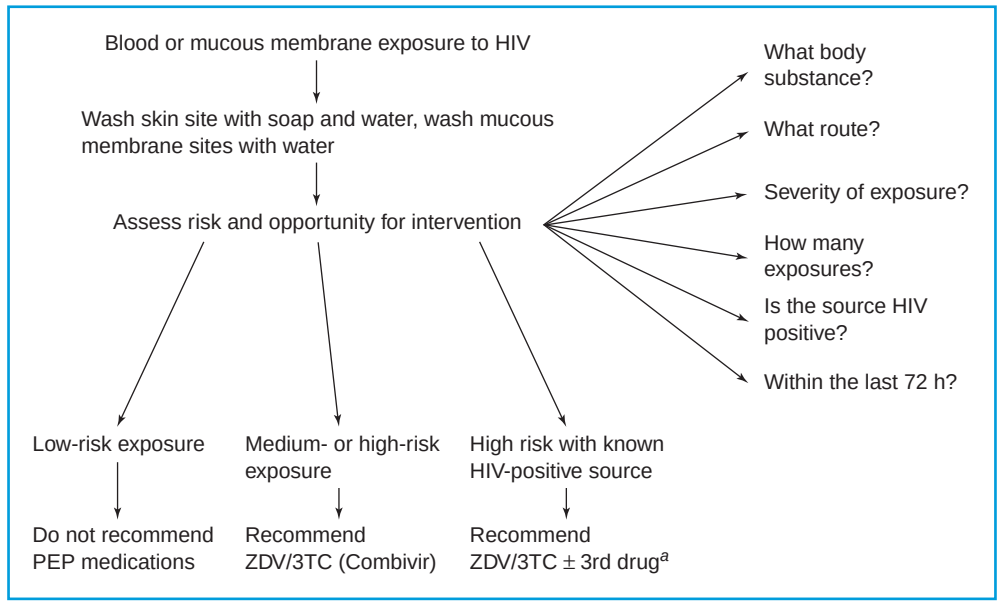

FIGURE 93.7 Postexposure prophylaxis (PEP) for possible community-acquired exposures to human immunodeficiency virus (HIV). When available, additional information regarding the source individual may alter recommendations. [a]3rd drug; commonly recommended: indinavir, nelfinavir, efavirenz or abacavir; other drugs only with expert consultation.

follow-up with clinicians knowledgeable about antiviral therapies and able to provide intensive emotional and behavioral counseling to help cope with the immediate event and to help them avoid situations likely to result in future exposure. Studies have demonstrated that compliance with these medications is poor. The antiviral medications, generally recommended to be taken for 4 weeks, can have significant side effects.

CHAPTER 94 ■ METABOLIC EMERGENCIES

DEBRA L. WEINER, MD, PHD

INTRODUCTION

Recognition and understanding of inborn errors of metabolism (IEMs) in the acutely ill child in the emergency department (ED) is critical for appropriate, and possibly lifesaving, management. Individually, metabolic diseases are rare, but collectively they are common. In the United States, the incidence is approximately 1 in every 4,000 newborns. IEMs usually manifest in the neonatal period or infancy but can present at any age, even during adulthood. Many IEMs are now diagnosed by newborn screen (NBS) performed using tandem mass spectrometry (MS/MS). Nearly all states screen for a core set of IEMs, additional IEMs screened for varies by state, results may not be available in the first days to weeks of life, and false negatives and false positives occur. Clinical diagnosis and management do not require an extensive knowledge of individual metabolic diseases or biochemical pathways. An understanding of the clinical manifestations of IEMs provides the basis for knowing when they should be considered. Most important in making the diagnosis of metabolic disease is a high index of suspicion. Successful emergency treatment of suspected and known IEMs depends on prompt institution of therapy to correct and prevent further metabolic derangement. The goals of this chapter are to provide insights into when the diagnosis of an IEM should be considered, the tests necessary to make the diagnosis, and the appropriate initial management of patients with suspected or known IEM, as well as evaluation and management of the asymptomatic neonate with a positive NBS.

PATHOPHYSIOLOGY

IEMs are usually caused by single gene defects that result in abnormalities in protein, carbohydrate, fat, or complex molecule metabolism. Most are due to a defect in, or deficiency of, an enzyme, enzyme cofactor, or transport protein that results in a block in a metabolic pathway. Clinical effects are the consequence of toxic accumulations of substrates before the block or intermediates from alternative metabolic pathways and/or defects in energy production and utilization due to a deficiency of products beyond the block. Toxic accumulation of substances results from disorders of protein metabolism (i.e., amino acidopathies, organic acidemias also referred to as *organic acidurias*, urea cycle defects), carbohydrate intolerance (e.g., galactose, fructose intolerance), and lysosomal storage (i.e., mucopolysaccharidoses, glycoproteinoses, sphingolipidoses, mucolipidoses). Defects in energy production or utilization result from disorders of glycogenolysis and gluconeogenesis (e.g., glycogen storage disorders), fatty acid oxidation defects, mitochondrial disorders (i.e., Kreb's cycle disorders, pyruvate dehydrogenase deficiency, electron transport chain disorders). Peroxisomal disorders (e.g., Zellweger syndrome, Refsum disease, adrenoleukodystrophy) are a diverse group of IEMs caused by defects of single or multiple peroxisomal enzymes, or of peroxisomal biogenesis that result in toxic accumulations, energy deficiency, and/or defects in biosynthesis of complex molecules. Other categories include disorders of metal metabolism (e.g., Wilson's disease, Menkes syndrome, acrodermatitis enteropathica, hemochromatosis); purine and pyrimidine biosynthesis (e.g., Lesch-Nyan syndrome); cholesterol biosynthesis (e.g., Smith-Lemli-Opitz syndrome); bone metabolism (e.g., hypophosphatasia); heme, bile acid, and bilirubin metabolism (e.g., porphyrias, Dubin-Johnson syndrome, Crigler-Najjar syndrome, Gilbert's disease); lipoprotein metabolism (hyperlipidemia, hypertriglyceridemia, hypercholesterolemia); and glycosylation (i.e., congenital disorders of glycosylation). Congenital adrenal hyperplasia is classified as an endocrine disorder and described in Chapter 86.

UNKNOWN SUSPECTED IEM

Background

An understanding of the clinical manifestations of IEMs provides the basis for knowing when IEM should be considered. Most important in making the diagnosis of metabolic disease is a high index of suspicion. Diseases involving the same metabolic pathways usually share similar features. In the ED, evaluation and management of patients with undiagnosed suspected IEM is usually guided by the potential metabolic category of disease and does not require a specific diagnosis. Prompt emergency treatment of physiologic and metabolic derangements, as well of precipitant causes of decompensation, is critical for optimizing outcome.

Clinical Manifestations

History

For a patient with an undiagnosed IEM, the history often provides clues that should prompt consideration of an IEM. Poor feeding, frequent vomiting, failure to thrive, lethargy in the morning before feeding or with delayed feeding, and onset of symptoms with change in diet and/or unusual dietary preferences, particularly protein or carbohydrate aversion, are concerning for possible IEM. Symptoms may be episodic in an otherwise apparently normal child. Physiologic stressors such

as fasting, illness, or surgery may precipitate symptoms, especially if the stressor induces a catabolic state. Intercurrent infection may result in decompensation out of proportion to the illness. A history of multiple hospitalizations for lethargy and dehydration with improvement following intravenous (IV) fluids and glucose is common. Psychomotor developmental delay, especially with loss of milestones, is also concerning for an IEM. Some patients, particularly those with developmental delay, may already have been labeled as having other conditions, commonly cerebral palsy. It is now recognized that many patients with a history of Reye syndrome have a previously undiagnosed IEM. Patients with what is thought to be idiopathic cardiomyopathy may also have an undiagnosed IEM. Certain findings suggest particular categories of IEMs. Vomiting occurs with many IEMs but is a prominent feature of organic acidemias and urea cycle defects. Diarrhea is also a common feature of many IEMs, particularly disorders of carbohydrate intolerance and mitochondrial disorders. Lethargy progressing to coma is common with organic acidemias, urea cycle defects, fatty acid oxidation defects, and certain disorders of carbohydrate intolerance. IEM should also be considered in any child with unexpected, unexplained sudden death, even without other history suggestive of IEM. Most IEMs are autosomal recessive in their inheritance, but they may be X-linked, mitochondrial, or uncommonly autosomal dominant. A history of suggestive findings; death due to neurologic, cardiac, and/or hepatic dysfunction; sepsis; or unexplained neonatal or sudden infant deaths in siblings or maternal male relatives is also concerning. Maternal illness during pregnancy, particularly acute fatty liver of pregnancy or HELLP (hemolysis, elevated liver enzymes, low platelets) syndrome, may be due to maternal heterozygosity for a fatty acid oxidation defect, specifically 3-hydroxyacyl-CoA dehydrogenase deficiency. Parental consanguinity increases the likelihood of autosomal recessive IEM because relatives are more likely to carry the same defective gene. Certain IEMs are more prevalent in particular ethnic or religious groups. A negative family history does not rule out an IEM because most carriers have no clinical manifestations of disease. A negative NBS does not exclude the possibility of an IEM. A report prepared by the American College of Medical Genetics for the Maternal and Child Health Bureau in 2005, recommend that states screen for a core panel of 29 conditions, 22 of which are IEMs, and an additional 25 conditions that are considered secondary targets on the basis of more mild symptoms and/or absence of treatment options, of which 24 are IEMs. Most, but not all states, now screen for core conditions, and at least some of the secondary targets (http://genes-r-us.uthscsa.edu/nbsdisorders.pdf).

False-negative results occur, most commonly due to screening too soon after birth, especially within the first 24 hours, prematurity, particularly in neonates less than 1,500 g, neonatal illness, medications, transfusions, inadequate sample and inappropriate sample handling. Results are often not available in the first several days of life. In addition, in some states, parents have the option of not having their child tested.

Physical Examination

Clinical manifestations of IEMs vary from those of acute life-threatening decompensation to subacute progressive degenerative disease (Table 94.1). Nearly all IEMs have several variants that differ in age of clinical onset and severity. Clinical manifestations may even vary among family members. Life-threatening diseases tend to present clinically during the neonatal period or infancy, whereas those with intermittent decompensation or insidious onset and slow progression tend to become apparent during infancy, childhood, adolescence, or even adulthood.

Disease onset and severity may be influenced by environmental factors such as changes in dietary intake; poor intake or sudden onset, intercurrent illness; surgery; or trauma. IEMs can affect any organ system, and often affect multiple organ systems, and therefore should be considered in patients who present with altered level of consciousness, cardiac failure, hepatic failure, skeletal muscle myopathy, and/or neuropsychiatric disturbance. Physical examination results may be normal, have subtle and/or nonspecific findings (as is often the case with disorders of amino acid metabolism; fatty acid oxidation defects; and disorders of carbohydrate intolerance, gluconeogenesis, or glycogenolysis), or have findings that provide more specific diagnostic information (most commonly with lysosomal, mitochondrial, or peroxisomal disorders) (Table 94.2). Findings tend to be related to abnormal anatomic proportion (i.e., size and shape), rather than to major structural defects and usually become more pronounced over time. Patients tend to have characteristic facies, short stature, organomegaly, and/or musculoskeletal abnormalities. Unrelated, affected individuals with IEMs who have characteristic physical findings usually look more alike than do patients and their unaffected siblings. It is also now recognized that some genetic diseases classically categorized as dysmorphic syndromes, and presumed due to disruption of morphogenesis, are actually IEMs, such as Smith-Lemli-Opitz syndrome. IEMs within each major category are listed in Table 94.3. Features of specific IEMs can be found in texts referenced at the end of this chapter and on various Web sites, including the National Center for Biotechnology Information's Online Mendelian Inheritance in Man Web site (http://www.ncbi.nlm.nih.gov/entrez/query.fcgi?db=OMIM).

Neonate. IEMs should be considered in any neonate who is critically ill. Most of the IEMs that are acutely life-threatening present during the neonatal period, usually as acute encephalopathy and/or hepatic disease. Among the most common life-threatening IEMs to present in the neonate are amino acidopathies, organic acidemias, urea cycle defects, galactosemia, and hereditary fructose intolerance. In neonates, clinical features of IEMs are usually nonspecific, especially at the onset of symptoms. Manifestations may include poor feeding, vomiting, diarrhea, dehydration, temperature instability, tachypnea or apnea, cyanosis, respiratory failure, bradycardia, poor perfusion, hiccups, jaundice, hepatomegaly, pseudoobstruction, irritability, lethargy, coma, seizures, involuntary movements (e.g., tremors, myoclonic jerks, boxing, pedaling), posturing (e.g., opisthotonus), and abnormal tone (e.g., hypertonia or central hypotonia). These same symptoms are also manifestations of sepsis, congenital viral infections, respiratory illness, cardiac disease, gastrointestinal obstruction, hepatic dysfunction, renal disease, central nervous system (CNS) problems, and drug withdrawal. The presence of these conditions does not rule out the possibility of an IEM. In term infants who develop symptoms of

TABLE 94.1

COMMON PRESENTATIONS OF INBORN ERRORS OF METABOLISM[a]

Acute Neonatal Catastrophe
Septic appearing
Temperature instability
Apnea, tachypnea, cyanosis, respiratory failure
Bradycardia, poor perfusion
Irritability, lethargy, coma
Seizures
Poor feeding, vomiting
Hypertonia, hypotonia
Sudden infant death

Neurologic Disturbance
Developmental delay, usually progressive, with or without loss of milestones
Autism
Learning disabilities, behavioral and/or emotional disturbances
Hallucinations, delirium
Ataxia, dizziness, headache
Lethargy, coma
Encephalopathy
Seizures
Movement disorder, posturing
Peripheral neuropathy
Stroke, stroke-like episode
Vision, hearing, speech impairment
Dementia

Cardiac Failure/Myopathy
Failure w/cardiomegaly ± skeletal muscle weakness
Cardiac arrhythmia, syncope, sudden death
Pericardial tamponade, effusion

Gastrointestinal/Hepatic Dysfunction, Failure
Poor feeding, food intolerances/aversion, failure to thrive
Chronic intermittent vomiting, decompensation out of proportion to illness
Chronic diarrhea
Abdominal pain
Pseudoobstruction
Acute pancreatitis
Hepatomegaly
Liver failure/hepatocellular dysfunction—jaundice (direct and/or indirect), coagulopathy, elevated liver function tests

Myopathy
Muscle weakness, pain, cramping
Exercise intolerance

Psychiatric Disturbance
Anxiety
Psychosis
Personality changes
Behavioral disturbances
Depression
Obsessive compulsive disorder
Delirium, hallucinations, schizophrenia

Biochemical Disturbance
Acidosis—chronic or acute recurrent
Hyperammonemia with or without alkalosis
Hypoglycemia with or without ketonuria, hypoketosis

[a]Findings may be in isolation or combination and may be either intermittent or progressive over time.

sepsis without known risk for sepsis, metabolic disease may be nearly as common as sepsis. Sepsis may in fact be the earliest recognized clinical manifestation of an IEM, occurring within the first days to weeks of life, even prior to availability of NBS results. *Escherichia coli* sepsis in galactosemia is the classic example. Other IEMs with increased risk of sepsis are, most notably, the organic acidemias and glycogen storage disorders.

One of the most important clues to an IEM in the neonate is a history of deterioration after an initial period of apparent good health ranging from hours to weeks, usually following an uncomplicated pregnancy and delivery in a term infant. For neonates with IEMs of protein metabolism and carbohydrate intolerance disorders, onset of symptoms occurs after there has been significant accumulation of toxic metabolites following the initiation of feeding. Onset of symptoms is usually between 2 and 5 days of life but may occur within hours. Absence of a symptom-free period does not exclude the possibility of an IEM, especially if there were unrelated perinatal complications. Initial symptoms often are poor feeding, vomiting, irritability, and lethargy. In the neonatal period, jaundice occurs most commonly with tyrosinemia, galactosemia, and hereditary fructose intolerance. Progression to coma, multisystem organ failure, and death is usually extremely rapid, although often somewhat fluctuating, usually occurring within 24 hours of symptom onset. Neonates with tyrosinemia may present with intracranial or pulmonary hemorrhage due to coagulopathy. Patients with organic acidemias may have recurrent or chronic subdural hemorrhages, sometimes mistakenly attributed to child abuse. Fatty acid oxidation disorders, particularly very long chain acyl-CoA dehydrogenase deficiency, may present during the neonatal period. Many of the peroxisomal disorders and some of the mitochondrial and lysosomal disorders also present in the neonatal period. Neonates with these disorders are less likely to have coma as an early manifestation and are more likely to have dysmorphic features, brain abnormalities, skeletal malformations, cardiopulmonary compromise, organomegaly, hepatic dysfunction, myopathy, and/or severe generalized hypotonia, usually evident at birth. Intractable seizures due to pyridoxine or folinic acid responsive disorders usually begin within the first few days of life, and biotin responsive multiple carboxylase deficiency may present within the first few days.

Infant and Young Child (1 Month to 5 Years). Infants or children with potentially acute life-threatening IEMs, most commonly partial deficiency of the urea cycle enzyme ornithine transcarbamylase, fatty acid oxidation defects, disorders of carbohydrate intolerance, and disorders of gluconeogenesis and glycogenolysis, typically present during infancy with recurrent episodes of vomiting and lethargy,

AA, amino acidopathies; OA, organic acidemias; UCD, urea cycle defects; FAOD, fatty acid oxidation defects; CID, carbohydrate intolerance disorders; CPUD, carbohydrate production/utilization disorders (glycogenolysis, gluconeogenesis); LSD, lysosomal storage disorders; MD, mitochondrial disorders; PD, peroxisomal disorders; ±, sometimes present; +, usually present; ++, always present; –, usually absent; A, appropriate; H, inappropriately high; L, inappropriately low/absent. Urine[b] or body odors: boiled cabbage or rancid butter—tyrosinemia; musty—phenylketonuria; sulfur—cystinuria; maple syrup—maple syrup urine disease; fruity—propionic acidemia, methylmalonic academia; sweaty feet—isovaleric acidemia, glutaric aciduria type II; tomcat urine—3-methylcronylCoA carboxylase deficiency, multiple carboxylase deficiency; ammonia—urea cycle defects.

[a]Within disease categories, not all diseases have all findings. For disorders with episodic decompensation, clinical and laboratory findings may be present only during acute crisis. For progressive disorders, findings may not be present early in the course of disease.

[b]Urine odor best detected by drying urine on filter paper or by opening container of urine kept at room temperature for a few minutes.

Adapted from Weiner DL. Inborn errors of metabolism. In: Aghababian RV, ed. *Emergency medicine: the core curriculum*. Philadelphia, PA: Lippincott-Raven, 1999:702.

which may progress to ataxia, seizures, coma, and even death. Some of the amino and organic acidopathies also present during infancy, usually with progressive neurologic deterioration. Most of the lysosomal storage disorders, as well as some of the mitochondrial disorders and peroxisomal disorders, also become apparent in infancy and early childhood, usually presenting with increasingly apparent dysmorphism or coarse features, organomegaly, myopathy, and/or neurodegeneration. More subtle and/or progressive findings in infants and children with IEMs include failure to thrive, chronic dermatoses, dilated or hypertrophic cardiomyopathy, liver dysfunction, hepatomegaly, pancreatitis, musculoskeletal weakness, hypotonia and/or cramping, impairments of hearing and vision, and developmental delay, sometimes with loss of milestones. With routine illnesses, children with IEMs may be more symptomatic, develop symptoms more quickly, or take longer than unaffected children to recover. Children with disorders of protein metabolism, even disorders that usually present in neonates, may present when changed from breast milk to cow milk formula, particularly if the breast-feeding mother is a vegetarian and the child has not yet started solid food or the solid food diet is low in protein. Fructose intolerance often manifests between ages 4 and 8 months when fruits are introduced into the diet. Disorders with decreased tolerance for fasting, particularly fatty acid oxidation defects and defects of gluconeogenesis and glycogenolysis, often manifest when children have poor intake due to illness or surgery and when infants begin to have longer overnight fasts, commonly between 7 and 12 months of age. The length of fast that produces symptoms is usually in the 6- to 8-hour range but may be less than 3 hours for disorders of glyconeogenesis and glycogenolysis,

TABLE 94.3

SPECIFIC INBORN ERRORS OF METABOLISM BY CATEGORY[a]

Amino Acidopathies
Alkaptonuria
Cystinuria types I–III
Hartnup disease
Hawkinsinuria
Histidinemia
Homocystinuria types Ia, Ib, II
Nonketotic hyperglycinemia
Phenylketonuria
Tyrosinemia types I–III

Organic Acidemias[b]
3-Hydroxy-3-methylglutaric aciduria
3-Methylcronylglycinuria
3-Methylglutaconic aciduria types I–IV
Biotinidase deficiency
Glutaric acidemia type I
Holocarboxylase synthetase deficiency
Hydroxyglutaric aciduria
Isovaleric acidemia
Maple syrup urine disease
Methylmalonic acidemia
Propionic acidemia types I, II
β-Ketothiolase deficiency

Urea Cycle Defects and Disorders of Ammonia Detoxification
Urea Cycle Defects
- Argininemia
- Arginosuccinic aciduria
- Carbamyl phosphate synthetase deficiency
- Citrullinemia
- N-acetyl glutamate synthetase deficiency
- Ornitine transcarbamylase deficiency

Hepatic Amino Acid Transport
- Homocitrullinuria, hyperonithinemia, and hyperammonemia (HHH) syndrome
- Lysinuric protein intolerance

Fatty Acid Oxidation Defects
- Carnitine palmitoyltransferase deficiency types I, II
- Carnitine transporter deficiency
- Carnitine-acylcarnitine translocase deficiency
- Hydroxymethylglutonyl-CoA (HMG-CoA) lyase deficiency, HMG-CoA synthetase deficiency
- Long chain 3-hydroxyacyl-CoA dehydrogenase deficiency (LCHAD)
- Medium chain 3-ketoacyl thiolase deficiency (MCKAD)
- Medium chain acyl-CoA dehydrogenase deficiency (MCAD)
- Short chain 3-hydroxyacyl-CoA dehydrogenase deficiency (SCHAD)
- Short chain acyl-CoA dehydrogenase deficiency (SCAD)
- Very long chain acyl-CoA dehydrogenase deficiency (VLCAD)

Disorders of Carbohydrate Metabolism
Carbohydrate Intolerance Disorders
- Galactosemia
- Galactokinase deficiency
- Hereditary fructose intolerance
- Fructosuria
- Fructose-1,6-diphosphatase deficiency

Carbohydrate Production/Utilization Disorders
- Glycogen storage disorder types 0, Ia (von Gierke), Ib/c, Ic, II (Pompe), IIb, III (Cori or Forbes), IV (Anderson), V (McArdle), VI (Hers), VII (Tarui), VIII, IX, X, XI

Lysosomal Storage Disorders
Mucopolysaccharidoses (MPS)
- MPS IH (Hurler), IH/S (Hurler-Scheie), IS (Scheie), MSII (Hunter), IIIA-D (Sanfilippo), IVA, B (Morquio), VI (Maroteaux-Lamy), VII (Sly)

Sphingolipidoses
- Canavan's disease
- Fabry's disease
- Farber's disease
- Gaucher's disease types I–III
- GM1 gangliosidosis types 1–3
- GM2 gangliosidosis types 1 (Tay-Sachs), 2 (Sandhoff)
- GM3 gangliosidosis
- Krabbe's disease
- Metachromatic leukodystrophy—infantile, juvenile, adult
- Multiple sulfatase deficiency
- Neimann-Pick disease—types IS, IC, IIA, IIS, IIC

Oligosaccharidoses (Glycoproteinoses)
- Asparylglucosaminuria
- Fucosidosis types I, II
- Galactosialidosis
- Mannosidosis α types I, II, β
- Pycnodysostosis (Maroteau-Lamy III)
- Schindler's disease
- Sialidosis types I, II (previously mucolipidosis I)
- Sialolipidosis

Mucolipidosis
- Mucolipidosis types II (I-cell), III (pseudo-Hurler), IV

Mitochondrial Disorders
2-Ketoglutarate dehydrogenase complex deficiency
Freidrich ataxia
Fumarase deficiency
Glutaric acidemia type II
Kaerns-Sayre syndrome
Leigh's disease
Mitochondrial encephalopathy lactic acidosis stroke-like episodes
Myoclonic epilepsy, ragged red-fiber disease
Pearson syndrome
Phosphoenopyruvate carboxylase deficiency
Pyruvate carboxylase deficiency
Pyruvate dehydrogenase complex deficiency
Succinate dehydrogenase deficiency

Peroxisomal Disorders
Adenomyeloneuropathy
Adrenoleukodystrophy neonatal, adult
Catalase deficiency
Glutaric acidemia type III
Leber's hereditary optic neuropathy
Refsum disease infantile, adult
Rhizomelic chondroplasia punctata
Wolfram syndrome
Zellweger syndrome

[a]Disease list is not comprehensive. Some diseases can be categorized in more than one category.
[b]Disease category and most diseases terms aciduria and acidemia are used interchangeably.

most commonly glycogen synthetase deficiencies, and 12 to 24 hours for fatty acid oxidation defects. When patients with these disorders present with vomiting, they are often initially indistinguishable from patients without IEM who are vomiting, but the severity of illness, particularly the lethargy, is usually out of proportion to the duration of illness and the amount of vomiting. Ketotic hypoglycemia, believed to be due to a noninherited condition commonly seen in children ages 1 to 5 years, has been shown, in some cases, to be due to fatty acid oxidation defects and less commonly due to amino acidopathies or organic acidemias. It is now recognized that Reye syndrome-like symptoms are more commonly attributable to an IEM, most often a fatty acid oxidation defect, particularly medium chain acyl-CoA dehydrogenase deficiency, or less commonly a urea cycle defect, particularly ornithine transcarbamylase deficiency, than actual Reye's syndrome, especially now that aspirin is rarely used in children. Mortality for those with a previously undiagnosed fatty acid oxidation defect may be more than 40% with the first clinical decompensation, depending on the specific disease. IEMs also explain sudden infant death syndrome (SIDS) in approximately 5% to 10% of cases, most commonly fatty acid oxidation defects that cause cardiac arrest due to arrhythmia and/or cardiomyopathy. The most common of these is medium chain fatty acyl-coA dehydrogenase deficiency, with SIDS occurring in 25% of the approximately 1 in 10,000 patients with this disorder. Other fatty acid oxidation defects, organic acidemias, and congenital adrenal hyperplasia account for most of the remainder of SIDS cases attributable to genetic defects.

Older Child, Adolescent, or Adult (Older than 5 Years). In the older child, adolescent, or even adult, undiagnosed metabolic disease should be considered in individuals with subtle neurologic or psychiatric abnormalities. Many will have had long-term manifestations believed to be due to other causes. Most typically, these children are diagnosed as having birth injury, behavioral problems, attention deficit hyperactivity disorder, psychiatric disorders, or atypical forms of medical diseases such as multiple sclerosis, migraines, epilepsy, or stroke. The more common findings include mild to profound developmental delay, autism, learning disabilities, irritability, aggressiveness, agitation, anxiety, emotional liability, social withdrawal, panic attacks, delirium, hallucinations, paranoia, insomnia, seizures, dizziness, ataxia, peripheral neuropathy, muscle weakness, and exercise intolerance. Hormonal changes associated with puberty may initiate or exacerbate symptoms. Manifestations may be intermittent, precipitated by the stress of illness or by dietary changes or fast, especially as teens take more control over their own diet, or may be progressive, with worsening over time. Most IEMs diagnosed in this age group are not immediately life-threatening. However, even a patient with a late-onset, presumably milder, form of an IEM that classically presents earlier in childhood may die with a first or subsequent metabolic crisis. An example is partial ornithine transcarbamylase deficiency, which can manifest at this time as a life-threatening encephalopathy. This is seen particularly in adolescent females with a history of protein aversion, migraine-like headaches, vomiting, abdominal pain, lethargy, and behavioral problems, particularly following protein ingestion. Fatty acid oxidation defects may also present at this time with sudden death or life-threatening cardiac arrhythmia, hypoketotic hypoglycemia, and/or rhabdomyolysis. Glycogen storage disorders that manifest as exercise intolerance, muscle weakness, cramping, and/or rhabdomyolysis often present in adolescents because of their greater participation in sports during these years. Some mitochondrial disorders present during adolescence or adulthood with loss of vision and/or hearing, cardiac dysfunction, myopathy, neurologic degeneration, and endocrine disturbances. Stroke or stroke-like episodes with or without encephalopathy may occur with amino acidopathies, in particular homocystinuria, urea cycle defects, organic acidemias, disorders of carbohydrate metabolism, and mitochondrial disorders, most notably MELAS (mitochondrial encephalomyelopathy, lactic acidosis, stroke-like episodes). Disorders in which psychiatric disturbances may be the initial presenting manifestation include homocystinuria; urea cycle defects, especially partial ornithine transcarbamylase deficiency; lysosomal storage disorders; peroxisomal disorders; and Wilson's disease, a disorder of copper metabolism. Patients with phenylketonuria who are no longer on a low-protein diet may also manifest psychiatric symptoms.

Studies

Laboratory Findings. Initially, evaluation for possible IEM, particularly those that are potentially acutely life-threatening, can usually be accomplished in the acute setting with a few screening tests. Along with laboratory studies, these may include imaging studies and electrophysiologic. In the patient with potentially life-threatening symptoms, evaluation for possible IEM should be initiated as soon as it is considered, not after other etiologies have been ruled out.

Laboratory studies to evaluate for possible IEM should be performed in all patients with suggestive history, physical examination, and/or consistent abnormalities of routine laboratory tests.

Initial laboratory findings in the acutely ill patient that may suggest an IEM include a complete blood cell count (CBC) that reveals neutropenia, anemia, and/or thrombocytopenia; serum electrolytes and blood gas analysis that detect electrolyte imbalances, an increased anion gap, and/or acid-base status abnormalities; blood urea nitrogen (BUN) and creatinine levels that reveal impaired renal function; total and direct bilirubin, aspartase (AST) and alanine (ALT) transaminases, prothrombin time (PT), partial thrombin time (PTT), and/or ammonia that indicate hepatic dysfunction or failure; hypoglycemia, particularly with low or absent urine ketones, that suggests inability to appropriately metabolize fatty acids or carbohydrates; or urine-reducing substances that suggest carbohydrate intolerance (Table 94.4). Complete metabolic screen may also reveal abnormalities in uric acid, calcium, phosphate, and/or magnesium. In addition to these studies, patients with history or physical examination suggestive of myopathy should have lactate dehydrogenase, aldolase, creatinine kinase, and urine myoglobin measured as part of their initial screen.

If a metabolic disease is suspected, consultation with an IEM specialist and/or the laboratory may be helpful in guiding further laboratory evaluation and assisting with appropriate collection and processing of specimens. Blood should be collected and, based on results of initial studies, sent for plasma amino acids and acylcarnitine profile, which reflect fatty acid oxidation and organic acid, and, indirectly, amino acid metabolisms

TABLE 94.4

INITIAL LABORATORY STUDIES[a]

Test	Laboratory abnormality metabolic diseases[a]	Indications, comments
Blood		
CBC (plasma)	Neutropenia (± vacuoles), anemia, and/or thrombocytopenia Organic acidemias Urea cycle defects Carbohydrate intolerance disorders Carbohydrate production/utilization disorders Lysosomal storage disorders Mitochondrial disorders	Neutropenia may be masked by infection. Patients with certain IEMs are at increased risk of infection; infection can also precipitate metabolic crisis Anemia hemolytic, megaloblastic, or normocytic, depending on specific IEM
Glucose (serum)	Hypoglycemia Amino acidopathies Organic acidemias Fatty acid oxidation defects Carbohydrate intolerance disorders Carbohydrate production/utilization disorders Mitochondrial disorders	Hypoglycemia may be due to primary defect of gluconeogenesis or glucose consumption that exceeds production
Test of acid-base status (serum) Electrolytes Anion gap pH (arterial or venous)	Primary metabolic acidosis Amino acidopathies Organic acidemias Fatty acid oxidation defects Carbohydrate intolerance disorders Carbohydrate production/utilization disorders Mitochondrial disorders Primary respiratory alkalosis Urea cycle defects	Na^+, K^+, Cl^- usually normal unless abnormal secondary to vomiting, which may produce hyperchloremic metabolic acidosis, or with rhabdomyolysis, which may result in hyperkalemia Normal bicarbonate does not rule out amino or organic acidemias
Ammonia (plasma)	Hyperammonemia Amino acidopathies Organic acidemias Urea cycle defects Fatty acid oxidation defects	Obtain if altered consciousness, persistent or recurrent unexplained vomiting, recurrent dizziness or ataxia, primary metabolic acidosis with increased anion gap, primary respiratory alkalosis in the absence of toxic ingestion. Must be free-flow venous (no tourniquet) or arterial. Arterial preferred because skeletal muscle releases ammonia, ice sample immediately, assay promptly Newborns 90–150 μg/dL, children 40–120 μg/dL, adults 18–54 μg/dL, (www.pediatriccareonline.org/pco/ub/view/Pediatric-drug-Lookup/153930/0/Normal-Laboratory-Values-for-Children) Normal <100 μg/dL neonate, <80 μg/dL >1 month False positives—valproic acid
Liver function tests (serum) Bilirubin Transaminases Clotting factors	Hyperbilirubinemia Amino acidopathies (tyrosinemia) Carbohydrate intolerance disorders Elevated transaminases Amino acidopathies Organic acidemias Urea cycle defects Fatty acid oxidation defects Carbohydrate intolerance disorders Carbohydrate production/utilization disorders Lysosomal storage disorders Mitochondrial disorders Peroxisomal disorders	Obtain if vomiting, jaundice, and/or hepatomegaly Hyperbilirubinemia predominantly conjugated, except galactosemia first few days may be unconjugated

(continued)

TABLE 94.4

CONTINUED

Test	Laboratory abnormality metabolic diseases[a]	Indications, comments
Muscle function tests (serum) Lactate dehydrogenase Aldolase Creatine kinase	Abnormal muscle enzymes Carbohydrate production/utilization disorders Fatty acid oxidation defects Mitochondrial disorders	Obtain if muscle weakness, tenderness, cramping, atrophy, exercise intolerance Carnitine deficiency due to carnitine transport disorders or secondary to organic acidemias, fatty acid oxidation defects
Urine		
Reducing substances (Clinitest®)	Amino acidopathies (tyrosinemia, alkaptonuria) Carbohydrate intolerance disorders	Clinitest® positive for reducing substances and dipstick negative for glucose (glucose oxidase reaction) False positives—penicillins, salicylates, ascorbic acid, drugs excreted as glucuronides Absence of reducing substances does not eliminate possibility of IEM
Ketones (Ketostix®, Acetest®)	Elevated ketones Amino acidopathies Organic acidemias Carbohydrate intolerance disorders Carbohydrate production/utilization disorders Mitochondrial disorders Absent ketones, hypoketosis Fatty acid oxidation defects	Ketones detected by Ketostix®, Chemstix®, Acetest® Inappropriate ketones: Ketonuria in neonates Ketonuria, normal glucose beyond neonate Low/absent ketones, hypoglycemia beyond neonate
Myoglobin	Myoglobin present Organic acidemias Carbohydrate production/utilization disorders Mitochondrial disorders	Not always present, even with rhabdomyolysis, especially if creatinine kinase <10,000 IU

IEM, inborn error of metabolism.
[a]Within disease categories, not all diseases have the laboratory abnormality. In disorders of protein metabolism, carbohydrate metabolism and fatty acid oxidation defects and abnormality may be present only during acute crisis.
Adapted from Weiner DL. Inborn errors of metabolism. In: Aghababian RV, ed. *Emergency medicine: the core curriculum*. Philadelphia, PA: Lippincott-Raven, 1999:705.

(Table 94.5). In neonates younger than or at 7 to 14 days of age, blood on NBS filter paper can be used for tandem mass spectrometry and should be considered not only if tandem mass spectrometry was not initially performed but also if the initial screen was negative. Urine should be collected for potential analysis of organic acids, acylglycine, and/or orotic acid. Additional blood and urine for possible further testing should be obtained, aliquoted, and stored. Cerebral spinal fluid (CSF), if obtained, should be collected at the same time as plasma and immediately frozen and stored for possible further testing for neurometabolic disorders, most commonly nonketotic hyperglycinemia, disorders of serine biosynthesis, and/or neurotransmitter disorders. Measurement of lactate and pyruvate in the acute setting may be of limited value, particularly in the patient with hypoxia, poor perfusion, and/or sepsis. Plasma-free fatty acids, ketones, endocrine studies, and disease-specific tests may also be appropriate. Laboratory abnormalities are often transient, particularly if fluids and/or glucose are administered; therefore, normal values do not rule out an IEM. It is critical to obtain pretreatment specimens, if possible. If pretreatment specimens were not obtained, as is often the case because many IEMs are first suspected based on results of routine laboratory studies, discarded pretreatment samples are likely to be more informative than those collected after therapy. Studies may need to be repeated during future episodes of illness. Collection of samples during acute illness is usually preferred to provocative testing by metabolic challenge performed when the child is otherwise well because this method may not yield diagnostic specimens and may be dangerous.

The confirmatory specific diagnosis of most IEMs requires additional specialized tests for detection of abnormal metabolites or abnormal concentrations of metabolites in plasma, urine, and/or cerebral spinal fluid; histochemical light and/or electron microscopic evaluation of affected tissues; and chromosome, DNA, and/or enzyme analysis in red blood cells, leukocytes, skin fibroblasts, and/or tissues from affected organs.

In the child who has died, it is still extremely important to attempt to diagnose an IEM because of the possibility that asymptomatic siblings, and with a few diseases, parents, are presently affected or that future children are at risk of being affected. Routine autopsy is usually not informative for the definitive diagnosis of IEM but may rule out other causes of death and offer clues. IEMs can be diagnosed in the child who

TABLE 94.5

SECONDARY TESTS

Test	Laboratory abnormality metabolic diseases[a]	Indications, comments
Blood		
Amino acids—quantitative (plasma or serum)	Amino acidopathies Organic acidemias Urea cycle defects Mitochondrial disorders	Tandem mass spectrometry, requires minimum 1 mL blood, 3 mL ideal,[b] heparin, or EDTA tube Obtain if metabolic catastrophe, neurologic, cardiac, GI/hepatic, musculoskeletal, psychiatric symptoms suggestive of possible IEM, metabolic acidosis, elevated anion gap, hypoglycemia, inappropriate ketonuria, hyperammonemia
Acylcarnitine profile (plasma or serum)	Organic acidemias Fatty acid oxidation defects Mitochondrial disorders Primary carnitine deficiency	Carnitine deficiency may be due to primary defect in carnitine or carnitine transporter, or secondary due to organic acidemia or fatty acid oxidation defect; can also occur in normal children during dehydration Free and total carnitine may also be helpful if carnitine deficiency is suspected
Lactate, pyruvate (deproteinized blood)	Disorders carbohydrate utilization Mitochondrial disorders	Samples must be free flow, deproteinized at bedside—1 mL into tubes with 2 mL perchloric or trichloroacetic acid, transport on ice Evaluate lactate, pyruvate, and ratio Lactate also increased in patient with hypoxia, poor perfusion, sepsis
Urine		
Organic acids	Amino acidopathies Organic acidemias Fatty acid oxidation defects Mitochondrial disorders Peroxisomal disorders	Urine best source for organic acids, minimum 2–5 mL, 10–20 mL ideal without preservative[c] Obtain if metabolic catastrophe, neurologic, cardiac, GI/hepatic, musculoskeletal, psychiatric, symptoms suggestive of possible IEM, metabolic acidosis, elevated anion gap, hypoglycemia, inappropriate ketonuria, hyperammonemia
Acylglycines	Organic acidemias Fatty acid oxidation defects	Should be performed only in conjunction with serum or plasma carnitines, minimum 2–5 mL without preservative[c]
Orotic acid	Urea cycle defects (ornithine transcarbamylase deficiency)	Send if hyperammonemia, minimum 1 mL without preservative
Cerebral Spinal Fluid		
Glucose, protein, lactate, pyruvate, glycine, serine, alanine, organic acids, neurotransmitters, folate, pterins, other disease-specific metabolites	Amino acidopathies Organic acidemias Mitochondrial disorders Nonketotic hyperglycinemia Neurotransmitter disorders	1–4 mL, freeze –20°C or –70°C

EDTA, ethylenediaminetetraacetic acid; GI, gastrointestinal; IEM, inborn error of metabolism.
[a]Within disease categories, not all diseases have the laboratory abnormality. In disorders of protein metabolism, carbohydrate metabolism and fatty acid oxidation defects and abnormality may be present only during acute crisis.
[b]Samples, quantities required, collection method, preparation, and storage are institution dependent. Tandem mass spectrometry measures amino acids and acylcarnitines, derived from carnitine, which combines with acyl-CoA derived from fatty acids and organic acids (which may have been derived from amino acids). Tandem mass spectrometry may be used as a screen for amino acidopathies, organic acidemias, and fatty acid oxidation defects. Confirmation of diagnosis usually requires further testing, including plasma amino acids, urinary organic acids, histologic examination, DNA analysis, and enzyme and/or biochemical assays.
[c]Total minimum is 4 mL for organic acids and acylglycines.

has just died, by collecting the appropriate specimens (Table 94.6). Specimens should be collected as soon after death as possible, ideally within the first 1 to 2 hours, before organ autolysis precludes the opportunity to obtain informative specimens. If not already collected during the resuscitation attempt, blood and urine should be obtained in the ED. Specimens to be collected at autopsy include additional blood, urine, and cerebral spinal fluid, and if not already obtained, skin biopsy, organ biopsies (brain, heart, liver, kidney, spleen, skeletal muscle), and bile. Aqueous humor from the anterior chamber of the eye, particularly if blood is not available, may be helpful. Photographs of children with dysmorphic features and imaging studies may be performed as part of the autopsy and are indicated if skeletal or organ abnormalities are suspected. If permission for an autopsy is not granted by the family, seek permission for aqueous humor aspiration, skin biopsy, and needle tissue biopsy,

TABLE 94.6

POSTMORTEM SPECIMENS COLLECTED AT AUTOPSY[a]

Postmortem specimens	Analyses	Comments on collection, storage
Blood[a]		
10-mL EDTA tube	Chromosome analysis	Obtain blood by vascular access or intracardiac puncture
4–6 filter paper spots	DNA analysis (requires PCR amplification)	For filter paper spots, apply free-flow blood to filter paper, saturate through to back, do not layer drops. Air-dry 3–4 h, do not heat, place in envelope, refrigerate
5-mL heparinized tube	Tandem mass spectrometry for organic acidemias, urea cycle defects, fatty acid oxidation defects,	
	Acylcarnitines	Freeze plasma at –20°C or –70°C, store erythrocytes at 4°C
	Amino acids	
	Bile acids	
Urine[a]		
Urine 10 mL in 1–2-mL aliquots	Amino acids	Collect by bladder catheterization, suprapubic aspiration. If unsuccessful, irrigate bladder with 20 mL normal saline and collect or perform intrabladder swabs at autopsy
	Organic acids	
	Acylcarnitines	
	Bile acids	Freeze at –20°C or –70°C
Cerebral Spinal Fluid (CSF)		
CSF 3–5 mL in 1-mL aliquots	Glucose	If not collected for clinical care, may be appropriate to collect postmortem
	Lactate, pyruvate	
	Glycine, serine	
	Neurotransmitters	Freeze at –20°C or –70°C
	Organic acids	
Aqueous Humor		
Aqueous humor	Organic acids	May be appropriate if blood not available
		Collect by intraocular puncture at autopsy
		Freeze at –20°C or –70°C
Skin Biopsy[a]		
Skin—2 samples, 3-mm diameter each	Chromosome analysis	Best collected premortem or immediately postmortem, usually viable 2–3 days, maybe 1 wk may be helpful to discuss with specialist
	DNA analysis	
	Enzyme activity	Skin, punch, or incisional biopsy, sterile technique, 2 sites—flexor surface forearm, anterior thigh, transport in sterile tube completely filled with tissue culture media, viral culture media, (do not use culture media if planing for microscopic studies), normal saline without preservative, or normal saline-soaked sterile gauze in sterile tube, freeze at –70°C
		Fibroblast culture provides unlimited specimen
Organ Biopsy		
Brain[b]	Histochemical light and/or electron microscopy	Biopsy potentially affected organs, collect within 1–2 h after death
Heart muscle[b]		
Liver[a] 1 cm^3, 10–20 mg, ≤0.5 cm thick	Enzyme activity	Needle or open incisional biopsy, sterile technique, wrap in aluminum foil, dry ice, freeze at –70°C, screw-top airtight vial.
Kidney[b]	Biochemical metabolites	
Spleen[b]	Mitochondrial studies	Some assays may need to be performed on fresh specimens
Skeletal muscle 20–50 mg, ≤0.5 cm thick		
Bile		
Bile 2 mL	Bile acids	
	Acylcarnitines	

EDTA, ethylenediaminetetraacetic acid; PCR, polymerase chain reaction; ED, emergency department.
[a]If autopsy refused by family or if unable to obtain autopsy within hours of death, collect blood, urine, and CSF; perform punch or open incisional biopsy of skin and needle biopsy of liver and skeletal muscle; take photographs if dysmorphic features; and obtain radiologic studies to evaluate for neurologic, cardiac, or skeletal abnormalities. Obtain parental permission. Tests that are not accurate using postmortem specimens are those for serum amino acids, lactate, pyruvate, and total and free carnitine assessment. Consider developing postmortem specimen collection kit for ED that contains necessary equipment, specimen containers, and institution-specific instructions.
[b]Obtain at autopsy if autopsy permission granted.

particularly of the liver as appropriate. Most IEMs can be categorized based on findings of initial laboratory evaluations. Nearly all patients with IEMs that present as acute life-threatening disease will have hypoglycemia, metabolic acidosis, and/or hyperammonemia. These initial findings will guide immediate treatment and further evaluation. Important exceptions are nonketotic hyperglycinemia, which usually presents within 48 hours of birth with lethargy, coma, seizures, hypotonia, spasticity, hiccups, and apnea, and pyridoxine deficiency and folinic acid responsive disorders, which present with intractable seizures with or without encephalopathy as early as the first day of life. Hypoglycemia, metabolic acidosis, and hyperammonemia are also usually not seen in lysosomal storage and peroxisomal disorders.

Hypoglycemia. Serum glucose level of less than 40 mg per dL in the neonate and less than 45 to 50 mg per dL at all ages beyond the neonatal period should be considered abnormally low. Even with poor oral intake and/or metabolic stressors, hypoglycemia with glucose less than 45 mg per dL is unusual in the normal child. Hypoglycemia may cause a decreased level of consciousness, ranging from lethargy to confusion to coma as well as irritability, and seizures. Newborns may also have a high-pitched cry, hypothermia, cyanosis, and poor feeding. In the older child or adult, symptoms may include headache, blurred vision, repeated yawning, diaphoresis, pallor, and nervousness. Hypoglycemia most commonly occurs with fatty acid oxidation defects, disorders of carbohydrate metabolism, and hyperinsulinemic states. Low serum glucose can also be seen with amino acidopathies and organic acidemias due to inhibition of hepatic gluconeogenesis in these disorders. In patients with hypoglycemia, inappropriate ketonuria is highly suggestive of a fatty acid oxidation defect, especially along with elevated anion gap, blood urea nitrogen, uric acid, creatine kinase, and liver transaminases. Ketonuria when present in the hypoglycemic neonate is always abnormal. Beyond the neonatal period, hypoglycemia with inappropriately low or absent ketones is also always abnormal. The presence of urinary ketones in a patient with hypoglycemia beyond the neonatal period does not rule out an IEM, particularly short chain fatty acid oxidation defects, organic acidemias, disorders of carbohydrate production or utilization, or ketotic hypoglycemia of childhood. Hypoketosis, if not evident from the urine, can be determined by measuring ketones (3-hydroxybutyrate and acetoacetate) and free fatty acids in blood. Normal glucose and appropriate ketonuria also does not rule out IEM. In patients with hypoglycemia, in addition to plasma amino acids and acylcarnitine and urine organic acids and acylglycines, serum cortisol and insulin should be sent, as well as liver function tests (LFTs) and ammonia, if not previously sent. Serum lactate, pyruvate and ketones, free and total carnitine and specialized blood, urine, fibroblast, and/or tissue tests may be helpful. Growth hormone is not an informative test in the acute setting. Causes of hypoglycemia other than IEM most commonly include liver diseases, hyperinsulinemia, and toxic ingestions of salicylates, β-blockers, ethanol or polyethylene glycol, maternal diabetes/gestational diabetes, prematurity or small for gestational age, asphyxia, and/or sepsis.

Metabolic Acidosis. IEMs must be considered in patients with metabolic acidosis with or without acidemia. Clinical manifestations of acidosis include vomiting and tachypnea. Primary metabolic acidosis is diagnosed by a low pH, low P_{CO_2}, and low bicarbonate. Urine pH higher than or equal to 5.5 suggests bicarbonate loss due to renal tubular acidosis but does not rule out IEM, particularly disorders of energy metabolism. Metabolic acidosis may also be due to bicarbonate loss in stool, but this also does not eliminate the possibility of an IEM because diarrhea is a prominent feature of many IEMs. In neonates believed to have pyloric stenosis, the diagnosis of IEM, particularly an organic acidemia, should be considered if the patient has metabolic acidosis rather than metabolic alkalosis. The anion gap ($[Na] - [Cl + HCO_3]$) should be determined in any patient with low serum bicarbonate, particularly if the value is out of proportion to the clinical presentation because an elevated anion gap acidosis (greater than 16 mmol per L) is characteristic of acute metabolic crisis with many IEMs. An elevated anion gap with a normal chloride usually reflects excess acid production, most often of lactate, ketone bodies, and/or other organic acids. Metabolic acidosis, usually severe, with marked ketonuria, with or without hyperammonemia or hypoglycemia, is a hallmark of organic acidemias. Fatty acid oxidation disorders may also present with metabolic acidosis, but usually with hypoglycemia and absent ketones or hypoketosis. The IEMs in which a primary lactic acidosis is the cause of the metabolic acidosis include disorders of gluconeogenesis and mitochondrial disorders of oxidation. Anion gap in renal tubular acidosis and acidosis from stool bicarbonate loss is usually normal. The absence of acidosis does not preclude an IEM. In patients with metabolic acidosis, concentration of serum ammonia and glucose, and presence or absence of urine ketones and reducing substances will also help direct further metabolic workup. Plasma amino acids, acylcarnitines and urine organic acids, and acylglycines should be measured. Measurement of serum lactate, pyruvate, ketones, and organic acids, specific metabolites or enzymes, and DNA analysis may also be helpful. Other causes of metabolic acidosis are hypoxia, poor perfusion, sepsis, seizures, Reye syndrome, diabetic ketoacidosis, uremia, and toxins, most notably, salicylates, ethanol, methanol, ethylene glycol, isoniazid, iron, and arsenic.

Hyperammonemia. Early manifestations of hyperammonemia are anorexia and irritability. Children and adolescents may report headache, abdominal pain, and fatigue. Progression to vomiting, lethargy, seizures, coma, and death may occur within hours. In addition to brain stem dysfunction, hyperammonemia can cause cerebral edema and intracranial hemorrhage. Some patients with chronic hyperammonemia adapt to their elevated ammonia level and may appear to have no overt symptoms despite ammonia concentrations above normal. Ammonia is an intermediary in the catabolism of nitrogen-containing compounds, particularly amino acids. Normally, ammonia is converted in the liver to either urea by the urea cycle or to glutamine by glutamine synthetase. Hyperammonemia is the hallmark of urea cycle defects. Plasma amino acids and urine orotic acid should be sent to establish the diagnosis of a urea cycle defect. Hyperammonemia also occurs with organic acidemias and fatty acid oxidation defects as a consequence of inhibition of the urea cycle. Normal ammonia levels are less than 100 μg per dL in neonates and less than 80 μg per dL beyond the

neonatal period. Proper collection and handling of blood for ammonia determination is critical to prevent falsely elevated values. Abnormal levels should be confirmed by immediate stat repeat by using proper technique for drawing and sending because inappropriate technique can result in values elevated several fold of normal. Ammonia levels are typically highest in urea cycle defects and may exceed 1,000 μg per dL. Ammonia levels in organic acidemias are usually less than 500 μg per dL during decompensation but may exceed 1,000 μg per dL. Hyperammonemia in fatty acid oxidation defects, if present, is usually less than 250 μg per dL. Transient hyperammonemia of the newborn should be considered in the differential diagnosis, particularly if hyperammonemia is present on the first day of life. Hyperammonemia directly stimulates the respiratory center, resulting in tachypnea. Ammonia level higher than 250 μg per dL with respiratory alkalosis in the absence of metabolic acidosis is highly suggestive of a urea cycle defect. Patients with urea cycle defects may have compensatory metabolic acidosis. Patient with organic acidemias and fatty acid oxidation defects and hyperammonemia have primary metabolic alkalosis usually without respiratory alkalosis. Patients with hyperammonemia due to organic acidemias usually have marked ketosis and normal glucose level, whereas those with fatty acid oxidation defects usually have hypoketotic hypoglycemia. Even during minor illnesses, protein catabolism may result in hyperammonemia. Normal ammonia level does not eliminate the possibility of an IEM, particularly in a patient who is dehydrated with decreased renal urea excretion and/or has an IEM with a partial enzyme defect. In patients with hyperammonemia, liver function should be evaluated. Mild elevation of transaminases may be seen in metabolic disorders in each category. Plasma should be sent for amino acids and acylcarnitines evaluation, and urine for organic acids, acylglycines, and orotic acid evaluation. For many disorders, leukocytes, fibroblasts, or organ tissue, most often liver, is required for confirmatory enzyme or molecular assay. Liver dysfunction due to causes other than IEM, including primary liver disease, hepatic infection, toxic insult, sepsis, and asphyxia, may also cause hyperammonemia.

Imaging Studies. In the ED, imaging studies may be useful to guide management of potential acutely life-threatening organ system failure, particularly cerebral edema, hemorrhagic or thrombotic stroke, or cardiac failure. Imaging studies to aid in diagnosis and long-term management are rarely appropriate in the ED setting.

Chest and abdominal radiographs may reveal cardiomegaly, an abnormal cardiac silhouette, pulmonary effusion or hemorrhage, and/or hepatomegaly. Head computed tomography (CT) scan, magnetic resonance imaging (MRI), or ultrasound (US) in the neonate may show structural and functional abnormalities of the brain (most commonly of the corpus callosum, basal ganglia, cerebellum, and/or gray–white matter), cerebral edema, intracranial hemorrhage and/or stroke, and stroke-like episodes. CT and US can be used to evaluate for organomegaly, pleural effusion, and/or ascites. Echocardiography (ECHO) can be performed to evaluate abnormalities in cardiac structure, pericardial fluid, and impaired cardiac function.

Electrophysiologic Studies. Electrocardiogram (EKG) should be performed as clinically indicated to evaluate for possible cardiomegaly, cardiomyopathy, structural heart disease, arrhythmia, and/or effusion. Electroencephalogram (EEG) may be informative to determine whether patients are having seizures and may suggest specific IEMs based on brain wave patterns and anatomic focus. EEG rarely needs to be performed emergently. Other electrophysiologic studies that may be informative but not indicated as part of the ED evaluation include electromyelogram (EMG) to differentiate between muscular and neural pathology in patients with myopathy and/or nerve conduction studies to distinguish between peripheral and axonal nerve degeneration in patients with concern of neuromuscular disorders, as well as evoked potential studies to evaluate visual and auditory function.

Management

Initial treatment of IEMs is aimed at correcting acute metabolic abnormalities. Even the apparently stable patient with mild symptoms may deteriorate rapidly with progression to death within hours. Failure to administer immediate, appropriate treatment for IEMs can result in long-term neurologic sequelae or death. For patients with IEMs of amino acid metabolism or carbohydrate intolerance, treatment is aimed at elimination of toxic metabolites. For disorders of fatty acid oxidation or gluconeogenesis and glycogenolysis, therapy is aimed at correcting the energy deficiency. With appropriate therapy, patients with these acutely life-threatening disorders may recover completely. In patients with lysosomal, mitochondrial, and peroxisomal disorders, emergent treatment is aimed at ameliorating the effects of organ dysfunction and usually involves temporizing measures that do not have long-term impact on the inevitable progressive, degenerative course of these disorders. As always, airway, breathing, and circulation must be addressed first. Treatment for a potential IEM should be started empirically as soon as the diagnosis is considered (Table 94.7).

Fluids

All oral intake should be stopped to prevent the introduction of potentially harmful protein or sugars. Fluid bolus(es), as clinically indicated, should be normal saline, 10 mL per kg for neonates or patients with concern of heart failure and 20 mL per kg for infants and children. Ringer's lactate should be avoided because it can worsen acidosis. Normal saline bolus fluid should contain 10% dextrose unless the patient is hypoglycemic.

Hypoglycemia

Hypoglycemia, if present, should be corrected by dextrose bolus instead of adding D_{10} to bolus fluid; 0.25 to 1 g per kg, D_{10} for neonates, D_{10} or D_{25} for those beyond the neonatal period. Hydration after fluid/dextrose bolus should be with D_{10} to D_{15} in ½ normal saline at 1 to 1.5× maintenance to provide 8 to 12 mg per kg per minute of glucose and maintain serum glucose level at 120 to 170 mg per dL, with the goal of preventing catabolism. Large, rapid fluctuations in glucose level should be avoided. Although controversial and rarely

TABLE 94.7

EMERGENT TREATMENT

Access and establish airway, breathing, circulation
- **Fluid** boluses normal saline, avoid lactated Ringer's. Avoid hypotonic fluid load due to risk of cerebral edema, particularly if hyperammonemia.

Discontinue intake of offending agents, provide adequate glucose to prevent catabolism
- **NPO** (especially no protein, galactose, or fructose).
- **Glucose** for hypoglycemia, 0.25–1 g/kg (i.e., D_{10} neonates; D_{10} or D_{25} infant, child).
- **D_{10} to D_{15} with electrolytes:** 8–12 mg/kg/min IV at 1–1.5× maintenance to maintain serum glucose level at 120–170 mg/dL).
- If necessary, treat hyperglycemia with **insulin** (0.2–0.3 U/kg/h) to further prevent hyperglycemia.

Correct metabolic acidosis (pH < 7.0–7.22) slowly, cautiously
- **Sodium bicarbonate and/or potassium acetate:** 0.25–0.5 mEq/kg/h (up to 1–2 mEq/kg/h) IV; if intractable acidosis, consider hemodialysis (peritoneal dialysis, hemofiltration, exchange transfusion much less effective).

Eliminate toxic metabolites
- **Hyperammonemia therapy:**
- **For organic acidopathies, fatty acid oxidation defects,** hyperammonemia is usually corrected by **treatment of dehydration, acidosis, and hypoglycemia. Hemodialysis** should be considered for persistent hyperammonemia for this conditions or suspected IEM.
- **For urea cycle defects,** recommendations of the New England Consortium dialysis for ammonia >300 μg/dL if concentration is rising, transfer to a facility/unit with dialysis capability for ammonia >200–250 μg/dL. If dialysis not immediately available or levels >100–125 μg/dL, use **sodium phenylacetate, sodium benzoate** as Ammonul® (Ucyclyd Pharma, 1-888-829-2593). If <20 kg load 250 mg/kg (2.5 mL/kg) in 10% glucose via central line over 90 to 120 min, then 250 mg/kg/day (2.5 mL/kg/day) in 10% glucose via central line continuous infusion, if ≥20 kg 5.5 g/m^2 (55 mL/m^2) over 90 to 120 min, then 5.5 g/m^2/day (55 mL/m^2/day) via central line; **arginine HCl** 600 mg/kg (6 mL/kg) IV in 10% glucose over 90 to 120 min, then 600 mg/kg/day IV continuous infusion. Ammonul® must be given by central line. Arginine HCl can be mixed with Ammonul®. Can decrease arginine HCl doses to 200 mg/kg if carbamyl phosphate deficiency, ornithine transcarboxylase deficiency. L-carnitine conjugates with and inactivates sodium benzoate; therefore, it must not be given with Ammonul®. Has also been used for **neonatal hyperammonemic coma of unknown etiology**.

Administer cofactors if indicated:
- **Pyridoxine** (B_6) 100 mg IV for possible pyridoxine-responsive disorder (seizures unresponsive to conventional anticonvulsants).
- **Folinic acid** as leucovorin; 2.5 mg IV for possible folate-responsive disorder (seizures unresponsive to conventional anticonvulsants)
- **Biotin** 10–40 mg NG tube for possible biotin-responsive disorder (seizures unresponsive to conventional anticonvulsants)
- **L-carnitine** 25–50 mg/kg over 2–3 min or as an infusion added to the maintenance fluid, followed by 25–50 mg/kg over 24 h, max 100 mg/kg not to exceed 3 g/day for presumed carnitine deficiency if life-threatening manifestations. Use is controversial, consultation with an IEM specialist is recommended.

Adapted from Weiner DL. Inborn errors of metabolism. In: Aghababian RV, ed. *Emergency medicine: the core curriculum.* Philadelphia, PA: Lippincott-Raven, 1999:707.

necessary in the ED, insulin (0.2 to 0.3 units per kg per hour) can be administered to prevent hyperglycemia rather than decreasing the concentration of glucose administered below 10%. Correction of hypoglycemia with glucose will improve most conditions with the exception of primary lactic acidosis due to disorders of gluconeogenesis involving pyruvate metabolism.

Metabolic Acidosis

For the immediate treatment of metabolic acidosis, sodium bicarbonate may be administered but must be given cautiously. Sodium bicarbonate should not be given unless it has been determined that the patient has metabolic acidosis and is maintaining adequate ventilation. Rapid and/or overcorrection of acidosis may have adverse CNS effects. In the patient with hyperammonemia, alkalinization of the blood favors the conversion of NH_4^+ to NH_3, which crosses the blood–brain barrier more readily and may cause cerebral edema and/or hemorrhage. Furthermore, alkalinization of the urine decreases excretion of ammonia. The pH for which sodium bicarbonate should be administered and the dose are controversial because data are lacking. Conservative guidelines recommend that sodium bicarbonate therapy be given for a pH of less than or equal to 7.0 at a dose of 0.25 to 0.5 mEq per kg per hour, but following these guidelines does not guarantee that complications from sodium bicarbonate therapy will be avoided. More aggressive guidelines recommend treatment of a pH of less than or equal to 7.2 with 1 to 2 mEq per kg per hour of bicarbonate. Continued administration of sodium bicarbonate is titrated based on acid-base status. Sodium bicarbonate may cause hypernatremia, which can in part be prevented by giving potassium as potassium acetate, which may decrease the need for bicarbonate. When using potassium acetate, however, the infusion rate must be no more than 0.1 to 0.25 mEq per kg per hour of potassium and requires frequent analyses of serum level. Definitive treatment of acidosis requires removal of the abnormal metabolites either by restricting intake of substances, primarily protein, or in severe cases, by dialysis, preferably hemodialysis.

Hyperammonemia

Significant hyperammonemia is life-threatening and must be treated immediately on diagnosis. Treatment protocols for hyperammonemia in neonates and infants and children are

detailed on the New England Consortium Web site and as per their site are meant to be used in consultation with an IEM specialist: http://www.childrenshospital.org/newenglandconsortium/NBS/neonate2.html and http://www.childrenshospital.org/newenglandconsortium/NBS/infant_child.html, for neonates and infants, respectively. The goals of emergent treatment of hyperammonemia are to eliminate protein intake, prevent catabolism, and enhance the elimination of ammonia. Intake of protein should be stopped. Fluid containing D_{10} or D_{15} at a rate of 1 to 1.5× maintenance to deliver 8 to 12 mg per kg per minute of dextrose and maintain serum glucose level at 120 to 170 mg per dL should be administered to prevent catabolism and enhance elimination of ammonia. If a urea cycle defect is the likely etiology of hyperammonemia, D_{10} at a rate to deliver 6 to 8 mg per kg per minute of dextrose should be adequate, since these urea cycle defects do not usually cause hypoglycemia. Use of insulin can be administered to prevent hyperglycemia. Colloids can be considered but should be used cautiously because they increase nitrogen load. Hypotonic fluid overload should be avoided, particularly in patients with hyperammonemia, because this could result in cerebral edema. Increased intracranial pressure in patients with hyperammonemia should not be treated with steroids or mannitol. Steroids increase catabolism and can therefore worsen hyperammonemia. Mannitol has not been shown to be effective.

Hemodialysis is the most rapid and effective method for removing ammonia. Extracorporeal membrane oxygenation (ECMO) is the most effective form of dialysis but has higher risks than other forms of dialysis, particularly in neonates. ECMO, which can reduce ammonia levels by more than 600 μg per dL in 1 to 2 hours, is up to 20 times more effective than hemofiltration and up to nearly 70 times more effective than peritoneal dialysis. Exchange transfusion is not effective. Consensus on ammonia concentration for which hemodialysis is indicated is lacking. Dialysis is most effective for ammonia concentrations higher than 300 to 350 μg per dL. Recommendations of the New England Consortium are to consider dialysis for ammonia level higher than 300 μg per dL if concentration is rising and transfer to a facility/unit with dialysis capability for ammonia level higher than 200 to 250 μg per dL. If dialysis is not immediately available or levels are higher than 100 to 125 μg per dL but lower than 200 μg per dL, pharmacologic agents for ammonia removal should be administered to patients with known or suspected urea cycle defect. Sodium phenylacetate and sodium benzoate, available in combination as the preparation Ammonul®, 100 mg each per mL (Ucyclyd Pharma, Inc, Scottsdale, AZ; 1-888-829-2593) eliminates nitrogen by an alternative pathway that does not rely on an intact urea cycle. Ammonul® does not remove ammonia rapidly enough to serve as primary therapy in patients with severe hyperammonemia. As per the package insert (http://www.medicis.com/products/pi/pi_ammonul.pdf), Ammonul® is "indicated as an adjunctive therapy for the treatment of acute hyperammonemia and associated encephalopathy in patients with deficiencies in enzymes of the urea cycle." It has also been used to treat neonatal hyperammonemic coma of unknown etiology. The dose is 2.5 mL per kg (250 mg per kg) for patients weighing less than 20 kg and 55 mL per m^2 (5.5 g per m^2) for those weighing more than 20 kg. This dose must be diluted in at least 25 mL per kg of 10% dextrose and administered as a bolus via central line over 90 to 120 minutes. The same dose in at least 25 mL per kg of 10% dextrose is then also given as a 24-hour infusion via central line. Arginine, which enhances urea cycle activity in patients with most urea cycle defects, should be administered using arginine HCl 10% at a dose of 600 mg per kg IV over 90 to 120 minutes, followed by the same dose over 24 hours. Arginine HCl can be mixed with Ammonul®. If Ammonul®/arginine HCl are being administered, the hourly infusion rate of maintenance fluids should be reduced by the volume of Ammonul®/arginine HCl being given. Given the high concentration of sodium in Ammonul® and chloride in arginine HCl, extreme caution must be taken if administering other sodium chloride–containing fluids. Sodium phenylacetate may deplete potassium. Potassium should be replaced as potassium acetate. Ondansetron (0.15 mg per kg up to every 8 hours) should be administered for vomiting and/or prophylactically if treating with Ammonul®. To assess patient response to treatment, ammonia should be monitored every 4 hours, plasma amino acids daily, and electrolytes, anion gap and acid base status every 4 hours to daily depending on last values. Usually, 2 to 3 days of therapy are necessary.

Other Treatment

L-carnitine may be administered in acutely life-threatening situations for disorders associated with carnitine deficiency, but its use is controversial and consultation with an IEM specialist is recommended. L-carnitine is given at a dose of 25 to 50 mg per kg over 2 to 3 minutes or as an infusion added to the maintenance fluid, followed by 25 to 50 mg per kg over 24 hours, up to 100 mg per kg per day, maximum 3 g per day. For seizures unresponsive to conventional anticonvulsants, empiric therapy with pyridoxine (B_6; 100 mg IV), folinic acid (leucovorin; 2.5 mg IV), and/or biotin (10 to 40 mg delivered by nasogastric tube) should be considered particularly in neonates, and also in infants, to treat a possible cofactor-responsive IEM. While there are other disease-specific pharmacologic agents, their administration is rarely indicated in the ED. Given that some IEMs are associated with increased risk of infection and that serious bacterial infection can precipitate metabolic crisis, antibiotics should be considered for any patient of concern for possible serious bacterial infection. Fresh-frozen plasma may be indicated for patients with coagulopathy.

KNOWN IEM

Background

Early recognition of acute metabolic decompensation and the potential for precipitous life-threatening deterioration is critical for the effective management of patients with a known IEM. A history of physiologic stress, such as intercurrent illness or recent surgery, and/or noncompliance with diet and/or therapeutic agents may precipitate symptoms. Manifestations and need for hospitalization with previous decompensations can provide insights into severity of disease and guide appropriate ED treatment and disposition.

Principles of evaluation and management are similar to those for patients with undiagnosed IEM as detailed in the

TABLE 94.8

LABORATORY ABNORMALITIES, EMERGENT TREATMENT OF KNOWN IEMS

IEM category	Laboratory abnormalities	Abnormalities to treat emergently (see Table 94.7 for specifics)[a]
Amino acidopathies	Hypoglycemia Metabolic acidosis ± Increased anion gap ± Elevated lactate Elevated transaminases	Hypoglycemia Acidosis
Organic acidemias	Ketonuria Neutropenia, anemia thrombocytopenia ± Hypoglycemia Metabolic acidosis Increased anion gap ± Elevated lactate ± Hyperammonemia Elevated transaminases Ketosis, ketonuria	Hypoglycemia Acidosis Hyperammonemia
Urea cycle defects, disorders of ammonia detoxification	Myoglobinuria	
Fatty acid oxidation defects	Hyperammonemia with respiratory alkalosis ± Elevated transaminases Hypoketotic hypoglycemia ± Hyperammonemia	Hyperammonemia Hypoglycemia Acidosis
Disorders of carbohydrate intolerance	± Elevated transaminases Hypoglycemia Hyperchloremic metabolic acidosis Direct hyperbilirubinemia	 Hypoglycemia Acidosis
Disorders of carbohydrate production/utilization	Urinary reducing substances Hypoglycemia Metabolic acidosis ± Increased anion gap ± Increased lactate, pyruvate ± Hyperammonemia ± Elevated transaminases Hyperuricemia Ketonuria	 Hypoglycemia Acidosis

IEM: inborn error of metabolism.
[a]Treatment must also include management of airway, breathing, circulation, life-threatening organ failure, and intercurrent illness including sepsis, which is associated with galactosemia, congenital adrenal hyperplasia, and certain organic acidemias and glycogen storage disorders.

section of this chapter on Management of Suspected IEM. Specifics of evaluation and treatment should be tailored to the IEM and the patient. Additional studies and treatment are indicated based on current clinical manifestations. Results should be interpreted relative to previous studies as available. Management for specific categories of disease is discussed below and presented in Table 94.8. The family may have an emergency treatment plan with them developed by an IEM specialist, specifically for their child. Families may also have a plan detailing desired resuscitation measures if resuscitation is necessary. Families without such plans should be encouraged to work with their IEM physician to develop and modify plans as appropriate on an ongoing basis. Some EDs that routinely care for specific patients maintain copies of these plans or have access to them through electronic medical records. Use of clinical pathways for treatment of patients with an IEM in the ED has been shown to improve timeliness and effectiveness of care.

Patients most likely to present to an ED with acute decompensation due to their IEM are those with the amino acidopathy tyrosinemia, organic acidemias, urea cycle defects, fatty acid oxidation defects, and galactosemia (Table 94.3).

Amino Acidopathies

Most amino acidopathies do not cause acute decompensation. Important exceptions include tyrosinemia type I and maple syrup urine disease. Maple syrup urine disease, while categorized as an amino acidopathy on NBS, has manifestations more similar to organic acidemias and is therefore discussed below, under "Organic Acidemias." Tyrosinemia type I, a disorder of phenylalanine and tyrosine metabolism that

results initially in liver failure and later in hepatocellular carcinoma, usually presents in early infancy but can present in the neonatal period. Clinical features include lethargy, vomiting, diarrhea, failure to thrive, hypoglycemia, jaundice, ascites, edema, bleeding, and renal tubular acidosis. Patients, particularly neonates, may have sepsis. Infants and children, in addition to manifestations seen in the neonate, may also have hepatosplenomegaly, rickets, hypotonia, and neurologic deficit. Some patients are asymptomatic until they develop hepatocellular carcinoma. Emergent treatment requires dietary elimination of tyrosine and phenylalanine. To treat dehydration, normal saline bolus(es), 10 mL per kg for neonates and 20 mL per kg for infants and children should be administered. Bolus fluid should also contain D_{10}, unless the patient is hypoglycemic, in which case dextrose should instead be administered as a bolus of 0.25 to 1 g per kg as D_{10} for neonates and D_{10} or D_{25} for infants and children. After administration of bolus fluid, D_{10} to D_{15} in ½ normal saline should be continued at 1 to 1.5× maintenance to provide glucose at 8 to 12 mg per kg per minute. Insulin 0.2 to 0.3 units per kg per hour can be administered as necessary to maintain serum glucose levels at 120 to 170 mg per dL. CBC, electrolytes, glucose, phosphate, calcium, albumin, PT, PTT, and blood gas levels should be evaluated and derangements corrected. As clinically indicated, cultures to evaluate for sepsis should be sent and antibiotics administered. Liver and renal transplant may be necessary. Ongoing treatment with nitisinone [NTBC; 2-(2-nitro-4-trifluor-methylbenzoyl)-1,3-cyclohexaanedione], which blocks metabolism of phenylalanine and tyrosine, can prevent manifestations in some patients if started at time of diagnosis.

Organic Acidemias

Organic acids are intermediary products of protein, fat, and carbohydrate metabolism. Their accumulation results in metabolic acidosis, which is often very severe and usually associated with elevated anion gap. Hypoglycemia is common because metabolic stress increases metabolic demand, which induces degradation of glucose, and because toxic accumulations of organic acids inhibit gluconeogenesis. Increased metabolism of fatty acids results in ketosis in certain organic acidemias, while others are characterized by hypoketotic hyperglycemia. Hyperammonemia results from inhibition of the urea cycle by organic acids. Organic acids also cause bone marrow toxicity that inhibits leukocyte and platelet maturation, resulting in neutropenia and thrombocytopenia. Organic acidemias most likely to be associated with acute decompensation are carnitine palmitoyltransferase deficiency types I and II, and carnitine uptake deficiency, glutaric academia type I, holocarboxylase synthase deficiency, HMG-CoA lyase deficiency maple syrup urine disease, methylmalonic acidemia, and propionic acidemia. Biotinidase deficiency, categorized on NBS as other disease rather than organic acidemia, results from a defect of biotin metabolism, the cofactor required by holocarboxylase synthase for metabolism of branch chain amino acids and therefore has manifestations similar to organic acidemias. Neonatal onset forms of organic acidemias usually present within the first week with life-threatening metabolic decompensation. Clinical features include lethargy and/or encephalopathy progressing to obtundation, feeding problems, vomiting, hepatomegaly, metabolic acidosis, hyperammonemia, and neutropenia. Several of the organic acidemias result in a characteristic urine or body odor (Table 94.2 footnote). Infantile, late-onset forms tend to have a more insidious presentation with failure to thrive, seizures, spasticity, hypotonia, and developmental delay. Affected individuals may have episodic metabolic decompensation with rapid progression to coma, particularly with physiologic stressors. Many of the clinical features can be prevented by initiation of disease-specific formula free of offending metabolites, and/or disease-specific vitamin therapy for vitamin-responsive disorders, as soon as the diagnosis is made.

Evaluation of patients with organic acidemias should include assessment of vital signs, temperature, and levels of cardiovascular stability electrolytes, glucose, calcium, ammonia, aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase, prothrombin time (PT), partial thromboplastin time (PTT), plasma amino acids, serum carnitine, blood gas, CBC, differential, platelets, urine specific gravity and ketones, urine organic acids, and as clinically indicated, analysis of blood, urine, cerebrospinal fluid (CSF), throat, and secretions for infection. Note that CBC may not be a reliable indicator of infection because of bone marrow suppression. If considering a lumbar puncture, recognize that patients may be hemodynamically unstable and/or may have cerebral edema due to toxic concentrations of organic acids and/or ammonia.

Goals of treatment are to stabilize cardiorespiratory status, restore and maintain hydration, correct metabolic derangements, decrease organic acid production, enhance elimination of organic acids, and treat precipitating causes, such as infection. All protein intake should be stopped for 48 to 72 hours in the acutely ill child. To treat dehydration, normal saline bolus(es), 10 mL per kg for neonates and 20 mL per kg for infants and children should be administered. Bolus fluid should contain D_{10}, unless the patient is hypoglycemic in which case dextrose should instead be administered as a bolus of 0.25 to 1 g per kg; D_{10} is given for neonates, and D_{10} or D_{25} for infants and children. Ringer's lactate should not be used. After administration of bolus fluid, D_{10} to D_{15} in ½ normal saline should be continued at 1 to 1.5× maintenance to provide glucose at 8 to 12 mg per kg per minute. Insulin, 0.2 to 0.3 units per kg per hour can be administered as necessary to maintain serum glucose level at 120 to 170 mg per dL. Because of the potential for severe metabolic acidosis in these patients due to accumulation of organic acids, treatment of acidosis needs to be more aggressive than with many other types of IEMs. Sodium bicarbonate, as much as 1 to 2 mEq per kg should be administered to correct acidosis, pH less than 7.2 or bicarbonate less than 14 to 16 mmol per L, and should be titrated based on acid-base status. Patients with organic acidemias may require as much as 10 to 15 mEq per kg per day of sodium bicarbonate. Potassium given as potassium acetate may decrease the amount of sodium bicarbonate required thus decreasing the risk of hypernatremia. Treatment of acidosis and hypoglycemia usually corrects hyperammonemia. Hemodialysis is indicated to hasten clearance of metabolic toxins in the obtunded or comatose patient and to correct persistent metabolic acidosis, hyperammonemia, and/or severe electrolyte abnormalities. L-carnitine (25 to 50 mg per kg over 2 to 3 minutes or as an infusion added to the maintenance fluid, followed by 25 to 50 mg per kg over 24 hours, up to

100 mg per kg per day, maximum 3 g per day) may benefit some patients with an organic academia, but its use is controversial and consultation with an IEM specialist is recommended. Glycine (150 to 300 mg per kg per day IV or PO), which enhances secretion of organic acids, should be considered for patients with isovaleric acidemia. Patients with holocaryboxylase synthase or biotinidase deficiency may improve with biotin (10 to 40 mg per day given PO or NG), those with maple syrup urine disease may benefit from hydroxycobalamin (vitamin B12; 1 mg IM). It is usually not imperative that these cofactor therapies be administered in the ED. Antibiotics should be administered as clinically indicated for infection. Administration of an oral, broad-spectrum antibiotic (e.g., neomycin) to reduce gut flora, a significant source of organic acids, may be beneficial but usually is not initiated in the ED. Efficacy of emergent treatment is monitored by ongoing assessment of mental status, fluid and cardiovascular status, signs of bleeding, and measurement of electrolytes, glucose, ammonia, and blood gas levels every 4 to 6 hours until the patient is stabilized. Resolution of metabolic crisis usually takes days to weeks.

Urea Cycle Defects

Disorders of the urea cycle result in toxic accumulation of ammonia generated by the catabolism of protein. Urea cycle disorders include carbamyl phosphate synthetase deficiency, ornithine transcarboxylase deficiency, citrullinemia, arginosuccinate lyase deficiency, and arginosuccinic aciduria. All except ornithine transcarboxylase deficiency, which is X-linked in its inheritance pattern, are autosomal recessive. Ammonia, in excess, is a neurotoxin that results in cerebral edema as well brain stem dysfunction. Those with severe enzyme deficiency present within the first few days of life, following consumption of protein in breast milk or formula. Others with partial deficiency present within the first few months of life, or even as adults, after intake of a quantity of protein that exceeds their metabolic capacity. Arginase deficiency typically presents later in life, ranging from infancy to adulthood, as a neurologic syndrome with developmental delay and progressive neurologic abnormalities and usually less severe hyperammonemia. Ornithine transcarboxylase deficiency, is the most common urea cycle defect, and in males, it is the most severe. Female carriers for ornithine transcarboxylase deficiency may manifest clinical disease due to disproportionate inactivation of their normal X chromosome (lyonization), but usually present later, including during adolescence. The other urea cycle defects, of which carbamoyl phosphate synthetase deficiency is the most common, affect males and females similarly. Presentation even later in life can be acute, severe, and even life-threatening. Acute manifestations are lethargy, irritability, vomiting, hepatomegaly, ataxia, seizures, progressing to coma, and death without appropriate emergent treatment. Duration of coma is a better predictor of outcome than is serum ammonia concentration. With late-onset forms, symptoms, although similar, are usually episodic and/or less severe and may include subtle findings such as failure to thrive in infants and learning and attention deficits, personality and behavioral disturbances, and migraine-like headaches in school-age children and adolescents. Level of alertness and cardiorespiratory status must be assessed and stabilized. Potential precipitating factors, such as infection, should be investigated and treated. Hyperammonemia is a brain stem respiratory stimulant that results in tachypnea. Increased intracranial pressure due to hyperammonemia may produce bradycardia and elevated blood pressure. Electrolytes, blood gas, glucose, AST, ALT, alkaline phosphatase, bilirubin, ammonia, and plasma amino acids levels, as well as CBC, urinalysis, and cultures to evaluate for infection, as clinically indicated, should be evaluated. Respiratory alkalosis is common, sometimes with secondary metabolic acidosis. Hepatotoxicity due to hyperammonemia may result in elevated LFTs. Even patients who are not lethargic may have significant hyperammonemia, masked by acclimatization to chronic elevations of ammonia.

Goals of acute therapy are to eliminate protein intake, avoid protein catabolism, and remove ammonia. Patients should be treated aggressively with fluids to correct dehydration and maintain hydration, glucose to prevent catabolism, and dialysis and/or sodium benzoate, sodium phenylacetate (Ammonul®), and arginine to correct hyperammonemia as described for suspected IEM (p. 989). Patients with urea cycle defects are usually not hypoglycemic, which is not usually the case for patients with a urea cycle defect. Arginine HCl should be given to all patients with urea cycle defect, except those with arginase deficiency because arginine is in excess in these patients. For patients with ornithine transcarbamylase deficiency or carbamyl phosphate synthetase deficiency, the arginine HCl dose is 200 mg per kg per day administered as a 10% solution. For patients with citrullinemia and arginosuccinic acidemia, the arginine HCl dose is 600 mg per kg per day as a 10% solution. In patients with OTC and CPS, enteral citrulline may be beneficial for enhancing elimination of ammonia, but it is not imperative that it be administered in the ED and should not be administered with patients who are vomiting and/or have decreased level of consciousness. Citrulline should not be administered to patients with citrullinemia or arginosuccinic aciduria because they already have excess citrulline. Although patients with urea cycle defects have low levels of carnitine and may be taking L-carnitine as a routine medication, patients should not receive L-carnitine while being treated with Ammonul® because it conjugates and inactivates sodium benzoate. For treatment of seizures, valproic acid should be avoided because it decreases urea cycle activity and may therefore worsen hyperammonemia.

Fatty Acid Oxidation Defects

Disorders include enzyme deficiencies involving metabolism of short, medium, long and very long chain fatty acids and carnitine transport defects. Medium chain acyl-CoA dehydrogenase deficiency is not only the most common fatty acid oxidation defect but also one of the most common IEMs with an incidence of approximately 1 per 10,000. Patients with a fatty acid oxidation defect usually present in infancy between ages 3 months and 2 years due to longer overnight fasts as the infant begins sleeping through the night or due to increased metabolic demand caused by intercurrent illness, often gastroenteritis, recent surgery or, particularly in children and adolescents, vigorous exercise. Hypoglycemia results in catabolism of fatty acids. Accumulation of fatty acid metabolites inhibits gluconeogenesis and has hepatotoxic effects. Initial clinical manifestations of fatty acid oxidation defects may also occur in the neonatal period, childhood, or adulthood. Sibs

and even parents of patients with certain fatty acid oxidation defects, particularly medium and short chain acyl-CoA dehydrogenase deficiency and carnitine uptake defect, should be tested even if they have been asymptomatic because severe decompensation, and even death, can occur with the initial crisis. Early manifestations of decompensation may include lethargy, dehydration, vomiting and/or diarrhea, hepatomegaly, and, usually but not always, hypoglycemia with absent or inappropriately low ketones, except in patients with short chain acyl-CoA deficiency who most often produce ketones with hypoglycemia. Decompensation may progress within hours to encephalopathy, coma, cardiac dysfunction, liver dysfunction, hypotonia, seizures, metabolic acidosis, and hyperammonemia. Patients with very long chain acyl-CoA dehydrogenase deficiency or long chain L-3-hydroxyacyl-CoA dehydrogenase deficiency may have exercise-induced rhabdomyolysis. Patients may be normal between episodes of decompensation or may have chronic manifestations of disease that can include failure to thrive, developmental delay, chronic peripheral neuropathy and/or motor deficits (with long chain L-3-hydroxyacyl-CoA dehydrogenase deficiency), retinitis pigmentosa (with glutaric academia type II, also known as multiple acyl-CoA deficiency, carnitine palmatoyl transferase deficiency, and carnitine/acylcarnitine translocase deficiency), and/or dysmorphic facial features. Patients with a fatty acid oxidation defect are at risk for SIDS and cardiac arrest due to hypertrophic cardiomyopathy and/or cardiac arrhythmia. Women who are pregnant with a fetus affected with long chain L-3-hydroxyacyl-CoA dehydrogenase deficiency are at risk for HELLP syndrome.

Laboratory assessment should include electrolytes, BUN, creatinine, blood gas, blood glucose, AST, ALT, alkaline phosphatase, PT, PTT, bilirubin, ammonia, carnitine, creatinine kinase in patients with muscle weakness, and as clinically indicated blood, urine and CSF, to evaluate for infection. Chest x-ray, EKG, and possibly ECHO to evaluate for cardiac failure, cardiomegaly, and/or pericardial effusion are indicated in all patients with long chain L-3-hydroxyacyl-CoA dehydrogenase deficiency and very long chain acyl Co-A dehydrogenase deficiency, as well as any patient with a fatty acid oxidation defect who manifests cardiac dysfunction. Fluids, glucose and acidosis are managed as described for suspected IEM (p. 983–985).

In patients with fatty acid oxidation defects, correction of acidosis and hypoglycemia usually corrects hyperammonemia. Administration of L-carnitine to patients with a fatty acid oxidation defect is controversial because in excess, long chain acylcarnitine may produce cardiac arrhythmias. Use of L-carnitine should be decided on a case-by-case basis based on the recommendation of the metabolic specialist. Underlying physiologic stressors should be treated. Drugs that induce hypoglycemia and epinephrine, which stimulates lipolysis, should be avoided, and if they must given, glucose concentration should be maintained with dextrose. Clinical and laboratory parameters should be monitored until the patient is stabilized and tolerating fluid well. Long term, patients may be on a high-carbohydrate, low-fat diet that includes a complex carbohydrate such as cornstarch to avoid hypoglycemia. Siblings and even parents of patients with a fatty acid oxidation defect, particularly medium or short chain acyl-CoA dehydrogenase deficiency, should be tested, even if they have never had symptoms, but especially if they have a history of "idiopathic cardiomyopathy."

Carbohydrate Disorders

Disorders of Carbohydrate Intolerance

Galactosemia. Classic galactosemia, characterized by less than 1% galactose-1-phosphate uridyltransferase activity, results in clinical symptoms usually within the first week of life, often within the first 2 to 3 days and may be rapidly fatal. Manifestations include poor feeding, vomiting, diarrhea, failure to thrive, bulging fontanelle lethargy that may progress to coma, jaundice and coagulopathy due to liver disease, and/or sepsis, classically with *E. coli*, which may be the initial manifestation. Most newborns will have cataracts although they may only be appreciated by slit lamp examination.

Urine dip will be positive for nonglucose reducing substances, that is, positive Clinitest®, and have negative or trace glucose with glucose oxidase strip, that is, Clinistix® or Glucostix®. CBC will reveal hemolysis. Electrolytes may be remarkable for hyperchloremic metabolic acidosis due to renal tubular dysfunction. LFTs are expected to reveal markedly elevated bilirubin level, initially indirect and after 1 to 2 weeks direct, alkaline phosphate and mild to moderately elevated AST and ALT, and markedly elevated PT and PTT. Given that most patients present as neonates, those with known diagnosis will likely have received the diagnosis based on NBS. Definitive diagnosis requires measurement of erythrocyte enzyme activity, and particularly in patients with less severe presentation, it may reveal more benign forms.

In addition to correction of dehydration, metabolic derangements, and infection, treatment requires complete lifelong exclusion of galactose from the diet. In neonates, breast and cow milk must be replaced with lactose-free soy formula, for example, Nutramigen®, Progestimil®. Even when galactose-free diet is initiated early, those who survive the neonatal period often have developmental delay or learning disabilities.

Disorders of Carbohydrate Production or Utilization

Glycogen storage disorders. Glycogen storage disease type 0 is most likely to present with acute decompensation. Presentation, evaluation, and management are similar to that for fatty acid oxidation defects.

NEONATE WITH POSITIVE NBS

Background

All neonates with a positive NBS require evaluation and confirmatory testing. Those with NBS positive for a condition that may result in decompensation in the neonatal period require emergent evaluation even if they appear to be asymptomatic. Most neonates with a positive NBS will have a false-positive result. To minimize the number of false-negative NBS results, cutoff values have been deliberately set low with a national goal of an overall 0.3% false-positive rate and a 20% positive predictive value. This has resulted in 12 to 60 false positives for every true positive, depending on the IEM. False positives also occur because of maternal IEM, which, in some cases is

undiagnosed. Even in the asymptomatic neonate, a false positive cannot be assumed. Evaluation should include history, physical examination, and routine laboratory tests to reveal clinical manifestations of disease or confirm absence of manifestations. In addition, confirmatory testing is required for all neonates with a positive screen. The IEMs most likely to cause acute decompensation in neonates include certain forms of tyrosinemia, organic acidemias, urea cycle defects, galactosemia, and, less commonly, biotinidase deficiency. Manifestations and treatment of these conditions is detailed in the section of this chapter on known IEMs. Patients with NBS positive for congenital adrenal hyperplasia (Chapter 86), considered an endocrine disorder, should also be evaluated emergently. Evaluation and management of neonates with positive NBS should be in consultation with a metabolic specialist, or an endocrinologist in the case of congenital adrenal hyperplasia, guided by NBS condition specific ACTion sheets developed by the American College of Medical Genetics (http://www.acmg.net/resources/policies/ACT/condition-analyte-links.htm), which provide an overview about the condition and information about potential clinical manifestations, and appropriate routine and confirmatory laboratory tests. The sheets also provide links to Web-based disease-specific information and resources. The New England Consortium Web site includes descriptions of some of the diseases (http://www.childrenshospital.org/newenglandconsortium/NBS/Disease_Descriptions.html) and analyte concentrations associated with probable versus possible disease (http://www.childrenshospital.org/newenglandconsortium/NBS/NBS_Protocols.html).

Clinical Manifestations

History

History should focus on details of pregnancy and delivery, including gestational age, complications, medications, exposures, route of delivery, Apgar scores, and complications; medications; family history of affected relatives, stillbirths, SIDS; and postnatal history, including fever, lethargy, feeding, vomiting, diarrhea, jaundice, abnormal movements, and abnormal odors. History may be unremarkable.

Physical Examination

Examination should take note of level of activity, vital signs, temperature, weight, height, head circumference, dysmorphic features, skin color, fontanelle, red reflex, cataracts, heart sounds, perfusion, respiratory distress, abdominal distension, bowel sounds, hepatomegaly, splenomegaly, ambiguous genitalia, cryptorchidism, suck, grasp, Moro, deep tendon reflexes, tone, symmetry, and seizures. Physical examination may be normal.

Studies

Laboratory evaluation should be disease specific. Routine tests may include electrolytes, BUN, creatinine, glucose, ammonia, AST, ALT, bilirubin, PT, PTT, CBC, differential, platelets, blood gas, and as indicated, blood, urine, and CSF to evaluate for infection. Appropriate tests for confirmation of the NBS condition for which the patient is positive should be sent, even if all routine laboratory tests are normal. In some cases, further testing is limited, at least initially, to repeat NBS, which may include measurement of standard analytes, as well as additional analytes, while in other cases, specialized tests including enzyme assays and/or molecular tests are indicated.

Management

Specifics of management depend not only on the condition for which the patient screened positive but also on the likely variant(s) of that condition, the concentration of the metabolite on NBS interpreted in the context of age at time of screening, and others factors that could modify test results. Cardiopulmonary abnormalities and metabolic derangements must be corrected. Dietary modification, vitamin cofactors, and/or medication may be appropriate and, in many cases, can prevent clinical manifestations. Patients with any abnormality should, in most cases, be admitted to the hospital. For patients who are discharged, a plan for very close follow-up and genetic counseling, even though confirmatory testing may rule out true disease, should be established.

SUMMARY

Collectively IEMs are not rare, and clinical manifestations are often nonspecific. Therefore, a high index of suspicion is essential for diagnosis. A few routine tests will serve as an informative screen for most IEMs. Evaluation and treatment of patients with known IEM should be disease specific. All neonates with positive NBS, even if asymptomatic, require evaluation and confirmatory testing, and if at risk for acute decompensation emergent initiation of treatment. Rapid initiation of appropriate treatment for patients with suspected or known IEM or positive NBS may not only be lifesaving but is also critical for optimizing long-term outcome.

CHAPTER 95 ■ PROBLEMS IN THE EARLY NEONATAL PERIOD

AMEER P. MODY, MD, MPH, AND BENJAMIN K. SILVERMAN, MD

INTRODUCTION

The evaluation and treatment of newborn infants in the emergency department (ED) setting can be an anxiety-provoking experience for all parties involved. Emergency physicians must be able to not only manage serious neonatal concerns, such as possible sepsis, complications of congenital heart disease, and bowel obstruction but also identify and manage variations in newborn physiology and behavior, such as jaundice and feeding problems (Table 95.1). This chapter serves as a guide to evaluating and managing the parents' concerns in the ED during the first week to 10 days with their new baby.

Many of the problems will be insignificant and can be dealt with by judicious reassurance, but it must be kept in mind that seriously ill newborns may present with only subtle, nondescript symptoms. The parents' expressed complaint may be only a clue to a serious problem far removed from their area of concern; so, a relevant perinatal history should be queried and, in most instances, a thorough physical examination performed.

The chapter is structured to allow the physician quick access to the complaint that precipitated the emergency visit. For conciseness and for easier access to information, the description of the presenting complaints is divided into subsections, based on physical, behavioral, and etiologic concerns. In most subsections, there is a delineation of those findings that are normal variants, those that might need further evaluation, and those that call for immediate attention. References are made to other chapters in this book where the more complicated problems are discussed in greater detail.

HISTORY

The emergency physician must be able to elicit relevant information needed to make decisions regarding diagnosis and management within a relatively short period. Time constraints, level of acuity within the ED, and the absence of long-term relationships can make communication in this setting particularly challenging. In the newborn period, not only is it essential to evaluate the health and physiologic stability of the baby, but often it is equally important to assess the psychosocial, emotional, and physical well-being of the caretaker; the ability and confidence in caring for the baby; the adequacy of support systems for the mother and family; and the access to follow-up care.

Because current concerns may have their origins in issues related to pregnancy or parturition, knowledge of the immediate history, a review of the events of labor and delivery, history of prior and current pregnancies, and a review of the family history are all essential components of the newborn history. Neonatal mortality is defined as the death of an infant between birth and 1 month of age. The leading causes of neonatal mortality—congenital anomalies, disorders related to short gestation and low birth weight, respiratory distress syndrome, and maternal complications of pregnancy—all have an association with pregnancy or parturition. Disclosure or identification of certain maternal, pregnancy, or infant-related factors (Table 95.2) may place the newborn at increased risk and should alert the practitioner to the potential for morbidity and mortality.

Certain points should be included in the history of all newborn infants, regardless of the presenting complaint. Always query regarding the infant's birth weight and gestational age because size of an infant at birth does not necessarily reflect gestational age. An infant who is born "small for gestational age" (SGA) or with "intrauterine growth retardation" (IUGR) is at higher risk for morbidity and mortality than an infant of the same gestational age who is "appropriate for gestational age" (AGA). An infant whose birth weight is below the 10th percentile for gestational age is SGA. SGA infants have a more than fourfold increase in perinatal mortality than AGA infants of the same gestational age. Conversely, an infant whose birth weight is above the 90th percentile for gestational age is "large for gestational age" (LGA). The most common causes for LGA infants are familial, infants of diabetic mothers, and overgrowth syndromes such as the Beckwith–Wiedemann syndrome. Hypoglycemia, hyperbilirubinemia, hypocalcemia, and polycythemia are all associated acute complications that may be seen in the macrosomic infant.

The clinician should inquire regarding the infant's general level of alertness, diet, and elimination patterns. Inadequate alimentation or infrequent urination may be clues to more serious problems. Parental concern about excessive crying or inability to soothe their infant requires attention because this excessive fussiness may have an underlying organic origin (see Chapter 16). Nonspecific complaints such as increased crying, sleepiness, and decreased appetite are sometimes the only symptoms of serious illness in the newborn.

More recently, there has arisen concern regarding the increasing number of infants delivered "near term" (late preterm). This refers primarily to infants who are scheduled to deliver by induction or by caesarian section 1 to 4 weeks before term (36- to 39-week gestation). Although not quantified, these infants are at increased risk for all potential problems in the

TABLE 95.1

FREQUENT PRESENTING COMPLAINTS AND FREQUENT DIAGNOSES OF NEWBORNS YOUNGER THAN 8 DAYS PRESENTING TO THE EMERGENCY DEPARTMENT

Most Frequent Presenting Complaints
Jaundice
Difficulty breathing
Feeding problem
Irritability
Abnormal bowel movement frequency
Lethargy

Most Frequent Diagnoses
Normal newborn
Jaundice
Feeding problem
Query sepsis
Dehydration

Adapted from Millar KR, Gloor JE, Wellington N, et al. Early neonatal presentations to the pediatric emergency department. *Pediatr Emerg Care* 2000;16:145–150.

TABLE 95.2

HIGH-RISK FACTORS FOR NEONATAL MORBIDITY AND MORTALITY

Demographic/Socioeconomic
Teenage pregnancy or advanced maternal age (age <16 or >40 yr)
Alcohol, tobacco, or illicit drug use
Poverty

Previous Pregnancies
History of prematurity, intrauterine fetal demise, or neonatal death
Previous infants with congenital malformations
Rh or other blood group sensitization

Current Pregnancy
Lack of prenatal care
Preexisting medical conditions: diabetes, hypertension, thyroid diseases, systemic lupus erythematosus
Gestational complications: preeclampsia, gestational diabetes, vaginal bleeding, multiple gestation
Infectious diseases: sexually transmitted diseases, HIV infection, group B streptococcal colonization of the cervix, TORCHES infections
History of alcohol, tobacco, or illicit drug use

Delivery/Intrapartum
Predates or postdates delivery (<37 wk or >42 wk)
Prolonged rupture of membranes
Meconium-stained amniotic fluid
Nuchal cord
Delivery: cesarean section, forceps delivery, breech presentation
Low Apgar scores

Newborn
Low birth weight (weight <2,500 g)
LGA (large for gestational age)
IUGR (intrauterine growth retardation)/SGA (small for gestational age)
Birth asphyxia
Congenital malformations
Prolonged neonatal jaundice
Prolonged hospitalization
Apnea
History of poor weight gain

HIV, human immunodeficiency virus; TORCHES, toxoplasmosis, rubella, cytomegalovirus, herpes virus, syphilis.

early neonatal period, including significant jaundice, respiratory problems, and feeding difficulties. Many of these infants are presenting to the ED with a variety of respiratory and neurological and feeding difficulties related to their immaturity.

Additional history should be guided by and focused specifically on the presenting complaint. Relevant historical suggestions are included in each of the "presenting complaint" subsections.

VITAL SIGNS

Growth

Weight gain serves as an important indicator of general well-being during the newborn period. Failure of a newborn to gain weight appropriately may be a sign of underfeeding or significant underlying illnesses such as heart disease, metabolic problems, or malabsorption. Weight gain, according to age-specific norms, can be one of the best indicators that the infant is well, despite nondescript symptoms, such as fussiness. Weight at presentation should be quantified as accurately as possible, preferably unclothed.

The average newborn infant weighs **3,400 g (7 lb, 8 oz), is about 50 cm (20 in.), and has a head circumference of 35 cm (14 in.).** The newborn will lose about 5% to 10% of his or her birth weight during the first several days of life and then regain this weight by 10 to 14 days of age. Typically, formula-fed infants will return to their birth weight before breast-fed infants. Thereafter, the newborn should gain about 25 to 35 g per day (roughly 1% of the birth weight per day). **The average newborn takes 60 to 90 mL (2 to 3 oz) of formula (the equivalent of about 10 minutes on each breast) every 2 to 3 hours. Elimination increases with each day of life to an average of 10 to 12 wet diapers and one to three bowel movements per day (as often as once after each feeding for breast-fed infants).** Because breast milk is easier to digest and passes out of the stomach quicker than formula (on average 1.5 hours vs. up to 4 hours for formula), the breast-fed infant will want to feed more frequently, with an increased number of nighttime feedings as well.

Temperature

The young infant's immature autonomic thermoregulatory responses, larger body surface area to mass ratio, immature sweating response, and limited ability to move away from or modify adverse environments all limit his or her thermoregulatory ability. Temperature instability, either *hypothermia* or *hyperthermia,* may be the only sign of significant infectious illness. It is unusual to see high temperatures in the newborn.

Even a septic newborn may develop only a slight elevation in temperature or will present with hypothermia. Therefore, any temperature higher than 38°C (100.4°F) should be regarded as a fever in the newborn and receive appropriate evaluation (see Chapters 27 and 92). A rectal temperature is the preferred method of temperature determination. The use of warm blankets or warming lights during evaluation and treatment of vulnerable infants can be helpful in avoiding iatrogenic hypothermia.

Heart Rate (See Chapter 84)

Normal resting heart rate is between 120 to 160 beats per min. It varies with respiration (increasing with inspiration) and activity (increasing significantly with crying and appreciably slowing during sleep). Cardiac output in the infant is primarily increased by increasing the heart rate rather than stroke volume. Sinus *tachycardia* (heart rate more than 180 beats per min) is a common response to many types of stress, such as pain, hypovolemia, fever, or cardiac disease (see Chapter 74). *Sinus tachycardia* may be differentiated from *paroxysmal supraventricular tachycardia (SVT)* (see Chapter 84) when the electrocardiogram (EKG) demonstrates a narrow QRS complex tachycardia with a P wave preceding each QRS complex. SVT is usually associated with a more rapid heart rate (usually more than 220 beats per min) than is sinus tachycardia and the P wave may be obscured or absent. SVT is commonly a fixed tachycardia, whereas the heart rate in sinus tachycardia will vary with crying or manipulation (beat to beat variability). Infants may tolerate SVT for a variable period, but eventually they develop irritability, tachypnea, poor feeding, and poor perfusion. The development of *bradycardia* (heart rate less than 80 beats per min) usually signals the presence of significant cardiorespiratory compromise and is an ominous sign that requires immediate attention (see Chapters 2 and 3).

Respiratory Rate

Normal resting respiratory rate is usually between 40 to 60 breaths per min. During sleep, most newborn infants will exhibit some degree of *periodic breathing,* in which normal respiration is interrupted with short pauses. This breathing pattern is especially common in premature infants. Periodic breathing must be differentiated from *pathologic apnea* (see Chapter 9).

In the simplest of terms, *apnea* is an absence of respiration that can have a central, obstructive, or mixed cause. Short periods of central apnea (less than 15 seconds) can be normal at all ages. However, pathologic apnea is a prolonged respiratory pause (more than 20 seconds) or a shorter pause associated with cyanosis, pallor, bradycardia, or hypotonia. Underlying disorders that must be considered in the evaluation of the apneic infant, include septicemia, severe anemia, intracranial hemorrhage, seizures, central hypoventilation, gastroesophageal reflux, metabolic disturbances such as hypoglycemia, and infant or maternal ingestion of narcotics or other central nervous system (CNS) depressants. The occurrence of apnea due to any of the above causes may result in an apparent life-threatening event.

Varying degrees of *expiratory grunting, chest retractions, nasal flaring*, *crackles,* or *rales* are all signs of respiratory distress in the newborn. In addition to a primary pulmonary cause, respiratory distress in the newborn can also be a presenting sign of *congestive heart failure.* Among term infants, especially those born by cesarean section, a common cause of respiratory distress presenting within the first 24 hours, usually beginning between 2 and 6 hours after birth, is *transient tachypnea of the newborn* (TTN). TTN is believed to be caused by a delay in the resorption of the normal fetal lung fluid. The differential diagnosis of TTN includes meconium aspiration pneumonitis, respiratory distress syndrome (less likely in the term newborn), pneumonia, and bronchiolitis. Symptoms of TTN typically resolve within 72 hours.

Blood Pressure

Normal systolic blood pressure in the term newborn after the first few days of life ranges between 60 and 90 mm Hg. Blood pressure may be lower during the first few days of life and in premature infants is related to weight and gestational age. Congenital renal abnormalities, renal tumors, and complications of umbilical artery catheters are some of the more common causes of *hypertension* (see Chapter 34) in the neonatal period. *Coarctation of the aorta* may be diagnosed by the combination of increased upper-extremity blood pressure, with lowered blood pressure or diminished pulses in the lower extremities.

Pulse Oximetry

Pulse oximetry measures the degree of oxygen-saturated hemoglobin in the arterial circulation and is an indirect measure of the partial pressure of arterial oxygen. It should be measured in any neonate in whom there is suggestion of respiratory distress, is febrile, appears cyanotic, is mottled, or has unusual cardiac or CNS findings. Normal pulse oximetry reading should be between 94% and 100%. Decreased oxygen saturation can indicate a wide variety of pathologies including sepsis, respiratory conditions, or cardiac disease in neonates.

COLOR CHANGES

Normal Variants

Racial and ethnic factors may result in variation of the baby's skin color. Comparison of the baby's color with the parents' pigmentation may offer assurances that the baby's color is appropriately normal. The skin of a normal Caucasian early neonate is a pink, flushed color. This in itself may be a cause for alarm to some parents but can be dismissed with reassurance if the remainder of the history and physical examination is not remarkable. A hemoglobin or hematocrit determination offers assurance that the baby is not abnormally polycythemic.

Alterations of the appearance to blue, deep yellow, orange, or pale may precipitate an ED visit. Evaluation and management of these changes are discussed here.

Cyanosis/Acrocyanosis (See Chapter 15)

The presenting complaint may be that "the baby is blue." Relevant questions to be asked include the following: When was the blueness first noted? Is it persistent or does it come and go? Does it involve all of the body or only the distal extremities and lips? Does it increase or lessen with crying or feeding? Is there emesis or diarrhea?

Physical examination should be complete. The distribution of the blueness should be carefully noted; particularly, check the color of the tongue. Does the intensity of the blueness decrease or increase with crying or with effort? Are the vital signs normal for a neonate? Is the baby responsive to stimulation? Is mottling present? Is there a cardiac murmur? Are respirations labored? Are the lungs clear? Is the liver enlarged? Are the femoral pulsations palpable?

The degree of cyanosis should be documented by pulse oximetry. The more likely causes are discussed in the following sections.

Acrocyanosis

An otherwise healthy baby with acrocyanosis appears cyanotic only in the hands, feet, and lips. The tongue is pink; pulse oximetry is normal. The transient color change may be associated with cool ambient temperature. Parent(s) should be reassured that the acrocyanosis is self-limited.

Cyanotic Congenital Heart Disease (See Chapters 15, 32, and 84)

Cyanosis is diffusely distributed and increases with crying. Pulse oximetry shows diminished saturation at rest, worsening with crying; cyanosis responds only minimally to oxygen therapy. A cardiac murmur is usually, but not necessarily, present. EKG, chest radiography, and echocardiography, if accessible, should be performed. Neonates with cyanotic heart disease only rarely go into cardiac failure, but lesions associated with obstructed pulmonary or systemic flow may cause extreme hypoxemia and shock. Consideration should be given to maintaining ductal patency with prostaglandin E1 (0.1 μg per kg per min), if cardiac consultation is not immediately available, with the knowledge that prostaglandin E1 infusions can result in apnea requiring intubation and airway management. Very early neonates with a strong suspicion of cyanotic cardiac defect should be admitted or transferred to an appropriate facility if cardiac consultation is not readily available and definitive diagnosis is uncertain.

Congestive Cardiac Failure (See Chapters 32 and 84)

Cyanosis is diffusely distributed, and pulse oximetry shows desaturation but improves somewhat with oxygenation. The infant is tachypneic, with or without increased respiratory effort. Rales may be apparent in lung fields. Cardiac murmur may be present or femoral pulsations may be absent. The liver is enlarged. Chest radiography and echocardiography should be performed, if available. If there is suggestion of obstructed systemic flow, consideration should be given to maintaining ductal patency with prostaglandin E1. Emergency treatment and admission are indicated.

Respiratory Distress (See Chapters 15, 68, and 98)

Respiratory disease is associated with tachypnea, noisy respirations, and possibly retractions. Pulse oximetry shows desaturation but usually improves significantly with rest, crying, and oxygenation. The clinician should think of respiratory infection or congenital intrathoracic defect. A chest radiograph should be obtained. After appropriate emergency treatment, the patient should be admitted. Laryngomalacia or tracheomalacia may simulate respiratory distress with noisy respirations originating in the upper airway, but oxygen saturation and chest radiographs are normal. If laryngomalacia is present, prone position across the examiner's arm will resolve the distress and/or stridor and can assist in making the diagnosis.

Primary Pulmonary Hypertension of the Newborn (PPHN)

This entity is becoming increasingly recognized in the cyanotic neonate with respiratory distress. It is more common in the larger baby, particularly the large postmature baby. The constriction of the pulmonary arterial vasculature results in hypertension of the right heart. This in turn causes right-to-left shunting of unoxygenated blood through the patent ductus or foramen ovale, resulting in hypoxia and severe cyanosis, not responding to oxygenation. When pulse oximetry readings are taken separately in each of the four extremities, oxygenation will be about 10% higher in the right arm, the preductal extremity. Aggressive treatment of PPHN, including extracorporeal membrane oxygenation, may be life-saving.

Hypovolemia, Acidosis, and Shock (See Chapters 3 and 70)

Hypovolemia, acidosis, and shock are characterized by cyanosis accompanied by mottling in an extremely lethargic, hypotonic baby with marked tachycardia and possibly hypotension. Pulse oximetry is desaturated. After appropriate emergency workup, including early treatment with hydrating parenteral fluids, the patient should be admitted.

Methemoglobinemia (See Chapter 102)

Methemoglobinemia is characterized by a cyanotic-appearing infant without underlying cardiac or pulmonary disease. The infant will look diffusely cyanotic to gray in color, with a factitiously almost normal-appearing pulse oximetry reading 85% or more. Supplemental oxygen also will not alter the color (an indication that the cyanosis is not from a primary pulmonary process). Acquired methemoglobinemia in infants is most commonly associated with diarrheal illnesses and dehydration. Methemoglobinemia may be confirmed by venous or capillary blood gas sampling or by the persistent chocolate-brown color of a drop of blood on filter paper. Volume resuscitation should first be initiated in infants with normal saline and dextrose.

If the methemoglobinemia persists, a dose of 1 mg per kg of methylene blue, should be considered. An infant with methemoglobinemia should be admitted.

Blue Sclerae

Blue color confined to the sclerae may be associated with osteogenesis imperfecta. The neonate's sclerae commonly may be normally blue although the intensity is less. If in doubt, the clinician should take a careful family history and examine for fractures of the extremities, ribs, and pelvis.

Jaundice (See Chapters 40, 41)

The parent may be concerned because the newborn appears yellow or orange. Because this may be a normal variant in Pacific rim or Native American racial or ethnic groups, the parents' coloring should be compared with the baby's.

Bilirubin is formed by the catabolism of hemoglobin and may accumulate when there is excessive hemolysis, failure of conjugation with glucuronic acid in the liver, or inadequate excretion through the liver canaliculi or the bile ducts. Bilirubin that has not been conjugated in the liver, tests as indirect and is related to excessive hemolysis of red cells; conjugated bilirubin is reported as direct and is elevated when excretion is obstructed.

If jaundice is identified, relevant questions to be asked should include the following: When was the jaundice first noticed? What is the color of stools and urine? What type of feeding is being used (breast or formula)? Are feedings adequate? What are the mother's and baby's blood types, if known? Has the infant vomited? Is there a family history of jaundice? Is the mother diabetic?

The most precise clinical method for determining whether the color change is truly jaundice is by examining the sclerae—yellow color of the sclerae is jaundice. A complete physical examination should be performed, with emphasis on vital signs, intensity and distribution of icterus, presence of cephalohematoma, or hepatosplenomegaly.

The intensity of jaundice is determined by the level of bilirubin in the blood and by its distribution. As a rule, jaundice is not discernible in infants at levels less than 5 mg per dL. Jaundice is usually first discerned in the face and becomes more obvious caudally as the total serum bilirubin (TSB) level increases. In each patient, a TSB level and a complete blood cell count (CBC) with blood smear should be performed. If subsequent TSB levels are indicated in the baby, the direct bilirubin level should be determined at least once.

Physiologic Jaundice (See Chapter 40)

Physiologic jaundice is icterus that is not pathologic. Discernible jaundice in the first 24 hours of life of a healthy term newborn is probably pathologic, so a cause must be sought and therapy inaugurated. Beyond the first day, however, if the CBC and smear are not abnormal and the physical examination is not remarkable, a degree of jaundice not exceeding the published standard can be assumed to be physiologic. Infants of diabetic mothers and babies with congenital hypothyroidism or those with resorption from large cephalohematomata may have higher levels of icterus than one would expect physiologically.

Management and disposition can be governed by the recommendations in Table 104.3 and will vary with the baby's age and the bilirubin level. Babies with TSB nearing the levels at which therapy is suggested should be followed with at least one repeat determination within 24 hours to get a sense of the rate of rise.

Breast Milk Jaundice (See Chapter 40)

In breastfed babies, jaundice may arise early because of inadequate caloric intake and the dehydration that may occur before there is sufficient milk. Later onset of jaundice associated with breast-feeding occurs for unknown reasons, probably related to undiscovered hormonal changes or excessive reuptake from the gastrointestinal tract. If TSB is not approaching levels at which phototherapy needs to be considered, breast-feeding should be continued and even encouraged more frequently. Higher TSB levels should be followed with at least one additional determination.

Blood Type Incompatibility (See Chapters 40 and 91)

If the TSB level is at or near levels requiring therapy (Table 95.3) and particularly if the jaundiced baby has a lower hemoglobin than expected, direct Coombs' test should be conducted. Mother and baby should be blood-typed for ABO and Rh factors. If there is an incompatibility and if the bilirubin is rising rapidly despite phototherapy, blood should be prepared for possible exchange transfusion. Rh incompatibility is uncommon in those mothers who have had ongoing obstetric care. ABO incompatibility is usually more insidious in onset

TABLE 95.3

MANAGEMENT OF HYPERBILIRUBINEMIA IN THE HEALTHY TERM INFANT ACCORDING TO TSB AND BABY'S AGE[a]

Age (h)	Initiate phototherapy[b] (mg/dL)	Exchange transfusion if intensive phototherapy fails[c] (mg/dL)
<25	8–10	17–20
25–48	12–15	19–22
49–72	17–19	22–25
>72	20–21	25

TSB, total serum bilirubin.
[a]These guidelines apply to well neonates of gestational age equal to or more than 35 weeks. The lower ends of the above TSB ranges apply to the youngest in each age range.
[b]Lower bilirubin levels than the above would warrant initiation of phototherapy in infants who have any of the following risk factors: shorter gestation, isoimmune hemolytic disease, glucose-6-phosphate dehydrogenase deficiency, asphyxia, significant • lethargy, respiratory distress, temperature instability, sepsis, acidosis, or albumin level higher than 3.0 g per dL. Consult neonatology and/or hematology regarding possible need for exchange transfusion or alternative therapy if levels significantly exceed these numbers or if the bilirubin is predominately conjugated (direct).
[c]Intensive phototherapy should produce a decline of TSB of 1 to 2 mg per dL within 4 to 6 hours, and the TSB level should continue to fall and remain below the threshold level for exchange transfusion. If this does not occur, it is considered a failure of phototherapy.
Adapted from American Academy of Pediatrics, Subcommittee on Neonatal Hyperbilirubinemia. Management of hyperbilirubinemia in the newborn infant 35 or more weeks of gestation. *Pediatrics* 2004;114:297–316.

and less severe than Rh. Other minor red cell incompatibilities may also result in hyperbilirubinemia.

Sepsis (See Chapters 70 and 92)

Sepsis need not be a consideration in the alert, well-appearing, jaundiced newborn. If the jaundiced baby is lethargic or extremely irritable, hypotonic, febrile, or excessively tachycardiac and has been feeding poorly, sepsis and/or urinary tract infection should be considered. The bilirubin may be indirect or direct.

Congenital Red Cell Defects (See Chapters 40 and 92)

Careful examination of the blood smear may provide a clue to red cell membrane defects. These babies may have indirect bilirubinemia and anemia and may have a positive family history for spherocytosis or elliptocytosis. More severe forms of glucose-6-phosphate dehydrogenase deficiency also may present with early jaundice and anemia, especially if the mother has received possibly precipitating drugs during late pregnancy. Elevated reticulocytes with a negative Coombs' test would heighten suspicion.

Other Congenital Problems (See Chapters 40 and 41)

The group of congenital infections that falls under the acronym of TORCHES (toxoplasmosis, rubella, cytomegalovirus, herpes virus, syphilis) may present with jaundice. These should be thought of in the baby with elevated direct bilirubin who presents with microcephaly, jitteriness, seizures, organomegaly, or petechiae. Elevated direct bilirubin also may be an early manifestation of galactosemia and cystic fibrosis.

Babies with the severe form of congenital glucuronyl transferase deficiency defined as Crigler–Najjar syndrome may present with extremely high levels of unconjugated bilirubin, which may rise despite phototherapy. This defect is mostly confined to geographical areas where conjugal-related marriage is more common.

The presence of gray-colored (acholic) stool and/or direct hyperbilirubinemia should raise the concern for obstructive jaundice. The differential diagnosis includes extrahepatic biliary atresia, intrahepatic biliary atresia (Alagille's syndrome), hepatitis secondary to TORCHES infections, or metabolic disorders. The presence of extrahepatic biliary atresia necessitates immediate admission or transfer to a specialty pediatric center for definitive management.

Pallor

The neonate may be brought to the physician because the neonate appears pale to the parents. A careful history and physical examination should be conducted to consider the possibilities of septic or cardiogenic shock, severe chemical or electrolyte imbalance, or significant anemia.

Questions should be asked regarding the mother's perinatal history, the baby's suck and feeding, the occurrence of vomiting or diarrhea, fever, and the baby's responsiveness. Physical examination should include a thorough evaluation of the vital signs. Is the baby extremely lethargic? The clinician should look at the inner palpebral conjunctivae and check the skin for petechiae or rashes. Is there a large cephalohematoma? Is there hepatosplenomegaly?

A CBC should be conducted and consideration given to a stat glucose and electrolyte panel and TSB level. Normal levels at this age for hemoglobin are in the range of 13 to 20 g per dL with a mean of 16 g per dL; for hematocrit, 42% to 65%, with a mean of 50%. Diagnostic considerations include the topics discussed in the following sections.

Fair Complexion

If the vital signs and the physical examination are normal and the CBC does not indicate anemia, the presenting concern probably relates to the baby's normal fair-skinned coloring. Offer appropriate explanation and discharge home.

Anemia (See Chapters 58 and 91)

Anemia in the neonate is not usually recognized as pallor until the hemoglobin level falls below 10 g per dL. It is most commonly, but not always, related to excessive hemolysis of the red cells and often is accompanied by jaundice. Possible etiologies might include the following:

- *Hemolytic disease of the newborn:* Complete maternal and neonate blood typing should be performed, as well as a Coombs' test. Depending on the degree of anemia and the baby's functional status, crossmatching for possible packed cell or exchange transfusion should be initiated.
- *Congenital erythrocyte membrane defects:* These defects can usually be suggested by careful evaluation of the blood smear.
- *Malignancy:* Congenital leukemia is a rare entity that should be discernible on the blood smear.
- *Congenital and aplastic anemias:* Diamond–Blackfan syndrome, transient erythroblastopenia of childhood, sickle cell disease, and Fanconi's syndrome do not usually manifest in the very early neonatal period.
- *Blood loss:* Blood loss can occur through the gastrointestinal tract (Meckel's diverticula; bleeding disorder) and should be suspected if a stool is positive for gross blood. Imaging evaluation is indicated. Significant blood loss can also occur into a large cephalohematoma or an intracranial hemorrhage in an infant.
- *Disseminated intravascular coagulopathy (DIC):* DIC may occur in association with bacterial sepsis, viremia (especially herpes simplex), and shock, accompanied by petechiae and purpura. Platelet count is significantly diminished in these ill children. Evaluation is directed at finding a cause and therapy at replacing deficient elements (see Chapters 3, 65, and 91).

Ill Children (See Chapter 3)

Pallor may be the most striking presenting complaint in the neonate who is ill. Children in septic or cardiogenic shock may appear pale because of poor perfusion, without necessarily being anemic. Hypoglycemic infants and those with severe electrolyte disturbances may also present with pallor. Rapid diagnosis and emergency administration of glucose and volume restoration are essential.

Mottling

Mottling in the neonate is the patchy appearance of the body surface, resulting from prominent dilation of the superficial

veins showing through the thin skin and causing a mosaic-like, patchy appearance. Mottling may be a normal variant when it appears in an otherwise normal baby, undressed in a cool ambient temperature. It is more likely to appear in a preterm baby with thin skin.

However, mottling can be an ominous diagnostic sign in a neonate. It may be indicative of hypovolemia and poor perfusion in a baby in shock or a septic baby. A careful history and complete physical examination with cautious evaluation of the vital signs need to be done. If there is doubt about the baby's status, a CBC, an electrolyte panel, and stat glucose should be drawn. Treatment of the underlying cause and restoration of hemodynamic stability should be inaugurated in the ED.

SKIN FINDINGS

The quality of the newborn's skin varies with the gestational age. The premature infant's thin, almost-translucent skin is in sharp contrast to the dry, cracked, peeling skin of the postterm infant. The term infant's skin is usually pale pink in color, with some diffuse superficial peeling noted at several days of age. Normal peeling of the superficial layers of the skin should be differentiated from the full-thickness skin loss that is associated with *staphylococcal scalded skin syndrome*. *Excoriations* when noted in an irritable or jittery infant, especially when they are located primarily on the nose or knees, may be a sign of withdrawal in an infant exposed to narcotics prenatally.

Seborrheic dermatitis (see Chapter 85) is a localized scaling or crusting eruption that most commonly involves the scalp (cradle cap), forehead, and area behind the ears. Occasionally, the diaper area may be involved. The eruption may have a greasy appearance and the lesions are generally nonpruritic.

Hair

Soft, downy, fine body hair, lanugo, located primarily on the back and shoulders, is a normal finding. However, a tuft of coarse, dark hair located in the midline lumbosacral region may be associated with spina bifida occulta.

Papular Rashes (See Chapters 63, 64, 65)

A variety of papular rashes may be observed in the healthy newborn. Characteristic body distribution patterns and age at appearance of these typical rashes may help differentiate them from more worrisome conditions.

Milia are small 1 to 2 mm ivory or yellow papules located primarily on the forehead, nose, and cheeks of the newborn. Milia are keratin retention cysts that require no treatment because they will spontaneously rupture and disappear during the first 3 to 4 weeks of life.

Erythema toxicum is a more generalized eruption of small papules or pustules on an erythematous base that may occur anywhere on the body. Usually presenting during the first 3 to 4 days of life, these lesions may be noted as late as 2 weeks of age. *Herpes simplex* infections, although usually vesicular (see below), and *impetigo*, usually pustular or crusted, may be entertained in the differential diagnosis of this eruption. If the diagnosis of erythema toxicum is in question, a smear of the papular contents will show a predominance of eosinophils, with a relative absence of neutrophils and no organisms.

Erythematous papules or pustules (rarely comedones) confined primarily to the cheeks, chin, and forehead are characteristic of *neonatal acne*. Lesions are secondary to the influence of circulating maternal hormones and usually appear at 3 to 4 weeks of age and disappear within a few weeks.

Vesicular Rashes (See Chapter 67)

The most important condition to consider when evaluating a vesicular eruption is a herpes simplex virus (HSV) infection because it has the most significant associated morbidity and mortality. Most neonatal *HSV infections* are caused by HSV type 2, although either type 1 or type 2 may be implicated. Although transplacental transmission of HSV can occur, the vast majority of neonatal disease is acquired from infection of the maternal genitourinary tract. Primary maternal infection at the time of delivery is associated with a 40% to 50% risk of disease transmission to the newborn, whereas recurrent maternal disease has a much lower risk of transmission (less than 5%). Therefore, most infected newborns are from mothers that are unaware of their own HSV infection. Clinical disease in the newborn includes (1) localized infection of skin, eyes, and mouth; (2) infection of the CNS with fever, seizures, and alteration of consciousness; or (3) disseminated viremia with multisystem involvement and shock. The infant generally appears well at birth but then becomes ill at any time from day 2 of life to day 28 (usually between days 4 and 7), at which time a vesicular eruption may be noted. Unfortunately, not all HSV-infected infants have the typical vesicular eruption, making early diagnosis difficult. Small (1- to 2-mm) vesicles on an erythematous base, which may become pustular in 24 to 48 hours, are the most common lesions. At times, only 1 or 2 vesicles may be present; lesions are noted most often on the scalp and face, the presenting part of the infant in a normal delivery. Early diagnosis and prompt initiation of antiviral therapy can improve morbidity and mortality.

Neonatal varicella may develop when maternal varicella infection occurs during the last 2 to 3 weeks of pregnancy or the first few days postpartum. The severity of neonatal disease depends on the timing of the maternal infection. If maternal disease onset is 5 or more days before delivery, the infection in the newborn is usually mild because of the transplacental passage of maternal varicella IgG antibody. In contrast, if maternal disease onset is within 5 days before delivery or within 48 hours after delivery, the neonate is at risk of developing severe infection with up to a 30% mortality, usually caused by pulmonary or visceral involvement. Diagnosis can usually be made by the history and the characteristic rash or vesicles on an erythematous base (dew drops on a rose petal). The primary differential diagnosis includes HSV-1 or HSV-2 infection. Acyclovir may be considered for moderate or severe cases of neonatal varicella. Varicella-zoster immunoglobulin is recommended for uninfected infants born to mothers whose onset of chickenpox was within 5 days before to 2 days after delivery.

Incontinentia pigmenti is an X-linked dominant disorder with both skin and systemic lesions (affecting the eyes, CNS,

and bone). It presents at birth or shortly thereafter with an inflammatory vesicular or bullous rash that develops in crops over the trunk and extremities. The cutaneous lesions have four phases (inflammatory vesicles or bullae, verrucous lesions, whorled hyperpigmentation, and hypopigmented patches) that may overlap and occur in an irregular sequence. Suspected cases should be referred to a dermatologist for evaluation because of the potential for systemic involvement.

Miliaria, or neonatal prickly heat, is caused by sweat retention and is characterized by easily ruptured, tiny (1- to 2-mm) vesicles located primarily on the face, chest, and back.

Impetigo appears as superficial vesicular, pustular, or bullous lesions on an erythematous base. In the newborn, lesions tend to occur primarily in the diaper area, folds of the neck, or axillae.

Vascular Lesions

The *salmon patch (nevus simplex)* is the most common vascular lesion of infancy. It is a pale pink macular lesion that is found most commonly on the nape of the neck (often called a *stork bite*), forehead, nasolabial region, or upper eyelids. With the exception of the lesions on the nape of the neck, most will fade within the first year of life.

Nevus flammeus (port-wine stain) consists of mature dilated dermal capillaries and presents at birth as pink to purple macular lesions that can vary tremendously in size, sometimes involving a significant portion of the body (Klippel–Trenaunay–Weber syndrome should be considered when the port-wine stain involves a lower limb). Unilateral facial port-wine stains in a trigeminal nerve distribution may be associated with the Sturge–Weber syndrome (seizures, intracranial calcifications, and hemiparesis). These lesions generally will not fade with time. Some are amenable to laser therapy.

Although *capillary hemangiomas (strawberry hemangiomas)* may be present at birth, most develop during the first few weeks of life. Lesions may occur anywhere on the body and typically begin as small, well-demarcated telangiectatic macules that subsequently develop into raised bright red or purple tumors with distinct borders. Most lesions will go through a period of rapid growth over the first 6 months of life, followed by a static period and then spontaneous involution, usually by 5 years of age.

Cavernous hemangiomas are deep-seated capillary hemangiomas that usually present at birth as a diffuse swelling with little change in the color of the overlying skin or a bluish hue. Most involute spontaneously with time.

Hemangiomas that may require intervention during the neonatal period are those that by location or size may compromise vital structures such as the eyes, nares, or auditory canals; lesions that by their size or location (e.g., perianal or labial lesions) are susceptible to trauma, ulceration and secondary infection; and large, rapidly enlarging hemangiomas associated with thrombocytopenia and a consumption coagulopathy (Kasabach–Merritt syndrome).

Pigmentary Changes

Mongolian spots are poorly circumscribed blue-black, gray, or brown large macular lesions generally located over the lumbosacral region, buttocks, and lower limbs in more than 80% to 90% of African American, Native American, Hispanic, or East Asian infants. The incidence is less than 10% in Caucasian infants. Lesions will usually fade during the first few years.

Café-au-lait macules are round or oval, brown macular lesions varying in size from less than 1 cm to more than 20 cm. Although normal individuals may have these lesions, they may be a sign of neurocutaneous disease, most commonly neurofibromatosis, particularly if multiple (more than 4) or large (larger than 1 to 2 cm).

Ash-leaf macules are irregular hypopigmented macules, often with an oval or "ash-leaf" appearance found in 70% to 90% of individuals with tuberous sclerosis. This is an autosomal dominant condition characterized by CNS lesions, seizures (infantile spasms), retinal lesions, cardiac rhabdomyomas, and renal lesions (hamartomas or cystic kidneys).

HEAD AND NECK PROBLEMS

Head Size and Shape

Shape, size, and symmetry are factors that must all be considered in the evaluation of the neonate's head. *Microcephaly* refers to a head circumference that is larger than 2 standard deviations below the mean, or smaller than the third percentile for age and sex. Microcephaly is usually a sign of a severe underlying abnormality of brain growth or development and is often associated with mental retardation. It may be secondary to a variety of causes, including Down syndrome, congenital TORCHES infections, and fetal alcohol syndrome. *Macrocephaly* is a head circumference that is larger than 2 standard deviations above the mean, or larger than the 97th percentile for age and sex. An excessively large head may be familial or suggestive of hydrocephalus, storage disease, or intracranial hemorrhage.

Molding of the skull bones during the vaginal delivery process is a common cause of temporary asymmetry and scalp edema, *caput succedaneum*. Caput succedaneum is an ill-defined, generalized swelling of the soft tissues of the scalp that extends across suture lines. Generally, both caput succedaneum and skull molding spontaneously resolve by 7 to 10 days of age. Trauma during the birth process may produce a cephalohematoma, a subperiosteal hemorrhage, distinguished from a caput by the fact that the swelling never crosses suture lines. However, the diagnosis can be difficult in the immediate newborn period if overlying scalp edema is present. Most commonly, a cephalohematoma is unilateral, but it can be bilateral. Cephalohematomas resolve slowly over 4 to 6 weeks, possibly with calcification and the formation of a hard bump on the scalp that may be a source of great concern to parents. Fetal scalp monitoring probes used during delivery may also leave a residual eschar or small bump on the scalp. Occasional complications resulting from the breakdown and resorption of large hematomas are jaundice or anemia.

Overriding cranial sutures, caused by the pressures exerted on the skull during its descent through the pelvis, may be noted for the first several days of life. Overriding sutures that are palpable beyond this time may be a sign of underlying brain pathology and deserve further evaluation. Ridging or

prominence of cranial sutures may be a sign of *craniosynostosis*, a premature fusion of cranial sutures. Overriding sutures are ballottable, but if the sutures are rigid and have a heaped-up solid closure, radiographs or even a computed tomography scan should be conducted to rule out craniosynostosis. Soft areas, *craniotabes*, are occasionally found on palpation of the parietal bones during the first several days of life, especially in premature infants. Soft areas noted in the occipital region may be suggestive of osteogenesis imperfecta or other syndromes and should be investigated.

At birth, the newborn has two *fontanels*. The anterior fontanel, situated at the junction of the coronal and sagittal sutures, usually measures about 2 cm × 2 cm (can be up to 5 to 6 cm in its largest diameter) and normally closes between 9 and 18 months. The posterior fontanel, situated at the junction of the lambdoidal and sagittal sutures, generally measures between 0.5 and 1 cm (may be closed at birth in some cases) and usually closes to palpation by 3 to 4 months of age. Enlarged fontanels may be associated with a variety of conditions, including prematurity, hypothyroidism, or hydrocephalus. Increased intracranial pressure produces a full or bulging fontanel, whereas dehydration produces a depressed fontanel. A fontanel that appears full while the infant is supine or crying should be reassessed while the infant is held upright and sleeping or feeding before it is determined to be full or bulging.

Face

Facial asymmetry is usually secondary to in utero position. Commonly, when the face and neck are pressed against the shoulder in utero, a characteristic flattening of the face and angle of the jaw is noted on that side because of displacement of the mandible. This facial asymmetry will resolve spontaneously in a few weeks.

Neck (See Chapters 44 and 45)

Congenital muscular torticollis is a positional abnormality of the neck, resulting in abnormal tilting and rotation of the head. It is believed to be secondary to intrauterine positioning or trauma to the soft tissues of the neck during delivery, with resulting ischemia of the sternocleidomastoid muscle secondary to venous occlusion. This leads to edema and degeneration of the muscle fibers with eventual fibrosis of the muscle body. Although congenital muscular torticollis may be noted at birth, it usually manifests at 2 to 4 weeks of age. The incidence is increased in breech presentations and difficult deliveries. Unilateral contracture and fibrosis of the sternocleidomastoid muscle results in a characteristic head tilt toward the affected side and the chin pointing toward the opposite side. On examination, a firm, nontender mass may be felt within the body of the sternocleidomastoid muscle. Treatment consists of passive stretching exercises of the neck and repositioning toys and mobiles in the crib to stimulate the infant to look toward the side opposite the preferred gaze. Occipitocervical spine anomalies, such as the Klippel–Feil syndrome (congenital fusion of two or more cervical vertebrae; clinical triad of short neck, limited neck motion, and low occipital hairline), are rare causes of torticollis that present in the newborn period.

Congenital neck lesions may present during infancy or sometimes much later in childhood. The most common lesions include, *thyroglossal duct cysts* (midline in the neck and inferior to the hyoid bone), *branchial cleft cysts* (along the lateral neck), and *cystic hygromas* (usually located behind the sternocleidomastoid muscle in the supraclavicular fossa; two-thirds of cystic hygromas are present at birth).

Redundant skin on the back of the neck or webbing in a female infant are suggestive of Turner's syndrome and may be associated with lymphedema of the dorsum of the hands and feet in the newborn.

EYE PROBLEMS

The newborn is very nearsighted at birth, with a visual acuity of about 20/400. The eyelids are closed most of the time, and any attempt to force them open usually meets with marked resistance and causes blepharospasm. Darkening the examination room, holding the infant upright and gently swaying him or her from side to side or up and down often induces the eyes to open spontaneously. Neonatal ophthalmologic concerns include leukokoria, neonatal conjunctivitis, excessive tearing, scleral and subconjunctival hemorrhages, and uncoordinated eye movements.

Leukokoria

The pupillary light reflex is a simple test that takes only moments and should be performed on all newborns. In the normal newborn, a "red reflex" is seen when the ophthalmoscope is held 10 to 12 in. in front of the eyes. A white pupillary light reflex, or leukokoria, is never normal in the newborn. Leukokoria may be a sign of several conditions of variable severity and prognosis such as colobomas, cataracts, retinal detachment, retinopathy of prematurity, or retinoblastoma [the most common signs are leukokoria (60%) and strabismus (20%)]. Therefore, all infants with an abnormal pupillary light reflex should be referred to an ophthalmologist for a prompt evaluation.

Conjunctivitis (See Chapters 23 and 127)

The major causes of *neonatal conjunctivitis*, or *ophthalmia neonatorum*, are chemicals, chlamydia, bacteria, and virus. The time of onset of symptoms after birth can help identify the causative agent. Mild inflammation of the conjunctivae that begins 12 to 24 hours after birth is typically caused by the prophylactic eyedrops instilled at birth. This *chemical conjunctivitis* usually resolves by 48 hours of age. *Neisseria gonorrhoeae* conjunctivitis generally appears 2 to 5 days after birth, whereas conjunctivitis caused by *Chlamydia trachomatis* presents between 5 and 14 days after birth because of its longer incubation period. Gonococcal infection may be delayed beyond 5 days of age because of partial suppression by the prophylactic drops instilled at birth. Gonococcal infection usually manifests as marked inflammation of the eyelids, chemosis, and copious purulent discharge. Presentation of chlamydial infection, which is primarily localized to the palpebral conjunctiva, can vary from mild inflammation to severe swelling of the eyelids with copious discharge. Of neonates

with chlamydial conjunctivitis, 10% to 20% have chlamydial pneumonia, which can either occur simultaneously with the eye infection or up to 4 to 6 weeks later. Gonococcal conjunctivitis is considered a medical emergency because the infection can spread to the cornea, producing corneal ulceration and perforation. HSV is a less common cause of neonatal conjunctivitis. The presence of characteristic skin lesions can help in the diagnosis. Gram stain and cultures are essential in the evaluation of neonatal conjunctivitis. Treatment is discussed in detail in Chapters 24 and 120.

Excessive Tearing (See Chapters 23 and 127)

Congenital obstruction of the nasolacrimal duct, *dacryostenosis*, is the most common cause of excessive tearing in the newborn. Dacryostenosis should be differentiated from *congenital* or *infantile glaucoma*, a serious but fortunately rare cause of excessive tearing. Most cases of infantile glaucoma presenting during the first 3 months of life are bilateral, whereas dacryostenosis is usually unilateral.

Increased wetness of the affected eye relative to the normal eye, excessive tearing, mucoid eye discharge, and crusting along the eyelid margins are the usual presenting symptoms of dacryostenosis. Gentle pressure along the medial canthal region over the lacrimal sac may produce a reflux of tears or purulent material onto the surface of the eye, confirming the diagnosis. Infants with glaucoma, in addition to excessive tearing, also present with rhinorrhea, photophobia, and corneal haziness. The cornea may be inspected after instillation of fluorescein dye to rule out a *corneal abrasion* as the reason for the excessive tearing. Uncomplicated cases of nasolacrimal duct obstruction should be managed with gentle cleansing of the eyes, followed by local massage of the nasolacrimal duct, several times per day. Topical ophthalmologic antibiotic ointments should be prescribed if there is associated conjunctivitis or purulent discharge. Suspected cases of infantile glaucoma require immediate ophthalmologic evaluation.

Scleral and Subconjunctival Hemorrhage

Scleral and subconjunctival hemorrhage are often noted in the newborn, secondary to birth trauma. These lesions are common and spontaneous resolution within 1 to 2 weeks is the rule. When the funduscopic examination is performed, similar hemorrhages may be noted on the retina in about 25% of newborns. The presence of retinal hemorrhages should also raise the possibility of intentional trauma. Specifically, the *shaken baby syndrome* has been associated with flame-shaped retinal hemorrhages and subdural hematomas (see Chapter 132).

Transient Neonatal Strabismus (See Chapter 24)

Intermittent esotropia or exotropia may be noted in normal infants during the first 2 to 3 months of life. These deviations are believed to be secondary to neuromuscular immaturity and generally resolve spontaneously by 4 months of age. If such eye deviations are constant instead of intermittent, the infant should be referred for an ophthalmologic examination. In many infants, a broad, flat nasal bridge and prominent epicanthal folds may obscure a medial portion of the sclera near the nose and create the appearance of esotropia. This *pseudostrabismus*, or apparent deviation of the eyes, is an illusion that can be dispelled by the finding of symmetric bilateral pupillary light reflexes.

MOUTH PROBLEMS (SEE CHAPTER 48)

Normal Findings

Common normal findings in the oropharynx include natal teeth and benign gingival cysts. The incidence of *natal teeth* (teeth present at birth) is about 1 in every 3,000 live births. The mandibular central incisors are the most commonly affected teeth. Because most natal teeth are primary teeth that have erupted early, they should be extracted only if they are loose and pose a danger of aspiration, cause discomfort to the mother or child during nursing, or are confirmed to be supernumerary by focused radiographic examination.

Benign gingival cysts (see Chapter 122) are found in 75% of newborns. *Epstein's pearls* are usually single, small, white, keratin-filled cysts found along the midline of the palate. *Bohn's nodules* are mucous gland cysts that appear as multiple, firm, grayish white lesions along the gums and occasionally on the palate. *Dental lamina cysts* are formed by remnants of dental lamina epithelium and appear as small, cystic lesions along the crests of the mandibular and maxillary mucosa. They are usually larger and more lucent than both Epstein's pearls and Bohn's nodules. These cysts generally disappear by 4 weeks of age.

Thrush

Thrush is caused by *Candida albicans*. Diagnosis may be based on clinical examination. Creamy white plaques located on the buccal mucosa or tongue that are difficult to remove and may cause bleeding when scraped are characteristic of candidiasis. Treatment consists of local application of nystatin oral suspension four times a day. Topical application of nystatin ointment to the mother's nipples may be indicated in recurrent or refractory cases if the infant is breast-feeding.

Lip and Palate Defects

Defects in the formation of the lip (harelip) are obvious on even casual visualization. Possibility of defects of the palate should be considered in any neonate with feeding difficulties. The defect may vary in size. These infants should be referred for eventual surgical repair and for monitoring of feeding techniques.

CHEST AND BACK FINDINGS

This section discusses those external lesions on the thorax and back of the neonate for which a parent may bring the baby to emergency care. Intrathoracic lesions and diseases that present

with secondary symptomatology are discussed in detail in other contexts elsewhere in this book (see Chapters 68, 98, and 118).

Normally, the term newborn's thorax is symmetric and barrel-shaped. It is graced with two nipples anteriorly, each about 10 mm in diameter and slightly elevated and stippled. Respiratory excursion should be symmetric and accompanied by simultaneous movement of the abdomen. In the midline of the back, the tips of the vertebrae can be palpated but not visualized. The rib cage is not flared or depressed. There are a number of variations of the apparent normal anatomy, some normal and some not, which may be striking enough for a parent to bring the child to the ED.

Respiratory Excursion (See Chapters 68, 92, and 98)

Intrathoracic disease or anomaly may be suggested by variations in the normal symmetric excursion of the thorax. If thoracic excursion is asymmetric or if there is significant tachypnea or retraction accompanied by grunting and either excessive or paradoxical excursion of the abdomen, pulse oximetry should be checked and a chest radiograph is warranted.

Fractured or Absent Clavicle(s)

In the course of vaginal delivery, the clavicle may be fractured, resulting in asymmetry at the shoulder girdle area. Palpation of the clavicle may reveal a "drop-off" in the continuity of the bone and possible crepitation when gentle pressure is applied. A confirmatory radiograph should be taken and appropriate reassurance offered for the healing process. Much more rarely, clavicles may be absent bilaterally with resultant low positioning of the shoulders. This positioning may be indicative of the dominant genetic defect known as *cleidocranial dysostosis* and requires orthopedic and genetic evaluation.

Pectus Excavatum

Relative depression of the lower sternum and rib cage is usually a normal variant unless accompanied by signs of respiratory distress.

Xiphoid Process

Parents may feel a firm, small mass in the midline at the distal end of the sternum. This is the xiphoid process angled outwardly and is a normal variant.

Breast (See Chapters 11 and 84)

Supernumerary Nipples

A round, possibly slightly elevated or slightly depressed lesion, about 10 mm in diameter, lighter in shade than the nipple, and located about 2 to 3 cm below, is a supernumerary nipple. This is a normal variant and will remain permanently. Uncommonly, these may be associated with renal lesions, but that possibility need not be investigated in a child who is otherwise well.

Breast Buds

Prominent, nontender breast tissue in the neonate of either sex is a normal variant, probably related to maternal estrogen. This subsides with time, and no therapy is indicated. Often, colostrum-like material can be extruded, but efforts to do this should be gentle and conducted under hygienic conditions.

Breast Cellulitis/Abscess

Breast tissue that is hypertrophied, reddened, and tender is probably infected. The child may or may not be febrile. Warm compresses and intravenous antibiotic treatment, including coverage for probable staphylococcal origin, should be inaugurated after appropriate cultures are taken. The baby should be admitted for continuing therapy.

Absent

An absent nipple may be associated with an ipsilateral absent pectoralis muscle. Chest radiograph should be taken and the baby referred for genetic and orthopedic evaluation.

Spinal Column Defects

Spina Bifida

A grossly apparent spina bifida lesion, complete with lower-extremity flaccidity and meningeal extrusion in the midline of the back, obviously should not have been missed in the hospital nursery. The baby delivered at home, however, may be referred into the ED for initial management. Sterile, moist dressing should be applied and the baby admitted for neurosurgical, orthopedic, and urologic management. If the home delivery occurred under less than sterile conditions, cultures should be taken and inauguration of appropriate antibiotic therapy considered.

Sacral Dimple

A midline dimple of the lower back, with or without a tuft of hair, or a lipomatous intracutaneous or subcutaneous lesion in that area may be clues to the presence of spina bifida occulta, a less obvious form of spina bifida. This may or may not be associated with lower-extremity deformity. The dimple may also be the external manifestation of a sinus tract connecting to the intradural space without vertebral anomaly, which would leave the infants susceptible to meningeal infection. On the other hand, the dimple may be a normal skin indentation. An infant with an open lesion requires admission for further workup of the dimple. A closed lesion can be referred for further imaging studies, such as ultrasound or magnetic resonance imaging.

ABDOMINAL AND PERINEAL FINDINGS

The neonatal abdomen is full but is neither distended nor scaphoid. The liver is normally palpable 2 to 3 cm below the right costal margin; the spleen is not usually palpable; the lower edges of the kidneys may be felt with deep palpation.

There should be no palpable extraneous masses. Constipation, meconium passage, and vomiting are discussed in Chapters 13, 78, 99, and 121. This section discusses those external findings in the abdomen and perineum that might cause a parent to bring the new baby to the ED.

Umbilicus

The umbilical cord is tied or clamped at the time of delivery and usually sloughs off by the 10th day. Umbilical care consists of gentle hygienic measures and cleansing with isopropyl alcohol several times a day. Still, the umbilical area may be a source of concern for parents, who may appear in the ED with their neonate.

Discharge

Discharge from the umbilical area may occur and is benign if it is clear or yellow-tinged and thin. Reassurance and instruction in hygienic measures are all that is necessary. A thick, purulent discharge accompanied by intense redness and apparent tenderness is omphalitis, a serious bacterial infection with the potential to spread into the abdominal wall and systemically. The infant should be admitted, cultures from the blood as well as the discharge should be obtained, and the intravenous antibiotics should be administered.

Granuloma

Granulation tissue, lumped into a small ball about 1 cm across and attached in the umbilical area, can be cauterized with a silver nitrate stick. Extreme caution should be used when applying silver nitrate, as severe burns have resulted, requiring skin graft. The parents should be forewarned that the area will turn transiently black. Often, this treatment has to be repeated in a week or so.

Umbilical Hernia

Umbilical hernia is a result of incomplete merging of the recti muscles at the ring through which the cord had been protruding. It is often accompanied by a larger rectus diastasis extending superiorly, sometimes to as high as the xiphoid process. The size can vary from as little as a few millimeters to as much as 4 or 5 cm. It is covered by skin. With crying or straining, portions of the intestine and omentum can be palpated, but not visualized, within the hernia. No treatment is necessary in the neonatal period because these almost always close as the baby becomes ambulant and strengthens the rectus muscles. Abdominal bandages are unnecessary. Rarely, at a later age, an umbilical hernia may strangulate and require surgery.

Omphalocele

An omphalocele is essentially a large hernia into the base of the umbilical cord, but it is covered only by peritoneum, not skin. It contains a significant amount of intestine and, rarely, a lobe of the liver. The child should be admitted for early surgery.

Genital Area

The penis should be at least 1 cm in length, with a urethral opening at the tip. The testes are usually palpable within the scrotal sac. The labia majora overlie and cover the labia minora.

Vaginal Discharge and Bleeding (See Chapters 76 and 77)

White mucoid discharge, which may be thick, in the vaginal opening is a normal finding. Vaginal bleeding after the first day or two and during the first week is also a normal occurrence. It is the result of postpartum estrogen withdrawal.

Inguinal Mass

A mass palpable in the scrotum may be an inguinal hernia or a hydrocele or a combination of the two. Hernias are usually easily reducible in the neonate. Hydroceles are fluid-filled and transilluminate readily. A mass within the labia majora is most likely ovary or intestine that has passed through an inguinal hernia. These are somewhat more likely to incarcerate than hernias in males.

Hypospadias

When the urethral opening is not at the tip of the penis but on the glans, the baby has first-degree hypospadias. When the opening is on the shaft, it is second-degree and on the perineum, third-degree. Infants with second- and third-degree hypospadias should be referred for urologic evaluation and imaging of the genitourinary tract.

Ambiguous Genitalia

The possibility of ambiguous genitalia should be considered in a male neonate if the apparent penis is small and there is third-degree hypospadias with a cleft in the scrotum; in the female neonate, genitalia are ambiguous if there appears to be an unusually long clitoris with partial or complete fusion of the labia majora and if there is a firm mass in the labia. In the female neonate, but not in the male neonate, such pseudohermaphroditism may be associated with *congenital adrenal hyperplasia*, with or without "salt-losing" symptomatology (see Chapter 86). To establish gender identity and to evaluate for the possibility of congenital adrenal hyperplasia, electrolyte, imaging, and chromosomal studies need to be conducted early in the child's neonatal period under the supervision of a urologist and geneticist and possibly an endocrinologist.

Imperforate Anus

An imperforate anus may not be obvious on external examination. The finding of an anus located considerably more anteriorly than expected might suggest a fistula from the lower rectum to the skin, detouring around an imperforate anus. Meconium may actually pass through this fistula, simulating normal rectal passage. The area should be examined carefully, looking for the normal perianal-anal puckering, which will not be present if the anteriorly placed opening is a fistula. The rectal examination should be performed gently. Imaging studies and surgical referral should be considered.

ORTHOPEDIC CONCERNS

Most neonatal orthopedic problems are deformities secondary to intrauterine positioning. Some problems (e.g., metatarsus adductus) require only parental reassurance and expectant

management, whereas others (e.g., congenital clubfoot and hip dysplasia) require early orthopedic attention.

Developmental Hip Dysplasia

Developmental dysplasia of the hip (DDH) applies to a range of hip pathology, from instability to frank dislocation, that may either be present at birth or develop during infancy. With the baby in the supine position and with hips and knees slightly flexed, abduct both thighs simultaneously. If both knees can be brought to touch the examining table without undue pressure, there is no dysplasia of the hips.

The time-tested Ortolani and Barlow maneuvers also may be used in the neonatal period to evaluate for hip instability. Both tests are performed with the infant in a supine position and the hips and knees flexed to 90 degrees. Each leg is examined separately, not simultaneously. In the Ortolani maneuver, gentle abduction and lifting of the femoral head anteriorly produces a palpable "thunk" or "clunk" as the examiner relocates a dislocated hip. Nonpathologic processes such as ligamentous snapping can produce hip clicks that differ from the pathologic "clunk" associated with DDH. In the Barlow maneuver, the examiner attempts to dislocate the hip by gentle adduction and posterior axial pressure on the thigh. If in doubt, confirmatory ultrasound should be performed and orthopedic consultation obtained in a timely manner.

Intoeing

The differential diagnosis of intoeing is guided by the age at presentation. In the newborn period, the most common causes of intoeing are metatarsus adductus and clubfoot. *Metatarsus adductus* is a functional deformity, resulting from intrauterine positioning, in which the forefoot is in adduction with respect to the hindfoot. Most cases resolve spontaneously by 3 to 6 months of age. If the forefoot cannot be brought into the neutral position either by stroking the lateral border of the foot or by gently straightening it, referral to an orthopedic surgeon for cast correction is indicated.

Congenital clubfoot is a pathologic deformity consisting of three components: forefoot varus, heel varus, and ankle equinus. Clubfoot may either be an isolated deformity or seen in association with other neuromuscular anomalies such as arthrogryposis, cerebral palsy, myelomeningocele, or amniotic band syndrome. Orthopedic treatment should begin in the first week of life.

Brachial Plexus Injuries (See Chapter 35)

Lateral traction on the head and neck during delivery can result in injury to the brachial plexus. Clinical signs relate to the site of the traumatic injury. *Erb's palsy*, the most common birth injury of the brachial plexus, results from injury to the upper plexus affecting the C5 and C6 roots, the upper trunk, or its divisions. The affected arm is held with the shoulder adducted and internally rotated, the elbow in extension and pronation, and the wrist in flexion (waiter's tip posture). On examination, the Moro reflex (allowing the infant's head to drop back suddenly) is asymmetric. On the affected side, there is abduction and upward movement of the arms, followed by adduction and flexion. There is weakness of shoulder abduction, flexion, and supination; the biceps reflex is decreased; and there is slight weakness of wrist and finger extensors. In addition, when the C4 root is also involved, ipsilateral hemidiaphragmatic paralysis may be appreciated by ultrasound examination.

Klumpke's paralysis results from injury to the lower plexus, affecting the C8 and T1 roots, the lower trunk, or its divisions. The injury primarily affects the muscles of the hand. The infant presents with clawing of the affected hand [hyperextension at the metacarpophalangeal (MCP) joints and flexion of the interphalangeal joints], the elbow is held in flexion and the wrist is usually held in extension, unless there is injury to the middle trunk. On examination, the palmar grasp and the triceps reflex are decreased.

Treatment consists of immobilization and appropriate positioning to prevent contractures. Orthopedic referral is indicated.

NEUROLOGIC CONCERNS

Neonatal Seizures (See Chapters 69 and 96)

Neonatal seizures may be difficult to recognize clinically, because it is rare for newborns to have symmetric, generalized tonic-clonic convulsions. It is much more common to see seizure episodes that present as focal abnormalities or subtle findings. Subtle seizures can be difficult to distinguish from the normal spectrum of newborn behaviors, jitteriness, or benign myoclonic movements. Benign myoclonic movements are isolated jerky movements of an extremity that occur primarily during sleep. Jitteriness may be differentiated from seizures by its disappearance when the affected extremity is touched or held (Table 95.4).

Four clinical seizure types are recognized in the newborn (Table 95.5): subtle, tonic, clonic, and myoclonic. Generalized tonic-clonic seizures tend not to occur in the first month of life because the newborn's immature nervous system is unable to produce and sustain this type of activity. Not all neonatal seizure types are associated with electroencephalogram (EEG) seizure activity (Table 104.5). It has been hypothesized that these seizures may be originating from areas of the CNS that cannot be detected by surface electrodes (e.g., brainstem or spinal cord).

TABLE 95.4

CLINICAL DIFFERENTIATION OF NEONATAL SEIZURES FROM JITTERINESS

Clinical characteristic	Seizure	Jitteriness
Stimulus sensitive	No	Yes
Movement ceases with restraint	No	Yes
Accompanied by autonomic changes	Yes	No
Speed of movements	Slower	Faster
Abnormal eye movements	Common	No

TABLE 95.5

CLASSIFICATION OF NEONATAL SEIZURES

Seizure type	Electroencephalogram seizure correlation
Subtle	
Sucking or chewing motion	Uncommon[a]
Lip smacking	
Bicycling of legs	
Apnea	
Eyelid fluttering	
Eye deviations	
Laughter	
Tonic posturing	
Tonic	
Focal	Common
Generalized	Uncommon
Clonic	
Focal	Common
Multifocal	Common
Myoclonic	
Focal	Uncommon
Multifocal	Uncommon
Generalized	Common

[a]Except for tonic eye deviation, which often has an electroencephalographic correlation.

Subtle seizures, perhaps the most common type of neonatal seizures, are stereotypical repetitive movements such as eye blinking, eye deviations, chewing motions, lip smacking, and bicycling or pedaling movements. Most subtle seizures, especially in term infants, are not consistently associated with EEG seizure activity.

Focal *tonic seizures* present as sustained posturing of a limb, whereas generalized tonic seizures are characterized by either tonic extension of all extremities (simulating decerebrate posturing) or, less commonly, flexion of the upper extremities with extension of the lower extremities (simulating decorticate posturing). These seizures may be seen in association with severe hypoxic brain injury or with intraventricular hemorrhage, not uncommon in premature infants but may also be seen in term infants.

A *clonic seizure* involves rhythmic jerking of one or more parts of the body. Clonic seizures can be focal (affecting only one extremity or both the upper and lower extremities on one side of the body) or multifocal (clonic activity in one extremity that randomly migrates to another part of the body—e.g., left arm jerking followed by right leg jerking). Although focal clonic seizures can result from focal brain lesions, they can also be caused by a generalized metabolic disturbance such as hypoglycemia.

Benign myoclonic jerks are often noted in sleeping infants, especially premature infants, during the first 6 months of life. Unlike this benign sleep-related phenomenon, *myoclonic seizures* occur during waking and are single or repetitive rapid jerks of either the entire body or a particular extremity. They are distinguished from clonic seizures by their more rapid speed and a predilection for flexor muscle groups. These seizures usually indicate severe underlying brain pathology or injury such as hypoxic brain injury. Infants with these seizures may later develop infantile spasms. Focal myoclonic seizures typically involve the upper extremity. Multifocal myoclonic seizures are characterized by asynchronous twitching of several areas of the body, whereas generalized myoclonic seizures present as bilateral flexion jerks of the upper extremities and sometimes also the lower extremities.

Although there are a variety of causes for neonatal seizures (Table 95.6), only a few causes (perinatal asphyxia, intracranial hemorrhage, metabolic disturbances, and infection or malformations of the brain) account for most cases. Benign or idiopathic neonatal seizures occur, but this diagnosis should be made only after other causes are thoroughly investigated.

Perinatal asphyxia is the most common cause of neonatal seizures. During the first several days to weeks of life, signs of acute *hypoxic-ischemic encephalopathy (HIE)* are lethargy, hypotonia, and decreased spontaneous movements. Mild asphyxia is often marked by a transient state of hyperalertness and irritability. Seizures, if they occur, generally begin within the first 24 hours of life and may be difficult to control. The diagnosis of HIE should be strongly considered in a hypotonic infant with increased deep tendon reflexes.

Intracranial hemorrhage is the second most common cause of neonatal seizures. Intraventricular hemorrhages are seen primarily in premature infants, whereas subarachnoid or subdural hemorrhages are more likely in large, term infants and may be associated with birth trauma.

A variety of metabolic disturbances are associated with neonatal seizures. SGA infants and infants of diabetic mothers are at risk for hypoglycemia during the first 24 hours of life. These infants may have a variety of findings, ranging from jitteriness to seizures. Infants of diabetic mothers are also at risk for hypocalcemic seizures during the first 24 hours. Premature infants and infants with perinatal asphyxia are also at risk for early-onset (within the first 2 days of life) hypocalcemia. Late-onset hypocalcemic seizures (after day 2 to 3 of life) may be caused by an imbalance in dietary intake, hypomagnesemia, or hypoparathyroidism. Inborn errors of metabolism, pyridoxine dependence, and mitochondrial disorders are less common

TABLE 95.6

COMMON CAUSES OF NEONATAL SEIZURES BY GESTATIONAL AGE

First 24 h
Hypoxic-ischemic encephalopathy
Infection (meningitis, TORCHES infection, sepsis)
Direct drug effects (inadvertent anesthetic injection)
Metabolic (hypoglycemia, hypocalcemia)
Intracranial hemorrhage (preterm—intraventricular hemorrhage; term—subdural/subarachnoid hemorrhage)
Pyridoxine dependency

>24 h
Infection (meningitis, sepsis, herpes simplex virus)
Intracranial hemorrhage
Metabolic [inborn errors of metabolism, hypocalcemia (dietary)]
Intracranial malformations
Drug withdrawal

metabolic causes of seizures in the newborn. Inborn errors of metabolism should be suspected when seizures are associated with vomiting, failure to thrive, hepatomegaly, and altered tone or consciousness.

Several bacterial and viral CNS infections can cause seizures in the newborn. Common bacterial causes are group B *Streptococcus* and *Escherichia coli* infections. HSV encephalitis is an important viral source that must be considered. A newborn with a history of a seizure associated with fever requires a comprehensive evaluation for the cause and should not be diagnosed with simple febrile seizures.

The evaluation of newborn seizures should include a detailed history of prenatal, perinatal, and postnatal events. The examination should be directed toward identifying treatable causes, such as infectious or metabolic disturbances. Minimal laboratory evaluation for all newborns with seizures includes a CBC; both rapid bedside and laboratory measurement of serum glucose level; serum electrolytes level, including calcium, phosphorus, and magnesium; blood culture; and cerebrospinal fluid analysis and culture. Cranial ultrasound is especially useful in identifying suspected intraventricular hemorrhages. Measurements of serum ammonia, serum amino acids, and urine organic acids levels should be obtained if a metabolic defect is suspected. Urine testing with the Clinitest reagent (detects excess excretion of both galactose and glucose) can screen for galactosemia.

Appropriate *medical management* includes early correction of metabolic abnormalities and consideration of empiric antibiotic therapy. If the results of serum glucose and calcium measurements will not be available in a timely manner, empiric chemical therapy may be instituted if the infant is actively seizing. Hypoglycemia (serum glucose level less than 40 mg per dL) is treated with a 5 to 10 mL per kg bolus over 20 minutes of a 10% dextrose solution. More concentrated forms of dextrose (25% or 50%) should be avoided to prevent sclerosis to infant peripheral veins. Treat symptomatic hypocalcemia (serum calcium level less than 8 mg per dL) with 100 to 200 mg per kg (1 to 2 mL per kg) of elemental calcium as a 10% calcium gluconate solution further diluted by slow intravenous drip.

For seizures, empiric anticonvulsant therapy may be instituted while awaiting consultation with a neurologist. Subtle seizures or patients who present with a history of seizure but a normal neurologic examination should not be treated with anticonvulsants before consultation. The anticonvulsant of choice for neonates is lorazepam, given intravenously at a dose of 0.1 mg per kg. Intramuscular administration can be considered, although absorption and clearance are more erratic. Diazepam may alternatively be used at a dose of 0.05 to 0.25 mg per kg. Careful monitoring of cardiorespiratory status and avoidance of hypoxia are essential at presentation and during therapy. Phenobarbital 10 to 20 mg per kg is the secondary drug of choice if the seizure persists beyond the second dose of benzodiazepine. Alternatively, phenytoin or fosphenytoin may be added although the kinetics are notoriously unpredictable. If the infant continues to actively seize, a trial of pyridoxine (50 to 100 mg intravenously) may be considered. If a second agent is required, particularly phenobarbital, significant respiratory depression must be considered and preparation to provide airway support with endotracheal intubation should be made.

Hypotonic Infant (See Chapter 96)

A healthy term newborn normally moves his or her extremities spontaneously and has a dominance of flexor tone. Compared with the term *newborn's tone*, the premature infant's tone is relatively hypotonic, so corrected gestational age must be taken into consideration during evaluation.

Decreased spontaneous movements, poor head and trunk control, and a preponderance of extensor tone are all characteristics of the hypotonic infant. The healthy, term newborn when supported by the trunk in an outstretched prone position, also known as *ventral suspension*, will flex all extremities against gravity, keep the back straight, and support the head in a neutral position with relation to the rest of the body. In the hypotonic and preterm infant, the forces of gravity may allow the back and head to droop downward and the extremities to hang in extension. When held by the axillae in vertical suspension, the hypotonic infant will "slip through" the hands of the examiner instead of reflexively flexing the upper extremities to maintain position. Because weakness is often associated with hypotonia, the newborn may present with resultant weak cry, poor suck, or respiratory effort. Weakness should also be suspected if the infant does not briskly withdraw a limb that is subjected to a forceful stimuli.

The causes of hypotonia depend on the level of the nervous system that is affected (Table 95.7). Motor dysfunction at any level from the CNS to the muscle itself may result in hypotonia. Central hypotonia involves pathology of the cerebral cortex down to the level of the lower motor neuron or can be caused by systemic disease affecting motor function. Neuromuscular disease can be caused by dysfunction at any of four anatomic sites: anterior horn cell (lower motor neuron), peripheral nerve, neuromuscular junction, and muscle.

Central Hypotonia

If muscle weakness is not a significant accompanying feature, a central source for the hypotonia should be considered. Features characteristically associated with central hypotonia include a decreased level of alertness, seizures, and a weak cry; muscle bulk is normal, and deep tendon reflexes are either normal or increased. Perinatal asphyxia and intracranial hemorrhage are the two most common CNS causes of hypotonia that presents in the neonatal period. Depressive symptoms are usually present during the first 1 to 2 days of life in these conditions. An infant who is normal at birth and then develops lethargy, hypotonia, vomiting, or seizures at several days of age after ingestion of milk protein and carbohydrate may have an inborn error of metabolism (Chapter 94). Metabolic diseases should always be taken into consideration in the evaluation of the hypotonic infant, especially when the clinical presentation does not readily fit into any distinct diagnosis. Occasionally, unusual odors (Chapter 46) of the infant or urine are noted (e.g., mustiness—phenylketonuria, sweaty feet—isovaleric acidemia, maple syrup—maple syrup urine disease).

Disorders of the Lower Motor Neuron

Disorders of the lower motor neuron are characterized by hypotonia, muscle weakness, and hypoactive to absent deep tendon reflexes in an otherwise alert infant. Spinal muscular

TABLE 95.7

DIFFERENTIAL DIAGNOSIS OF NEONATAL HYPOTONIA

Central Nervous System Disease
Perinatal asphyxia (hypoxic-ischemic encephalopathy)
Intracranial hemorrhage
Infection
Hyperbilirubinemia
Neonatal drug withdrawal
Metabolic diseases
  Organic and aminoacidemias
  Hypercalcemia
Chromosomal abnormality
  Down syndrome
  Prader–Willi syndrome

Neuromuscular Disease
Anterior horn cell diseases (lower motor neuron)
  Type I spinal muscular atrophy (Werdnig–Hoffman disease)
  Neonatal poliomyelitis
  Type II glycogen storage disease (Pompe's disease)
Peripheral nerve diseases
  Leukodystrophies
  Guillain–Barre syndrome
Neuromuscular junction diseases
  Infantile botulism
  Neonatal myasthenia gravis (congenital or acquired transient myasthenia)
Muscle diseases
  Congenital myopathies
  Mitochondrial myopathies
  Glycogen storage disease
  Hypothyroidism

atrophy (Werdnig–Hoffman disease) is the most common of the lower motor neuron diseases. In the classic, early-onset form of the disease, infants may present at birth or during the first several weeks of life with generalized weakness, absent deep tendon reflexes, muscle atrophy, fasciculations, and cranial nerve abnormalities, including disordered sucking and swallowing. Infants have a characteristic posture with flaccid tone, abducted limbs, and little spontaneous movement. Respiratory distress may be present. The disease is unfortunately rapidly progressive, and death usually occurs in most patients by 3 years of age.

Disorders of the Neuromuscular Junction

Disorders of the neuromuscular junction are important to recognize because supportive and therapeutic interventions are available. Infants with neuromuscular disorders have hypotonia and weakness like infants with lower motor neuron disease, but infants with neuromuscular disease have normal muscle bulk and normal deep tendon reflexes. Infantile botulism (see Chapter 92) is a toxic abnormality of the neuromuscular junction that is seen in infants younger than 12 months. It is caused by the ingestion of *Clostridium botulinum* spores (from soil, honey, or corn syrup), which germinate in the gastrointestinal tract and produce botulinum toxin. Early symptoms include constipation and poor feeding as a result of poor sucking and swallowing. A descending paralysis develops over the next several days, with development of ptosis, loss of head control, weak cry, flat facial expression, and eventually, generalized hypotonia. Treatment with botulinum antitoxin should be considered. Supportive nutritional and electrolyte care are essential; ventilatory support may be required for respiratory failure.

Disorders of Muscle

A variety of primary muscle disorders may present during the neonatal period, with the nonspecific features of hypotonia, weakness, decreased muscle bulk, and normal to decreased deep tendon reflexes. Metabolic myopathies are caused by abnormal energy metabolism in the muscle and include disorders of the mitochondria and carnitine metabolism. A mitochondrial myopathy should be considered in a hypotonic infant with lactic acidosis.

Laboratory evaluation of hypotonia is guided by the level of the nervous system believed to be affected. If CNS disease is suspected, brain imaging, an EEG, and endocrine and metabolic determinations may be appropriate. When neuromuscular disease is suspected, muscle enzyme determinations, nerve conduction velocities, electromyography, and nerve or muscle biopsies can be conducted on a scheduled basis.

Most importantly, it is essential to consider the possibility that hypotonia is really lethargy related to shock or sepsis.

Neonatal Screening

Screening for congenital metabolic disorders through tandem mass spectrometry has significantly increased the number of patients diagnosed with these disorders. This technology is now available in 47 states. Tandem mass spectrometry detects amino acid and urea cycle disorders, fatty acid oxidation disorders, and organic acid disorders. Blood samples are generally taken prior to discharge from the nursery and become available in the first 2 weeks of life. States require physician notification of positive screening results. Families may be directed to the ED (or they may come of their own volition) upon notification of a positive newborn screen. Confirmatory testing and disposition should be performed in conjunction with the designated metabolic specialist and/or referring physician.

CONGENITAL INFECTIONS

There are a group of transplacentally transmitted congenital infections, often referred to jointly by the acronym TORCHES, which vary in their postpartum presentation according to the time during the pregnancy when they were acquired and with the intensity of the inoculum. These include toxoplasmosis, rubella, cytomegalovirus, herpes virus infections (herpes simplex and varicella), and syphilis.

Fetal infection with these agents acquired in midpregnancy may result in a neonate born with a complex of findings that may include low birth weight or SGA; jaundice, purpura, and thrombocytopenia; hypotonia; microcephaly;

cataracts; microphthalmia; chorioretinitis; hepatosplenomegaly; intracerebral calcifications; congenital heart disease; hypoplastic limbs; hearing loss; cicatricial scarring of the skin; and seizures. Obviously, not all, not even most, of these findings will be present in any one affected infant, but their presence should at least arouse suspicion for the TORCHES syndrome.

Clinically, it is often difficult to distinguish one of these infections from the other. Rubella is more likely to be associated with cataracts and cardiac lesions; toxoplasmosis with chorioretinitis and cerebral calcifications; herpes simplex and varicella with vesicular or cicatricial skin lesions; cytomegalovirus with hearing loss; and syphilis with bone lesions, snuffles, and palm and hand bullae. However, symptoms overlap. The essentials in management include a careful maternal history and appropriate serologic testing and culturing of both mother and infant.

The clinician should keep in mind the possibility, however, that aspects of this symptom complex, particularly purpura and jaundice in a hypotonic baby, may be associated with an active acute septic infection.

Infants may acquire human immunodeficiency virus (HIV) vertically from mothers transplacentally, through delivery, or through breast-feeding. At birth, infants may test negative for infection by traditional assays and may not appear ill. Infected infants commonly have no symptoms. Symptomatic infants may have failure to thrive, recurrent thrush, hepatosplenomegaly, lymphadenopathy, diarrheal illness, or recurrent lower respiratory tract infections. Chapter 93 describes the care of HIV-infected children in detail.

NEONATAL DRUG WITHDRAWAL

Maternal substance abuse during pregnancy places the newborn at risk for a variety of medical, developmental, behavioral, and psychosocial problems. The particular effects on the newborn infant depend on the type of drug or drugs, the timing of the exposure during gestation, and the frequency of the exposure. In addition to illicit drugs, many infants are exposed to cigarettes and alcohol.

- *Narcotics:* Prenatal exposure to heroin and methadone results in physiologic addiction in the newborn. The symptoms of withdrawal are nonspecific and may not be detected in the newborn nursery, especially when the maternal history of drug abuse is unknown or when the infant is discharged home within 24 hours of delivery. Narcotic antagonists such as naloxone may precipitate withdrawal and should be avoided at the time of delivery. Heroin has a short serum half-life, so clinical signs of withdrawal are generally apparent on the first day of life, whereas clinical signs of methadone withdrawal seldom occur before 24 to 48 hours of age because of its longer half-life. Symptoms of narcotic withdrawal include irritability, jitteriness, tremors, seizures, disorganized suck and poor feeding, vomiting, diarrhea, sweating, and sneezing. Additional signs of withdrawal that may be noted in the older infant include failure to gain weight and abraded marks along the nose, shins, or occiput caused by the infant's tremulousness and irritability.
- *Cocaine:* In utero cocaine exposure has been associated with an increased incidence of abruptio placentae, low birth weight, and preterm delivery. Classically, the cocaine-exposed infant is not so much jittery as he or she is disorganized in sleeping and feeding. These infants are lethargic and poorly responsive but are easily overstimulated and become irritable when awake, making feeding a challenge for many of them. Gavage feeding may be necessary in some instances. Any history of feeding intolerance, vomiting, or abdominal distension needs to be investigated because necrotizing enterocolitis has been noted in term, cocaine-exposed infants. Stool occult blood may be positive, secondary to bowel necrosis caused by the vasoconstrictive actions of cocaine. Small CNS bleeds have been described in the basal ganglia and frontal lobes.
- *Amphetamines:* Methamphetamine-exposed infants are often described as being too quiet and may need to be awakened regularly for feedings. Prolonged sleep, depression, and voracious appetite when awakened are characteristic of amphetamine withdrawal. Infants born to methamphetamine-abusing mothers are frequently born small for gestational age and are at increased risk for future neurodevelopmental problems.
- *Selective serotonin reuptake inhibitors* (SSRIs), commonly used for maternal depression, readily cross the placenta and can cause a neonatal withdrawal or discontinuation syndrome in infants exposed during the third trimester in utero. Although SSRIs do not appear to increase teratogenic risk, there have been several reports of neonatal complications, possibly caused by their common discontinuation syndrome. Symptoms, including irritability, constant crying, shivering, increased tone, eating and sleeping difficulties, and seizures, have been noted within a few days after birth and lasting up to 1 month after birth.

Evaluation

In general, toxicologic screening can be performed on infants on medical grounds without parental consent. Metabolites of cocaine can be detected for 1 to 2 days after use in the adult and 5 to 7 days in the newborn; amphetamine is present for 1 to 2 days in the adult; and marijuana can be detected in the urine for up to 7 days after use. Most urine toxicology screens use immunoassays and are inexpensive and sensitive but not specific (e.g., antihistamines can cross-react with amphetamines). Using infant hair or meconium samples to check for the presence of illicit drugs, especially cocaine, provide a broader window on drug use during pregnancy and are able to document the presence of drugs in the time before delivery.

The *Neonatal Abstinence Score* (NAS) developed by Finnegan is an objective way of assessing the severity of narcotic withdrawal symptoms (Table 95.8). Infants should be scored at 4-hour intervals for the first several days of life. Three consecutive scores higher than 8 or two scores higher than 12 are an indication for pharmacologic therapy. The NAS can also be used to guide effectiveness of pharmacologic therapy.

Management

Swaddling and minimizing sensory stimulation are two of the simplest and most effective techniques in managing neonatal

TABLE 95.8

NEONATAL ABSTINENCE SCORE

Signs and symptoms	Score
Central Nervous System	
High-pitched cry (excessive or continuous)	2 or 3
Sleeps <1, 2, or 3 h after feeding	3 or 2 or 1
Moro reflex (hyperactive or significantly hyperactive)	2 or 3
Tremors when disturbed (mild or moderate to severe)	1 or 2
Tremors undisturbed (mild or moderate to severe)	3 or 4
Increased muscle tone	2
Excoriations	1
Myoclonic jerks	3
Generalized convulsions	5
Vasomotor/Respiratory	
Sweating	1
Fever (99–101°F or >101°F; 37.2–38.3°C)	1 or 2
Frequent yawning (>3–4 times/interval)	1
Mottling	1
Nasal stuffiness	1
Sneezing (>3–4 times/interval)	1
Nasal flaring	2
Respiratory rate (>60/min or >60/min with retractions)	1 or 2
Gastrointestinal	
Excessive sucking	1
Poor feeding	2
Regurgitation or projectile vomiting	2 or 3
Stools (loose or watery)	2 or 3

Modified from Finnegan LP. Neonatal abstinence. In: Nelson NM, ed. *Current therapy in neonatal-perinatal medicine*. Philadelphia, PA: BC Decker, 1990:314–320.

drug withdrawal. A blanket or sheet can be draped over the infant's bed to minimize light exposure. Often, these infants do well when placed in a "snugly or front pack" over the mother's chest and abdomen. The mother's regular, monotonous cardiorespiratory sounds can be soothing. Demand feeding with hypercaloric formula (24 to 27 cal per oz) may be necessary to maintain weight.

Indications for pharmacologic therapy for neonatal abstinence syndrome are seizures, poor feeding, diarrhea and vomiting resulting in excessive weight loss and dehydration, irritability interfering with sleeping or feeding, and hypothermia or hyperthermia. Other causes of these symptoms, such as infection, hypoglycemia, hypocalcemia, hypomagnesemia, hyperthyroidism, CNS hemorrhage, and anoxia must be excluded before initiating treatment. Benzodiazepines for alcohol withdrawal and methadone for opioid withdrawal are the only agents approved by the U.S. Food and Drug Administration for the treatment of drug withdrawal. However, several agents, such as tincture of opium, paregoric, morphine, clonidine, phenobarbital, chlorpromazine, and diazepam, have shown favorable effectiveness in neonatal narcotic withdrawal. Infants presenting with neonatal abstinence syndrome to the ED should be admitted for stabilization and initiation of pharmacologic therapy.

Prognosis

Drug-exposed infants are at increased risk for abuse and neglect because of a combination of environmental (chaotic family environments, limited financial resources, and limited parenting skills because of the impact of the substance abuse) and infant risk factors (poor attachment, high-pitched cry, irritability, difficult to console, and poor feeding).

ACKNOWLEDGMENT

The authors thank Dr. Geeta Grover, MD, Behavior/Developmental Department, Children's Hospital of Orange County, California, for essential contributions to this chapter.

CHAPTER 96 ■ NEUROLOGIC EMERGENCIES

MARC H. GORELICK, MD, MSCE, AND CHARLES D. BLACKWELL, MD

Signs and symptoms of neurologic dysfunction in children either are produced by primary nervous system disorders or are secondary to systemic disease. The differential diagnosis of many such neurologic findings can be found in the second section of this book (Chapters 10, 12, 20, 26, 55, 69, and 73). This chapter focuses on the management of conditions primarily involving the various parts of the nervous system, including the brain, spinal cord, and peripheral nerves. The illnesses are classified by their most prominent clinical manifestations: seizures, altered mental status, headache, weakness, disorders of balance, abnormal movements, and cranial nerve dysfunction.

SEIZURES (SEE ALSO CHAPTER 69)

Seizures are among the more common neurologic symptoms that lead to an emergency department (ED) visit. Epidemiologic studies indicate that from 3% to 6% of children will have at least one seizure in the first 16 years of life; most of these are simple febrile seizures, discussed in the following section. Fortunately, recurrent seizures or other signs of neurologic dysfunction occur in only a small number of these children. However, the first seizure is always frightening and produces anxiety.

A *seizure* is defined as a transient, involuntary alteration of consciousness, behavior, motor activity, sensation, and/or autonomic function caused by an excessive rate and hypersynchrony of discharges from a group of cerebral neurons. The term *convulsion* is often used to describe a seizure with prominent motor manifestations. *Epilepsy*, or seizure disorder, is a condition of susceptibility to recurrent seizures.

Most seizures are brief, lasting for less than 10 to 15 minutes. *Status epilepticus (SE)* refers to seizures that are continuous for 30 minutes or longer or to repetitive seizures between which the patient does not regain consciousness. Many authorities now consider that seizures lasting for longer than 5 minutes or multiple seizures with no return to baseline in between constitute early SE.

Pathophysiology

The basic pathophysiologic abnormality common to all seizures and convulsions is the hypersynchrony of neuronal discharges. Many precipitating factors, including metabolic, anatomic, and infectious abnormalities (see Chapter 69), may produce seizures. Seizures that result from an identified precipitant are called *symptomatic*, or provoked, *seizures*, whereas those with no precipitating factor are called *idiopathic* or *cryptogenic*. Febrile seizures (seizures occurring in association with a febrile illness, without evidence of intracranial infection or other identified cause) are a particular type of provoked seizure seen in children between the ages of 6 months and 6 years. The exact cause of febrile seizures remains elusive. Elevated body temperature lowers the seizure threshold, and the immature brain appears to have a particular susceptibility to seizures in response to fever. It is unclear whether height of fever or rate of temperature rise is more important in inducing febrile seizures, but individual predisposition plays an important role.

During a seizure, cerebral blood flow, oxygen and glucose consumption, and carbon dioxide and lactic acid production increase. If the patient remains well ventilated, the increase in cerebral blood flow is sufficient to meet the increased metabolic requirements of the brain. Brief seizures rarely produce lasting deleterious effects on the brain; however, prolonged and serial seizures, especially SE, may be associated with permanent neuronal destruction.

Clinical Manifestations

When the physician is examining a child with an acute paroxysmal event, the first step is to distinguish seizures from other nonepileptic phenomena. If the event is indeed a seizure, it may be classified according to type. Finally, a specific causative factor should be sought. The extent of the emergency evaluation is determined by the clinical scenario; some of the diagnostic assessment may be deferred. Of course, when a child is actively seizing, the first priority is to provide necessary resuscitation measures and control the seizures (see Chapter 69 and the following sections).

Nonepileptic Paroxysmal Events

Paroxysmal events other than seizures that involve changes in consciousness or motor activity are common during childhood and may mimic epilepsy (Tables 69.2 and 96.1). Breath-holding spells occur in children 6 months to 4 years of age. Breath-holding spells take two forms: cyanotic and pallid. In the cyanotic form, the infant begins crying vigorously, often in response to an inciting event, then holds his or her breath and becomes cyanotic. After approximately 30 to 60 seconds, the child becomes rigid. As the spell ends, the child becomes limp and may have a transient loss of consciousness and twitching or jerking of the extremities, but the child quickly returns to full alertness. A pallid breath-holding spell may follow a seemingly insignificant trauma. The child may start to cry, but then turns pale and collapses. There is a brief period of apnea and limpness, followed by rapid recovery. In both types of

TABLE 96.1

NONEPILEPTIC EVENTS THAT MAY MIMIC SEIZURES

Breath-holding spells
Syncope
Migraine
Jitteriness
Benign myoclonus
Shuddering attacks
Tics
Acute dystonia
Gastroesophageal reflux
Night terrors
Sleep paralysis
Narcolepsy
Pseudoseizures

breath-holding spells, the typical history and lack of postictal drowsiness help determine the diagnosis. Breath-holding spells may be recurrent but disappear spontaneously before school age.

Syncope is a brief, sudden loss of consciousness and muscle tone. There are numerous causes of syncope, many of which can be detected on the basis of historical information, physical examination, and simple laboratory tests (see Chapter 73). A syncopal episode can usually be distinguished from a seizure on the basis of the description. The child is typically upright before the event and often senses a feeling of light-headedness or nausea. The child then becomes pale and slumps to the ground. The loss of consciousness is brief, and recovery is rapid. On awakening, the child is noted to have signs of increased vagal tone, such as pallor, clammy skin, dilated pupils, and relative bradycardia. Patients with narcolepsy also experience sudden alterations in alertness, with sleep occurring suddenly and uncontrollably during the daytime. In about half of the patients, narcolepsy is associated with cataplexy, an abrupt loss of muscle tone brought on by a sudden emotional outburst. Narcolepsy is far less common than syncope; both occur more often in adolescents than in younger children.

Single episodes of staring, involuntary movements, or eye deviation have been found to occur commonly in the first months of life, although they rarely lead to the parent seeking medical attention. In some children, however, these episodes occur frequently. Children with benign shuddering attacks have episodes of staring and rapid tremors involving primarily the arms and head, sometimes associated with tonic posturing. The episode lasts only a few seconds, and afterward, the child resumes normal activity. Acute dystonia, usually seen as a side effect of certain medications, can mimic a tonic seizure. The child having a dystonic reaction, however, does not lose consciousness and has no postictal drowsiness.

Several paroxysmal events are associated with sleep. Night terrors (see Chapter 131) usually begin in the preschool years. The sleeping child wakes suddenly, is confused and disoriented, and appears frightened, often screaming and showing signs of increased autonomic activity (tachycardia, tachypnea, sweating, dilated pupils). Such episodes typically last only a few minutes, and the child does not usually recall the event. Benign myoclonus is characterized by self-limited episodes of sudden jerking of the extremities, usually upon falling asleep. There is no alteration of consciousness. In sleep paralysis, there is a transient inability to move during the transition between sleeping and waking, also with no change in the level of consciousness.

Pseudoseizures are occasionally seen, often in patients with an underlying seizure disorder or with a relative with epilepsy. Some features suggestive of pseudoseizures are suggestibility; lack of coordination of movements; moaning or talking during the seizure; lack of incontinence, autonomic changes, or postictal drowsiness; and poor response to treatment with anticonvulsant agents.

The most important diagnostic test in distinguishing nonepileptic events from seizures is a careful history, including a detailed description of the event from the person who witnessed it. In atypical or unclear cases, referral for electroencephalogram (EEG) or video EEG monitoring may help in establishing the diagnosis.

Types of Seizures

Clinically, seizures may be divided into partial and generalized seizures (Table 96.2). Generalized tonic-clonic seizures (previously called *grand mal seizures*) are the type most often seen in acute pediatric care. The onset of generalized tonic-clonic seizures is usually abrupt, although 20% to 30% of children may experience a sensory or motor aura. If sitting or standing, the child falls to the ground. The face becomes pale, the pupils dilate, the eyes deviate upward or to one side, and the muscles contract. As the increased tone of the thoracic and abdominal muscles forces air through the glottis, a grunt or cry may be heard. Incontinence of urine or stool is common. After this brief tonic phase (10 to 30 seconds), clonic movements occur. The child is unresponsive during the seizure and remains so postictally for a variable period. After the seizure, there may be weakness or paralysis of one or more areas of the body (Todd's paralysis). In atonic, or akinetic, seizures (drop attacks), there is abrupt loss of muscle tone and consciousness. *Myoclonic seizures* are characterized by a sudden dropping of the head and flexion of the arms (jackknifing); however, extensor posturing may also occur. The episodes occur quickly and frequently, as often as several hundred times daily.

Absence (petit mal) seizures are generalized seizures, marked by sudden and brief loss of awareness, usually lasting 5 to 30 seconds. With typical absence seizures, there is no loss

TABLE 96.2

SEIZURE TYPES

Generalized	Partial (focal)
Absence (petit mal)	Simple (no impaired consciousness)
Typical	Motor
Atypical	Sensory
Tonic-clonic (grand mal)	Autonomic
Clonic	Psychic
Tonic	Complex (impaired consciousness)
Myoclonic	Partial seizures becoming partially generalized
Akinetic/atonic (drop attacks)	

of posture or tone and no postictal confusion. There may be a minor motor component such as eyelid blinking.

The child with simple partial (focal) seizures has unimpaired consciousness. Motor signs are most common in children, although sensory, autonomic, and psychic manifestations are possible. The motor activity usually involves the hands or face and spreads in a fixed pattern determined by the anatomic origin of the nerve fibers that innervate the various muscle groups. Focal seizures may become secondarily generalized, in which case there will be alteration of consciousness. Complex partial seizures, also called *psychomotor* or *temporal lobe seizures*, exhibit a diverse set of clinical features, including alterations of perception, thought, and sensation. In children, they are usually marked by repetitive and complex movements with impaired consciousness and postictal drowsiness.

Establishing an Underlying Cause

The first steps in the evaluation of seizures are a thorough history and a physical examination, the results of which are helpful in determining the direction of the search for a specific cause (see Table 69.1 and Fig. 69.1). Important historical items to elicit include fever, trauma, underlying illnesses, current medications, and possible toxic ingestions. A complete neurologic assessment to evaluate for signs of increased intracranial pressure (ICP), focal deficits, or signs of meningeal irritation is also essential.

An important distinction is whether the seizure is associated with fever. Simple febrile seizures are those that are single, brief (lasting less than 15 minutes), and generalized. Approximately 20% of febrile seizures are complex, meaning they are focal, are prolonged (last for more than 15 minutes), or occur multiple times during the same illness. In children older than 12 months with a typical simple febrile seizure and no evidence of meningeal signs, no further evaluation of the seizure is generally required. However, lumbar puncture (LP) is mandatory if meningitis is suspected on the basis of physical findings. An LP should be considered in children younger than 12 months, in whom signs of meningitis may be subtle, such as irritability and poor feeding, when the febrile seizure is complex, or if there has been pretreatment with antibiotics. In addition, LP should be considered for children with prolonged fever before the seizure, particularly those who have sought medical care in the previous 48 hours, as a prior visit is associated with a higher risk. Other laboratory tests discussed in the next paragraph have been found to have little yield in the child with a typical febrile seizure and are unnecessary. Appropriate diagnostic tests to determine the source of the fever are determined by other features such as the intensity of fever and child's age, because the frequency of specific infections such as occult bacteremia is not increased in children who have experienced a febrile seizure.

For the child who presents with a first-time, nonfebrile seizure, laboratory or radiologic evaluation to search for a specific treatable cause of the seizure may be indicated. There is little utility in extensive, routine workups; rather, ancillary test selection should be guided by the results of the history and physical examination. In young infants, children with prolonged seizures, and those with a suggestive history or physical examination, determination of serum glucose, sodium, and calcium levels is indicated. Other ancillary tests that may be indicated, depending on the clinical picture, include serum magnesium, hepatic transanimases, ammonia, serum or urine toxicology tests, electrocardiogram (EKG), and computed tomography (CT) scan of the brain. LP is rarely emergently necessary in the afebrile child without meningeal signs, although it should be considered in neonates even without fever.

In children with a known seizure disorder, subtherapeutic anticonvulsant levels are the most common reason for recurrent seizures. The name and dosage of anticonvulsant medications used should be elicited, as well as the time of the last dose given, any missed doses, the last change in dosage, and recent levels if known. Intercurrent illness may also play a role because the metabolism of some medications is affected by systemic illness. Such children should have blood drawn for measurement of anticonvulsant levels. Although many drugs have a standard therapeutic range (Table 96.3), individual patients may require levels outside that range for adequate seizure control; conversely, dose-dependent toxic effects may be observed in some children even at typically therapeutic levels.

CT and magnetic resonance imaging (MRI) allow detailed visualization of the gross anatomy of intracranial structures by a noninvasive technique. Presently, CT is more available on an emergent basis in most institutions. It is also a shorter procedure, and patient monitoring is usually easier. CT (or MRI, if available) is indicated in the emergency evaluation of prolonged or focal seizures, when focal deficits are present, when there is a history of trauma, when the child has a ventriculoperitoneal shunt, or when there are associated signs of increased ICP. For other children, an imaging study may be useful in identifying structural anomalies and determining prognosis, but such studies may be deferred to a follow-up visit. Cranial imaging is not indicated in the evaluation of simple febrile seizures.

EEG is also helpful in the evaluation of children with nonfebrile seizures. It is rarely beneficial in acute management, but children with nonfebrile seizures should be referred for outpatient testing.

Management

Resuscitation and Supportive Care

The administration of nasal oxygen and maintenance of an adequate airway are vital parts of the initial management of the unconscious, actively convulsing child (see Chapter 69). Trismus often occurs in generalized seizures but is transient. If the teeth are tightly clenched, even the placement of the airway should be deferred until it can be inserted without undue trauma during a phase of relaxation. Seizure-associated hypoventilation and apnea are common with prolonged seizures, often as a side effect of anticonvulsant medications, and providers caring for such children should be prepared to offer assisted ventilation. Intravenous (IV) access should be established promptly; however, because of the potential for increased ICP, fluid therapy should be used judiciously until a more thorough evaluation is performed. The child with active convulsions should be protected from trauma. There is no benefit of placing objects in the child's mouth to prevent tongue biting.

TABLE 96.3

COMMONLY USED ANTICONVULSANT AGENTS

Drug	Seizure type	Daily dose (mg/kg)	Oral dosage forms	Serum half-life (h)	Therapeutic blood levels (μg/mL)
Carbamazepine (Tegretol)	Generalized motor, partial, complex partial	10–30	Tablets: 100, 200 mg Suspension: 100 mg/5 mL	8–24	4–12
Phenytoin (Dilantin)	Generalized motor, partial, complex partial	3–10	Capsule: 100 mg Chewable tab: 50 mg Suspension: 125 mg/5 mL	10–36	10–20
Phenobarbital	Generalized motor, partial, complex partial	3–6	Tablets: 15, 30, 60, 100 mg Elixir: 20 mg/5 mL	24–96	15–40
Valproate (Depakote)	Absence, myoclonic, partial complex, generalized motor	20–40	Tablets: 125, 250 mg Sprinkles: 125 mg Syrup: 250 mg/5 mL	6–18	50–100
Ethosuximide (Zarontin)	Absence	20–40	Capsule: 250 mg Syrup: 250 mg/5 mL	20–60	40–100
Lamotrigine (Lamictal)	Partial, atonic, myoclonic, mixed types	10–15	Tablets: 25, 100, 150 mg	24	1–5
Clonazepam (Klonopin)	Atonic, myoclonic, generalized motor	0.05–0.2	Tablets: 0.5, 1, 2 mg	18–50	0.02–0.08 (20–80 ng/mL)
Topiramate (Topamax)	Partial, Lenox–Gastaut syndrome	6–15	Tablets: 25, 100, 200 mg	19–23	Not known
Oxcarbazepine (Trileptal)	Partial	10–40	Suspension: 300 mg/5 mL Tablets: 150, 300, 600 mg	9	Not known
Tiagabine (Gabritril)	Partial	Not established for <12 yr	Tablets: 2, 4, 12, 16 mg	2–10	Not known
Gabapentin (Neurontin)	Partial, generalized	25–35	Solution: 250 mg/5 mL Tablets: 600, 800 mg Capsules: 100, 300, 400 mg	5	Not known

Stopping the Seizure

It is unusual for the child with a brief seizure to arrive in the ED actively convulsing because, by definition, such seizures last for less than 15 minutes. Therefore, the actively convulsing child is usually already in a prolonged or serial seizure state, and pharmacologic intervention to terminate the seizure is required (Fig. 96.1).

IV access is established, and blood is drawn for diagnostic studies. If hypoglycemia is documented by rapid glucose assay or if rapid determination is unavailable, IV glucose is given most commonly in a dose of 2 to 4 mL per kg of 25% dextrose in water, although 10% and 50% glucose in equivalent doses may also be used (D10W should be used in infants). In neonates or in children with suspected isoniazid toxicity, IV pyridoxine 100 mg may be administered.

In most situations, benzodiazepines are the first drug of choice for acute seizures because of their rapidity of action. Lorazepam (Ativan) is the historically preferred agent. Given in a dose of 0.05 to 0.1 mg per kg IV (usual maximum 4 mg per dose), it has an onset of action of 2 to 5 minutes, and the duration of anticonvulsant effect is 12 to 24 hours. The dose may be repeated after 5 to 10 minutes. An alternative is diazepam (Valium), 0.2 to 0.4 mg per kg IV (usual maximum 10 mg per dose), which has a similarly rapid onset of action but a much shorter duration of anticonvulsant activity, usually less than 30 minutes. Thus, if diazepam is used, another agent for longer-term control, such as fosphenytoin (Cerebyx), may be needed to prevent seizure recurrence. If IV or intraosseous

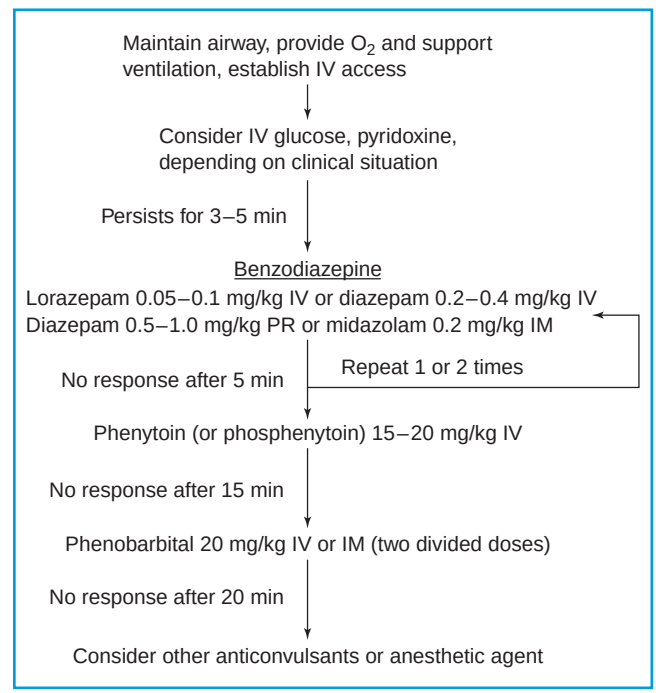

FIGURE 96.1 Treatment of status epilepticus. O_2, oxygen; IV, intravenous; PR, per rectum; IM, intramuscular.

access cannot be established, diazepam may be administered rectally in a dose of 0.5 mg per kg (maximum 20 mg per dose), instilling the IV formulation with a slip-tip syringe (remove needle) or by using a specific rectal gel preparation. Intramuscular (IM) midazolam (Versed) has also been shown to be effective in a dose of 0.2 mg per kg (maximum 7 mg per dose). IV midazolam may also be given ; the intranasal and buccal routes have also been described and appear to have promising initial results.

All the benzodiazepines can cause sedation and respiratory depression. Equipment for establishing an airway and supporting respiration must be available, especially if repeated doses are used. Sedation and respiratory depression may persist for hours, particularly with diazepam. Hypotension is uncommon but may be a problem with multiple doses or when barbiturates are administered concomitantly.

If the seizures have not been controlled within 10 minutes with benzodiazepines, phenytoin or fosphenytoin should be given. Fosphenytoin is a prodrug of phenytoin, which is rapidly metabolized to the active form. It offers several advantages over phenytoin, including more rapid administration and fewer local and systemic side effects. Fosphenytoin may also be given IM, unlike phenytoin. The dose of the two drugs is identical; fosphenytoin doses are expressed as phenytoin equivalents. The loading dose of fosphenytoin is 15 to 20 mg phenytoin equivalents (PE) per kg IV, at a rate of 2 mg PE per kg per min to a maximum of 150 mg per min. In the absence of any clinical effect, an additional 10 mg per kg IV may be administered. Cardiac monitoring is required because rapid IV infusion may lead to hypotension, QT prolongation, and cardiac dysrhythmias. (If phenytoin is used instead, the maximum rate of administration is 50 mg per min.) In patients known to be taking phenytoin chronically, a smaller dose of 5 to 10 mg per kg should be used initially unless the serum level is known to be very low. Each 1 mg per kg of phenytoin administered raises the serum level by approximately 1 μg per mL, although phenytoin kinetics are notoriously unpredictable. Phenytoin is highly lipid soluble and reaches therapeutic levels in the brain within 10 to 20 minutes, with duration of action of 12 to 24 hours. Unlike other anticonvulsant medications, phenytoin does not cause sedation or respiratory depression.

Phenobarbital is the next agent often added if phenytoin is not effective or contraindicated (e.g., allergy, known therapeutic level). The loading dose of phenobarbital is 20 mg per kg, sometimes given in two divided doses. The drug is given over 5 to 10 minutes IV (maximum 30 mg per min), or IM in the absence of IV access. Onset of action is usually within 15 to 20 minutes and lasts more than 24 hours. Phenobarbital, like other barbiturates, may cause significant sedation and hypotension.

IV valproate (VPA) and IV levetiracetam (Keppra) may also serve as an alternative to phenobarbital or phenytoin in the treatment of SE. A recent study demonstrated that valproic acid may be particularly useful for patients with a known seizure disorder, who are currently using VPA, when low serum concentrations are suspected. Effective loading doses in one study were 10 mg per kg IV when subtherapeutic levels were suspected and 25 mg per kg IV when the patient was not being treated with VPA. In this study, no adverse effects related to hypotension or heart rate were observed.

Similarly, IV levetiracetam may also serve as an alterative therapy in the treatment of SE that is refractory to benzodiazepines. In a recent report, levetiracetam was used for 18 episodes of benzodiazepine refractory focal SE in 16 patients. SE was controlled in all patients by the given combination of drugs, with no adverse events such as hemodynamic instability. However, further study is still needed to investigate the efficacy of IV levetiracetam for the use in treatment of SE.

Patients with SE that lasts for more than 30 to 60 minutes present a special problem. Further management should be done, when possible, in conjunction with a neurologist and with EEG monitoring. Continuous infusion of benzodiazepines may be used. Previously, paraldehyde and lidocaine hydrochloride have been used to treat SE. However, these medications have not demonstrated any advantage over the conventional therapies already discussed and have more serious side effect profiles. In addition, paraldehyde is no longer available in the United States. Other agents potentially useful in the management of refractory SE include continuous infusion pentobarbital or midazolam and general anesthetics such as isoflurane, etomidate, and propofol.

With prolonged seizures, the duration of postictal drowsiness and confusion may also be protracted. However, the child who fails to arouse within 15 to 30 minutes after cessation of seizures should be evaluated carefully to rule out nonconvulsive SE. Children with SE, even if successfully treated in the ED, should be admitted to the hospital for monitoring and observation.

Rarely, a child may enter the ED in absence status. In this case, the child may be sitting in a confused or dreamy state. Such attacks may last for hours or even days. The drug of choice in the treatment of absence status is lorazepam or diazepam at the dosages already outlined.

At times, a child may present with continual focal seizure activity (with or without clouding of consciousness), a condition known as *epilepsia partialis continua*. The treatment for partial seizures is less urgent than that for generalized seizures, and such seizures are often intractable to anticonvulsant medication. In such cases, fosphenytoin in a dose of 15 to 20 mg per PE per kg can be infused slowly. All such patients should be admitted to the hospital for further observation and evaluation. Other pharmacologic attempts to control these focal seizures should be performed in the hospital.

Initiating Anticonvulsant Medication

Nonfebrile Seizures. The decision to initiate long-term prophylactic therapy with anticonvulsant medications is based on a consideration of a number of factors, including the patient's age, type of seizure, risk of recurrence, coexisting medical conditions, and family factors. The consequences of further seizures must be balanced against the potential side effects of the anticonvulsant agents. Treatment is seldom started after a single, uncomplicated nonfebrile seizure because most such patients will not experience a seizure recurrence. However, a patient who has had two or more such seizures should generally receive anticonvulsant therapy. When possible, it is preferable for long-term treatment decisions to be made in conjunction with the provider who will be responsible for ongoing follow-up of the patient, either a neurologist or the child's primary care physician. Sometimes, it may be necessary to begin prophylactic treatment in the ED, pending a more complete outpatient evaluation.

A number of drugs are effective in preventing seizures (Table 96.3). Some are better for certain types of seizures, and all have different profiles of adverse effects. The following principles should guide selection of an anticonvulsant medication:

1. Choose a drug that is effective for the particular type of seizure. When more than one agent is available, choose the least toxic one. Initial therapy should be with a single agent.
2. Start at the low end of the dosage range.
3. Arrange for a serum level of the drug to be measured, when appropriate. This is done after a steady state is anticipated, usually five times the half-life of the drug.
4. If a child is already taking an anticonvulsant medication and has an adequate level, consider adding another agent.

Carbamazepine (Tegretol). Carbamazepine is effective against generalized tonic-clonic seizures as well as simple and complex partial seizures. The effective serum concentrations of carbamazepine range between 4 and 12 μg per mL, but with this drug there is a variable correlation among clinical efficacy, toxicity, and the serum concentration. Initial dose is 5 to 10 mg per kg per day; recommended maintenance dosages range between 10 and 35 mg per kg per day, divided into three daily doses. The administration of a total maintenance dose to a previously untreated patient often results in drowsiness, blurred vision, and at times, severe lethargy; so, this drug should be initiated by gradual increases in dosage (10 mg per kg per day to start, increased by 5 mg per kg per day every 3 to 4 days) until a full maintenance level is reached. Note that carbamazepine induces its own metabolism around day 14, and levels may suddenly become subtherapeutic and should be monitored closely. Unlike several other agents, it is not available in an IV form. Concomitantly administered medications that may lead to toxic carbamazepine levels include macrolide antibiotics (e.g., erythromycin), isoniazid, cimetidine, verapamil, and diltiazem.

Carbamazepine may cause hepatic and hematologic toxicity but causes little, if any, cognitive dysfunction in most patients. Therefore, it is often the drug of choice for children with generalized seizures.

Phenobarbital. Phenobarbital is another broad-spectrum anticonvulsant useful for generalized tonic-clonic and partial (simple and complex) seizures. It remains a commonly used initial drug, primarily because of its low cost and low toxicity. The effective serum concentration ranges between 15 and 40 μg per mL. This serum level can usually be maintained with a dosage of 3 to 6 mg per kg per day in children and 1 to 2 mg per kg per day in adolescents, administered in divided doses twice daily. A loading dosage of approximately twice the maintenance dosage (6 to 10 mg per kg per day in children and 2 to 4 mg per kg per day in adolescents) for 2 to 3 days brings the serum concentration to the therapeutic range within 48 to 72 hours. Such loading dosages are usually associated with considerable transient drowsiness. There is a wide margin between the anticonvulsant and soporific effects of phenobarbital, and drowsiness rarely persists at the recommended dosages. Decreased attention, hyperactivity, and alterations of mood occur in 30% to 50% of children maintained on phenobarbital. These behavioral changes are the most commonly encountered side effects and are often sufficiently undesirable to force the change to another drug. Possible associated long-term cognitive effects also makes phenobarbital problematic, and many clinicians do not consider it a first-line drug. Primidone (Mysoline) and mephobarbital (Mebaral) are related drugs.

Phenytoin (Dilantin). Phenytoin is another agent effective in the treatment of several seizure types, including generalized motor seizures and both simple and partial complex seizures. The effective serum concentration of phenytoin is between 10 and 20 μg per mL. The usual maintenance dosage is 7 to 10 mg per kg per day in children weighing less than 20 kg, 5 to 7 mg per kg per day in children weighing between 20 and 40 kg, and 5 mg per kg per day in children weighing more than 40 kg, given in once or twice daily doses. However, there is considerable variation in metabolism among patients. Saturation of biotransforming enzyme systems often occurs between serum levels of 10 and 20 μg per mL, so small changes in a dose in this range may lead to relatively large changes in serum levels.

Loading dosages of four times the daily dosage (maximum 20 mg per kg per day) on the first day and two times the daily dosage for the next 2 days will bring serum levels into the therapeutic range within 24 hours; side effects rarely occur with this loading dosage. Gingival hyperplasia is a common side effect and may be seen with phenytoin concentrations in the therapeutic range; this cosmetic side effect and the drug's tendency to cause hirsutism and coarsening of facial features often limit long-term use, especially in girls. Drowsiness, ataxia, nystagmus, and seizures are dose-dependent toxic effects rarely seen with levels in the therapeutic range. Other adverse effects include drug rashes (Stevens–Johnson syndrome) and hematologic and hepatic side effects. Several medications may cause increased phenytoin levels: cimetidine, estrogens, chlorpromazine, chloramphenicol, and isoniazid.

Valproate (Depakote). VPA is highly effective in the treatment of generalized epilepsy, including especially absence and myoclonic seizures, as well as simple and complex partial seizures. Doses of 20 to 40 mg per kg usually result in therapeutic levels of 50 to 100 μg per mL, although doses of up to 100 mg per kg per day may be necessary when combined with other enzyme-inducing antiepileptics. However, serum drug levels may not be highly predictive of efficacy or toxicity. The primary side effects include gastrointestinal upset and drowsiness; hepatic, renal, pancreatic, and hematologic dysfunction are also seen. Carnitine is often prescribed for patients receiving doses higher than 50 mg per kg per day, in attempt to avoid hepatotoxicity. Children younger than 2 years are at particular risk of idiosyncratic fatal hepatotoxicity. Therefore, VPA is rarely the initial drug of choice for young children with generalized seizures.

Clonazepam (Klonopin). Clonazepam is used to control myoclonic and atonic seizures. The usual dosage is 0.05 to 0.2 mg per kg per day, given in two to four divided doses. The therapeutic range is 0.02 to 0.08 μg per mL (20 to 80 ng per mL). Patients taking clonazepam may experience drowsiness, ataxia, and drooling.

Ethosuximide (Zarontin). Ethosuximide is indicated for the management of absence seizures. It is given at a dosage of 20 to 40 mg per kg per day, divided into twice-daily doses, with a usual therapeutic level of 40 to 100 μg per mL. Side effects include headache, nausea, and vomiting; erythema multiforme and a lupus-like syndrome have also been reported.

Lamotrigine (Lamictal). Lamotrigine is indicated for treatment of partial seizures, atonic and myoclonic seizures, and intractable mixed seizures (Lennox–Gastaut syndrome). The usual dosage is 10 to 15 mg per kg per day, which is reduced to 5 mg per kg per day when given in conjunction with VPA. Initial doses are substantially lower, starting at 0.6 mg per kg per day and 0.2 mg per kg per day, respectively. Drowsiness, vomiting, nystagmus, ataxia, and life-threatening drug rashes (including Stevens–Johnson syndrome) are reported side effects. If the patient develops a rash while on lamotrigine, particularly in the first 3 months of therapy, the drug should be stopped immediately and not rechallenged without consultation with a pediatric neurologist.

Topiramate (Topamax). Topiramate is available for adjunctive therapy in the treatment of refractory partial epilepsy and Lennox–Gastaut syndrome. The usual dosage is initiated at 0.5 to 1.0 mg per kg per day, in two divided doses for 1 week. This may then be increased by 0.5 to 1.0 mg per kg per day per week until an effective dose is achieved. The usual minimum effective dose is 6 mg per kg per day, in two divided doses. Side effects can include drowsiness and impairment of physical and speech coordination. It should be used with caution in patients having renal dysfunction or previous allergic reactions to sulfa-based medications.

Oxcarbazepine (Trileptal). Oxcarbazepine is used for treatment of partial epilepsy. Like many other anticonvulsants, it is metabolized in the liver by the cytochrome p450 pathway; concomitant administration with inducers or inhibitors of this pathway may alter serum levels. The usual dose range is 10 to 40 mg per kg per day. Adverse effects include somnolence, anxiety, rash, hyponatremia, and hypersensitivity. There is a 25% to 30% incidence of cross-hypersensitivity with carbamazepine.

Diazepam (Diastat-R). Diazepam rectal gel has been used intermittently to successfully stop seizure activity in the outpatient setting. The most effective use is in a selected group of patients with refractory epilepsy who are on stable regimens of antiepileptic drugs. In this setting, the most common side effect is sedation.

Levetiracetam (Keppra). Levetiracetam is a newer anticonvulsant that is indicated for adjunctive therapy of partial-onset seizures in children older than 4 years, as well as treatment for generalized tonic-clonic seizure in those older than 6 years and juvenile myoclonic seizures in those older than 12 years. The usual dose begins at 20 mg per kg per day, divided in 2 doses. Adverse effects can include dizziness, somnolence, and headache.

Other Agents. Several other antiepileptic medications are available but are generally reserved as add-on therapy prescribed in consultation with a pediatric neurologist. These include gabapentin (Neurontin), tiagabine (Gabitril), and zonisamide (Zonegran). Several new agents are more recently available in the United States or are currently under investigation, notably lacosamide (Vimpat), pregabalin (Lyrica), and rufinamide (Banzel). Another new agent, fluorofelbamate, is under development as a derivative of an older medication, felbamate (Felbatol). Felbamate is restricted to use in children with intractable seizures refractory to other treatment due to the risk of severe hepatotoxicity. The new compound was created to avoid the production of the metabolite thought to cause this side effect. Vagus nerve stimulation is a novel nonpharmacologic approach to the management of children with intractable seizures. Intermittent electrical stimulation is delivered to the cervical vagus nerve trunk by an implanted device. The lead is typically located on the left side of the neck, and the generator is implanted in the chest wall. In addition to the programmed impulses, patients with an aura of an impending seizure may trigger additional impulses with a handheld magnet. Adverse effects are generally mild and include hoarseness, cough, and paresthesias. If the device needs to be inactivated temporarily, this is accomplished noninvasively with a telemetry wand.

Febrile Seizures. For children with febrile seizures, the issue of chronic prophylactic medication is more controversial. Presumptive antipyretic therapy for a nonspecific illness does not appear to reduce the risk of seizure recurrence, although it may give the parent a sense of "doing something." Phenobarbital was widely used in the past for children with recurrent febrile seizures, but this practice is much less common now because of concerns about adverse cognitive and behavioral effects of the medication. To be effective, phenobarbital must be given continuously. Other commonly used anticonvulsant agents such as phenytoin and carbamazepine appear to be ineffective. More recently, some clinicians have used diazepam, administered intermittently during febrile illnesses (0.33 mg per kg every 8 hours), to prevent febrile seizures. One controlled trial showed this treatment to be effective, albeit with a high incidence of side effects; while other studies have failed to confirm the effectiveness of this approach, largely as a result of poor compliance or inadequate recognition of fever. With little evidence that febrile seizures (even febrile SE) cause permanent neurologic damage or that their control results in a lower incidence of subsequent epilepsy, there is little need to treat most patients. In carefully considered individual cases, long-term continuous therapy with phenobarbital or intermittent therapy with diazepam may be considered. This should usually be done in conjunction with the child's primary care provider.

Disposition. Hospital admission is generally required for children who have had a prolonged seizure requiring acute treatment with anticonvulsant medication. With the exception of very young infants, other children, even those with a first-time seizure, can generally be followed as outpatients if they appear well after the seizure, follow-up can be ensured, and the parents are comfortable with home management. Seizure first aid should be explained to the family before discharge. Some practitioners may choose to prescribe rectal diazepam until a decision is made about instituting chronic anticonvulsant therapy.

After a simple febrile seizure, hospitalization is seldom necessary, and children may be followed by their primary physician. Some useful information can be given to parents after a first febrile seizure. First, they should be informed of the benign nature of the convulsions and the lack of evidence that they cause any type of neurologic injury. Approximately one-third of children with a first febrile seizure will have another one. Of recurrences, 75% occur within 1 year, and they are uncommon beyond 2 years; fewer than 10% of children with febrile seizures have more than three. The recurrence rate is lower if the seizures begin after the first year of life, and the risk is also reduced in children with higher temperature and longer duration of fever before the initial febrile seizure. For example, the recurrence risk is about 35% when the first seizure occurs at a temperature of 38.5°C (101.3°F), compared with a risk of 13% with a temperature of 40°C (104°F). Having a complex first febrile seizure (even febrile SE) does not increase the risk of recurrence, nor does it increase the chance that a recurrent seizure, if it occurs, will be complex.

Many parents are concerned that febrile seizures will lead to future epilepsy. A child who has had a febrile seizure but no other risk factors for epilepsy may have a slightly increased risk of future nonfebrile seizures, but the magnitude of this increase is still extremely small: 1% to 2% lifetime risk versus a 0.5% to 1% lifetime risk in the general population. Several risk factors that increase the likelihood of a child experiencing future nonfebrile seizures have been identified. These risk factors include a family history of epilepsy, a complex febrile seizure, and the presence of an underlying neurologic or developmental abnormality. Importantly, even with two or more of these risk factors, the risk of epilepsy is only 10%. Thus, for most children with no risk factors, the parents may be reassured that future epilepsy, although possible, is extremely unlikely. Furthermore, there is no association between febrile seizures and any type of developmental or learning disabilities.

DISORDERS THAT PRESENT WITH ENCEPHALOPATHY (SEE ALSO CHAPTER 12)

Encephalopathy is an imprecise term that implies diffuse brain dysfunction with or without alterations in the level of consciousness. The emergency physician often must decide whether the child's degree of irritability, uncooperativeness, and lethargy is proportionate to the degree of systemic illness; whether it is caused by fear; or whether it represents cortical dysfunction. Encephalopathy may be a sign of numerous systemic disorders, or it may result from primary disorders of the central nervous system (CNS), the most common of which is encephalitis.

Encephalitis

Background

Encephalitis is an inflammation of the brain parenchyma. When there is an associated leptomeningeal involvement (as often occurs), the term *meningoencephalitis* may be applied, whereas *encephalomyelitis* implies involvement of the spinal cord as well. CNS dysfunction is caused by direct invasion of brain by a pathogen, most often a virus, or is secondary to immunologic mechanisms, as in postinfectious encephalomyelitis.

TABLE 96.4

AGENTS OF VIRAL ENCEPHALITIS

Arboviruses
Eastern equine encephalitis
Western equine encephalitis
St. Louis encephalitis
Japanese encephalitis
California (LaCrosse) encephalitis
West Nile
Herpesviruses
Herpes simplex
Varicella-zoster
Epstein-Barr
Cytomegalovirus
Mumps
Measles
Enteroviruses
Rabies

Viral encephalitides are caused by a wide variety of viruses that lead to clinically similar illnesses (Table 96.4). Currently, an etiology is not identified in most cases, even with an extensive laboratory evaluation. Mumps was the most common cause of meningoencephalitis before the introduction of vaccination, with up to 50% of patients with mumps parotitis having cerebrospinal fluid (CSF) pleocytosis. Classically, the illness occurs several days to 2 weeks after the onset of parotitis but may precede the onset of systemic illness or occur without parotitis and tends to be mild. Measles encephalitis is less common since the advent of widespread live immunization. The onset usually occurs during the prodromal period or after the rash has appeared. Ataxia is the most common neurologic abnormality, and sequelae occur in up to 30% of cases. Varicella encephalitis occurs 2 to 9 days after the onset of the rash; severe infections are uncommon, except in the immunosuppressed host.

The arthropodborne encephalitides—including St. Louis, Western equine, Eastern equine, and California encephalitis—occur in sporadic and epidemic forms, often in late summer or early fall, and tend to cluster in localized geographic areas. Sequelae may be severe and mortality high, especially in Eastern equine encephalitis. West Nile virus is another agent in this family that first appeared in the United States in 1999. Since then, it appears to have become endemic in large parts of North America, although infections in children are uncommon.

Herpes simplex virus (HSV) is a relatively common cause of sporadic encephalitis. Disease in neonates is usually caused by HSV type 2, acquired from perinatal transmission. In previously healthy older children and adults, encephalitis more often results from infection with HSV type 1 and may be a complication of acute primary infection or reactivated latent infection. Recognition of herpes encephalitis is often difficult early in the course but is important because specific antiviral therapy reduces the substantial morbidity and mortality of this disease.

Infection with rabies virus, although rare in the United States, is an important cause of encephalitis worldwide. Nonviral pathogens, including *Mycoplasma pneumoniae,* Lyme disease, and rickettsiae, may also cause encephalitis.

Postinfectious encephalitis may follow infection with numerous viruses, including measles, varicella, influenza, and Epstein-Barr virus. The CNS involvement may be confined to a specific area, as in acute cerebellar ataxia after varicella infection, or may be widespread. The latter condition is often designated *acute disseminated encephalomyelitis*. A particularly virulent form with high mortality is known as *acute hemorrhagic leukoencephalitis*. A clinical syndrome of encephalopathy after immunization, particularly with whole-cell pertussis vaccine, is also described, although more recent epidemiologic evidence has called into question the association with pertussis immunization.

Pathophysiology

Viral encephalitis usually follows a viremia, although direct spread can occur less commonly via peripheral nerves or the nasal mucosa. Upon reaching the CNS, viral replication in neural cells interferes with cellular function and may lead to cell death. Cerebral edema may result from capillary leakage, with subsequent increased ICP. The degree and extent of neuronal dysfunction depends in part on the pathogen involved and also on host factors, especially immunocompetence. In general, the incidence of overt neurologic findings and sequelae is higher in children younger than 1 year.

Postinfectious encephalitis is presumed to be an immune-mediated phenomenon, involving the white matter of the CNS. Demyelination, the pathologic hallmark of the disease, may be focal or widespread.

Clinical Manifestations

The clinical picture of viral encephalitis ranges from a mild febrile illness associated with headache and minimal changes in mentation to a severe, fulminant presentation with coma, seizures, and death. The onset of encephalitis may be abrupt or insidious. Typical features consist of fever, headache, vomiting, and signs of meningeal irritation. Altered consciousness, ataxia, and seizures are also seen. Focal neurologic deficits may occur in certain types of encephalitis, particularly HSV. Flaccid paralysis may be seen in cases of encephalomyelitis, and rarely, respiratory or cardiac dysfunction results from brain stem involvement. Rash or mucous membrane lesions are often seen with the exanthematous viruses such as measles and varicella; however, cutaneous findings are uncommon with HSV encephalitis.

Laboratory assessment is often nonspecific. The peripheral blood count usually shows a mild polymorphonuclear or mononuclear leukocytosis. With viral encephalitides, CSF pleocytosis is variable and, if present, is usually fewer than 500 cells per cubic millimeter. These cells may be predominantly polymorphonuclear early in the course of the illness; however, a mononuclear predominance is common later. Red blood cells are present in the CSF in approximately 50% of children with herpes encephalitis. Spinal fluid protein and glucose levels are usually normal with viral encephalitis, but the protein level may be greatly elevated in postinfectious encephalomyelitis.

Virus isolation from the CSF may be difficult but should be attempted, as should viral isolation from other body sites, including the nasopharynx, skin lesions, urine, and feces. Serologic evidence for viral infection based on acute and convalescent IgG titers, although useful later, gives little help in making an immediate diagnosis. Infection with arboviruses may be established more rapidly by detecting virus-specific IgM in CSF or serum.

Herpes simplex poses a special problem because early diagnosis is important in instituting effective therapy. Although not usually available with rapid turnaround time, polymerase chain reaction testing of CSF yields rapid evidence of viral nucleic acid and is relatively sensitive and specific. Imaging studies, although less sensitive, may also be useful. Either CT or MRI may demonstrate focal parenchymal involvement or edema of the temporal lobes (Fig. 96.2). MRI is more sensitive than CT, although both may show normal results in the early stages of disease. Similarly, EEG may demonstrate focal slowing or epileptiform discharges localized to the temporal lobes, but absence of such findings does not rule out herpes encephalitis.

Management

Presently, the treatment of nonherpes viral encephalitis is primarily supportive. Children with aseptic meningitis and mild manifestations may be followed at home, but those with encephalitis should be hospitalized for observation and monitoring of neurologic status, treatment of increased ICP if present, and fluid restriction and monitoring of urine output and serum sodium because of the risk for inappropriate antidiuretic hormone secretion.

Herpes simplex encephalitis causes death or neurologic sequelae in more than 70% of patients. Treatment with acyclovir (60 mg per kg per day divided q8h daily for 14 to 21 days) has resulted in a decrease in mortality and some improvement in morbidity. Obviously, treatment should be initiated as early as possible after deciding that HSV is a reasonably likely diagnosis (although institution of therapy in the first 24 to 48 hours has never been shown to convey a statistically significant advantage over late treatment). Thus, acyclovir should be considered in all patients suspected of having herpes encephalitis on the basis of clinical or epidemiologic grounds (e.g., oral vesicles, focal neurologic or radiographic findings); because clinical features and laboratory tests are not perfectly sensitive, initial presumptive treatment may be indicated even in the absence of corroborating evidence.

DISORDERS THAT PRESENT WITH HEADACHE

Headaches of varying character, severity, and origin affect patients of all ages. Much of the CNS, including the brain parenchyma, is devoid of pain sensors. However, headache may result from compression, inflammation, or distortion of a number of pain-sensitive cranial structures, including the proximal portions of the large cerebral arteries, the arteries of the dura and scalp, the intracranial venous sinuses, the dura, the facial sinuses, orbits, teeth, scalp, muscles, and cervical roots of the spinal cord. A full discussion of the differential diagnosis of headache is given in Chapter 55.

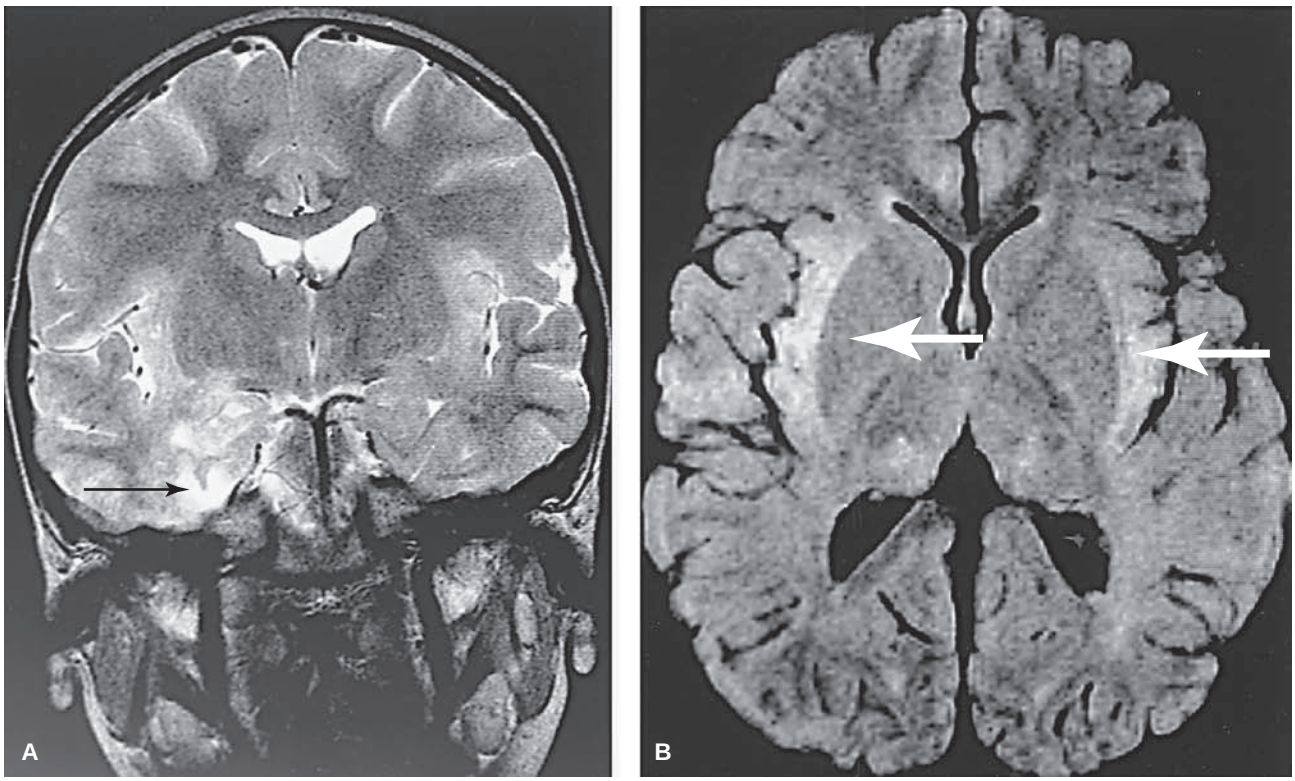

FIGURE 96.2 Coronal (**A**) and axial (**B**) T_2-weighted magnetic resonance images showing multifocal areas of abnormal signal in the medial aspects of both temporal lobes *(large arrow)* and left posterior parietal lobe *(small arrow)* in a patient with herpes simplex encephalitis.

Migraine

Background

Migraine—recurrent headaches separated by long, symptom-free intervals—is probably the most common specific cause of episodic headaches in afebrile children. In epidemiologic studies, prevalence estimates for migraine in children range from 3% to 10%. A number of forms of migraine are recognized. Migraine is considered "classic" when the headache is well localized and preceded by an aura and considered "common" when it is not. The common form of migraine predominates in children. Basilar migraine is a migraine variant that involves the posterior cerebral circulation in which brain stem symptoms, possibly including transient loss of consciousness, predominate. Cluster headaches, which are unilateral, occur in runs and are associated with autonomic changes. They represent a rare migraine variant in childhood. Cyclic vomiting, a syndrome of recurrent, discrete attacks of abdominal pain, nausea, vomiting, and pallor, is also believed to be a migraine variant, sometimes called *abdominal migraine*.

Pathophysiology

Migraine is a result of an underlying hyperexcitable cerebral cortex. In a genetically predisposed individual, a variety of stimuli can trigger episodes of "cortical spreading depression," a slowly propagating wave of neuronal hyperpolarization followed by depolarization. This in turn triggers a neuronally-mediated vascular instability that results in intracranial hypoperfusion (which may produce the migraine aura of premonitory motor, visual, or sensory symptoms), followed by vasodilation and a sterile, neurogenic inflammation, which are responsible for the headache.

Clinical Manifestations

Prolonged (up to 24 to 48 hours), moderate to severe headache is characteristic of migraine. The headaches may be pulsating and unilateral but assume this pattern less often in children than in adults. Migraine is commonly associated with nausea, vomiting, abdominal pain, and photophobia or phonophobia. Auras occur in less than half of children who experience migraines. During the headaches, standard, oral analgesics may be relatively ineffective, and children seek a quiet, dimly lit area to rest or sleep. Occasionally, the attacks awaken the children from sleep. The physical examination usually shows no focal neurologic deficits, although hemiplegia and ophthalmoplegia may occur in complicated migraine. Unless these episodes have occurred previously, their presence warrants further neurologic evaluation, usually in the form of CT or MRI scanning.

A family history of migraine is helpful in diagnosis, and a disproportionate number of children who experience migraines have episodes of motion sickness, dizziness, vertigo, or frank paroxysmal events. Common trigger factors for migraine in children include emotional stress, lighting changes, and minor head trauma. Particularly in adolescents, it is useful to screen for depression or other psychosocial stressors that may warrant separate treatment. Foods, such as lunch meats, which

contain nitrates, and cheeses, which contain tyramine, are less common but important triggers.

The diagnosis of migraine is based almost exclusively on the history and is supported by the absence of abnormalities on examination. There are no diagnostic laboratory tests or imaging studies. Given an accurate history, differentiation from tension headaches, sinusitis, and headaches secondary to intracranial lesions is usually possible; studies such as EEG, CT, and MRI are rarely indicated. Of children who experience migraines, 20% to 90% have been reported to have nonspecific EEG abnormalities, but the EEG is usually not helpful in diagnosis.

Management

A number of agents are available for the treatment of acute migraine (Table 96.5). For many children, mild oral analgesics such as acetaminophen or ibuprofen combined with bed rest may provide sufficient relief and should be considered the first-line agents of choice. Ketorolac (Toradol), a nonsteroidal anti-inflammatory agent for parenteral use, may be used when nausea or vomiting limits oral intake. A short course of a narcotic analgesic such as oxycodone may occasionally be needed if nonnarcotic agents have failed, especially if the headache prevents sleep.

When nausea and vomiting are severe, antiemetic medications such as metoclopramide (Reglan), prochlorperazine (Compazine), and promethazine (Phenergan) are useful. In addition to their antiemetic effect, these agents often provide some relief of the headache as well and may permit the use of other oral medications. All these agents have the potential to produce dystonic reactions. Due to fewer side effects, ondansetron (Zofran) and granisetron (Kytril) have also become first-line agents in the treatment of nausea and vomiting for migraine headaches.

Sumatriptan succinate (Imitrex) is a serotonergic agent available for oral, intranasal, or subcutaneous administration. Its effectiveness in relieving symptoms of acute migraine has been demonstrated in clinical trials in children and adults, but it has not been approved by the U.S. Food and Drug Administration for use in younger children. The dose for children 12 years and older is 6 mg subcutaneously or 100 mg orally. Sumatriptan is generally well tolerated; side effects include irritation at the injection site, flushing, tachycardia, disorientation, and chest tightness that lasts for several minutes after parenteral administration. In one trial, adverse effects were more common in younger children. A reasonable approach is to use sumatriptan after a trial of analgesics in an older child, although older children or adolescents with recurrent migraine and a history of successful treatment with sumatriptan in the past may benefit from earlier use of this agent. Other agents in this family include rizatriptan (Maxalt), zolmitriptan (Zomig), and naratriptan (Amerge).

Ergot preparations act primarily as cerebral vasoconstrictors and are specifically indicated for aborting acute migraine attacks. Ergotamine tartrate is administered orally or sublingually, but it must be used early in the headache to be effective, preferably at the outset of the prodrome. Because most young children cannot identify an aura, their use is limited before adolescence. Common side effects of ergot preparations include nausea, vomiting, cramps, and distal paresthesias, all of which may intensify the symptoms of migraine. Dihydroergotamine (DHE) is an injectable ergot derivative with fewer side effects. Ergot preparations should not be used concomitantly with triptans. For acute migraine, DHE can be given to older children and adolescents in an initial dose of 0.5 mg IM or IV (no milligram-per-kilogram dose has been established). The initial dose of DHE may be repeated in 1 hour if necessary. One study in adults reported that 3 mg administered intranasally is also effective. Antiemetics may be useful to control the nausea and vomiting that often occur after DHE administration.

If migraines are frequent and severe, prophylactic treatment is possible. Many drugs have been used, but because some require close, serial examination and have no effect on the acute attack, generally they should not be started in the ED. Among the medications used for chronic suppressive therapy are propranolol, tricyclic antidepressants, cyproheptadine (Periactin), valproic acid, and calcium channel blockers. More

TABLE 96.5

AGENTS FOR ACUTE TREATMENT OF MIGRAINE

Drug	Usual dose
Analgesics	
Acetaminophen	10–15 mg/kg/dose PO or PR q4h
Ibuprofen	5–10 mg/kg/dose PO q6h
Ketorolac (Toradol)	30 mg initial dose, then 15–30 mg/dose (0.5 mg/kg) IV or IM, or 10 mg/dose PO, q4–6h
Codeine	0.5–1 mg/kg/dose PO q4–6h
Antiemetics	
Metoclopramide (Reglan)	0.5–2 mg/kg/dose PO or IV q4–6h
Prochlorperazine (Compazine)	0.1 mg/kg/dose PO, IM, or IV q6h
Promethazine (Phenergan)	0.25–1.0 mg/kg/dose PO, PR, IV, or IM q4–6h
Specific Antimigraine Agents	
Dihydroergotamine	0.5–1.0 mg/dose IV or IM; may repeat after 1 h
Sumatriptan (Imitrex)	6 mg SC or 100 mg PO

PO, orally; PR, per rectum; IV, intravenously; IM, intramuscularly; SC, subcutaneously.

recent studies of antiepileptic medications have shown some efficacy in preventing migraine headaches in adult patients, including gabapentin, topiramate, lamotrigine, and tiagabine. However, pediatric studies regarding prevention of migraine with antiepileptic drugs have not been conducted.

Idiopathic Intracranial Hypertension (Pseudotumor Cerebri)

Background and Pathophysiology

Idiopathic intracranial hypertension (IIH), also called *pseudotumor cerebri*, is a poorly understood condition of increased ICP. It may occur at any age during childhood but is more common in adolescents, especially in obese individuals. The female population is more commonly affected. A number of other conditions have been reported in association with IIH; these include infections (otitis media, mastoiditis, Lyme disease), endocrinologic conditions (hyperthyroidism, Addison's disease), medications (steroid withdrawal, tetracycline, hypervitaminosis A), and mild head trauma. However, a causal relationship remains unproved, and in most cases of IIH, no cause is identified. The mechanism of increased ICP in IIH remains unknown, although several hypotheses have been postulated, including vasogenic brain edema and impaired reabsorption of CSF by the arachnoid villi.

Clinical Manifestations

Headache of variable severity and duration is the most common presenting symptom. It is typically worse in the morning. Nausea, vomiting, dizziness, and double or blurred vision also occur. If the process is long-standing, decreased visual acuity or visual field deficits can result. Infants often have nonspecific symptoms of lethargy or irritability. Papilledema is seen in virtually all cases. Other neurologic symptoms and signs are often absent; however, cranial nerve palsies, particularly affecting the cranial nerve VI, may be seen.

Diagnosis should be considered when a child with a prolonged history of headache is found to have evidence of papilledema without other neurologic findings. Pseudotumor cerebri is a diagnosis of exclusion, and mass lesions and infectious processes must be ruled out. Because posterior fossa tumors and obstructive or nonobstructive hydrocephalus may mimic pseudotumor early in the course of disease, CT or MRI scan should be obtained in all children with this constellation of findings. In cases of IIH, the ventricles will appear normal or small. If no mass lesion is present, an LP should be performed with a manometer to measure opening pressure. The patient must be recumbent with legs extended to ensure an accurate reading of the opening pressure. Children with primary pseudotumor (e.g., not secondary to Lyme infection or other causes) have elevated opening pressure (greater than 200 mm H_2O) but normal CSF cell count, protein, and glucose. In children with intermittent symptoms, the opening pressure may be normal when the headache is waning, even though papilledema may persist for several weeks.

Management

Removal of sufficient CSF to normalize ICP usually leads to relief of symptoms. Treatment may then be started with acetazolamide (Diamox) to decrease CSF production (60 mg per kg per day divided four times daily). Although recommended by some authorities, corticosteroids have not been proven to be effective in the management of this condition. However, in cases of IIH following withdrawal of steroid therapy, a course of prednisone or dexamethasone may be beneficial. Patients with mild symptoms and good response to LP may be discharged to home with close follow-up arranged. Children with severe or persistent symptoms or those with visual changes may require hospital admission. Intracranial hypertension may be recurrent or chronic, and long-term monitoring, particularly of visual function, is important.

DISORDERS OF MOTOR FUNCTION (SEE ALSO CHAPTER 79)

Every level of the neural axis is involved in the performance of motor tasks. Anatomic localization is usually possible after evaluation of the distribution and character of the deficit (Table 96.6). Paresis refers to partial or complete weakness of a part of the body.

Various clinical designations are used to describe some patterns of weakness: paraplegia (or paraparesis), affecting the

TABLE 96.6

LOCALIZING LEVEL OF NEUROMOTOR DYSFUNCTION

	Tone	Distribution	Reflexes	Babinski	Other
Upper motor neuron	Increased (may be decreased acutely)	Pattern (e.g., hemiparesis, paraparesis) Distal > proximal	Increased (may be decreased acutely)	Extensor	Cognitive dysfunction possible
Anterior horn cell	Decreased	Variable, asymmetric	Decreased to absent	Flexor	Fasciculations; no sensory involvement
Peripheral nerve	Decreased	Nerve distribution	Decreased to absent	Flexor	Sensory involvement
Neuromuscular junction	Normal	Fluctuating	Usually normal	Flexor	
Muscle	Decreased	Proximal > distal	Decreased	Flexor	Tenderness, signs of inflammation possible

lower half of the body; quadriplegia, affecting all limbs; and hemiplegia, referring to weakness of one side of the body. Paraplegia most often results from spinal cord involvement, whereas hemiparesis is most often a sign of cortical disease. Some of the common conditions affecting various levels of the neuromotor system that may present with acute motor dysfunction are discussed next.

Stroke/Cerebrovascular Accident

Background

Stroke is defined as a syndrome of acute onset of focal neurologic deficit that persists for more than 24 hours, although some pediatric neurologists include more transient deficits. Stroke is relatively rare in healthy children but may complicate a number of other pediatric medical conditions. For example, among children with sickle cell disease, the incidence of stroke has been reported to be 6% to 9%. Others at risk are those with various forms of cardiac disease, which is one of the most common causes of stroke in children. Table 96.7 lists some of the common causes of stroke, as well as some more uncommon conditions in which stroke is a prominent clinical feature.

TABLE 96.7

CAUSES OF STROKE IN CHILDREN

Vascular
Arteriovenous malformation
Aneurysm
Moyamoya disease
Fibromuscular dysplasia

Cardiac
Valvular heart disease (including endocarditis)
Right-to-left shunts
Atrial tumors
Arrhythmia
Cardiomyopathy

Infectious
Meningitis (especially tuberculous)
Mycotic aneurysm
Mastoiditis, otitis media, or sinusitis leading to venous sinus thrombosis

Trauma
Intracranial hemorrhage
Cervical trauma with vertebral artery injury
Intraoral trauma with carotid injury

Brain tumor

Drugs
Cocaine
Amphetamine
Oral contraceptives
Ergot poisoning

Metabolic
Homocystinuria
Fabry's disease
Mitochondrial encephalopathies (MELAS syndrome)
Organic acidemias
Hyperlipidemias

Hematologic/Autoimmune
Sickle cell disease
Coagulopathies (e.g., hemophilia)
Anticoagulant deficiency (protein C, protein S, antithrombin III)
Polycythemia
Acute myelogenous leukemia
Systemic lupus erythematosus

Neurocutaneous Syndromes
Neurofibromatosis
Tuberous sclerosis
Sturge–Weber syndrome

Pathophysiology

Generally, stroke is classified as either primarily ischemic (including embolic phenomena) or hemorrhagic. In ischemic stroke, there is focal reduction in cerebral blood flow, with hypoxic damage to brain parenchyma, leading to neuronal injury and death. Further damage ensues from reperfusion of ischemic areas. More recently, attention has focused on secondary factors that play an important part in determining the extent of damage after acute ischemia; these include excess accumulation of excitatory amino acids and generation of free radicals. Hemorrhagic strokes are relatively more common in children than adults, accounting for 30% to 60% of pediatric stroke.

Clinical Manifestations

The presentation of stroke in children is highly variable, influenced by the portion of the cerebral vasculature affected and the child's age. Hemiparesis is most often observed, with facial weakness either ipsilateral or contralateral to weakness in the rest of the body. Involvement of the anterior cerebral artery leads primarily to lower-extremity weakness, whereas compromise of the middle cerebral artery circulation produces hemiplegia with upper limb predominance, hemianopsia, and possibly dysphasia. Less commonly, the posterior circulation is affected, which results in vertigo, ataxia, and nystagmus, as well as hemiparesis and hemianopsia. Older children often have concomitant headache, whereas children younger than 4 years are more likely to have associated seizures. The child with a stroke may also have a diminished level of consciousness.

Investigations in a child with acute hemiparesis should be directed at confirming the diagnosis of stroke and attempting to identify an underlying cause if none is known. Imaging studies are useful. Cranial CT without contrast is the study of choice for identifying acute hemorrhage. However, CT scan may be normal in the first 12 to 24 hours after an ischemic stroke; MRI, in contrast, may show changes as early as 6 hours after infarction. A usual approach is to obtain a noncontrast CT, followed by MRI with magnetic resonance angiography if no hemorrhage is seen.

In a child without a known predisposing condition, ancillary tests may be revealing of the cause of the stroke. Studies worth considering in such patients, depending on the clinical picture, are listed in Table 96.8. In one large series of 129 children with ischemic stroke, no cause was found in 35%.

Management

Initial treatment after an acute stroke is focused on stabilization and supportive care, including control of any seizures. Several aspects require special attention. Although evident hypotension should be treated with volume expansion, administration of free water should be restricted because of the potential for edema formation. Hypertension, if present, must be treated cautiously, and the blood pressure lowered gradually. Both hypoglycemia and hyperglycemia can exacerbate ischemic stroke, so careful monitoring of serum glucose level and judicious use of insulin are important. Fever, which can occur in children with stroke, may also contribute to ischemic damage and should be controlled with antipyretics.

Further therapy is determined by the type of stoke. With hemorrhagic stroke, neurosurgical intervention may be required

Serum amino acids
Urine organic acids
Toxicology screen
Lactate

Lumbar Puncture

to evacuate a hematoma or control a bleeding arteriovenous malformation (AVM). Catheter-directed embolization may also be possible in cases of AVM. Children with sickle cell disease and stroke should have acute transfusion to decrease the level of hemoglobin S to less than 30%. Thrombolytic and anticoagulant therapies have been shown to be effective in adults with ischemic stroke but remain untested in children. Similarly, novel therapies such as calcium channel blockers and free radical scavengers have not been studied in pediatric patients; their use remains experimental.

Overall, prognosis for children with stroke is better than that in adults. However, regardless of treatment, long-term morbidity of stroke in children is high, with more than 75% of affected children experiencing sequelae such as hemiparesis, seizures, and learning difficulties.

Spinal Cord Dysfunction

Background

Dysfunction of the spinal cord may result from any of a variety of disorders, either intrinsic or extrinsic to the spinal cord, with a great deal of overlap in their clinical presentation. *Transverse myelitis* is an intramedullary disorder, involving both halves of the cord over a variable length, with involvement of motor and sensory tracts. It occurs in children and adults, although it is rare in the first year of life. Transverse myelitis is believed to be a localized form of acute disseminated encephalomyelitis, discussed previously. Like the latter disorder, transverse myelitis may occur after a number of infections; among those commonly reported are Epstein-Barr virus, cytomegalovirus, measles, mumps, *Campylobacter jejuni*, and *M. pneumoniae*. Transverse myelitis may also result from systemic autoimmune disorders such as lupus erythematosus or scleroderma. In some older children and adolescents, transverse myelitis is a first manifestation of multiple sclerosis.

Acute spinal cord compression in children is usually caused by trauma, infection, or cancer. Spinal trauma may lead to contusion or concussion of the cord with hemorrhage, edema, and local mass effect or to development of a spinal epidural hematoma.

Parenchymal injury usually presents acutely, but an epidural hematoma may develop over several days after the antecedent trauma. Epidural abscess is the most common infectious cause of spinal cord compression. It is usually caused by hematogenous spread of bacteria, with *Staphylococcus aureus* being the most common pathogen. Neoplastic causes include both primary intraspinal tumors (ependymoma and astrocytoma) and extrinsic lesions such as neuroblastoma or lymphoma.

Pathophysiology

Transverse myelitis is believed to be caused by an autoimmune process, with demyelinating lesions found in the spinothalamic and pyramidal tracts and posterior columns of the spinal cord. During the course of the illness, the initial area or areas of spinal cord inflammation may extend rostrally and caudally to involve an extensive portion of the spinal cord.

Mass lesions may cause damage by direct compression of spinal cord tissues or, secondarily, by interference with the tenuous arterial (or, less commonly, venous) blood flow to the spine with resultant spinal infarction.

Clinical Manifestations

Spinal cord dysfunction from any cause is characterized by paraplegia and hyporeflexia below the level of involvement; sensory symptoms, such as band-like pain at the level of compression; and sensory loss or paresthesias below the area of damage. If the lower spinal cord is involved (the conus), there is usually early loss of bowel and bladder control. Compression of the cauda equina usually results in asymmetric symptoms, radicular pain, and focal lower-extremity motor and sensory abnormalities.

Transverse myelitis may affect any level of the spinal cord, but thoracic involvement is the most common. Initial symptoms include lower-extremity paresthesia, local back pain, unilateral or bilateral lower-extremity weakness, and urinary retention. A preceding respiratory or gastrointestinal illness is usually reported, and at the time of diagnosis, fever and meningismus are sometimes seen in children. Characteristically, the insidious onset of paresthesia or weakness of the lower extremities progresses over days or, rarely, weeks and then is replaced by the abrupt occurrence of static paraplegia or quadriplegia and, in the cooperative child, a detectable sensory level. In other children, the course of progression may be less than 12 hours. The sensory loss generally involves all modalities, although a spinothalamic deficit (pain) may occur without posterior column dysfunction (vibration). The weakness is usually symmetric but may be asymmetric. After a variable interval, initial flaccidity may be replaced by spasticity. Sphincter disturbance of the bowel and bladder occurs in most

patients, bladder distension being the most common initial sign of damage.

Traumatic and infectious spinal lesions are usually accompanied by relatively acute onset of local back pain, which is exacerbated by direct percussion of the area. Pain from an infectious cause occasionally may precede other symptoms for days. With tumors, however, there may be weakness in the absence of pain. Patients with epidural abscess often have systemic signs of infections such as fever, headache, vomiting, and, perhaps, neck stiffness. Bony tenderness in such a patient may indicate vertebral osteomyelitis or discitis, which can also present with weakness, although usually less severe than is seen with actual spinal cord involvement.

Prompt diagnosis of spinal cord lesions requires a high level of suspicion. Detailed neurologic examination is essential, with particular attention to the quality of deep tendon reflexes, any asymmetry of reflexes or strength, evaluation for a sensory level, and assessment of anal tone and cremasteric reflexes (in male patients). Note also any point percussion tenderness.

Diagnosis is confirmed by emergency neuroimaging, with precautions to immobilize the patient with the possibility of an unstable lesion. Plain spine films are useful initially in trauma. MRI of the spine is the procedure of choice to detect compressive mass lesions, but if not immediately available, plain or CT myelography is an alternative. In transverse myelitis, the cord may be widened at the level of involvement. This is easier to detect with MRI, which in some cases may also reveal evidence of focal intramedullary demyelination.

LP alone should not be performed if a diagnosis of spinal cord compression is entertained. If no mass lesion is noted and transverse myelitis is a diagnostic possibility, LP may be useful, showing a normal or slightly elevated opening pressure and a mild CSF pleocytosis in the CSF in nearly 50% of patients at the time of presentation. The CSF protein level is often elevated and may demonstrate oligoclonal bands or increased myelin basic protein, but the glucose level is usually normal.

Management

Treatment of children with spinal injury from trauma begins with splinting and immobilization of the spine. If trauma is likely, some experts recommend high-dose methylprednisolone, which was shown in one study, when given within 8 hours of injury at an IV dose of 30 mg per kg followed by infusion at 5.4 mg per kg per hr for 23 hours, to improve the quality of neurologic outcome. Neurosurgical consultation should be obtained as soon as possible; however, early surgical attempts to decompress the swollen spine (laminectomy or midline myelotomy) have proven ineffective and, possibly, detrimental.

In cases of possible epidural abscess or tumor-related mass, IV dexamethasone at a loading dose of 2 mg per kg (up to a maximum of 100 mg) should be given, followed by 1 to 2 mg per kg per day IV in four divided doses over the next 24 hours. In patients with a presumed infectious cause and those with cancer of unknown origin, surgical decompression is indicated on an emergent basis to alleviate pressure and pinpoint diagnosis. Further treatment depends on the organism or exact tumor type found.

Treatment of transverse myelitis is supportive, and some degree of recovery occurs in approximately 80% of cases. All children with this syndrome should be hospitalized. Although there are no controlled trials of their efficacy, there is a consensus supporting the use of systemic corticosteroids. Some experts have also recommended IV immunoglobulin, again without supportive evidence from clinical trials.

Acute Polyneuritis (Guillain–Barré Syndrome)

Background and Pathophysiology

Acute polyneuritis, also called *Guillain–Barré syndrome*, is characterized by symmetric ascending paralysis. Pathologically, the hallmark of this disease is primary demyelination of motor and sensory nerves, believed to be secondary to autoimmune mechanisms. It occurs in children in all age groups but is uncommon before 3 years of age. An antecedent respiratory or gastrointestinal infection or immunization precedes the onset of illness by 1 to 2 weeks in more than 75% of childhood cases.

Clinical Manifestations

Weakness, commonly with an insidious onset, is the usual presenting complaint. Paresthesias or other sensory abnormalities such as pain or numbness are prominent in up to 50% of cases, particularly in older children. The paresthesias and paralysis are usually symmetric and ascending, although variations may occur. Early in the course of illness, distal weakness is more prominent than proximal weakness. Deep tendon reflexes are depressed or absent at the time of diagnosis. Affected children often have an ataxic gait. Similar clinical findings may be seen in West Nile virus infection.

Cranial nerve abnormalities occur during the illness in 30% to 40% of cases and may be the predominant finding, especially in the Miller-Fisher variant of this syndrome, which is characterized by oculomotor palsies, ataxia, and areflexia without motor weakness of the extremities. The most common cranial nerve deficit is VII (facial) nerve palsy, followed in decreasing frequency by impairment of cranial nerves IX, X, and XI and oculomotor abnormalities. Autonomic dysfunction occurs commonly and results in blood pressure lability, postural hypotension, and cardiac abnormalities; it is a disproportionate cause of morbidity and mortality. Urinary retention, if it occurs, is usually seen late in the illness. As the paralysis ascends, muscles of breathing may become involved, leading to respiratory embarrassment.

The primary aid in diagnosis is LP, which demonstrates an elevated protein level, normal glucose level, and fewer than 10 white blood cells per cubic millimeter—the so-called albuminocytologic disassociation. The protein elevation occurs in almost all cases but may be delayed for weeks, usually peaking in the second or third week of illness. Electrophysiologic evidence for Guillain–Barré syndrome is the presence of nerve conduction velocity delay, which is usually not demonstrable until the second or third week of illness. Emergency electromyography (EMG) and nerve conduction velocity testing are not indicated.

Management

Because of the potential for progression to life-threatening respiratory compromise, the child with Guillain–Barré syndrome

should be hospitalized and observed closely. Impending respiratory distress must be anticipated, and routine respiratory monitoring should be aided by specific measures of respiratory function, particularly measurement of negative inspiratory force. Because autonomic dysfunction is common, blood pressure must be monitored closely and abnormalities treated vigorously.

Acute polyneuritis is generally self-limiting, with more than 90% of children in most series having complete or near-complete recovery. In mild cases, in which children retain the ability to ambulate, only supportive care is required. However, immunomodulatory therapy may be of benefit in more severely affected children. Plasmapheresis and IV immunoglobulin both have been used. Although well-controlled, blinded studies of these treatments in children are lacking, the available data suggest that both are effective in reducing the duration and severity of illness in those most severely affected, especially when begun early in the course of the disease. Corticosteroids have not been shown to be beneficial in acute Guillain–Barré syndrome; a recent metaanalysis demonstrated that oral corticosteroids actually delayed recovery.

Myasthenia Gravis

Background and Pathophysiology

In myasthenia gravis, antibodies directed against the acetylcholine receptor protein of the postsynaptic neuromuscular junction cause intermittent failure of neuromuscular transmission and fluctuating weakness. Myasthenia manifests as fluctuating weakness of cranial and skeletal musculature, exacerbated by exertion. More commonly a disease seen in adults, myasthenia gravis occurs in children in three major forms: transient neonatal, infantile (congenital), and juvenile (most common).

Clinical Manifestations

The juvenile form of myasthenia clinically mimics the adult disease. The mean age of onset is 8 years, with a female predominance of approximately 4:1. The onset of symptoms may be insidious or acute. Most cases affect the cranial nerves, and any cranial nerve can be involved in combination or isolation. Bilateral ptosis is the most common cranial nerve deficit, followed in incidence by oculomotor impairment. Generalized truncal and limb weakness is present at onset in up to half of cases and eventually develops in most children with myasthenia. The diagnosis should be suspected if there is a history of worsening weakness during continual activity or if fatigability of muscle strength is demonstrable. Illnesses confused with myasthenia include the muscular dystrophies, congenital myopathies, inflammatory myopathies, acute and chronic polyneuropathies, and in the infant, botulism.

The Tensilon test is useful in ED diagnosis. In this procedure, the anticholinesterase drug edrophonium (Tensilon), which has a 30-second onset and approximately a 5-minute duration of action, is given slowly IV at a dosage of 0.2 mg per kg, up to a maximum dose of 10 mg. Atropine should be immediately available to treat potential severe cholinergic reactions (e.g., bradycardia). Initially, one-tenth of the total dose is given, and if no hypersensitivity or severe reactions are noted, the remainder of the dose is administered. Because edrophonium is short-lived, interpretation of the response requires close monitoring of a muscle or muscle group in which improvement can be seen clearly, such as the eyelid elevators. In small children, this is often impossible and longer-acting anticholinesterases, such as neostigmine (0.125 mg in an infant and 0.04 mg per kg in an older child), can be used. EMG provides electrophysiologic evidence for myasthenia gravis, with a decremental response to repetitive nerve stimulation, but may be negative when the disease is confined to the cranial nerves.

Management

Although myasthenia gravis is potentially life-threatening, specific management can usually be delayed until after diagnosis is made. If there is evidence of respiratory compromise, ventilatory support is mandatory. Treatment is begun with the use of cholinesterase inhibitors to prolong the availability of acetylcholine at the neuromuscular junction. At present, the anticholinesterase of choice is pyridostigmine (Mestinon) at a starting dosage of 1 mg per kg by mouth every 4 hours, adjusted according to the clinical response. If there is any concern about respiratory compromise or if severe weakness is present, the child should be hospitalized immediately.

Myasthenia has a fluctuating, unpredictable course that can be exacerbated by intercurrent illness and by certain drugs, particularly the aminoglycoside antibiotics. In a known myasthenic, rapid worsening and respiratory compromise (myasthenic crises) may be difficult to differentiate from deterioration secondary to overdose of anticholinesterases (cholinergic crises) because the muscarinic side effects of the anticholinesterases, such as nausea, vomiting, cramps, and muscle fasciculations, may be absent. At times, differentiation can be made by giving 1 to 2 mg of IV edrophonium after ensuring respiratory sufficiency. This should result in rapid improvement in the patient with a myasthenic crisis. This procedure may be falsely positive, however, and if the diagnosis is unclear, the patient should be withdrawn from all anticholinesterases and, if necessary, maintained on mechanical respiration for 48 to 72 hours. Cholinergic crises require the immediate withdrawal of all anticholinesterases. Myasthenic crises respond variably to additional anticholinesterases, and plasmapheresis or steroid therapy may be particularly useful in this situation. Both myasthenic and cholinergic crises mandate admission to the hospital.

Botulism (See Also Chapter 92)

Background and Pathophysiology

Infantile botulism is a cause of acute weakness in previously well infants younger than 6 months. The illness is secondary to intestinal colonization by *Clostridium botulinum*, which produces a neurotoxin that impairs acetylcholine release from the nerve terminal. Spores of *C. botulinum* are of ubiquitous origin, found in soil and agricultural products. Honey has been found to be a particularly significant reservoir. Although infant botulism occurs throughout the United States, the incidence is highest in certain areas; approximately half the cases reported have been from California, Utah, and Pennsylvania. The various host factors that predispose certain infants to intestinal colonization are poorly understood.

Clinical Manifestations

The initial symptom of infantile botulism is usually constipation, followed insidiously by lethargy and feeding difficulties. Physical findings at the time of presentation are hypoactive deep tendon reflexes, decreased suck and gag, poorly reactive pupils, bilateral ptosis, oculomotor palsies, and facial weakness. Differential diagnosis includes all the potential causes of lethargy and poor feeding in infancy, and infants are often misdiagnosed initially. Laboratory test results, including the leukocyte count and LP, are normal. The diagnosis is confirmed by identification of *C. botulinum* toxin (usually type A or B) in the feces or isolation of the organism in stool culture, which is less sensitive. EMG may supply immediate information. Characteristic EMG findings are brief, small-amplitude action potentials; posttetanic facilitation; and normal nerve conduction velocity.

Management

Affected infants require hospitalization to observe for respiratory compromise. In one large series of 57 patients, 77% required endotracheal intubation because of loss of protective airway reflexes, and 68% received mechanical ventilation for some period. Nasogastric or nasojejunal feedings are usually needed as well.

Human botulism immunoglobulin, with activity against type A and B toxins, is approved for use in infant botulism (often referred to as BabyBIG). Trials have shown a decrease in duration of illness in treated infants. Equine botulinum antitoxin has a high rate of anaphylactic reaction in infants and is not recommended. The use of cathartics or other laxatives to reduce the amount of *C. botulinum* present in the intestine has not proved beneficial. Antibiotics such as penicillin, although widely used, have not been shown to eradicate the organism from the bowel or result in clinical improvement. Aminoglycosides, which can cause neuromuscular blockade, should be avoided.

Periodic Paralysis

Background and Pathophysiology

Familial periodic paralysis is a rare illness, inherited in an autosomal-dominant fashion that results in episodes of severe weakness associated with an abnormality of circulating potassium during attacks. Two major forms of illness—hyperkalemic and hypokalemic—are recognized. (A third type, normokalemic, has been described but most likely represents a rare variant of the hyperkalemic variety.) Other disorders that can produce weakness and electrolyte abnormalities, such as use of corticosteroids or diuretics, thyrotoxicosis, hyperaldosteronism, and renal insufficiency, may mimic the periodic paralyses. The serum potassium abnormalities in familial periodic paralysis are believed to be epiphenomena of yet undelineated muscle membrane abnormalities.

Clinical Manifestations

Many of the clinical features are common to the various forms of periodic paralysis. Characteristically, a previously well patient develops a flaccid weakness in his or her trunk and upper thighs, and the weakness gradually involves the remainder of the skeletal muscles. Deep tendon reflexes are diminished. The attacks last from hours to days, and between the attacks, muscular strength is usually normal, although a minority of patients have residual muscular weakness.

Hypokalemic periodic paralysis, the most common type, occurs primarily in adolescents and young adults. Trigger factors include vigorous exercise, heavy carbohydrate meals, alcohol, and the cold. During an attack, potassium levels are usually 2 to 2.5 mEq per L, and electrophysiologic examination demonstrates unstimulatable muscles. The hyperkalemic form usually begins in the first decade of life, and attacks occur predominantly during the period of rest after vigorous exercise or after fasting. The episodes are more common than in hypokalemic paralysis but often last less than a few hours. Myotonia is usually associated with the illness. During the attack, plasma potassium level is moderately elevated, although it is often in the upper normal range. In both forms of periodic paralysis, EKG changes consistent with the serum potassium abnormality may be noted and cardiac arrhythmias may rarely arise.

Management

Emergency treatment of hypokalemic periodic paralysis includes oral, or rarely IV, potassium. Prophylactically, patients should avoid precipitants such as vigorous exercise or large carbohydrate loads. Recurrences may be prevented with spironolactone or acetazolamide.

Attacks of hyperkalemic periodic paralysis are often brief enough that acute treatment is unnecessary. In severe attacks, inhaled albuterol and IV calcium gluconate may be helpful. Acetazolamide, thiazide diuretics, and albuterol have been used for prevention of recurrences.

DISORDERS OF BALANCE (SEE CHAPTER 10)

Acute Cerebellar Ataxia

Background and Pathophysiology

Acute cerebellar ataxia, characterized by the acute onset of unsteadiness in a previously well child, is the most common cause of ataxia in young children. It is seen primarily between the ages of 1 and 4 years but can occur at any time during childhood. The exact cause of the illness is unclear; however, it is believed to be a parainfectious or postinfectious demyelinating phenomenon and likely represents a localized form of postinfectious encephalitis. Acute cerebellar ataxia occurs most commonly after primary varicella. Other infections implicated include infectious mononucleosis, enteroviruses, HSV, influenza, *Mycoplasma*, and Q fever. Ataxia is usually seen 5 to 10 days after the onset of illness, although symptoms may be delayed for up to 3 weeks, and there are some reports of cerebellar ataxia preceding the rash of chickenpox.

Clinical Manifestations

The child develops acute truncal unsteadiness with a variable degree of distal motor difficulty, such as tremor and dysmetria. Dysarthria and nystagmus are variably present. Some children

have nausea and vomiting, presumably caused by vertigo. Headache is rare.

When acute ataxia follows varicella in a child with no other neurologic findings, the diagnosis may be made on clinical grounds. In atypical cases, CT or MRI may be necessary to rule out a cerebellar mass. LP is not usually necessary in typical cases; if performed, it reveals a mild CSF pleocytosis in approximately half of the cases.

Management

Treatment is supportive. Resolution of symptoms is complete in most children within 2 weeks of onset, but mild residual neurologic deficits have been reported in 10% to 30% of cases. Varicella-associated cases appear to have the most benign prognosis.

Benign Paroxysmal Vertigo

Benign paroxysmal vertigo is an illness that affects children primarily between 1 and 4 years of age, although it can occur any time during the first decade. It manifests with acute episodes of dizziness and imbalance, lasting seconds to minutes. Between episodes, the child is asymptomatic. During the spell, the child characteristically becomes frightened and pale but does not lose consciousness. He or she may have associated nausea, vomiting, or visual disturbance. The physical examination is usually normal except for nystagmus, which may be present. Although the cause of this illness is unknown, it is believed to be a migraine variant. Many children go on to develop more typical migraine headaches later, and there is often a family history of migraine disease. As the name suggests, the course of benign paroxysmal vertigo is self-limiting and benign, and treatment is supportive.

MOVEMENT DISORDERS

Involuntary movements are components of many CNS disorders and tend to be complex. A classification into specific subtypes, based on the character, predominant anatomic localization, rhythmicity, and frequency, is arbitrary but useful in deducing the cause of the disorder (Table 96.9). Movements such as chorea, athetosis, dystonia, ballismus, and certain types of tremors suggest dysfunction of the extrapyramidal nervous system. Involuntary movements are also caused by damage to the cerebellum or its outflow tract, especially static (on maintaining fixed position) and intention tremors. Myoclonus may occur secondary to cerebral cortex, brain stem, or spinal cord disease. Tics, another form of involuntary movement, may be extremely difficult to distinguish from chorea and are best differentiated by their stereotypic character. They probably represent the most common involuntary movement disorder but are not true neurologic emergencies. Many illnesses may present with involuntary movements and are diagnosed by associated neurologic findings.

Acute Dystonia

Dystonia is marked by involuntary, sustained muscle contractions, typically of the neck and trunk, that cause twisting movements and abnormal postures. In generalized dystonia, the head is usually deviated to the side and there is grimacing of the face. Acute dystonia in children is nearly always the result of exposure to an antidopaminergic agent such as a neuroleptic, antiemetic, or metoclopramide. Chronic dystonias are rare but may be seen as an isolated disorder or as a manifestation of cerebral palsy. Dystonia must be differentiated from torticollis, an abnormal tilt of the head and neck usually resulting from irritation or spasm of the sternocleidomastoid muscle. Another clinically similar condition is Sandifer's syndrome, which describes intermittent arching of the back and neck, observed in infants with gastroesophageal reflux.

Acute dystonia resulting from exposure to antidopaminergic drugs is treated with diphenhydramine [1 mg per kg per dose IV, orally (PO), or IM] or benztropine (Cogentin; 1 to 2 mg per dose IM). Because the half-life of many of the precipitating agents is fairly long, treatment should be continued for 24 to 48 hours.

Sydenham's Chorea

Background

Sydenham's chorea, the most common form of acquired chorea seen in children, occurs primarily between the ages of 3 and 13 years. Marked by involuntary movements, coordination difficulties, and emotional lability, its onset may be abrupt

TABLE 96.9

CATEGORIZATION OF MOVEMENT DISORDERS

Movement	Character	Location	Speed	Rhythmicity	Stereotype
Chorea	Jerky	Anywhere, may be universal	Rapid	Irregular	No
Athetosis	Writhing	Primarily distal	Slow	Irregular	At times
Dystonia	Writhing	Primarily proximal	Slow	Irregular	At times
Ballismus	Flailing	Proximal	Rapid	Irregular	No
Tremor	May be resting, static, or intention	Primarily distal	Variable	Regular	Yes
Myoclonus	Jerky	Anywhere	Rapid	Irregular	Variable
Tic	Jerky	Anywhere (especially face, neck, hands)	Rapid	Variable	Yes

or insidious. Sydenham's chorea is believed to be a poststreptococcal disease and may occur months after the primary bacterial infection. It is one of the major diagnostic criteria for rheumatic fever (see Chapter 92).

Clinical Manifestations

The involuntary movements may be subtle at first and exacerbated by stress. Initially, the movements classically affect the face and distal portion of the upper extremities and consist of rapid, involuntary random jerks. This results in the "milkmaid hand," in which the child's hand cannot maintain a uniform strength while grasping the examiner's hand. The involuntary movements disappear during sleep. There is usually associated muscular hypotonia and marked coordination difficulties and speech is often jerky. Hemichorea, in which the abnormal movements are predominantly unilateral, occurs in some cases. The deep tendon reflexes are normal, although occasionally, the patellar reflex is said to be "hung up." There is no evidence for upper motor neuron disease.

Serologic evidence for preceding streptococcal infection is absent in up to 25% of cases, and only one-third of patients have associated manifestations of rheumatic fever at the time of diagnosis. In the absence of such confirmatory evidence of a poststreptococcal cause, other disorders that may present with chorea must be considered in the differential diagnosis. These include atypical seizures, drug intoxication, choreoathetoid cerebral palsy, familial choreas, chorea gravidarum, collagen vascular disease, Wilson's disease, and Lyme disease.

Management

Initially, all patients should have a hematologic profile, sedimentation rate, and serologic tests performed for streptococcal infection. An EKG should also be performed to look for evidence of rheumatic carditis (e.g., prolonged P-R interval). If there is a question concerning diagnosis, further tests, such as CT, MRI, LP, and serologic evaluation for collagen vascular disease, might be helpful, but they are not usually necessary on an urgent basis.

The success of any treatment is hard to evaluate because the course is so unpredictable. Haloperidol (0.5 to 1 mg PO twice daily) has been reported to result in improvement within 2 to 3 days. Valproic acid and carbamazepine have also been used. In patients with severe symptoms refractory to these agents, methylprednisolone, IV immunoglobulin, and plasmapheresis have all been described, in case series. Because patients with Sydenham's chorea have an increased incidence of rheumatic carditis, prophylactic penicillin should be used unless another specific cause is determined for the chorea.

DISORDERS OF CRANIAL NERVE FUNCTION

Optic Neuritis

Background

Optic neuritis is an acute inflammation or demyelination of the optic nerve, characterized by an impairment of vision, progressing over hours or days and associated with tenderness of the eyeball exacerbated by eye movement. The disease is primarily unilateral but an increased incidence of bilateral involvement is found in children. Optic neuritis in children is most commonly presumed to be on an autoimmune basis following a viral disease, including the childhood exanthems. At times, a contiguous sinusitis may cause the illness. Of patients with unilateral optic neuritis, 20% will develop multiple sclerosis at a later date, but there is little reason to make this diagnosis before the development of other symptoms of neurologic dysfunction.

Clinical Findings

On examination, decreased visual acuity and decreased color vision are associated with a relative afferent pupillary deficit to light and a central scotoma in the affected eye. The relative afferent pupil defect is demonstrated by the swinging flashlight maneuver, during which the pupil of the affected eye constricts briskly when light is shone into the contralateral eye (the consensual light reflex) and dilates when light is immediately shone into the affected eye. With bilateral disease, the change in pupillary reflexes may not be apparent. Funduscopic examination discloses a hyperemic, swollen optic disc; in the rare cases of retrobulbar optic neuritis, funduscopic examination is normal.

Optic neuritis must be distinguished from papilledema, secondary to increased ICP. Papilledema is almost always bilateral and associated with normal vision and normal pupil reactivity until late in the disease. In cases of bilateral optic neuritis, differentiation may be impossible because funduscopic findings are identical in the two illnesses. If any doubt of increased ICP persists, the patient should undergo evaluation by CT or MRI of the brain and, if normal, CSF analysis. In optic neuritis, the opening pressure is normal, but there may be a mild lymphocytic pleocytosis or elevated CSF protein level.

Management

The course of the illness is variable, with most patients recovering to normal or near normal vision over 4 to 5 weeks. Treatment with high-dose systemic corticosteroids has not been shown to improve the ultimate prognosis but may result in a slightly faster resolution of symptoms.

Facial Nerve Palsy

Background

Weakness in the distribution of the cranial nerve VII (facial) may be produced by either central (upper motor neuron) or peripheral (lower motor neuron) dysfunction. Peripheral disease is most common in children, particularly when the facial weakness is an isolated finding. Bell's palsy refers to peripheral facial nerve weakness with no identifiable underlying cause. It is believed to be secondary to edema of the facial nerve as it passes through the facial canal within the temporal bone. There is often a history or preceding upper respiratory tract infection, and in at least a subset of patients, there is evidence of reactivation of infection with Epstein-Barr virus or HSV. Seventh nerve palsy may occur in association with otitis media, in which case it may indicate the presence of mastoid involvement. Facial palsy may also be a manifestation of early-disseminated Lyme disease. It usually occurs in isolation,

although there may be other signs of CNS disease. Although in general most cases of facial nerve palsy in children are of the idiopathic (or viral reactivation) type, in endemic areas, Lyme disease may be the most common cause.

Clinical Manifestations

Facial weakness may be partial or complete. On the affected side, there is flattening of the nasolabial fold at rest, and the child has difficulty closing the eye or raising the corner of the mouth to smile. In many cases, pain localized to the ear precedes the paralysis. With upper motor neuron involvement, there will be some residual capacity to furrow the brow because of crossed innervation, whereas the entire face is involved with peripheral disease. There may be bilateral involvement in Lyme disease, in contrast to Bell's palsy, which is always unilateral.

In children with facial nerve palsy caused by Lyme disease, other manifestations, such as erythema migrans, are rarely seen (27% in one series). Thus, even in the absence of other findings, serologic evidence for systemic Lyme infection should be sought in all children with isolated cranial nerve VII paresis in endemic areas, although only about 50% of affected children will have elevated titers at the time of diagnosis. An LP should be performed if there is other evidence of meningoencephalitis such as headache; however, the need for LP in a child at risk for Lyme disease with isolated facial nerve palsy is controversial. Other associated neurologic abnormality, specifically in the other cranial nerves, or concomitant otitis media, necessitates further evaluation, including CT or MRI.

Management

Symptomatic treatment for facial nerve palsy consists of protection of the cornea by the instillation of bland ointments (e.g., Lacri-Lube). For patients with facial nerve palsy due to Lyme disease, oral antibiotic treatment is indicated as for other manifestations of early-disseminated Lyme disease (see chapter 101). Parenteral antibiotics are reserved for those with findings of meningitis.

Specific treatment for facial nerve palsy not associated with Lyme disease is somewhat controversial, but steroids may be beneficial when started early in the course of the disease. Although earlier studies are mixed, a recent large controlled trial demonstrated greater long-term improvement in adults with Bell's palsy treated with prednisolone. Only one trial has included children, and all patients in that study recovered regardless of treatment. However, based on adult studies, many authors have recommended a course of prednisone (1 to 2 mg per kg per day) over 7 to 10 days if the patient is seen within the first 72 hours of disease. Studies in adults suggest that antiviral agents combined with prednisone may provide additional benefit, with valacyclovir showing greater efficacy than acyclovir. However, studies have been mixed, and the lack of evidence for antiviral therapy in children mandates against routine administration.

Regardless of treatment, complete recovery is seen in 60% to 80% of children, beginning during the second to third week of illness. Those with partial paralysis generally have a better prognosis. During the recovery period, special care should be taken to protect the cornea by the instillation of bland ointments (e.g., Lacri-Lube). The child should be referred for reexamination to ensure a recovery during the expected time period.

Children with clinical or serologic evidence of Lyme-associated facial nerve palsy should be treated with oral antibiotics (amoxicillin, tetracycline, or erythromycin) for 21 to 28 days. The effectiveness of steroids in such patients has not been evaluated. Parenteral antibiotic treatment is recommended for children who also have evidence of meningitis. Peripheral facial nerve palsy in association with otitis media may require myringotomy.

CHAPTER 97 ■ ONCOLOGIC EMERGENCIES

AMY L. BILLETT, MD, AND JENNIFER C. KESSELHEIM, MD, M.ED

INTRODUCTION

Every year in the United States, approximately 12,000 children and adolescents are diagnosed with cancer and 2,300 children die of their disease or side effects of treatment. Both cancer and treatment can cause significant morbidity for children. This chapter is organized in three major sections. The first section addresses the diagnosis and initial care of a child who presents to the emergency department (ED) at the time of new cancer diagnosis or at recurrence of disease. While this first section is organized by both the kind of cancer and by location of initial signs or symptoms, it does not address how to complete a diagnostic workup for cancer or initiate a definitive treatment plan. The second section addresses complications of treatment that may lead to an ED visit. The section is organized by the organ system affected. The final section addresses pain management and end-of-life care.

In general, when considering the pediatric oncology patient in the ED, the approach outlined in Table 97.1 will help the practitioner obtain historical information that is often unique to this patient population. A detailed medication history is critical because patients may be on multiple medications whose side effects may be contributing to the cause of the current ED visit. The antibiotic history should explore if the medication is being given to prevent an infection, to treat a known infection, or to suppress colonization. When taking a history from a pediatric oncology patient, we emphasize the paramount importance of the patient/parent point of view. While we as clinicians do have significant knowledge, the patient and family experiencing the cancer diagnosis are truly the experts. Exploring the perspective of the patient and parents about what the potential cause of the problem and how the patient is doing is a crucial step in the evaluative process. One last introductory principle is to consider always the extreme psychosocial stress that a pediatric cancer diagnosis places on a family. The care of these patients therefore requires the highest level of compassion and professionalism from clinicians.

INITIAL CARE OF THE CHILD WITH NEW OR RECURRENT CANCER

Childhood cancer can present with nonspecific signs and symptoms that can overlap with those of many childhood illnesses (Table 97.2). This is common with hematologic malignancies or with widely metastatic solid tumors. Even when the chief complaint is a localized symptom, disseminated disease may be present. Thus, the diagnosis of possible cancer in the ED may require not only a thorough history and physical examination but also an initial laboratory and radiologic workup.

In general, once the diagnosis of cancer is suspected, a child should be referred to a center skilled in the management of childhood cancer and whose staff includes a pediatric oncologist as well as other subspecialists such as pediatric surgeons and radiation oncologists. Supportive care for life-threatening complications may need to be initiated in the ED prior to referral. In general, the specific workup, including obtaining tissue for diagnosis, should be carried out under the direction of a pediatric oncologist so that optimal information can be obtained. Histologic slides and paraffin blocks from a standard biopsy are often insufficient because viable tissue is essential for critical immunologic, cytogenetic, and molecular testing necessary to categorize the disease and choose the appropriate treatment. A number of studies have shown improved outcome for older adolescents and young adults when treated by pediatric oncologists using pediatric treatment programs. This information should be considered when referring a patient with a new or presumed diagnosis of cancer for further care. No patient should be discharged from the ED without a specific plan for definitive diagnosis and management.

The emergency physician should describe the findings and concern about possible cancer to the patient and family. It is appropriate to reassure them that most childhood cancer is curable. Specific details about diagnosis, treatment, and prognosis are best deferred to the pediatric oncologist to address once definitive information is available. The possibility of a cancer diagnosis usually causes fear and distress and requires empathic care and support from the health-care team in the ED.

Leukemia

Leukemia is a cancer of white blood cells (WBCs), and their precursors, that proliferate in excess within the bone marrow and other hematopoietic tissues. The presentations of childhood leukemia that a clinician in the ED may encounter are varied and, in some cases, the diagnosis of leukemia is not at all obvious (Table 97.2). Symptoms are usually secondary to bone marrow replacement or from infiltration of leukemic blast cells into tissues outside of the bone marrow. Leukemia is the most common childhood malignancy accounting for 29% of all cancer diagnoses in children from 0 to 14 years of age. Approximately 3,500 children are diagnosed with leukemia each year in the United States. Leukemias are classified as either acute or chronic. More than 95% of pediatric leukemias are acute, and acute lymphoblastic leukemia (ALL) accounts for the vast majority. ALL includes B-precursor ALL and T-lineage ALL. The other leukemias seen in children in order of decreasing

TABLE 97.1

HISTORICAL DATA NEEDED FOR EVALUATION OF PEDIATRIC ONCOLOGY PATIENTS IN THE EMERGENCY DEPARTMENT

Category	Specific history to explore
Primary diagnosis	Tumor type Primary or metastatic Where are sites of metastatic disease? Date of diagnosis Status of disease In remission, on treatment In remission, off treatment Relapsed
Surgical history	Date of surgical procedures Surgical complications Extent of tumor resections
Recent treatments	Chemotherapy Drugs included in current treatment plan Dates of last chemotherapy doses Radiation therapy Doses of radiation used Location of radiation field(s) Dates of radiation therapy Stem cell transplant Autologous or allogeneic Use of immunosuppressants History of graft-versus-host disease
Central venous access	Type History of infections in line
Current medications	Chemotherapy: Prophylaxis for *Pneumocystis jiroveci* or other infections Growth factors Pain treatment Supportive care medications such as Antiemetics GI acid blockade Bowel regimen Antihypertensives
Patient/family perspective	How is the patient acting? Has this problem happened before? Are symptoms getting worse or better? What does parent or patient believe to be cause of the problem?

frequency include acute myeloid leukemia (AML), chronic myelogenous leukemia (CML), and chronic myelomonocytic leukemia (CMMoL). Specific classification is based on morphology, immunologic surface markers, and cytogenetic abnormalities from the bone marrow aspirate. Children with trisomy 21 are at increased risk of transient myeloproliferative disorder of the newborn, AML (younger than 4 years), and ALL (older than 1 year).

Leukemia presents in a variety of ways. As the leukemia proliferates in the bone marrow, normal hematopoietic elements are decreased leading to anemia, thrombocytopenia, and neutropenia. This is most common in the setting of leukemia but can occur with solid tumors, such as neuroblastoma and rhabdomyosarcoma with marrow metastasis. Anemia can be mild or severe but is often asymptomatic because of its slow development. Anemia with associated clinical signs or symptoms should be treated with a red cell transfusion. Thrombocytopenia can present with mucocutaneous bleeding such as epistaxis, gingival bleeding, petechiae, and ecchymosis. Concurrent nonsteroidal antiinflammatory drugs (NSAIDs) can increase the bleeding manifestations. The risk of bleeding may also be compounded by coagulopathy from the leukemia itself or from disseminated intravascular coagulation (DIC) related to sepsis.

Tumor lysis syndrome (TLS) is a metabolic complication resulting from the rapid death and destruction of tumor cells. As dying leukemic cells release their intracellular contents into the blood, potassium, phosphate, and uric acid rise. The elevated phosphate complexes with calcium and leads to hypocalcemia. The resulting calcium phosphate crystals can then deposit in the renal tubules causing renal insufficiency or in other tissue sites. Urate crystals can precipitate in the acidic renal tubular environment, causing an obstructive uropathy and renal insufficiency. TLS is common with acute leukemias and lymphomas but can also occur with neuroblastoma or other solid tumors with a very high tumor burden. The risk of TLS is highest in advanced Burkitt's lymphoma and ALL with hyperleukocytosis. Screening and preemptive therapy with hydration and allopurinol is appropriate for all patients at risk of TLS. The use of allopurinol or rasburicase (Elitek®) to decrease uric acid levels is often driven by institutional protocol.

Management of TLS relies on protecting the function of the kidneys while preventing severe metabolic derangements (Table 97.3). Alkaline hydration should be initiated to achieve brisk, dilute urine output with a pH 7 to 7.5 as long as the patient is not expected to receive rasburicase. If using rasburicase, hydration without alkalinization should be given. Alkalinization of the urine helps dissolve uric acid crystals but the pH should be kept below 8 to avoid increasing the probability of calcium phosphate crystal deposition in the kidney. In addition to IV hydration, all patients should either receive therapy with allopurinol (10 mg per kg per day with maximum dose 300 mg) or rasburicase. Allopurinol is a xanthine oxidase inhibitor that impairs the production of uric acid. Rasburicase, a recombinant urate-oxidase enzyme, causes direct lysis of uric acid and leads to a rapid drop in uric acid levels. The usual starting dose is 0.2 mg per kg IV. Rasburicase is indicated in patients who are at higher risk of TLS complications such as patients who present with compromised renal function or an extremely elevated uric acid level (e.g., greater than 12); who have advanced Burkitt's lymphoma; who cannot tolerate hydration [e.g., central nervous system (CNS) hemorrhage], or whose uric acid is rising despite allopurinol. There is no need to alkalinize the urine when rasburicase is used. Rasburicase is contraindicated in glucose-6-phosphate dehydrogenase (G6PD) deficiency as it can result in oxidative stress and hemolysis.

Of note, not all electrolyte abnormalities in the setting of TLS should be corrected (Table 97.3). Hyperphosphatemia can be treated using aluminum hydroxide as frequently as every 2 to 4 hours. Hypophosphatemia should not be corrected unless it is

TABLE 97.2

COMMON PRESENTING SYMPTOMS AND SIGNS OF PEDIATRIC CANCER

[a]Patients with solid tumors invading the marrow may have symptoms and signs similar to those seen in leukemia.

TABLE 97.3

EMERGENCY DEPARTMENT CARE OF PATIENT WITH PROBABLE OR CERTAIN ACUTE LEUKEMIA

Diagnostic Evaluation for All Patients
Detailed medical history and complete physical examination
CBC count with manual differential and peripheral blood smear
Electrolytes, including potassium, calcium, phosphorus
Uric acid
Assessment of renal function with BUN and creatinine
Coagulation studies, PT, PTT
Blood group type, antibody screen
Liver function tests
Chest x-ray to assess for mediastinal mass

Supportive Care for All Patients
Results of CBC count should be examined to determine if patient has anemia or thrombocytopenia requiring transfusion (please see below)
IV fluids should run at approximately 1½ times maintenance and should be alkalinized with $NaHCO_3$ to ensure a urine pH of 7–8
Allopurinol

Specific Problems that Require Immediate Intervention

Problem	Required data/findings	Therapy/management
Tumor lysis syndrome	Frequent lab monitoring (q 4–6 h) Uric acid Electrolytes BUN and Creatinine Ca and PO_4 Follow urine output	Preemptive Management of patients at risk for tumor lysis syndrome[a] IV fluids 1.5–2× maintenance with $NaHCO_3$ 40 mEq/L Target urine pH 7–8 Target urine output >1 mL/kg/h No potassium in IV fluids Allopurinol Treatment of patients with TLS[b] IV fluids as above Allopurinol or rasburicase Rasburicase, if renal function is impaired at presentation, if uric acid levels are rapidly rising or extremely high, or if there is a contraindication to hyperhydration No alkalinization needed if rasburicase given Replacement of phosphorus for serum level <1 Hyperkalemia: furosemide, insulin/glucose, kayexalate Hypokalemia: No replacement of potassium unless critical level with high risk of cardiac arrhythmia Hypocalcemia: no calcium replacement unless symptomatic hypocalcemia Consider whether renal function or metabolic derangements may necessitate dialysis
Hyperleukocytosis	WBC count >100,000/mL	Ensure IV fluids are being given at maximum tolerated volume Avoid transfusion of packed red blood cells, which can increase viscosity Monitor for leukostasis
Leukostasis (occurs in some patients with hyperleukocytosis)	Clinical symptoms of respiratory distress or change in neurologic status Chest x-ray findings may be present	Urgent leukopheresis to decrease viscosity Continue IV fluids Proceed with caution if PT or PTT elevated
Mediastinal mass	Chest x-ray and/or chest CT scan Assessment of respiratory status while upright and supine Peak flow	Mass will likely shrink quickly in response to chemotherapy Support respiratory mechanics No sedation/anesthesia
Fever	Blood culture Additional culture from any site with localizing symptoms Avoid lumbar puncture	All patients should be assumed neutropenic, even if ANC >500 Empiric broad-spectrum antibiotics (see Figure 97.4) Tylenol, no NSAIDs

(*continued*)

TABLE 97.3

CONTINUED

Problem	Required data/findings	Therapy/management
Anemia	Hemoglobin <7 g/100mL Symptoms related to low red blood cell mass	Please see Table 97.7 for special guidelines for transfusions in the oncology population Avoid red cell transfusions in the setting of hyperleukocytosis If severe anemia, transfuse slowly to avoid precipitating congestive heart failure
Thrombocytopenia	Platelet count <150,000/mL	Please see Table 97.7 for special guidelines for transfusions in the oncology population
Coagulopathy	PT, PTT, fibrinogen, D-dimer	Fresh frozen plasma 10 mL/kg If hypofibrinogenemia exists in isolation, treat with cryoprecipitate, 1–2 U/10 kg Platelet transfusion if count <50,000/mL Leukopheresis and lumbar puncture may be contraindicated until coagulopathy corrected
CNS symptoms	Neurologic examination WBC count to screen for hyperleukocytosis PT, PTT, fibrinogen, D-dimer to assess risk for CNS hemorrhage Serum electrolytes Lumbar puncture with cell count and cytology Head and/or spinal cord imaging with CT or MRI	Leukopheresis to decrease viscosity and leukostasis, if WBC >100,000/mL and symptomatic Correct coagulopathy Fresh frozen plasma 10 mL/kg Cryoprecipitate 1–2 U/10 kg Platelet transfusion if count <50,000/mL Manage TLS as above to minimize electrolyte abnormalities Initiation of chemotherapy is best management for CNS leukemia or chloroma Consultation with radiation oncology in the setting of spinal cord compression

q, every; IV, intravenous; BUN, blood urea nitrogen; TLS, tumor lysis syndrome; WBC, white blood cells; PT, prothrombin time; PTT, partial thromboplastin time; CT, computed tomography; ANC, absolute neutrophil count; NSAIDs, nonsteroidal antiinflammatory drugs; CNS, central nervous system; MRI, magnetic resonance imaging.
[a]Patients with possible acute leukemia, advanced lymphoma. Consider for patients with likely neuroblastoma or rhabdomyosarcoma and high tumor burden.
[b]Patients with hyperuricemia, hyperkalemia, hyerphosphatermia, hypocalcemia, or elevated Cr.

in a critically low range (less than 1 mEq per L). Serum potassium levels must be aggressively monitored. Hyperkalemia in the setting of TLS should be managed as it would in other disease states (see Chapter 100) with Kayexelate®, insulin, and glucose, and dialysis, if needed. Hypokalemia should not be corrected unless the patient's serum potassium falls in a critically low range (less than 2 mEq per L) or EKG changes develop. Hypocalcemia should remain uncorrected as well, unless clinical signs or symptoms of hypocalemia develop. Supplemental calcium may increase the risk of formation of calcium phosphate precipitates in the kidney.

Hyperleukocytosis is defined as WBC count above 100,000 per mm^3. When hyperleukocytosis is present, the clinical findings of leukostasis may develop from sludging of WBCs in the capillary beds. The most vulnerable beds are those in the lungs and CNS where increased viscosity can cause either thrombosis or hemorrhage. Leukostasis is much more common with myeloid leukemia than with ALL. In the setting of hyperleukocytosis, hydration should be initiated immediately to reduce viscosity. Transfusion of red blood cells and diuretics should be avoided to prevent further increases in blood viscosity. Platelet transfusions should be given to reduce the risk of CNS hemorrhage. Leukocytopheresis, a technique to reduce blood viscosity acutely, should be initiated immediately whenever even mild respiratory or neurologic symptoms are present. The use of prophylactic leukocytopheresis when the WBC count exceeds 100,000 per mm^3 in AML or greater than 300,000 per mm^3 in lymphoid leukemias is controversial and should be considered only in consultation with a pediatric oncologist. Since new onset leukemia may have an associated coagulopathy, we recommend obtaining coagulation studies to determine the risk of bleeding during leukocytopheresis.

As leukemia develops, malignant cells can infiltrate tissue outside of hematopoietic locations. It is possible for these extramedullary sites of disease to cause the leukemia to come to clinical attention. Anterior mediastinal masses occur primarily with T-lineage ALL and can lead to life-threatening airway compromise and/or superior vena cava (SVC) syndrome. The approach to the presentation and management of anterior mediastinal masses is discussed in more detail in the section on thoracic tumors. Chloroma, a mass of leukemic blasts in the soft tissue, can occur in body part. Chloromas are much more common with AML than ALL. When this mass develops and rapidly expands near the spinal cord, compression of the cord can result (see "Tumors In and Around the Spinal Cord" section). Adenopathy, hepatomegaly, and splenomegaly are very common manifestations of leukemia. Leukemic involvement in the spinal fluid can cause meningeal symptoms, cranial

nerve palsy, headache, seizure, increased intracranial pressure (ICP), or visual disturbances (from retinal infiltrates). Boys can present with testicular enlargement. There may also be skin lesions due to leukemia cutis (more common in monocytic leukemias and infant leukemia) and (in the case of AML) gingival hypertrophy due to leukemic infiltration.

Fever is common at the time of presentation with acute leukemia. Management is summarized in Table 97.3. Rarely, patients present with sepsis at the time of diagnosis or relapse. The increased risk of sepsis may be because of neutropenia and or immune dysfunction caused by the leukemia itself. Management of sepsis in the setting of leukemia is not unique and the principles are similar to those described more thoroughly in Chapter 91. For some patients, limp or a refusal to walk or bear weight on the legs is the first sign of the leukemia. In fact, it is not uncommon for a patient to receive diagnoses such as osteomyelitis or septic hip, and even receive IV antibiotics, before the diagnosis of leukemia is uncovered. It is essential for the emergency physician to ensure that a refusal to walk is not because of cord compression from chloroma as discussed above. Pain in the legs, or other bones, is usually because of replacement of the bone marrow with leukemic cells that are rapidly proliferating, thereby causing strain on the marrow spaces. Pathologic fractures may develop in children with leukemia as the expanding marrow compartments but strain on and weaken the bony cortex.

Tables 97.3 includes management guidelines for leukemia in the ED. The evaluation should begin with a thorough history and physical examination. The history should focus on the time frame in which symptoms developed and should screen for the complications described above. The physical examination should include assessment of airway, breathing, and circulation as well as an evaluation for lymphadenopathy and hepatosplenomegaly. Evidence for soft tissue infiltration by leukemia cells should be explored, such as a skin infiltration (leukemia cutis) or testicular enlargement in male patients. A thorough neurologic examination is also essential to screen for cord compression and CNS effects of the leukemia. Any abnormalities on the neurologic examination warrant CNS imaging to determine whether a neurologic complication of the leukemia has occurred.

Laboratory evaluation should begin with a complete blood cell (CBC) count, WBC differential, and peripheral blood smear to be reviewed by a hematologist-oncologist or pathologist. Automated differentials might count leukemic blasts as either atypical lymphocytes or monocytes so abnormal numbers of these cell types should raise concern for leukemia. It is possible for leukemia to present without peripherally circulating blasts, as is often the case in T-cell ALL. The ED can also send a sample of peripheral blood for flow cytometry analysis. This testing can provide important clues as to what kind of leukemia a patient has by analyzing the proteins of the blast cell surface. Specific diagnosis requires a bone marrow aspirate, which is not routinely performed in the ED and should be done only in consultation with an oncologist.

In constructing a differential diagnosis, it is helpful to consider whether leukemic blasts are present in the peripheral circulation. If blasts are present in substantive quantities (greater than 20%), then leukemia is the most likely diagnosis. However, a smaller percentage of blasts could indicate a myelodysplastic syndrome, a myeloproliferative disorder, recovery from an aplastic process, or a leukemoid reaction. If blasts are not evident on the CBC count, and the patient has pancytopenia, one must consider leukemia but also bone marrow failure, which can be because of aplastic anemia, infections (usually viral), and marrow replacement by a solid tumor involving bone marrow. If the patient is not pancytopenic and if only one to two cell lines seem to be affected, the clinician must consider the differential diagnoses for each cytopenia individually (see Chapter 91).

Assess airway patency, which may be compromised in the setting of a mediastinal mass. A chest x-ray should also be obtained to screen for the presence of a mediastinal mass. Assessment of the patient's breathing should include attention to the respiratory rate and oxygenation with O_2 saturation, both of which can become compromised in the setting of anemia, leukostasis, congestive heart failure, and pulmonary infection. To attend to the patient's circulation, the clinician must establish intravascular access and assess for signs or symptoms of SVC syndrome. The patient should not be allowed to eat or drink in case sedation or anesthesia will be needed for the diagnostic evaluation or treatment. In addition to the laboratory investigations needed to diagnose the leukemia, the evaluation should screen for TLS by checking serum chemistries, including potassium, calcium, magnesium, phosphorus, and uric acid. Renal function should be assessed with a blood urea nitrogen (BUN) and creatinine. The results of the CBC should be reviewed to assess needs for transfusions of blood products and a prothrombin time (PT) and partial thromboplastin time (PTT) should be checked to look for coagulopathy (Table 97.3). The patient should receive alkalinized intravenous hydration and allopurinol or non-alikalinized hydration and rasburicase as described in Table 97.3.

It is not uncommon for patients with leukemia to be febrile at presentation. Although the fever may be an inflammatory reaction driven by the leukemia itself, serious infection must be explored. It is essential to determine if the patient is neutropenic in the setting of the fever. If absolute neutrophil count (ANC) is less than 500, broad spectrum antibiotics intended to empirically cover gram-positive and -negative bacteria as well as pseudomonas should be administered in the ED. If localizing signs of a bacterial infection are evident, or if high fevers are present (greater than 39°C), empiric therapy should be initiated even if the patient is not neutropenic.

Histiocytic Diseases

Histiocytic diseases are a complex and sometimes confusing group of disorders for two reasons. First, several different disease entities make up this group, although efforts have been made to simplify the terminology for these various diagnoses. Second, significant clinical heterogeneity exists between the major disease entities in this category. Histiocyte is a term referring to several different cells that are thought to derive from a common CD34+ progenitor in the bone marrow. Depending on the cytokines to which the progenitors become exposed, the differentiation can yield tissue macrophages, dermal/interstitial dendritic cells, or Langerhans cells (see Fig. 97.4). In general, disorders involving histiocytes are rare; of the group, the most common is Langerhans cell histiocytosis (LCH), which has an incidence of three to five cases per million children. The most

significant histiocyte disorders include LCH and hemophagocytic lymphohistiocytosis (HLH).

LCH has clinical heterogeneity and the locations involved in the disease have implications for therapy and prognosis. Low-risk LCH may present at any age and systemic symptoms (e.g., weight loss or fever) are rare. The organs usually involved in these cases are skin, bone, lymph nodes, or a combination of these. Skin involvement can present as a red papular rash, resembling a candidal diaper rash, that may appear on the groin, abdomen, back, or chest. There may also be seborrheic flaking of the scalp, often misdiagnosed as "cradle cap" in infants, draining otitis externa, or ulcerative lesions behind the ears, on the scalp, or in the genital region. Boney involvement may be asymptomatic or the patient may complain of pain in a localized area of bone. A lytic lesion of the skull that presents as a tender mass is the most common but any bone may be involved. Loose teeth from involvement of the jaw occur. Certain sites of disease have become known as "risk" organs because their involvement implies more aggressive disease. These patients are often very young with disease that involves the lung, liver, spleen, and/or bone marrow. Lung involvement is rare but worrisome and usually manifests first as hypoxia, in which case imaging with chest x-ray or chest CT scan is needed. Liver and spleen involvement is usually accompanied by enlargement of those organs, although hepatic dysfunction may also be present. Bone marrow involvement usually presents with cytopenias, which should prompt a bone marrow aspirate and biopsy.

Diabetes insipidus (DI) is the most frequent endocrine abnormality in LCH; some patients may present with an apparent "idiopathic" presentation of DI before other lesions are identified. DI is caused by involvement of the posterior pituitary. A few patients may present with diarrhea or malabsorption as colitis related to LCH has been described. In these cases, endoscopic examination with biopsies are needed.

HLH is a very rare, severe, and life-threatening systemic disease with rapid progression from presentation to death without appropriate intervention. Thus, consideration of this diagnosis in the ED can be critical to outcome. For these reasons, it is essential for the emergency physician to have some familiarity with this disorder. Congenital HLH presents in infants and very young children. Other forms of HLH develop secondary to Epstein-Barr virus (EBV) infection, malignancy, or severe rheumatologic disorders or without a specific trigger. Regardless of etiology, HLH presents with fever, hepatosplenomegaly, adenopathy, and rash. Laboratory analysis reveals a markedly high serum ferritin as well as transaminitis, hypertriglyceridemia, hypofibrinogenemia, and cytopenias. Bone marrow evaluation may show characteristic hemophagocytosis.

All patients with suspected histiocytic disorders need thorough history and physical examination as well as overall assessment of whether they are systemically ill or not. Patients with HLH may have significant systemic illness with organ dysfunction and even vital sign instability and will require inpatient management, often in an ICU. On the other extreme, patients with a single site suspected to be LCH may require little to no intervention in the ED but need only close follow-up with oncology.

Laboratory evaluation should include CBC count, liver function testing, electrolytes to screen for DI, and inflammatory markers such as erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP). If HLH is suspected, ferritin and triglycerides should be obtained. Pulse oximetry should be checked to screen for hypoxia if LCH is suspected, and consideration given to a chest x-ray if hypoxia is detected. Consultation with oncology can be useful to guide the evaluation and management of systemically ill patients, as in the case of HLH, or allow for careful follow-up of more stable patients with LCH.

Tumors of the Central Nervous System

Tumors of the CNS, most commonly affecting the brain, represent the most common solid tumor in the pediatric population and the second most common pediatric cancer overall. There are approximately 2,000 new malignant brain tumors diagnosed annually in children. These tumors can affect children and adolescents of any age group but the peak incidence is in school-aged children, 5- to 10-year old. The risk of developing a pediatric brain tumor is increased in certain syndromes, such as neurofibromatosis type I, which is associated with gliomas. Brain tumors in children are usually primary, not metastatic. Since tumor location usually drives presenting signs and symptoms, this is the most useful categorization for the ED (Table 97.4). Supratentorial tumors are more common in children younger than 1 year and older than 10 years. Infratentorial lesions are more common between ages 1 and 10 years.

Some of the symptoms of brain tumors in children are nonspecific and nonlocalizing complaints can be present for a variety of tumor types. Examples include headache, altered behavior, vision changes, altered growth or weight, somnolence, and altered school performance. The diagnosis of brain tumor may be delayed in these patients whose presentation is not specific. Once patients develop signs and symptoms more easily referred to the CNS, their presentations tend to hinge on the tumor's location (Table 97.4).

Infratentorial tumors may present with cranial nerve deficits, such as facial nerve palsies, dysphagia, or paresis of cranial nerve VI, causing diplopia or strabismus. Alternatively, ependymomas of the fourth ventricle may present with hydrocephalus and increased ICP. Cerebellar lesions can elicit truncal ataxia and a reeling gait when located on the midline. When only one cerebellar hemisphere is involved, patients may display an ipsilateral hypotonia, resulting in falling to the affected side. An example is medulloblastoma involving the cerebellar vermis. Herniation of the cerebellar tonsil can cause head tilt toward the tumor and neck pain or stiffness. Astrocytomas may present in infratentorial locations.

In contrast, supratentorial masses may present with signs and symptoms derived from the involved anatomic locations. Supratentorial tumors unassociated with the ventricles are often glial tumors, of which a wide variety exists. Tumors near the optic chiasm may present with vision deficits. Craniopharyngiomas, located in the pituitary gland, can cause visual disturbances, headache, and alterations in the endocrine function. Growth hormone deficiency or hypothyroidism may cause delayed growth and DI or syndrome of inappropriate antidiuretic hormone (SIADH) may cause derangements in the serum sodium levels. Pineal tumors may cause hydrocephalus by obstructing the aquaduct of Sylvius or can cause Perinaud's syndrome (deficits in upward gaze, convergence nystagmus,

TABLE 97.4

TUMORS AFFECTING THE CENTRAL NERVOUS SYSTEM

Location	Specific tumor types	Presenting signs and symptoms	Comments
Supratentorial hemispheric	Low grade gliomas Pilocytic Fibrillary High grade glioma Mixed neuronal-glial Neoplasms Ganglioglioma Ependymoma Choroid plexus Tumors Primitive neuroectodermal tumor (PNET)	Varies with site Hemiparesis Hemisensory deficits Seizure Hemianopsia	Outcome for these tumors usually improved by extensive resection
Supratentorial midline	Chiasmatic/hypothalamic glioma Craniopharyngioma Germinoma/malignant germ cell Tumors Pineoblastoma PNET	Vision deficits Diencephalic syndrome Neuroendocrine symptoms Hydrocephalus Parinaud's syndrome	Germinoma and germ cell tumors require bx as treatment, usually just chemotherapy, not surgery
Infratentorial	Medulloblastoma Cerebellar astrocytoma Ependymoma Diffuse malignant brainstem glioma Benign focal brainstem glioma	Cranial nerve palsies Cerebellar signs Ataxia Dysmetria Brainstem signs Weakness Unsteady gait Increased intracranial pressure	

bx, biopsy

and impaired papillary response). Hypothalamic tumors may cause diencephalic syndrome, which includes failure to thrive, wasting, and unusual euphoria. If a tumor is located near the third ventricle, hydrocephalus and symptoms of increased ICP can result. Masses within the cerebral hemispheres themselves usually present with focal motor dysfunction or seizure.

The spinal cord may be the site of a primary tumor or, in some cases, can be affected by a "dropped metastasis" from a primary lesion within the brain. These can present with focal neurologic deficits attributable to areas of the spinal cord inferior to the lesion (see "Tumors In and Around the Spinal Cord" section).

Brain tumors can cause increased ICP by blocking CSF drainage. The symptoms of increased ICP can vary based on patient age. Infants with an open fontanelle can sometimes present with bulging of the fontanelle as well as seizure, vomiting, irritability, or loss of acquired skills. Older children often have headache and early morning vomiting. Sixth nerve palsies are common. Sometimes increased ICP is detected only on imaging of the brain that reveals enlargement of the ventricles or effacement of the gyri. Whether the diagnosis of increased ICP is made radiographically or by history, its management is the same. First, if ICP is known or suspected to be elevated, a lumbar puncture should be avoided, as this theoretically may precipitate a rapid change in ICP followed by herniation of the brain. The pressure may be relieved using steroids such as dexamethasone at a dose of 2 to 4 mg every 6 hours. Mannitol mannitol may be useful in bringing down the ICP. In some situations, intubation may be needed to allow for hyperventilation as the low P_{CO_2} works to ameliorate swelling in the brain. Neurosurgical consultation can address the appropriateness of a ventriculostomy or debulking procedure.

Seizures developing in the setting of a child with cancer, whether due to a CNS tumor or another malignancy, should be managed as described in Chapter 69. Brain tumors should be considered in the differential diagnosis of new onset seizures.

Patients with brain tumors are at risk for several metabolic complications, which may lead to the initial presentation in the ED. The presence of an intracranial tumor may be a cause for cerebral salt wasting or SIADH. Also, DI can result from tumor involvement of the pituitary gland. Patients should be screened for these abnormalities with serum chemistries. However, these complications are not managed uniquely because of the brain tumors. Chapter 135 provides guidelines on evaluation and management.

After ensuring the patient has stable airway, breathing, and circulation, the evaluation in the ED should focus on a thorough history and physical examination. The history should assess for any neurologic symptoms and should screen for complications of brain tumors described above. A complete physical examination should follow including a thorough ophthalmologic and neurologic assessment. Physical examination should also include evaluation of the patient's external genitalia for precocious puberty or virilization, since some pediatric brain tumors may be hormone secreting. A rectal examination to evaluate the anal "wink" is also useful as a screen for spinal cord compression. If the history or physical examination raises concern for increased ICP or spinal cord

compression, then therapy should be initiated as described above. Imaging is an important component of the evaluation with a CT scan being useful to rule out hemorrhage and assess for increased ICP. A CT scan can sometimes be used to visualize a brain tumor; however, the study may miss infratentorial masses. In most cases, an MRI (magnetic resonance imaging) with gadolinium will ultimately be needed. Laboratory evaluation should include serum electrolytes to ensure that the patient exhibits neither SIADH, salt wasting, nor DI. A CBC count is also useful to ensure the patient's hematocrit and platelet count are adequate for any upcoming procedures.

The decision about whether to admit a patient with a newly diagnosed brain tumor hinges mostly on the neurologic status. Patients may have altered airway, breathing, or circulation due to the tumor compressing the brainstem. Cranial nerve dysfunction may compromise a patient's ability to eat normally. The tumor may cause symptoms such as headache, nausea, or vomiting, which require inpatient management. Or the neurologic examination may be compromised leading to functional deficits making discharge problematic. In any of these cases, patients should be admitted to the hospital either to a neurosurgical service or, in some cases, to the operating room directly. Prompt consultation with pediatric oncology, pediatric neurology, and pediatric neurosurgery is essential to ensure that patients are referred to experienced centers for definitive management.

Tumors of the Head and Neck

Children can present with intraorbital tumors, which may involve any of the tissues contained by the orbit including bone, muscle and soft tissue (further distinguished by whether the tumor has an intraconal or extraconal location), and the globe itself. Masses in these regions have a wide differential diagnosis, which includes benign etiologies such as infections (periorbital and orbital cellulitis), orbital myositis, benign germ cell tumors, or cystic lesions such as a dermoid cyst. The most common malignancies affecting the boney orbit are LCH and neuroblastoma. Presenting symptoms usually include proptosis or strabismus. Soft tissue tumors with intraconal locations usually include rhabdomyosarcomas and germ cell tumors, whereas extraconal tumors are likely to be rhabdomyosaromas as germ cell tumors occur more rarely in this location. Here again, presenting symptoms usually include proptosis and strabismus. Vascular tumors including capillary hemangiomas of the orbit may present with red or purple nodular lid lesion or proptosis.

Retinoblastoma is the most common intraocular malignancy in children. It occurs in 1 in 23,000 births and is usually diagnosed by age 2 years. Retinoblastoma occurs in both a hereditary and sporadic form. Two-thirds of patients present with a white pupil (leukocoria) noted by parents. This is the tumor as seen through the vitreous. Children with leukocoria should have an ophthalmologic examination under anesthesia to help differentiate retinoblastoma from other possible etiologies such as congenital cataract, coloboma, idiopathic retinal detachment, and others. Other ophthalmologic complaints such as hyphema, red painful eye, strabismus, fixed pupillary dilation, and proptosis are all possible. Direct extension via the optic nerve into the meninges and spinal fluid is a possible but unlikely complication of the tumor. Presentations are usually local and therefore cured by enucleation, but chemotherapy, cryotherapy, laser therapy, and insertion of radioactive plaques are all being explored to preserve vision. Leukemia and lymphoma can infiltrate the retina. Ocular melanoma is very rare in children. Management of retinoblastoma hinges on the probability of useful vision in the affected eye. Ophthalmology should be consulted early to determine if the patient's visual acuity has already been affected by the mass and to plan the urgency of examination under anesthesia. Management of intraorbital tumors may be possible on an outpatient basis, in conjunction with an experienced pediatric ophthalmologist, if the mass is unlikely to affect vision quickly or if vision is already profoundly impaired in the affected eye.

Tumors of the aerodigestive tract include sarcomas, lymphoid tumors, and carcinomas. While the latter are commonly seen in the adult population, carcinoma is rare in pediatrics. Masses in this region may also be benign, infectious, or reactive in etiology. Regardless of the tissue of origin, these masses usually present with symptoms related to their anatomic position. Oropharyngeal tumors can cause snoring and obstructive sleep apnea as well as chronic otitis media and unilateral tonsillar hypertrophy, in the case of lymphomas such as Burkitt's. Gingival hypertrophy may be a sign of a monocytic leukemia. LCH or Burkitt's lymphoma of the mandible can present with loose teeth. Rhabdomyosarcoma of the salivary or parotid gland often presents with pain or a visible/palpable facial mass. Malignant tumors of the nose, nasopharynx, and sinuses can present with purulent or bloody rhinorrhea, epistaxis, or sinusitis. Nasopharyngeal carcinoma tends to have a long duration of symptoms before diagnosis because symptoms are rarely specific. Malignant tumors of the sinuses and base of the skull can present with cranial neuropathies such as deviation of the eyes due to compression of the cranial nerves by the tumor. Rhabdomyosarcoma of the middle ear can present with persistent otitis, pain, or cranial neuropathy. The external ear canal can be affected by LCH leading to otorrhea and otitis externa.

The clinician in the ED should carefully assess airway, breathing, and circulation as tumors in some of these locations can threaten vital structures within the head or neck. Following this, a complete history and physical examination are necessary. Often radiographic imaging and laboratory evaluation is not needed. However, in the case of suspected leukemia or lymphoma, laboratory studies should be obtained to assess for hyperleukocytosis, cytopenias and TLS (see preceding discussion on leukemia). Radiographic imaging should be pursued if more information is needed about the tumor's position in relationship to the patient's airway and other vital structures of the head and neck. Management of these tumors can sometimes occur on an outpatient basis, in conjunction with a pediatric oncologist and a specialist, such as a dentist or otorhinolaryngologist with expertise in the anatomic region of the tumor. However, specific symptoms such as uncontrolled pain, difficulty with oral hydration, TLS, or any evolving threat to the airway would make inpatient management essential.

Neck masses due to benign, congenital anomalies of the neck such as branchial cleft cysts or cystic hygromas can cause masses, which may grow suddenly, as a result of infection or bleeding, prompting an ED visit. Neck masses are commonly because of enlarged lymph nodes. Lymphadenopathy in children is common and usually benign and either reactive or infectious in etiology. Bilateral nodes may be associated with

viral infections such as EBV or cytomegalovirus (CMV). Unilateral lymphadenopathy, especially in infants and young children, may be associated with *Staphylococcus aureus* or group A streptococcus infections. Even lymph node enlargement with a chronic time course is still most likely infectious (e.g., mycobacteria, cat scratch disease, toxoplasma). Lymph nodes can appear large even without infection or malignancy, as observed in Castleman's, Kikuchi's, and Rosai-Dorfman syndromes. Enlarged lymph nodes in the neck due to malignancy can be from lymphoma or leukemia or can be because of metastasis from an adjacent solid tumor such as rhabdomyosarcoma, neuroblastoma, or nasopharyngeal carcinoma. It can be difficult to distinguish the primary tumor mass from a lymph node in these circumstances.

Children with neck tumors, regardless of etiology, must be evaluated for impact on the airway, breathing, and circulation. If any of these are at risk, inpatient management will be needed. Clinicians should explicitly consider the following:

- Does the mass impinge on or compress the airway?
- Does the patient experience respiratory distress or any compromise to his or her breathing due to the mass?
- Does the mass interfere with circulation of the head and neck leading to SVC syndrome (discussed in section on "Thoracic Tumors")?
- Does the tumor threaten to compress the cervical spine (see "Tumors In and Around the Spinal Cord" section)?

Following this assessment, a careful history should address the duration the mass has been present and its rate of growth, any recent infectious illnesses, the patient's immunization status, cat exposure, medications, and the presence or absence of systemic systems. Physical examination should screen for other masses or lymphadenopathy in the body. In evaluating nodes of the neck, infected or reactive nodes are often small, mobile and soft, or, if enlarged, the enlargement is often accompanied by redness and tenderness. Characteristics that make malignancy more likely are nontender masses, very firm/hard texture, diameter more than 3 cm, adherence to other structures, irregular margins, and absence of signs or symptoms of infection.

Diagnostic evaluation in the ED should focus on defining the relationship between the mass and the airway and major vessels of the neck. A CT scan is often helpful in establishing the neck anatomy in this way. In addition, a chest x-ray should be obtained to explore whether the disease could include a mass in the anterior mediastinum. Laboratory evaluation should include a CBC count with differential, ESR and lactate dehydrogenase (LDH) (which may be elevated in certain lymphomas), testing for any relevant infectious etiologies, and consideration of thyroid function testing.

Tumors of the Thorax

Thoracic tumors can be caused by a number of childhood cancers. While hematologic malignancies are common, embryonal neoplasms such as neuroblastoma, sarcomas such as PNET, and carcinomas can also present in the chest. In general, there are no specific predisposing conditions or factors. The most critical decision making and care in the ED is the differentiation of emergent from nonemergent. This difference is frequently driven by tumor location.

FIGURE 97.1 Chest radiograph demonstrating a large, homogenous anterior mediastinal mass. Patient presented with persistent cough and progressive orthopnea.

Tumors that arise in the anterior and middle mediastinum often present with respiratory symptoms ranging from mild cough to severe respiratory distress (Fig. 97.1). These tumors can compress the great vessels and cause SVC syndrome. They also may be "asymptomatic" and identified during evaluation for nonspecific systemic symptoms or, less commonly, an asymptomatic presentation on a chest radiograph performed for another reason. In contrast, posterior mediastinal masses are frequently identified on a chest radiograph performed for another reason. They may, however, cause local pain from nerve root involvement and/or cord compression (see "Tumors In and Around the Spinal Cord" section).

The differential diagnosis is also usually based on location. The "4 Ts" of the anterior medastinal tumors include "terrible lymphoma," "teratoma," "thymoma," and "thyroid carcinoma." The latter three are rare. Nonmalignant conditions with anterior mediastinal masses include adenopathy associated with infection, sarcoid, and normal thymus (especially if the chest radiograph is interpreted by a radiologist unfamiliar with children). Common lymphomas (Table 97.5) in the anterior mediastinum include T-cell lymphoblastic lymphoma (or T-cell ALL with an associated anterior mediastinal mass), Hodgkin's lymphoma, and diffuse B-cell large cell lymphoma. Lymphoma can also occur in the middle mediastinum, which can also be the site of masses associated with pulmonary sequestration and other developmental anomalies. "Teratoma" of the mediastinum includes benign and malignant germ cell tumors. Posterior mediastinal masses include neuroblastoma and other neurogenic tumors such as malignant peripheral nerve sheath tumors (especially in patients with neurofibromatosis, type 1), or benign lesions such as schwannoma.

The initial focus should include a thorough assessment of airway, breathing, and circulation, all of which may be compromised by an anterior mediastinal mass. Since an anterior mediastinal mass may compress the airway below the level of the carina, intubation can be ineffective to manage respiratory fail-

TABLE 97.5

LYMPHOMA PRESENTATIONS AND CONSIDERATIONS IN THE ED

Lymphoma	Typical presentation	Potential complications at diagnosis and considerations for ED management
Hodgkin's disease—Classical	Painless, hard adenopathy: neck and supraclavicular common AMM common, with or without symptoms Pleural effusions uncommon May have "B" symptoms Fevers Night sweats Weight loss	Superior vena cava (SVC) syndrome Tracheal obstruction
Hodgkin's disease—nodular lymphocyte predominant	Painless, hard adenopathy: often neck or supraclavicular. Can be inguinal. Often at a single site B symptoms rare AMM rare	SVC syndrome Tracheal obstruction (very rare)
Lymphoblastic lymphoma	Painless, hard adenopathy at any site Respiratory symptoms from rapidly, growing mediastinal mass, often with pleural effusions (T-lineage, advanced stage) GI tract involvement rare	Tumor lysis syndrome SVC syndrome Tracheal obstruction Pleural effusions
Burkitt's lymphoma	Single site of enlarged lymphoid tissue(low stage) Incidental finding on appendectomy Asymmetric enlarged tonsil Lead point for intussusception in >3 yr A single, painless enlarged node Painless, hard adenopathy with rapid growth (usually advanced stage) Rapidly progressing abdominal distension with diffuse involvement of the GI tract/liver with ascites and pleural effusions (advanced stage)	Rapid assessment for tumor lysis syndrome (TLS): High risk of severe tumor lysis, even prior to treatment (advanced stage) First dose rasburicase in ED if uric acid >8 and low-risk for G6PD deficiency Urgent consultation with oncology Admission to center with available pediatric dialysis
Diffuse large B-cell lymphoma	Painless, hard adenopathy at any site, neck/supraclavicular common AMM common, symptoms variable (advanced) Symptom progression can be rapid (advanced stage) Systemic symptoms of malaise, weight loss common with advanced disease GI symptoms/abdominal mass from GI tract and mesenteric nodes involvement	TLS SVC syndrome Tracheal obstruction
Anaplastic large cell lymphoma	Painless, hard adenopathy at any site Skin/subcutaneous nodules GI symptoms/abdominal mass from GI tract and mesenteric node involvement Systemic symptoms (fevers, night sweats, weigh loss, malaise) common with advanced disease	TLS

AMM, anterior mediastanial mass; G6PD, glucose-6-phosphate dehydrogenase.

ure. Management must focus on prevention of respiratory failure through such strategies as oxygen therapy and maximizing respiratory mechanics via keeping the patient calm and upright. Do not put the patient in a supine position if evidence of respiratory distress. Do not sedate or anesthetize the patient. Do not start empiric steroids without a discussion with an oncologist to ensure that steroids will not interfere with ability to establish the diagnosis subsequently. If there is evidence of SVC syndrome with plethora, facial edema, and jugular venous distension, ensure adequate intravascular volume to support systemic return, the patient should not receive anesthesia as it can lead to severe cardiovascular collapse. Diuresis should not be attempted either since tumors of the thorax can grow toward the spinal column, a careful neurologic history and examination is needed to assess for possible cord compression (see "Tumors In and Around the Spinal Cord" section).

There may be useful clues to the diagnosis from the history and physical examination. A recent history of new onset asthma in an older child that responded to a course of steroids but has now returned is consistent with partial treatment of lymphoblastic leukemia or lymphoma. Many lymphomas can also present with nonspecific systemic symptoms such as weight loss, fatigue, unexplained fevers, night sweats, and malaise. Itching can be a paraneoplastic phenomenon associated with Hodgkin's lymphoma. The pace of symptom development and severity of current symptoms should be used to

determine the rate at which subsequent workup must occur. Examination should include assessment of all nodal groups (including axilla and supraclavicular) to both aid in the differential diagnosis and establish a site for possible biopsy. Of note, almost all pediatric lymphomas are high grade and have an acute to subacute course.

Diagnostic workup in the ED should always include a chest radiograph, including a lateral view, to help establish the location of the mass. Chest CT scan should only be performed in a patient who can lie flat comfortably. A CT contrast should not be given without verifying adequate renal function since TLS can occur with lymphoma (see "Leukemia" section). Laboratory evaluations should include CBC to assess for evidence of marrow replacement and to identify circulating blasts, and metabolic screening for possible TLS. Patients with symptoms from an anterior mediastinal mass must be admitted to a center with pediatric oncology expertise and may frequently require ICU admission. Those with minimal or no symptoms from the mass and no metabolic disturbances may be discharged to the care of a pediatric oncologist for further workup as an outpatient.

Primary lung tumors are vanishingly rare in childhood but presentation of lung metastasis at diagnosis or relapse is not uncommon. The initial complaints may include respiratory insufficiency, postobstructive infection, foreign body–type symptoms, or hemoptysis. Presentation may also involve the discovery of pulmonary nodules on a chest radiograph performed for a different reason. Primary lung tumors in children include pleuropulmonary blastoma that may be associated with congenital cystic adenomatoid malformation or very small bronchogenic carcinomas. Most of these latter are asymptomatic. Many pediatric sarcomas, some lymphomas, germ cell tumors, Wilm's tumor, and rarely neuroblastoma can present or recur with lung metastasis. These typically involve multiple small or large lung nodules in the pulmonary parenchyma or are pleural-based. In children, infection is a more common cause of lung nodules than cancer. In general, there are no emergency management issues unique to lung tumors versus other lung problems. Patients who are systemically ill require admission for further evaluation and management. Askin's tumor (PNET or primitive neuroectodermal tumor) is a unique chest wall tumor that occurs in children and young adults. If the tumor is relatively exophytic, it may present as a chest wall mass with or without pain. More commonly, it presents with respiratory symptoms from an effusion as described below.

Pulmonary effusions can be the presenting sign of childhood cancer. Effusions can be caused by malignant cells in the pleural space or from obstruction of lymphatic drainage. Effusions are common with anterior medastinal masses due to leukemia or lymphoma and can also occur with posterior mediastinal neuroblastoma, lung metastasis, and chest wall tumors. They may be symptomatic or asymptomatic. The effusion may obscure a mass on both chest x-ray and chest CT scan. Malignant pericardial effusions are most often associated with leukemias and lymphomas. For general diagnosis and management of pulmonary and pericardial effusions (see Chapters 84 and 98). If fluid is drained from either space in the ED for relief of symptoms, a fluid sample should be sent to pathology for cytology if malignancy is suspected. In general, patients who are not compromised by a malignant effusion should not have fluid drained for diagnostic purposes while in the ED.

Tumors of the Hepatobiliary Tree

Tumors of the hepatobiliary tree in children are more likely to include tumors that metastasize to liver than primary tumors of the liver (Table 97.6). Of the primary tumors, hepatoblastoma (HB) and hepatocellular carcinoma (HCC) are the most common (Fig. 97.2). HB usually occurs in patients younger than 6 years and is associated with such risk factors as overgrowth syndromes (e.g., Beckwith-Wiedmann), prematurity, and familial adenomatosis poli. In contrast, HCC starts to become more common in patients older than 6 years, particularly in children older than 10 years. Risk factors include chronic liver injury from inborn errors of metabolism such as tyrosinemia, glycogen storage disease type I, chronic hepatitis, chronic iatrogenic androgen exposure, or cirrhosis for any reason. In general, these latter risk factors rarely lead to cancer in childhood.

Typical presenting symptoms include abdominal mass, abdominal pain, and very rarely acute abdomen from massive hepatomegaly or tumor rupture. Other primary liver masses include embryonal sarcoma (extremely rare), vascular lesions that are nonmalignant such as infantile hemangioendothelioma, and malformations such as hamartoma. Focal nodular hyperplasia can cause a mass on liver imaging but rarely has associated symptoms or hepatic enlargement. Metastatic disease usually is characterized by diffuse nontender enlargement of the liver or multiple small nodules rather than a single dominant mass. Neuroblastoma and advanced hematologic malignancies such as ALL, AML, lymphoblastic lymphoma, and Burkitt's commonly metastasize to the liver. Although tumors may block biliary drainage, hepatic synthetic function is rarely affected by malignancy in the liver.

Emergent management is rarely required except in the extremely rare setting of liver failure (see Chapter 89), tumor rupture that may require rapid repletion of intravascular volume and blood loss while consulting surgery, or severe coagulopathy (see Chapter 91). History may elicit a risk factor or systemic symptoms such as malaise and anorexia that are more common with HCC than HB. Pain does not help with the differential diagnosis but requires management. Jaundice is most common with HCC but can occur with all liver tumors.

Initial workup in the ED should include AST, ALT, bilirubin total and direct, CBC count with platelets, PT, PTT, and fibrinogen. Alpha fetoprotein (AFP) can be elevated in both HB and HCC. It is also important to note that normal AFP values are high in the first months of life, especially in premature infants. Initial diagnostic imaging in the ED should include an ultrasound, which can help identify if the palpable mass is likely to be hepatic in origin and if the liver contains one or multiple masses. If a CT scan is done in the ED, it is important to give intravenous contrast to look for intravascular extension of tumor from the hepatic veins, into the inferior vena cava, and possibly into the right atrium. Renal function should be checked before giving intravenous contrast. Since HB can metastasize to the lungs, consider if a chest CT scan should be performed at the same time in patients younger than 10 years who have a primary liver tumor.

TABLE 97.6

BENIGN AND MALIGNANT ABDOMINAL AND PELVIC MASSES

Location	Benign	Malignant
Hepatic	Adenoma Hemangioma Storage disease Hamartoma Infectious	Hepatoblastoma Hepatocellular carcinoma Sarcoma Metastatic disease Leukemia
Kidney/adrenal	Hydronephrosis Cysts Renal vein thrombosis Adrenal hemorrhage	Wilm's tumor Renal cell carcinoma Rhabdoid tumor Neuroblastoma Pheochromocytoma
Gastrointestinal	Torsion/duplication Feces (constipation) Hernia Abscess Appendicitis	Gastrointestinal stromal tumor Lymphoma
Pancreas	Trauma Pseudocyst	Pancreaticoblastoma
Ovary	Torsion Cyst Immature teratoma	Lymphoma Germ cell tumor Sex cord/stromal tumor Carcinoma
Bladder/prostate	Duplication Cyst	Rhabdomyosarcoma

Children who are clinically stable and have a new liver tumor may be discharged from the ED to the care of a pediatric surgeon experienced with liver tumors or a pediatric oncologist. If the patient is unstable, they should be admitted to a center with experience in treating childhood malignancies.

Tumors of the Pancreas

Pancreatic tumors in children are very rare and in some cases develop in the setting of a predisposition, such as multiple endocrine neoplasias type 1 (MEN-1) syndrome, which is associated with insulinomas of the pancreas. Insulinomas will present with signs and symptoms of hypoglycemia and a history of "irrational behavior." Other tumors of the pancreas cause either an abdominal mass or vague, nonspecific abdominal symptoms. The differential diagnosis of a pancreatic mass includes nonmalignant adenoma or cystadenoma as well as malignant entities. Malignant tumors of the pancreas in children may be cystadenocarcinoma, pancreaticoblastoma, an embryonal tumor, or an endocrine tumor such as insulinoma, gastrinoma, or VIP-oma. The pancreas may also be affected by metastatic disease from end-stage refractory cancer such as neuroblastoma or rhabdomyosarcoma.

A thorough history and physical examination should assess for endocrinological ramifications that require medical management (such as hypoglycemia). The evaluation should include a serum AFP, which can be elevated in pancreaticoblastoma. Diagnostic imaging may include a CT scan or MRI of the abdomen, but these tests are rarely needed in the ED.

Consideration should be given to whether the patient with a newly diagnosed pancreatic tumor may be discharged to home. Discharge may be considered if the patient is otherwise well appearing and if arrangements have been made for an appropriate evaluation, including consultation with a pediatric surgeon, to continue in the outpatient setting. If the patient is ill, or if appropriate follow-up is otherwise unclear, then it is safest to admit the patient to the hospital. Surgical intervention is an important facet of the management plan for patients with pancreatic tumors, as several pancreatic tumors may be managed with just surgery alone.

Tumors of the Gastrointestinal Tract

Tumors in the gastrointestinal (GI) tract in children include lymphomas, leukemias, gastrointestinal stromal tumors (GISTs), LCH, desmoplastic small round cell tumor and colorectal carcinomas. Risk factors for GI lymphomas include primary immunodeficiency. Neurofibromatosis, type 1, increases the risk of GIST. Familial adenomatous polyposis (FAP), Li-Fraumeni syndrome, and ulcerative colitis increase the risk of colon cancer.

Common presentations include nonspecific GI symptoms such as weight loss, nausea/vomiting, loss of appetite, change in bowel habits, abdominal distension, or abdominal pain. Chronic GI blood loss can cause iron deficiency anemia. Abdominal distension, from masses or ascites, may be present. Severe GI bleeding is a rare presentation of GI malignancy but one that requires immediate management as in

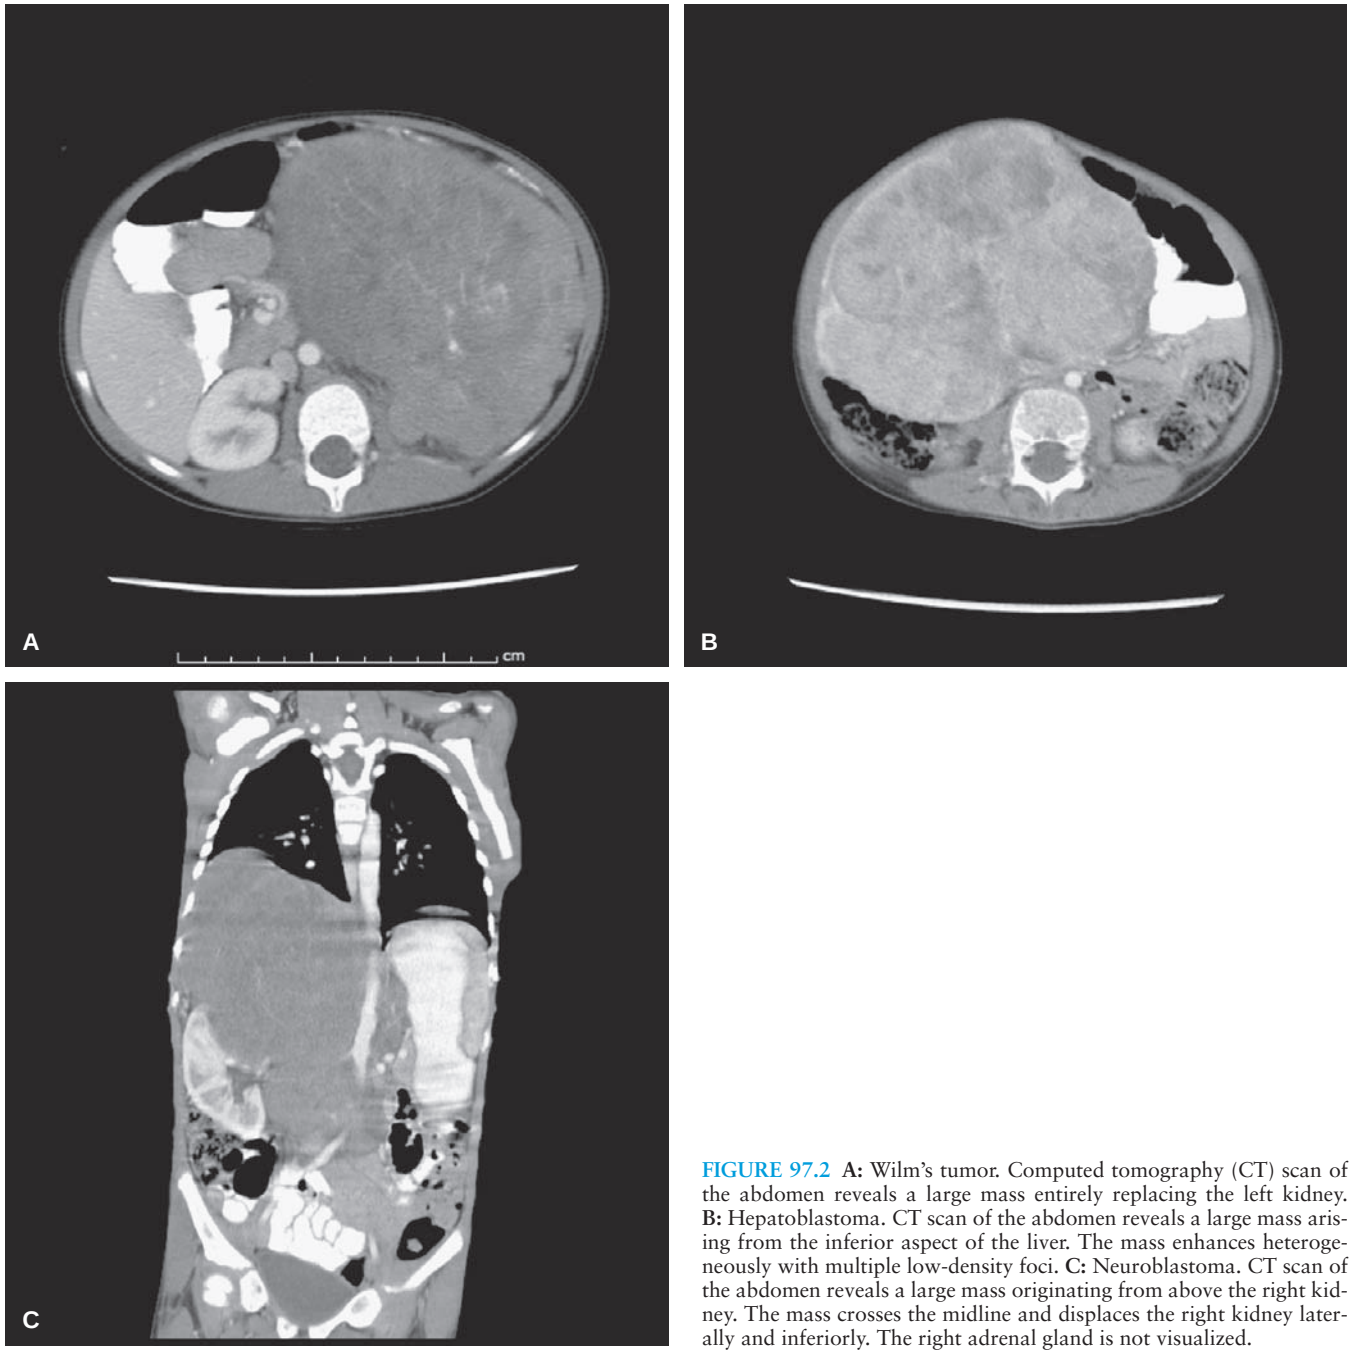

FIGURE 97.2 **A:** Wilm's tumor. Computed tomography (CT) scan of the abdomen reveals a large mass entirely replacing the left kidney. **B:** Hepatoblastoma. CT scan of the abdomen reveals a large mass arising from the inferior aspect of the liver. The mass enhances heterogeneously with multiple low-density foci. **C:** Neuroblastoma. CT scan of the abdomen reveals a large mass originating from above the right kidney. The mass crosses the midline and displaces the right kidney laterally and inferiorly. The right adrenal gland is not visualized.

Chapter 29. Symptoms of intermittent GI obstruction may be present. Complete obstruction is an extremely rare presentation and may require urgent surgical intervention. The lead point for intussusception in children older than 3 years may be a primary GI lymphoma. Incidental findings on appendectomies in children can include Burkitt's lymphoma or carcinoid tumor.

Lymphomas involving the GI tract and/or mesenteric nodes in children include Burkitt's lymphoma and large cell lymphoma (Table 97.5). MALT (mucosa-associated lymphoid tissue) lymphoma is extremely rare in children. Lymphoblastic lymphoma rarely involves the GI tract. Advanced Burkitt's lymphoma should be suspected in patients with a rapidly evolving clinical picture of progressive abdominal distension, abdominal masses and/or ascites. Leukemia can also present with any of the signs or symptoms above. If the initial evaluation of a pediatric patient with abdominal symptoms demonstrates evidence of a very high uric acid, LDH that is many times normal, or renal insufficiency, the diagnosis of advanced Burkitt's lymphoma should be suspected immediately. Colorectal carcinoma is extremely rare in children and often presents with advanced stage disease. LCH, particularly in children younger than 1 year, can present with GI involvement manifested by formula intolerance or occult or overt lower GI

blood loss. Other signs and symptoms of LCH are usually present (see section on "Histiocytic Diseases" for details on LCH). Desmoplastic small round cell tumor is an extremely rare intraabdominal tumor often based in the omentum or peritoneum. Multiple tumors and ascites are common, with or without a single dominant mass. The pace of symptoms is often rapid and the disease occurs in males more than females, older children and adolescents. GISTs tend to occur in older children and adolescents and often involve the stomach and upper GI tract. This tends to be a slow-paced disease and may present with vague GI symptom and/or evidence of upper GI bleeding. Carcinoid tumors are almost always an incidental finding on pathology. Mesenteric adenopathy alone should not raise the suspicion of malignancy since a reactive process is far more likely than a malignancy in children. Mesenteric adenopathy can be associated with most of the diseases above but there is usually evidence of other abnormality on imagining. Massive adenopathy can also occur in three extremely rare nonmalignant conditions, sinus histiocytosis, Castleman's disease, and Kikuchi's disease.

As above, severe GI bleeding or complete GI obstruction require rapid assessment and intervention (see Chapters 29 and 89). In most patients, however, the evaluation can proceed at a more measured pace. The history and physical examination should focus on the specific findings noted above that can lead to the suspicion of a GI-based malignancy. Laboratory evaluation should include a CBC count to look for evidence of blood loss and baseline hepatic and renal function. If initial evaluation suggests that an advanced lymphoma is included in the differential, a full metabolic assessment as in the section on "Leukemia" should be completed urgently. Diagnostic imaging should be performed based on the findings and suspected diagnoses. An abdominal x-ray can be helpful to look for abnormalities of the bowel gas pattern suggestive of ascites or mass. Ultrasound can be helpful to assess the likely organ of origin of a palpable abdominal mass but rarely is sufficient to establish a likely diagnosis. Ultrasound findings consistent with lymphoma can include bowel wall thickening or intussusception. If a primary GI malignancy is suspected, a CT scan with both intravenous and oral contrast should be performed after establishing that renal function is adequate for intravenous contrast. In otherwise stable patients, this imaging can be performed subsequent to the ED evaluation.

Patients with evidence of high cell turnover on metabolic assessment and a suspected diagnosis of advanced Burkitt's lymphoma must be admitted to a center capable of performing pediatric renal dialysis. Other patients with a suspected GI malignancy should be admitted or referred to a center with pediatric oncology expertise.

Neuroblastoma

Neuroblastoma is derived from neural crest cells that can exist not only within the adrenal medulla but also along the sympathetic chain. It is the most common solid tumor of childhood outside the CNS, accounting for 7% to 10% of pediatric tumors overall. With an incidence of 1 per 7,000 live births, neuroblastoma preferentially affects very young children; 90% of cases are diagnosed by age 5 years and 50% by age 2 years. In approximately two-thirds of cases, the primary tumor is in the abdomen, specifically in the adrenal gland in 40% of children and 25% of infants. Regardless of location, the tumor's presentation can be clinically variable. Neuroblastoma may cause systemic symptoms due to a variety of processes. Bone pain may develop if the tumor involves osseous sites. Marrow replacement can cause signs or symptoms of anemia, thrombocytopenia, or neutropenia. Large masses of the chest or abdomen may impair pulmonary function and cause respiratory distress. Abdominal masses may cause dysfunction of GI motility, such as constipation or bowel obstruction, as well as inability to tolerate oral intake and secondary cachexia.

Potentially life-threatening or organ-threatening complications of neuroblastoma include the development of SVC syndrome from a mass in the posterior mediastinum that extends anteriorly or cord compression from tumor growing through the neural foramina into the spinal canal. See sections on "Thoracic Tumors" and "Tumors In and Around the Spinal Cord" for management strategies for these complications. However, at times neuroblastoma presents in a healthy, well-appearing child with an abdominal mass incidentally detected. Other unique presentations include: ipsilateral Horner's syndrome (ptosis, miosis, and anhydrosis) from involvement of the cervical sympathetic ganglia; "raccoon eyes" from periorbital bone and soft tissue involvement causing proptosis and ecchymosis; and opsoclonus myoclonus. This latter is a paraneoplastic syndrome characterized by "dancing eyes and dancing feet" and is associated with a favorable cancer prognosis but a poor neurocognitive outcome. Neuroblastoma can secrete catecholamines that cause hypertension and vasoactive intestinal peptide that causes secretory diarrhea. Subcutaneous nodules can occur.

Initial assessment of a child with possible neuroblastoma should include an assessment of the patient's airway, breathing, and circulation, followed by a complete history and physical examination that focuses on the potential signs and symptoms above. Given the risk of cord compression from a retromediastinal or retroperitoneal tumor, all patients should have a thorough neurologic examination including percussing the vertebral bodies, with emergent imaging should neurologic deficits be detected. The patient's blood pressure should be measured and carefully matched against norms for age. Signs and symptoms of pain should also be explored to localize potential tumor masses and pain should be treated as needed.

Laboratory evaluation should include CBC count, liver function testing, renal function testing (BUN and creatinine), and urine catecholamines. If neuroblastoma is suspected and the disease burden seems high, TLS may develop (see "Leukemia" section). If the CBC count shows evidence of marrow replacement, platelet and packed red blood cell transfusions may be needed (Table 97.7). A plain film of the chest or abdomen may be useful since calcifications are common in neuroblastoma. Abdominal ultrasound may be valuable to define the location of a mass or its relationship to other structures. CT scans should only be performed at centers skilled in imaging pediatric tumors and should include the suspected site of the primary tumor, the surrounding lymph node groups, and the liver (a common site of metastasis). If a thorough evaluation and initial management finds no life-threatening or organ-threatening problems, no uncontrolled pain, and no evidence of severe systemic illness, discharge to the care of a pediatric oncologist may be possible.

TABLE 97.7

TRANSFUSIONS IN ONCOLOGY PATIENT IN THE EMERGENCY DEPARTMENT

	Platelets	Red cells	
Indication	Platelet count <100,000/mm^3 and major surgery or trauma Platelet count <50,000/mm^3 and minor surgery or trauma or moderate mucosal bleeding (e.g., epistaxis) Platelet count <20,000/mm^3 and mild mucosal bleeding Platelet count <10,000/mm^3 to prevent spontaneous intracranial hemorrhage Platelet count <100,000/mm^3 and active bleeding	To support circulation in a setting of acute blood loss or sepsis Elective transfusion of symptomatic patient to avoid admission (only if per institutional policy and feasible to transfuse in ED)	
	Product specifications		
	Platelets	**Red cells**	**Comment**
Type and Cross needed	No, if type done at blood bank previously	Yes	
ABO matched	If product available	Yes	Slightly better response to ABO-matched platelets
Rh matched	Preferred	Yes	If Rh+ platelets to Rh donor, anti-D product within 72 h
Irradiated	Yes	Yes	Prevent WBCs in product from proliferating and causing graft-versus-host disease
Leukopoor	Yes	Yes	Prevent CMV transmission in donor white cells Minimize exposure to donor white cell surface proteins and risk of subsequent transfusion reaction
CMV	*	*	Most institutions use leukopoor as a substitute. Some literature controversy. Follow institutional policy.
HLA matched	Unable in ED	No	May be useful in setting of patient refractory to platelets. Takes time to arrange
Single donor	Apheresis platelets from a single donor preferred	No	
Premedications	Possible	Possible	Highly transfused population, at risk for reactions: Acetaminophen if h/o febrile reactions Diphenhydramine if h/o allergic reaction Hydrocortisone if h/o allergic reaction despite diphenhydramine or very severe allergic reaction
Amount	1 unit/10 kg Institutional guidelines: 1 unit <10 kg 3 units 10–30 kg 6 units 30–80 kg 8 units >80 kg Continuous infusion: for platelet-refractory patient with on-going significant bleeding, most coordinate with blood bank	Acute severe blood loss: see chapter on bleeding Elective transfusion: 10 mL/kg or 2 units for >50 kg patient	Volume-reduced platelets in patients very sensitive to volume overload decreases effectiveness of transfusion

ED, emergency department; WBC, white blood cells; CMV, cytomegalovirus; HLA, human leukocyte antigen; h/o, history of; ABO, blood group system; Rh, Rheus (Rh) blood group system.
*Not applicable as long on product has been leukeoreduced.

Tumors of the Kidney

There are several different causes of renal tumors in children, some malignant and some benign. Wilm's tumor, the most common pediatric renal tumor, arises from embryonic renal blastemal cells. Overgrowth syndromes such as Beckwith-Wiedemann, Soto syndrome, hemihypertrophy, and Denys-Drash syndrome also predispose to embryonal tumors such as Wilm's. There are 500 cases of Wilm's diagnosed annually in United States with peak incidence between the ages of 2 and 3 years. Eighty percent of cases are diagnosed by age 5 years.

Wilm's tumors most commonly present with a painless mass found incidentally by either the parents or pediatrician in a child who is otherwise well-appearing (Fig. 97.2). Masses are deep in the flank, smooth, and either firm or soft. Wilm's tumor may have more serious or life-threatening presentations including

- hypertension, due to increased rennin secretion from renal artery compression, in <15% of cases;
- gross hematuria in less than 25% of cases (although microscopic hematuria is very common);
- hematologic complications such as anemia, tumor thrombus in the renal veins with or without extension into the inferior vena cava; and
- abdominal compartment syndrome from a massive renal tumor in a very small child.

The differential diagnosis of a pediatric renal mass also includes benign lesions such as hydronephrosis, multicystic or polycystic kidneys, and mesoblastic nephroma. The age of the patient can help clarify the likely etiology of a renal mass. For example, a neonatal mass is less likely to be malignant and more likely a congenital malformation of the genitourinary (GU) tract. Both neuroblastoma and Wilm's tumor most commonly develop in the 1 to 5 year age range. Other malignant tumors, less common than Wilm's, include rhabdoid tumor of the kidney, clear cell sarcoma, and mesoblastic nephroma. Carcinomas, including medullary carcinoma and renal cell carcinoma, are extremely rare. Hematologic malignancies often metastasize to the kidney but rarely present with a solitary lesion.

A thorough history and physical examination is needed, including assessment of measured blood pressure against normal values for age. Because Wilm's tumor can be associated with other syndromes, such as Beckwith-Wiedemann syndrome and WAGR (Wilm's tumor, aniridia, GU anomalies, mental retardation) syndrome, the physical examination should screen for physical anomalies that may signal that the renal mass is part of a larger picture. The clinician should screen for signs and symptoms of pain and treat pain as needed. Laboratory evaluation should include a CBC to look for evidence of bleeding, a urinalysis, and liver and renal function testing (BUN and creatinine). Serum calcium should also be measured as this value may be elevated in rhabdoid tumor of the kidney or congenital mesoblastic nephroma.

Radiographic evaluation can be helpful in further defining the tumor. Ultrasound can define the anatomic position of the mass, explore whether it has cystic or solid components, and assess for any hydronephrosis or ureteral obstruction. The radiologist should assess for tumor thrombus in renal veins or inferior vena cava. Centers skilled in pediatric imaging may elect to perform a CT scan with intravenous contrast. If it is certain that the mass is renal in origin, it is appropriate to include the chest to evaluate for presence of lung metastasis.

As in adrenal tumors discussed above, the initial management of renal masses should focus on a determination of how ill the patient is and consultation with a pediatric oncologist or pediatric surgeon. Well-appearing patients without evidence of bleeding, may be discharged to home if appropriate follow-up with a pediatric oncologist or surgeon is arranged.

Tumors of the Lower Genitourinary Tract

While tumors of the lower GU tract in adults are most commonly carcinomas, in the pediatric population these tumors are more likely to be sarcomas. Their presentation is determined by their location. Vaginal tumors are most commonly rhabdomyosarcomas of the botryoid histology. These tumors classically present protruding from the vagina, accompanied by a mucous/bloody discharge. Uterine tumors more commonly present in adolescent girls and may cause a palpable mass or vaginal discharge. Tumors of the bladder may present with hematuria, urinary obstruction, or extrusion of tumor tissue from the urethra. Bladder tumors, most common in children younger than 4 years, are usually within the lumen of the bladder. Prostate tumors are usually rhabdomyosarcomas that can cause constipation, urinary obstruction, or a large pelvic mass. Paratesticular tumors present as painless unilateral scrotal enlargement or swelling (see section on "Gonadal Tumors" for details on testicular tumors).

The management of patients presenting with these tumors should begin with a thorough history and physical examination. Children are not usually acutely ill at the time of presentation. Most of the evaluation can be done on an outpatient basis, in consultation with a pediatric oncologist. The clinician in the ED should ensure adequate bowel, bladder, and renal function as well as good analgesia. An ultrasound may be useful to determine where the tumor is located. The most common reason for admission is management of urinary obstruction.

Gonadal Tumors

In children, most gonadal tumors are derived from malignant transformation of the primordial germ cells, although other tissues within the gonads may be the source of malignant cells. Presentation of these tumors varies based on the gender of the patient and the stage of development (i.e., the maturity) of the germ cell when the malignancy begins. During embryonic development, germ cells migrate to the gonads, but aberrant migration in the setting of malignancy can lead to extragonadal germ cell tumors. This section will focus on tumors located within the gonads themselves.

The gonads contain three different cell types, all of which can experience malignant transformation.

- Germ cells: Many histologic subtypes exist for ovarian and testicular germ cell tumors. Tumors range from benign teratomas (mature and immature) to a number of malignant histologies including germinoma (also called dysgerminoma), embryonal carcinoma, endodermal sinus tumor (also called

yolk sac tumor), choriocarcinoma, and mixed germ cell tumors, which include two or more germ cell histologies. Dysgenesis of the gonad increases the risk of developing a germ cell tumor.
- Sex cords: Cells can develop into ovarian granulosa cell tumors or testicular Sertoli or Leydig cell tumors.
- Epithelia: These neoplasms are seen mostly in adults and are extremely uncommon in children.

Tumors of the ovary are rare and account for only 1% of pediatric cancers overall. While they may occur at any age, the incidence begins to increase at 8 to 9 years and peaks at 19 years of age. Two-thirds of pediatric ovarian tumors are germ cell tumors. Abdominal pain is the most common presenting symptoms, occurring in 80% of patients. Pain may be chronic or acute, mimicking an acute abdomen, as the tumor can cause ovarian torsion. Other presenting signs and symptoms include a palpable abdominal mass, dysfunction of the bowel or bladder, or menstrual changes. Some ovarian tumors may cause precocious puberty or virilization.

If a patient has a known or possible ovarian mass, the history and physical examination should include a thorough menstrual history as well as assessment of any virilization or precocious puberty. Laboratory evaluation should include a CBC count, chemistries, quantitative β-HCG (beta human chorionic gonadotropin) (obtained from the serum), AFP, LDH, and CA-125. Ultrasound can clarify whether the tumor is cystic or solid as well as location. Further imaging should generally be carried out only in conjunction with the managing oncologist or surgeon and rarely needs to be performed in the ED.

Differential diagnosis should include benign etiologies, such as an ovarian cyst or torsion, as well as malignant causes of the mass. Malignant masses are most commonly germ cell derived. Of these, the more common are dysgerminoma, which may be bilateral in 20% of cases, and endodermal sinus tumor (yolk sac tumor), which presents with an elevated AFP. Malignant tumors may also be derived from nongerm cell ovarian tissue or from nonovarian tissues, as is the case for ovarian involvement in leukemia or lymphoma.

Tumors of the testicle are rare and account for only 2% of solid neoplasms in boys. While they may occur at any age, testicular tumors seen in adolescents are similar to those found in adult males but prepubertal boys have tumors with unique clinical manifestations and different prognostic implications. The major risk factor for the development of a testicular tumor is the presence of an undescended testicle, even after repair. Approximately 75% of pediatric testicular tumors are germ cell tumors (as compared with more than 90% in the adult population).

Testicular tumors commonly present as irregular, nontender scrotal masses that do not transilluminate. They may have minimal to no associated symptoms, which may cause a delay in diagnosis. At the time of diagnosis, 20% of patients will also have an inguinal hernia and another 20% will have a hydrocele. About 75% of these tumors are localized at diagnosis, but sites of potential metastases include retroperitoneal lymph nodes and the chest.

Testicular tumors usually present with an enlarged testicle. The clinician in the ED should perform a thorough history and physical examination looking for evidence of virilization or precocious puberty as occurs with functional tumors. Laboratory evaluation should include a CBC count, chemistries, quantitative β-HCG (obtained from the serum) and AFP. Imaging of the mass should begin with an ultrasound that can clarify whether the tumor is cystic or solid and whether it is derived from the testicle itself or paratesticular tissues.

When evaluating scrotal enlargement, it is critical to distinguish testicular tumors from paratesticular tumors from other etiologies such as varicocele or scrotal edema. Almost all paratesticular tumors are rhabdomyosarcomas. Malignant tumors in the testis itself include germ cell tumors of all histologies, sex cord tumors, leukemia, lymphoma, and neuroblastoma. Teratomas, representing 10% of testicular tumors, develop mostly in children younger than 4 years. Embryonal carcinoma, the testicular tumor most commonly seen in adults, is rare in the pediatric population until late adolescence.

Tumors In and Around the Spinal Cord

Tumors can come into contact with the spinal cord through various mechanisms. Those derived from tissues in close proximity to the spinal cord can grow into and impinge upon the cord. Primary tumors from either adjacent bone (see "Tumors of Bone" section) or adjacent parameningeal soft tissues, as in neuroblastoma or soft tissue sarcomas (STS), or from the spinal cord itself (gliomas, ependymomas) can cause cord compression. The same tumors when present at another site can also metastasize to tissue in or around the spinal cord. Tumors in the fourth ventricle can have drop metastases that grow and compress the spinal cord. Neuroblastoma, in particular, is known for its ability to spread through spinal foramina and then expand within the spinal canal. In addition, leukemic blasts can infiltrate the paraspinal soft tissues to form a chloroma, which can enlarge to compress the spinal cord as well (see "Leukemia" section).

Evaluation of spinal cord compression, regardless of the tumor type causing the compression, begins with a thorough history during which the clinician should explore whether the patient has had pain or focal neurologic symptoms including weakness or paresis, which could indicate cord compression. More subtle complaints such as urinary retention, fecal incontinence, or constipation could indicate compression of the spinal cord. A thorough neurologic examination should follow and any asymmetry or focality detected on that examination should provoke neuroimaging with, in most cases, a spine MRI. Findings could include loss of reflexes, focal or asymmetric weakness, sensory deficits, or an upgoing Babinski reflex. Percussion tenderness of the posterior vertebral elements should be assessed. Management of cord compression should include analgesia, as patients are frequently in extreme pain. Glucocorticoids usually improve the pain within several hours, but most patients require opiate analgesics to tolerate the physical examination and necessary diagnostic studies. Management of the compression begins with steroids, most commonly dexamethasone at a starting dose of 0.25 to 0.5 mg per kg IV (maximum dose is usually 10 mg as an initial dose followed by doses of 4 mg every 6 hours thereafter). Multispecialty consultation with neurosurgery, radiation oncology, and pediatric oncology is optimal when choosing among surgical decompression, radiation therapy, and chemotherapy. Decisions must consider both

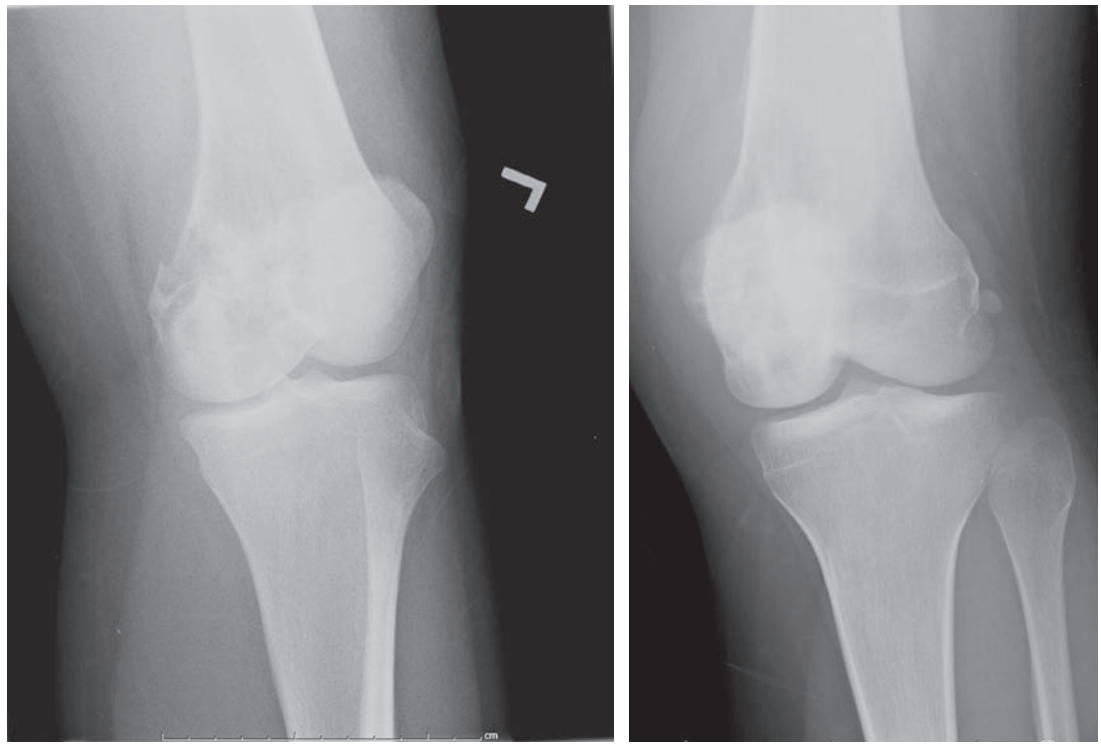

FIGURE 97.3 Two plain radiographs demonstrating osteosarcoma of the distal femur.

the short-term efficacy of the treatment to relieve the compression as well as the long-term consequences.

Tumors of Bone

Primary bone tumors are uncommon pediatric malignancies, representing the sixth most common neoplasm in children. However, bone tumors are the third most frequent malignancy of adolescent and young adults. In the United States, it is estimated that 2,400 primary bone tumors are diagnosed annually in children. Presentation commonly includes pain at the tumor site (present in 80% to 90% of cases), soft-tissue swelling, and/or a painful limp. The pain may wake the patient at night in some cases (less than 25%).

The differential diagnosis of a bony mass includes both benign and malignant entities. Subacute osteomyelitis can present with fever, elevated inflammatory markers, pain and swelling over the involved bone, as well as a bone scan with increased uptake of tracer. Benign tumors of bone account for half of the bone tumors in children and include entities such as giant cell tumor of bone, eosinophilic granuloma, and aneurysmal bone cysts. Benign lesions usually have smooth, well-defined borders on plain radiographs and rarely have associated soft tissue masses. Osteosarcoma and Ewing sarcoma are the most common primary malignant bone tumors. Osteosarcoma is characterized by its production of immature bone or osteoid. It is the most common malignant bone tumor in children and adolescents, presenting most often in the second and third decades of life. Although Ewing sarcoma is second to osteosarcoma in overall frequency, it affects children and adolescents of all ages and is more common than osteosarcoma in children younger than 10 years. Leukemia, lymphoma, LCH, and metastases from neuroblastoma, sarcomas, and other childhood tumors can all cause bone pain and abnormalities on radiograph (Fig. 97.3).

Diagnostic evaluation in the ED should include a thorough history and physical examination. There is frequently a history of trauma. Pain in retrospect may be intermittent and nondescript for weeks or months. Constitutional symptoms or signs, such as fever, fatigue, and weight loss may occur with Ewing sarcoma/PNET. If tumor is present in an extremity, a hard mass may be felt. Osteosarcoma usually involves the metaphyseal end of long bones, most commonly around the knee or proximal humerus. Ewing can occur in any bone but tends to involve the diaphysis when in a long bone. Pelvic lesions often produce no specific physical findings. Lesions of the vertebral body may evoke neurologic symptoms such as neuropathic pain or cord compression. In this setting, a careful history of bowel and bladder function should be taken and a thorough neurologic examination performed. Any focal neurologic deficits should prompt immediate imaging of the spinal cord to determine if compression is present. Should the bony mass be in an extremity, that extremity should be completely examined in terms of pulses, perfusion, range of motion, and sensation for compartment syndrome due to swelling or bleeding within the mass.

Laboratory evaluation should include a CBC count, evaluation of renal and liver function, inflammatory markers such as ESR and CRP, and serum LDH. Diagnostic imaging should being with a plain radiograph of the affected region. Characteristic findings of primary bone tumors include a lytic lesion with

cortical destruction. Early changes include loss of soft-tissue fat planes and periosteal elevation (Codman triangle), which has been associated with osteosarcoma. Later, there is an "onion skin" periosteal reaction caused by repetitive episodes of the lesion pushing out the periosteum and followed by the periosteum responding by laying down calcium. This finding has been associated with Ewing sarcoma. Neither finding is specific. With osteosarcoma, the associated soft tissue mass is sometimes ossified in a radial or "sunburst" pattern. "Benign" bone tumors such as eosinophilic granuloma, aneurysmal bone cysts, and giant cell tumor of bone can present as lytic lesions that tend to have smooth, well-defined borders. Plain films should always be assessed for the presence of a pathologic fracture. A large lesion with a thin cortex in a weight-bearing bone may require immediate immobilization to prevent pathologic fracture.

Often patients with bony masses can be discharged with follow-up securely arranged with an orthopedic surgeon with oncology expertise or a pediatric oncologist for further diagnostic workup and initiation of appropriate therapy. An improperly performed biopsy may prevent subsequent limb-sparing surgery. A plan for analgesia should be established prior to discharge. Patients with tumors affecting the lower extremities should refrain from bearing weight on the affected limb so as to avoid causing a pathologic fracture. Weight bearing activity should not resume unless so directed by an orthopedic surgeon. Inpatient management may also be needed for pain control or if cord compression or compartment syndrome complicates the presentation.

Tumors of the Soft Tissues

Tumors of the soft tissues present the clinician with a very broad differential diagnosis. Many of these lesions may be benign. Rhabdomyosarcoma is the most common soft-tissue sarcoma in children. There are many other types of STS that collectively account for less than 1% of all pediatric cancer. They can arise in any anatomic location because connective tissue is located throughout the body. Masses are frequently painless and asymptomatic. Any presenting symptoms are usually because of invasion of nerves locally leading to pain or weakness. Systemic symptoms are rare. The histologic variants of rhabdomyosarcoma tend to have characteristic presentations. Botryoid tumors tend to grow in potential spaces such as the bladder and vagina, present in young children and have a very good prognosis. Embryonal tumors often occur in GU tract, the orbit and head, the neck, and the parameningeal locations. Alveolar tumors often present in the extremities and have a worse prognosis. Rhabdomyosarcoma can metastasize to local lymph nodes, lungs, bone, and rarely bone marrow.

There are many benign causes of soft tissue masses in children but the emergency physician needs to consider cancer as a possible cause. Diagnostic evaluation in the ED should include a thorough history and physical examination. The history should focus on symptoms caused by the mass and other systemic or constitutional symptoms that may be present. When a reasonable suspicion for cancer exists, laboratory evaluation should include a CBC count, renal and liver function tests, and serum LDH. A plain radiograph of the affected area can be useful to look for bone destruction or fracture from an underlying bone lesion. A true soft tissue mass, however, is best imaged with an MRI, which is often not performed in the ED. Often patients can be discharged with follow-up securely arranged with a pediatric oncologist for further diagnostic workup and initiation of appropriate therapy. Inpatient management may be needed for pain control or if cord compression complicates the presentation.

Cancers of the Skin

Primary cancers of the skin, such as squamous or basal cell carcinoma or melanoma, are seen in the adult practice setting but rarely occur in children. Melanoma accounts for less than 3% of all childhood malignancies but occurs occasionally in adolescents 15 to 19 years old. There may be increased risk in the setting of immunosuppression, immunodeficiencies, history of radiation therapy or stem cell transplant, giant congenital nevi, giant congenital melanocytic nevi, or xeroderma pigmentosum. Other pediatric cancers may involve the skin, such as leukemia, which may produce leukemia cutis (particularly in infant ALL or in AML). Rash may be part of the presentation of histiocytic disorders, such as HLH or LCH. Neuroblastoma does not affect the skin but may present with subcutaneous pigmented nodules visible through the skin.

Skin abnormalities can result from the presence of a cancer even if the cancer itself does not affect or involve the skin. Petechiae, purpura, or bruising can indicate malignant replacement of the bone marrow due to a primary cancer of the marrow (i.e., leukemia) or metastatic disease of the marrow. Pallor may indicate anemia either due to marrow replacement or bleeding into a mass. The skin may appear jaundiced if there is a mass obstructing biliary flow.

Management in the ED should begin with a thorough history and physical examination. The examination should be used to screen for other skin lesions, lymphadenopathy, hepatosplenomegaly, masses, other signs of malignancy that might be related to the skin findings. If the history and physical examination suggest a particular diagnosis, then further laboratory or radiographic evaluation may be helpful. If not, and if the patient appears to be stable without signs or symptoms of systemic illness, then the patient can be discharged to home with follow-up secured with either oncology or dermatology. When cancer is suspected, a biopsy will likely be needed to help make a diagnosis and involvement from a dermatopathologist with pediatric experience will be essential. Some melanocytic lesions in children may appear malignant to pathologists without sufficient experience with the pediatric population.

COMPLICATIONS OF CANCER TREATMENT

Introduction

This section focuses on the complications of cancer treatment that are likely to lead to an ED visit for care. Complications that tend to occur only in patients who are already hospitalized are not covered in this section. The review of management

focuses on the initial care of the patient and does not address the more detailed evaluation and management needed subsequently. A detailed oncology history, as described in Table 97.1, is critical to all patients coming to the ED during or shortly after treatment.

Hematologic Complications of Cancer Treatment

Most but not all chemotherapy causes reversible myelosuppression. Neutrophils have a very short half-life and thus their numbers may drop rapidly but also may recover quickly. Platelets have a slightly longer half-life and thus tend to drop and recover slightly more slowly. Because red blood cell half-life is over 100 days, chemotherapy effects tend to be more chronic than acute. The nadir blood counts usually occur 7 to 10 days after start of treatment and recovery usually occurs 10 to 14 days after start of treatment. Many factors can influence the pattern of myelosuppression in terms of depth, duration, or specific cell line effect. The pattern of myelosuppression differs by chemotherapy regimen. For example, most solid tumor regimens allow for complete recovery within 10 to 14 days, while acute myelogenous leukemia regimens may delay recovery until 4 to 6 weeks after treatment. Even within a given regimen, there is variation both between patients and between cycles for one patient. In general, recovery is slower for patients who have already received many cycles of chemotherapy, whose course has been complicated by infection, or whose bone marrow has been extensively replaced by tumor. Radiation to the marrow cavity, especially including the spine or pelvis, can also cause myelosuppression during treatment and/or delayed recovery after treatment.

Significant neutropenia is usually defined as an ANC below 500 cells per μL. The ANC is calculated by multiplying the percentage of WBCs that are neutrophils or bands by the total WBC count. The absolute phagocyte count (APC) includes monocytes as well as neutrophils and bands. It is less widely used than the ANC as a measure of neutropenia. Patients with an ANC below 500 have an increased risk of bacterial infections related to insufficient numbers of phagocytic cells to fight bacteria. The risk increases dramatically when the ANC is below 100. Patients may develop infections with bacteria that are not pathogens in normal hosts. There is also a risk of fungal infections. The incidence of fungal infections increases with prolonged (more than 21 days) and severe (ANC below 500) neutropenia. The infectious risks of neutropenia are increased by a number of contributing factors. Indwelling foreign bodies such as central lines, ventriperitoneal shunts, and bone allografts provide a foreign surface that increases the likelihood of infection and the difficulty of treatment. The mucosal injury that typically accompanies myelosuppression increases the risk of bacteria entering the circulation. Immunosuppression decreases phagocytic function as well.

Neutrophil and/or monocytic specific growth factors can decrease the duration but not the depth of neutropenia. The short-acting growth factors are filgrastim (G-CSF, Neulasta®) and sargramostim (GM-CSF, Leukine®). These drugs are usually given daily by subcutaneous injection starting 1 day after the end of chemotherapy and continued until adequate ANC recovery after the expected nadir. There may be a temporary rise in the WBC and ANC prior to the expected nadir, then a fall, and subsequent recovery. PEG-filgrastim (Neulasta®), a long-acting form of filgrastim that is given 24 to 72 hours after chemotherapy is complete, has a usual duration of action of 10 to 14 days. Its usage is usually limited to near adult-sized patients on solid tumor regimens with expected ANC recovery by 14 days.

There is no specific management of neutropenia itself but careful attention must be paid to the associated infectious risks (see "Infectious Complications of Cancer Treatment" section). Neutropenic patients should be isolated from the potential infectious exposures that can occur in an ED by rapid triage and placement in a private room. In addition, the assessment should avoid increasing the risk of bacteremia by routine procedures such as a rectal examination or urinary catheterization. When neutropenia is present in the setting of sepsis, the literature does not support starting or increasing the dose of growth factor although this is the practice at some institutions. There is also an inconclusive literature about the use of WBC transfusions in neutropenic patients with bacteremia, if the neutrophil recovery is expected within the next 7 to 10 days.

Thrombocytopenia is defined as a platelet count of less than 150,000 per μL, but the risk of bleeding at a given platelet count may vary (Table 97.7). There are no commercially available growth factors to prevent chemotherapy-induced thrombocytopenia. The urgency of the need for platelet transfusion varies with the circumstance. In the ED, it may be more expedient to give platelets during a procedure rather than transfusing in advance and rechecking a platelet count prior to the procedure. Institutional guidelines should prevail regarding AB matching, use of anti-D products in males, and prophylactic transfusion criteria. In a patient with active life-threatening bleeding, transfusion should not be delayed to await apheresis platelets. If there is severe bleeding in a patient who is refractory to platelet transfusions, the blood bank should be consulted to arrange a continuous infusion of platelets.

Anemia is very common in oncology patients and tends to be a chronic problem due to underproduction. The need for transfusion in the ED varies with the severity of the anemia and clinical circumstances (Table 97.7). Additional information on transfusions in the actively bleeding patient and administration guidelines can be found in Chapter 91.

Most chemotherapy causes immunosuppression that affects WBC function, independent of WBC count. The immunosuppression persists throughout treatment, and for 6 to 12 months after completion of chemotherapy. The severity of immunosuppression varies by chemotherapy regimen. The impact of immunosuppression may be more profound in the patient younger than 1 year because of the immaturity of the immune system. Stem cell transplant recipients have very severe immunosuppression (see "Complications of Hematopoietic Stem Cell Transplant" section).

One of the infectious risks attributable to the immunosuppression of chemotherapy is *Pneumocystic jiroveci* (formerly known as *Pneumocystis carinii*) pneumonia. Patients younger than 1 year and those receiving treatment for leukemia or high-stage lymphoma are at increased risk. Most, if not all, pediatric oncology patients are thus treated with prophylactic trimethoprim-sulfamethoxazole to prevent infection. Those who do not tolerate trimethoprim-sulfamethoxazole are on

second-line agents such as atovaquone, dapsone, aerosolized pentamidine, or intravenous pentamidine.

Prophylaxis for other infections is more variable in usage. Fungal prophylaxis is increasingly common with specific regimens that are associated with a high frequency of fungal disease. For example, many patients with acute myelogenous leukemia take prophylactic voriconazole throughout their treatment. Respiratory syncytial virus (RSV) prophylaxis with RSV immunoglobulin Palvizumab® may be used in children younger than 1 year on highly immunosuppressive regimens.

Bleeding complications are common in oncology patients. Aside from thrombocytopenia, bleeding may occur because of coagulopathy resulting from a number of different factors. Leukemia itself may cause coaguloapathy. Asparaginase, a chemotherapy drug, impairs protein synthesis and leads to abnormal coagulation parameters on testing that cause both a bleeding and a clotting diathesis. Many patients are also on anticoagulation therapy for previous clotting problems. Any bleeding risk from the anticoagulation may be exacerbated by intercurrent thrombocytopenia. Bleeding in and around solid tumors tends to be more common at diagnosis and with relapse. Bleeding can also occur after biopsy or tumor resection. Mucosal injury from treatment can contribute to bleeding throughout the GI tract.

The management of bleeding is outlined in Chapter 91. The oncology-specific history is critical to identify contributing factors. The platelet count should always be checked immediately and transfusion given as indicated (Table 97.7). Reversal of any anticoagulation (see Chapter 91) should be considered in a patient with significant bleeding.

Cancer patients have an increased risk of clotting due to a number of factors such as compression of vessels by tumor, disturbance of flow from central lines, asparaginase-induced deficiency of endogenous anticoagulants such as protein C and protein S, decreased physical activity, and immobilization due to surgery. Catheter-related clots may present with line dysfunction, obvious or subtle signs of edema in the head or one upper extremity, or collateral vessels visible on the upper chest.

Other thrombotic complications may include pulmonary emboli (PE), deep venous thromboses (DVT), or central venous sinus thrombosis, a rare complication in patients on asparaginase chemotherapy. The presentation of central venous sinus thrombosis usually consists of vague and/or nonspecific symptoms including seizure, headache, nausea, and vomiting. Physical examination may or may not have focal neurologic findings, altered mental status, or papilledema. If a clot is suspected, the CBC count, PT, PTT, and fibrogen should be checked. CT scans may not be sensitive enough to diagnose a central venous sinus thrombosis, but MRI is generally reliable. Once the diagnosis is established, management consists of supportive care and initiation of anticoagulation. Of note, for patients on asparaginase receiving anticoagulation for a thrombus, the antithrombin level must be monitored regularly. Since asparaginase usually depletes antithrombin, a protein required for the proper function of heparin (unfractionated or fractionated), a level above 50% must be maintained. Should levels fall below 50%, antithrombin III should be repleted. To calculate the replacement dose, the following formula can be used:

$$\text{Dose (IU)} = \{[\text{Desired Level} - \text{Patient's Level}] \times [\text{Weight (kg)}]\}/1.4$$

Infectious Complications of Cancer Treatment

Infection is an extremely common problem in oncology patients due to the neutropenia and immunosuppression associated with treatment. Identification of infection can be challenging because typical symptoms may be absent or decreased. Nonetheless, prompt initiation of appropriate management is critical to optimal outcome.

Fever in a neutropenic patient is a true emergency, even in a well appearing patient (Fig. 97.4). The depth and duration of neutropenia helps to predict the risk of serious infections. All patients with an ANC below 500 or with a rapidly falling ANC that will shortly be below 500 should be considered at risk. Although fever itself can be a manifestation of some cancers, this is a diagnosis of exclusion, particularly in a patient with neutropenia. While fever should certainly raise concern for infection, the absence of fever should not overly reassure the clinician. Fever may be absent or minimized in patients on high-dose steroids and/or patients with hypothalamic dysfunction from tumor. In addition, localizing signs of infection may be blunted because the lack of neutrophils prevents many of the usual manifestations such as pus, significant local erythema, or edema.

Certain elements of the history can be very helpful. Patients or family members may know if the patient is already neutropenic. Specific questions to elicit any focal pain can direct the physical examination and empiric treatment decisions since this may be the only evidence of a localizing infection. The presence of any indwelling devices such as a central line, ventriculoperitoneal shunt, or metal hardware used for bone tumors can also help with the differential diagnosis and/or empiric antibiotic coverage. Since antibiotic allergies may be common in this population, a thorough allergy history is critical to avoid prescribing inappropriately.

The physical examination of the patient must be detailed and meticulous with careful attention paid to all mucocutaneous surfaces to elicit any focal tenderness, erythema, or edema, which may be slight. Sites to examine include any central venous access devices including both the skin entrance site and/or subcutaneous reservoir, as well as along the subcutaneous line tract, nails beds on both fingers and toes, and a thorough external rectal examination with circumferential palpation. Do not perform an internal rectal examination as it may increase the risk of bacteremia.

Diagnostic testing should include a stat CBC count with differential and blood culture from all line lumens or via venipuncture in patients without a line. Institution-specific guidelines should be followed regarding the need for peripheral blood cultures in addition to line cultures and if additional orders or specimens are needed for anaerobic cultures. Additional diagnostic testing can be obtained as needed after empiric antibiotics are started. A chest radiograph should only be obtained in patients with respiratory symptoms. A urine analysis is not valuable for screening for infection since there are too few WBCs for the leukocyte esterase to be of value. A urine culture should be obtained as long as it does not delay start of antibiotics or require catheterization, which may also increase the risk of bacteremia. If the patient has a history of urinary tract infections, the risk of urinary catheterization may

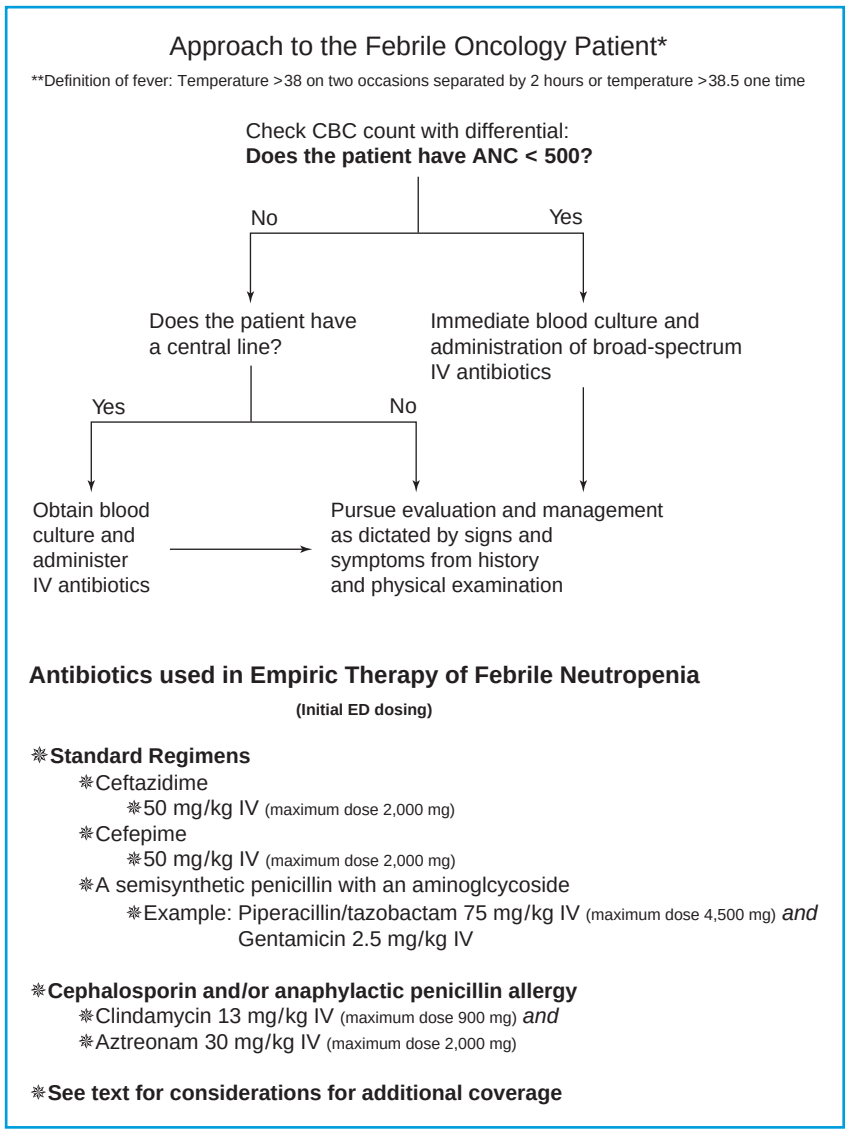

FIGURE 97.4 Management guidelines for the febrile oncology patient. Risk assessment and management hinges substantially on whether the absolute neutrophil count (ANC) is below 500, whether the patient has localizing signs or symptoms, and whether an indwelling catheter is present.

be justified. Throat cultures may be of value if there are focal findings involving only the pharynx and/or tonsils but are rarely informative in a patient with diffuse mucositis. Specific imaging may be of value based on physical findings.

Treatment should be initiated within 1 hour of patient arrival with the institutional standard regimen. Regimens need to cover both gram-positive and gram-negative organisms, including opportunistic pathogens (Fig. 97.4). Specific coverage, in addition to empiric therapy, is indicated for several clinical settings. Third-generation cephalosporins may have inadequate gram-positive coverage for patients with a soft-tissue site infections and consideration should be given to a semisynthetic penicillin and an aminoglycoside or the addition of vancomycin, given the rising incidence of MRSA. With signs or symptoms of sepsis, double coverage for gram-negative organisms should be added in addition to vancomcyin to cover for possible Streptococcus viridans, especially in patients with advanced hematologic malignancies. Fungal coverage is often added for patients in shock. All pediatric patients with fever and neutropenia less than 500 to 1,000 per mm^3 should be admitted to the hospital unless there is an institutional management guideline that includes a specific follow-up plan for outpatient management of low-risk fever and neutropenia. In the case of sepsis or septic shock, acute management as described in Chapter 92 should be followed for oncology patients, with the empiric antibiotic coverage described above for neutropenia. Stress-dose steroids should be considered in patients who have received prolonged steroids recently either as part of cancer treatment or management of nausea and vomiting.

Typhlitis, also known as neutropenic colitis, is a potentially life-threatening infection that occurs in patients with neutropenia and GI mucosal injury. This infection occurs in the watershed regions of the cecum, appendix, and terminal ileum. It is much more common in patients with advanced hematologic malignancies but can occur in patients with solid tumors. Initial symptoms can mimic appendicitis with periumbilical pain preceding right lower quadrant pain. As the infection progresses, abdominal pain can become severe and examination findings include distension and persistent right lower quadrant tenderness. Empiric antibiotics should be started as soon as the diagnosis is

suspected. Antibiotic coverage should include broad-spectrum coverage of gram-negative enteric flora as well as specific anaerobic coverage. Typical regimens are a carbapenem alone or a combination regimen such as piperacillin/tazobactam with gentamicin or ceftazidime with metronidazole. Laboratory studies should include coagulation studies and lactic acid, as well as CBC with differential and basic chemistries to assess hydration and renal function. Uncontrolled coagulopathy and/or acidosis are consistent with necrotic bowel. Serial abdominal x-rays should be performed to look for intramural air (pneumatosis), which is a hallmark of this diagnosis, or free air, which is an indication for surgery. A CT scan of the abdomen can be useful for better delineation of the degree of bowel wall injury. If CT scan is unavailable, ultrasound can show bowel wall thickening. Early surgical consultation is appropriate. Surgery itself is reserved for uncontrollable coagulopathy or acidosis as a consequence of bowel necrosis or evidence of perforation.

Clostridium difficile colitis is relatively common in oncology patients due to treatment with broad-spectrum antibiotics that eradicates normal bowel flora. This diagnosis should be considered in patients with abdominal pain and diarrhea with or without abdominal distension. Abdominal tenderness is generally minimal except in patients with very severe colitis. A CT scan can confirm involvement of the colon but is not necessary for most patients. Either vancomycin (oral) or metronidazole (parenteral or oral) can be used for treatment.

Pediatric oncology patients are also at risk for common viral infections such as RSV, CMV, EBV, influenza, and adenovirus. In general, the presentation of these infections is the same as in immunocompetent hosts. Of note, primary varicella zoster infection can rapidly progress to a life-threatening infection in an immunocompromised patient. Thus as soon as characteristic vesicles on an erythematous base are seen, empiric coverage with acyclovir 10 mg per kg IV every 8 hours should be initiated. The patient should be assessed for pneumonitis with careful respiratory examination, oxygen saturation, and chest radiograph and liver enzymes should be checked for possible hepatic involvement (see "Skin Complications of Cancer Treatment" section).

Metabolic Complications of Cancer Treatment

Complications affecting metabolic balance and the endocrinologic system are common in children with cancer. These may be because of the neoplastic disease itself, as has been addressed in the sections on newly diagnosed cancer, or to complications due cancer therapy. TLS is probably the most noteworthy example of metabolic derangement in the setting of cancer (see "Leukemia" section). TLS can be present at the time of diagnosis or may be subsequently induced as chemotherapy is initiated and tumor cells begin to die in response.

Renal tubular dysfunction is common in oncology patients. Patients may waste electrolytes such as potassium, calcium, magnesium, and phosphorus through their kidneys as a result of specific treatment exposures or prior renal injury. Ifosfamide, cisplatin, and carboplatin all are likely to cause salt wasting. Antifungal agents such as amphotericin and ambisome cause potassium wasting, which may have clinical significance. Calcineurin inhibitors, such as tacrolimus or cyclosporine, which may be used after stem cell transplantation, can cause significant magnesium wasting. Patients with hypomagnesemia are more likely to experience seizures when on calcineurin inhibitors so the magnesium should be kept more than 1.8 mEq per L in these patients. In addition, patients with tumors of the CNS may renally waste sodium so monitoring of serum sodium is crucial, especially in the postoperative period.

Patients receiving drugs for cancer that cause salt wasting are often prescribed oral electrolyte replacement. However, inability to tolerate oral medications or nonadherence may interfere with these strategies, allowing electrolyte abnormalities to develop. Most of these derangements are clinically asymptomatic with the notable exception of hypocalcemia, which can cause tetany or cardiac arrhythmias and hyponatremia resulting in refractory seizures. For the most part, management and replacement strategies for these electrolyte abnormalities do not differ from children who do not have cancer (see Chapter 100). However, when replacing calcium in pediatric oncology patients, the clinician should remember that hypomagnesemia, a common side effect of cancer therapies, can complicate efforts to address hypocalcemia.

Elevated blood sugar can be a transient side effect of corticosteroids as well as asparaginase therapy. Asparaginase affects the body's ability to make many proteins, including insulin. In ALL treatment, steroids and asparaginase may be used together and hyperglycemia may result. Treatment need not include insulin if dietary measures alone are sufficient to control the serum blood sugar. If blood glucose is greater than 250 mg per dL or is significant enough to cause glycosuria or ketonuria, treatment with small doses of insulin may be considered. However, the approach to insulin use in this setting should be conservative so as to limit the risks of hypoglycemia. Diabetic ketoacidosis is rare in this situation.

High serum calcium levels are observed commonly in the setting of adult malignancy but are far rarer in children with cancer. Hypercalcemia is usually related to the tumor destroying bone or to ectopic production of parathyroid hormone by the tumor itself. This complication is more common if patients are also taking calcium supplements or calcium-containing medications such as antacids. If asymptomatic, hypercalcemia does not always require intervention. When present, symptoms may include nausea/vomiting, constipation, altered mental status, and renal failure. Management in these cases is similar to strategies to address hypercalcemia outside of the oncology setting (see Chapter 91). However, steroids should be avoided in patients with known or suspected leukemia or lymphoma. In addition, control of the underlying malignancy is the best way to address the hypercalcemia.

Although the SIADH can develop as a result of some cancers themselves, particularly those involving the lungs or CNS, treatment with vincristine and cyclophosphamide can be associated with SIADH. Management of this complication, which hinges on fluid restriction, does not differ from that of SIADH developing in other settings (see Chapter 91).

Pain

Unfortunately, pain is a common symptom in oncology patients with data showing that more than 30% of pediatric cancer patients have experienced pain in the last week. When pain leads to visits to the ED, it requires careful and immediate management. Severe pain is a true emergency, in and of

itself, and also may be particularly upsetting for cancer patients who may have already confronted significant pain as part of their cancer diagnosis, who may anticipate or fear future pain, and who may worry (usually needlessly) that their pain is a sign of progressive cancer.

In some cases, pain may be related to the tumor itself and therefore often will respond to chemotherapy or other cancer-directed therapies. Tumors can cause neuropathic pain when they directly invade local nerves or when they cause local edema that affects the nerves in the vicinity. Tumor infiltrating an organ may cause ill-defined pain as the organ capsule becomes stretched. Bone pain may signify a pathologic fracture from a tumor weakening the bone, as can occur with Ewing sarcoma or osteosarcoma. The bones may also hurt due to tumor invading the bone marrow space. Pain in the head and neck may result from increased ICP or tumor involvement of the meninges/cerebrospinal fluid (most common in hematologic malignancies).

On the other hand, pain may be related to cancer treatment. In these cases, the patient or family may report that this particular pain has been historically linked to a specific therapy. Patients may complain of pain secondary to surgical procedures they have experienced. Such cases are very common and are not substantially different from postoperative pain in children without cancer. A particularly challenging example of this is the phantom pain that can occur after limb amputation. In addition, oncology patients may experience pain of the mouth, GI tract, or even urethra as part of mucositis. Pain could also represent a focal infection, complicating the patient's compromised immune system. Bony pain may reflect recent therapy with hematopoietic growth factors to stimulate neutrophil recovery after chemotherapy. Radiation therapy can induce local tissue injury, which may be very painful.

Abdominal pain is a common complaint in cancer patients and can arise from several sources. The differential diagnosis may be very wide including pancreatitis, hepatitis, cholecystitis, constipation, mucosal injury, intraabdominal infection, and bowel obstruction (see "Hepatic and Gastrointestinal Complications of Cancer Treatment" section).

An important first step in management is to explicitly address pain when taking the patient's history. Even patients who come to the ED for other reasons may have pain complicating their presentation. Pain should be assessed with an age-appropriate scale.

Upon determining that a patient is in pain, according to the patient's report as opposed to the clinician's assessment, the emergency physician must initiate immediate pain treatment. The remainder of the history and physical examination should be used to identify the cause of the pain and to explore specific treatment for that cause.

Acetominophen is a useful analgesic with minimal side effects for most patients, remembering to avoid the rectal route if the patient is neutropenic. NSAIDs and aspirin may be effective as pain relievers but are generally avoided in this patient population due to their antiplatelet effect in the setting of frequent thrombocytopenia. Opioids represent the mainstay of pain treatment for the pediatric oncology patient. General principles of dosing include the following:

- A dose that is commonly used as a standard starting dose may be insufficient to provide adequate pain relief if the patient is not opioid-naïve.
- Far more important than the actual dose is the dose to *effect*. Patients may need repeated doses in order to get control of their pain and repeated doses should not be limited when analgesia has not yet been attained.
- A patient-controlled analgesia (PCA) pump is frequently needed for several types of pain, particularly mucositis where oral intake can be limited. Such pumps may be initiated in the ED using morphine, fentanyl or hydromorphone, institutional standard permitting. Small children and infants may benefit from nursing-controlled analgesia (NCA), should they not be old enough to handle a PCA. Parents should not control analgesic pumps except in the setting of end-of-life care, per institutional policy.
- Long-acting opioids, such as MS Contin®, Oxycontin®, and methadone, may be appropriate in the setting of chronic pain. These medications should not be used in the setting of acute pain and are rarely initiated in the ED unless in consultation with a pain expert.

Careful consideration must be given to decisions about whether patients in pain may be discharged to home. If oral medications seem to be relieving the pain, then it is generally acceptable to discharge the patient after ensuring that he/she has an adequate supply of the analgesics for use at home. If the pain is inadequately controlled on oral medications and parenteral administration is required, then the patient will need to be admitted.

Neurologic Complications of Cancer Treatment

Neurologic complications in children with cancer are extremely common and may relate to disease, cancer treatment, or supportive care medications. Drug-related side effects are extremely frequent. Many of the common problems are fully reversible but a few can lead to permanent neurologic injury. The cancer-specific history is critical to identify the likely causes of neurologic problems. The diagnosis and management of neurologic problems in children is covered in Chapter 96. This section focuses on the unique considerations in the pediatric cancer patient.

Both motor and sensory peripheral neuropathies are common in children with cancer. Vincristine and vinblastine, two chemotherapy agents used to treat many kinds of childhood cancer, both cause reversible neuropathy affecting motor, sensory, and autonomic nerves. Thalidomide can also cause peripheral neuropathy, which may or may not be fully reversible.

Initial management tends to focus on establishing the diagnosis by the cancer-directed history and physical examination. Pain responds best to agents with efficacy against neuropathic pain such as gabapentin. Such drugs rarely have immediate effect and thus narcotics may be needed in the short run.

There is a wide differential to consider when evaluating a pediatric cancer patient with new onset cranial nerve palsy. Symmetric involvement may reflect vincristine-induced neuropathy, particularly when it involves ptosis. Increased ICP from shunt malfunction or tumor progression should also be considered. Asymmetric involvement can occur with fatigue or vincristine-induced exacerbation of baseline weakness. Vincristine can also cause asymmetric ptosis in some patients, but this tends to be a diagnosis of exclusion. Increased ICP should be

suspected in a child with a sixth nerve palsy. Carcinomatous meningitis should be considered in patients with a history of tumors likely to involve the cerebrospinal fluid or meninges, such as leukemia, lymphoma, parameningeal sarcomas, and meningeal seeding brain tumors, such as medulloblastoma. Patients treated with a scopolamine patch for nausea may develop pupillary asymmetry as scopolamine transferred by fingertip from the patch to the eye can elicit unilateral mydriasis.

Management in the ED requires an appropriate oncology-directed history and physical examination to establish the potential differential. Unless drug effect can be established as the most likely cause, a head CT scan to rule out increased ICP may be required. The CT scan findings may also direct the specific ED and post-ED management. Admission for observation may be required for some patients where the diagnosis or trajectory is uncertain.

The most common cause of proximal muscle weakness in pediatric cancer patients is prolonged steroid exposure as part of cancer treatment or management of side effects. Diagnosis can usually be established by the appropriate history and physical examination. Patients with very severe symptoms whose families cannot manage care at home may require admission for respite care or initiation of rehabilitation.

Altered mental status in pediatric cancer patients has an extremely broad differential (Table 97.8). Cerebrovascular accident (CVA) as a cause of altered mental status should be considered in patients with risk factors such as thrombocytopenia, DIC, asparaginase-induced coagulopathy. Cytarabine can cause cerebellar dysfunction that in severe forms can progress to coma. This usually only occurs with doses of at least 1 g per m^2 given over several hours or less. Onset usually occurs within hours of treatment and thus would be more likely to be identified in an inpatient rather than during an ED visit after discharge. Ifosfamide can cause an acute neurologic syndrome including confusion, inappropriate laughter, somnolence, or psychosis. Onset is usually within hours of treatment but can occur several days later. Thalidomide can also cause somnolence, especially at times of dose escalation. Somnolence can be a side effect of many supportive-care medications such as narcotics, gabapentin, antihistamines, some antiepileptics, and antidepressants. Cranial radiation causes somnolence syndrome 6 to 12 weeks after treatment that may last several weeks in duration. Typical manifestations are extreme amounts of sleep (up to 20 hours per day) with normal mental status and function when awake.

An oncology-directed history, with particular attention to a detailed medication history, is critical to narrowing the differential diagnosis. Physical examination should look for other findings such as papilledema or focal neurologic findings that may also narrow the differential diagnosis. Laboratory evaluation should be carried out as recommended in Chapter 96. If a drug-related cause is suspected, specific drug levels when available may be helpful. If a lumbar puncture is planned to look for malignant cells or an infectious etiology, the risk of herniation and the resultant need for imaging should be assessed. Imaging studies may also be appropriate if an intracranial lesion is suspected or when the diagnosis is unclear. A CT scan without contrast can be useful to identify midline shift, increased ventricular size, or a hemorrhagic stroke. A CT scan with contrast can identify likely carcinomatous meningitis or a supratentorial mass lesion. MRI can identify mass lesions anywhere in the CNS, including below the tentorium; ischemic stroke; hypertensive encapalopathy; or encephalitis.

TABLE 97.8

ETIOLOGY OF ACUTE ALTERATION IN MENTAL STATUS IN CHILDREN WITH CANCER

- Tumor
  - Primary CNS tumor
  - Metastatic tumor
  - Leukemic or carcinomatous meningitis
  - Hyperleukocytosis
- Infection
  - Meningitis—bacterial, fungal
  - Viral encephalitis
  - Brain abscess
  - Septic shock
- Cerebrovascular accident
- Seizure/postictal state
- Increased intracranial pressure
  - Shunt malfunction
  - All transretinoic acid (Tretinoin)
- Treatment
  - Cytotoxic chemotherapy
    - Methotrexate
    - Cytosine arabinoside
    - Ifosfamide
    - Thalidomide
  - Supportive care
    - Narcotics
    - Benzodiazepines
    - Gabapentin
    - Anticonvulsants
    - Tricyclic antidepressants
    - Antihistamines
    - Dronabinol
- Leukoencephalopathy
- Metabolic derangements
  - Hyponatremia/SIADH
  - Hypo/hyperglycemia
  - Hypomagnesemia
  - Uremia
- Postradiation therapy somnolence syndrome
- Hypo/hypertension
- Hypoxia
- Liver failure
- Depression

SIADH, syndrome of inappropriate antidiuretic hormone.

Management of drug-related altered mental status usually involves withholding the offending agent and supporting the patient until resolution. If narcotic-related, avoid rapid reversal with standard doses of naloxone, which could cause excrutiating pain that will be unresponsive to further narcotics for 2 to 3 hours. Supportive care such as stimulation should be tried prior to reversal. If reversal is required, the appropriate dose of naloxone (0.1 mg per kg) should be diluted in 10 mL of normal saline and then administered in 1 mL aliquots while titrating to effect. Alternatively, dosing can be initiated at 1 mcg/kg for mild respiratory depression and 10 mcg/kg for reversal of moderate to severe respiratory depression as needed. Laboratory evaluation of hepatic and renal function may identify contributing factors to increased drug effect. If ifosfamide neurotoxicity is suspected, many recommend methylene blue treatment using dosages that have been extrapolated from other settings. The usual dose for adolescents and adults is 50 mg administered orally or by slow IV push. There is no clear dosage for younger children but there

are case reports using 1 to 2 mg per kg as in the treatment for methemoglobinemia. For management of hypertensive encephalopathy, see Chapter 34.

Patients with improvement of symptoms in the ED for whom a likely cause of altered mental status has been established may be discharged to home. Most others will require admission for further evaluation and/or observation.

The presentation and management of increased ICP is not unique to pediatric cancer patients (see Chapter 96). The differential diagnosis includes tumor (see the "Tumors of the Central Nervous System" section) or shunt malfunction more often than treatment effect. Tretinoin (all transretinoic acid), an agent uniquely used in the treatment of APML causes increased ICP. Children are particularly sensitive to this side effect. For patients with severe symptoms attributable to tretinoin, a diagnostic and therapeutic lumbar puncture may be needed. Opening pressure should be measured and cerebrospinal fluid should be withdrawn to reduce the pressure (see Chapter 96).

Children with cancer are at increased risk of seizures from the causes summarized below. Severe metabolic disturbances can result from SIADH (a side effect of vincristine and high-dose cyclophosphamide) or from renal tubular wasting of electrolytes (see "Metabolic Complications of Cancer Treatment" section). Seizures can also be caused by primary brain tumors, particularly supratentorial, CNS metastasis of refractory solid tumors, or carcinomatous meningitis. Some chemotherapy agents such as intrathecal administration or high-dose systemic administration of methotrexate or cytarabine can cause seizures. New onset seizures can be a sign of a bacterial abscess (more likely with *Bacillus cereus* bacteremia), fungal abscess, or a viral encephalitis such as those caused by herpes simplex virus or CMV. The approach to seizure management is not unique in patients with cancer and is addressed in Chapter 96. Specific consideration should be given to assess and correct problems with metabolic abnormalities.

Children with cancer are at increased risk of CVAs. Specific causes in children with cancer include sagittal sinus thrombosis (a potential complication of asparaginase chemotherapy) and intracranial bleeding with contributing factors of hypertension, coagulopathy, thrombocytopenia, intracranial tumor, prior surgery, and radiation. Spontaneous intracranial hemorrhage is extremely rare except when the platelet count is less than 5,000 per μL (see "Hematologic Complications of Cancer Treatment" section). The approach to diagnosis and management is addressed is Chapter 96. Specific consideration should be given to assess and correct problems with coagulopathy and/or thrombocytopenia.

Side effects of some supportive-care medications can include extrapyramidal reactions. Symptoms of such reactions can range from oculogyric crisis with mild repetitive eye deviation and/or neck motion to severe torticollis and eye deviations. Reactions can also include tardive dyskinesia ("frozen") and akathisia (restless/agitation). The key to diagnosis involves not only a thorough physical examination but also a thorough medication history. Dopamine-receptor antagonists used as antiemetics are the most common trigger in cancer patients. Such drugs include high-dose metoclopramide; phenothiazines such as compazine, chlorpromazine (thorazine), and thiethylperazine (torecan); and butyrophenones such as droperidol and haldol. Since more effective antiemetics, such as serotonin-receptor antagonists, have become available, the use of these drugs has decreased along with the incidence of this side effect. If an extrapyramidal reaction is suspected, management should include diphenhydramine 1 mg per kg IV (maximum dose 50 mg). If symptoms are refractory to diphenhydramine, benztropine (Cogentin®) should be given at a dosage of 0.02 mg per kg (maximum 1 mg) IV. If symptoms do not remit or diagnosis remains unclear, patients should be admitted.

Cardiovascular Complications

Cancer treatment can affect cardiac function in patients both on active treatment and long after completion of therapy.

Anthracycline-induced cardiomyopathy is the most common cause of cardiac damage in pediatric oncology patients although only a small percentage of them are affected. Anthracycline chemotherapy is widely used in the treatment of leukemia, lymphoma, sarcoma, and embryonal tumors such as neuroblastoma and Wilm's tumor. The most commonly used anthracyclines include doxorubicin (Adriamycin®) and daunorubicin (Daunomycin®). Other drugs included in this category are epirubicin, idarubicin, and mitoxantrone. These drugs injure and potentially kill individual cardiomyocytes and can cause acute cardiomyopathy during and up to one year after the end of treatment. Late cardiomyopathy may develop 8 or more years after completion of therapy. Typical findings on echocardiogram include decreased shortening fraction/ejection fraction and/or increased afterload. Specific risk factors include high total dose (greater than 300 mg per m^2), high dose rate, very young age at treatment, and trisomy 21. Most regimens today are designed to minimize the risk of cardiomyopathy by limiting total dose and dose rate and/or giving dexrazoxane, a cardioprotectant.

Patients exposed to substantial doses of anthracycline are screened with echocardiograms to look for early cardiac dysfunction. Early-onset cardiomyopathy usually presents as acute cardiac failure or cardiac dysfunction out of proportion to a stressor such as sepsis. Late onset cardiomyopathy is generally a slowly progressive process that may be detected on screening. Both forms may be associated with arrhythmias. The initial management of this problem follows the standard regiment for cardiac failure (see Chapter 84).

Radiation to the heart can cause long-term injury to the endothelial surfaces leading to early onset atherosclerotic vessel and/or valve disease. The heart is exposed in mantle radiation for Hodgkin's disease and total body irradiation as part of a transplant preparative regimen.

Hypertension may occur in pediatric oncology patients. Contributing factors include steroid exposure, salt overload, and renal injury from treatment. Most hypertension is not an emergency and is better addressed by the treating oncologist as part of long-term management. Hypertensive emergencies (see Chapter 34) are rare in pediatric oncology patients.

Hepatic and Gastrointestinal Complications of Cancer Treatment

Cancer treatment frequently affects the GI tract and liver. The majority of complications are minor and fully reversible. A few complications are potentially severe and/or have long-term consequences. Chemotherapy frequently impairs the ability of the mucosal lining of the GI tract to regenerate itself. Severity varies with different chemotherapy regimens. Time to occurrence is

similar to the timing of myelosupression with onset 7 to 10 days after treatment and recovery by 14 days. Radiation also causes temporary injury to any areas of mucosa included in the radiation field. This injury becomes evident after several weeks of treatment and will persist/worsen until treatment is complete.

Initial assessment must include a thorough oncology history to elicit chemotherapy or radiation exposures as well as localizing symptoms and a complete physical examination. Chemotherapy-induced mucositis can affect part or all of the GI tract from oropharnyx to the rectum and may be manifest as oral ulceration, throat pain, esophagitis, gastritis, enteritis, or rectal ulceration. Radiation-induced mucosal injury is often associated with skin manifestations in the treatment field. Oropharyngeal involvement usually includes pain and visible mucosal injury ranging from irregular mucosal surfaces to scattered ulcerations to severe diffuse ulceration with swelling of the lips and inability to open the mouth. Esophagitis may be evident only by refusal to swallow and/or retrosternal pain. Enteritis, common with radiation fields that include the intestines, may be evident with crampy watery diarrhea. Mucosal injury to the rectum leads to pain with defecation, tenesmus, or rectal pain. There may be obvious perirectal erythema or ulceration. Do not do an internal rectal examination, which may cause an increased likelihood of bacteremia.

Management of moderate to severe mucositis usually requires pain control with parenteral narcotics. Cancer patients may require higher than standard starting doses, especially if already on narcotics at home. Patients and their families should be asked whether they have preferences based on prior episodes of pain which narcotic works best. PCA with both continuous and bolus dosing should be initiated in the ED if available. Do not use NSAIDs for pain control since they usually have platelet inhibitory effects and thrombocytopenia frequently coincides in time with mucositis. Avoid regular use of acetaminophen, which may mask fever since neutropenia also often occurs at the same time. Assess hydration and provide intravenous support as needed. Patients with adequate oral pain control and oral hydration can be discharged to home. Others will need to be admitted for pain control and/or hydration until the mucositis resolves.

Nausea and vomiting are common symptoms in oncology patients. It is critical to consider the differential diagnosis and not just attribute all such symptoms to chemotherapy-induced nausea and vomiting (CINV). CINV can be divided into three categories: acute, delayed, and anticipatory. Acute symptoms occur within 24 hours of emetogenic treatment. Delayed symptoms occur 2 to 5 days after treatment and are particularly common with cisplatin. Anticipatory symptoms are conditioned symptoms that occur without emetogenic treatment with a variety of emotional or sensory triggers. These anticipatory symptoms can become chronic in some patients. Despite appropriate prophylactic therapy, almost all cancer patients experience some nausea and vomiting. Radiation to the GI tract or the CNS is also emetogenic. Other causes of nausea and vomiting include GI injury from a variety of causes such as gastritis from steroids, obstipation/constipation, medication side effects (e.g., narcotics), pancreatitis (from asparaginase), GI obstruction (e.g., adhesions from prior surgery), or superior mesenteric artery syndrome in patients with severe malnutrition.

Initial management should focus on developing an appropriate differential diagnosis based on the patient's oncology-specific history, medication history, and physical examination. Symptoms may also be multifactorial. Specific evaluations should be carried out based on the differential diagnosis. An abdominal x-ray can be quite helpful if obstruction or obstipation/constipation is suspected. Amylase and lipase should be measured in patients who are being treated with asparaginase.

A strategy for symptom management for CINV (or radiation-induced) is outlined in Table 97.9. As with pain management, all medications are less effective when treating established symptoms. Standard hydration and electrolyte management should be considered for all patients with severe nausea/vomiting.

Obstipation and constipation are very common in oncology patients. Contributing factors included decreased GI motility from vinca alkaloids, narcotics, poor oral intake, decreased activity, and/or withholding due to rectal pain from mucositis. Patients may present with complaints of nausea/vomiting, abdominal discomfort and/or abdominal distension. The evaluation should include a detailed history to elicit any of the contributing factors as well as a specific bowel history. Physical examination should *not* include an internal rectal examination due to potential increased risk of bacteremia. Abdominal x-ray may be helpful in establishing the amount of stool. Treatment of constipation in oncology patient should include only those agents that can be given by mouth. Rectal suppositories and enemas should be avoided except in extreme circumstances. Patients with severe symptoms may need to be admitted for clean out.

Transaminitis with elevations in AST and/or ALT are common in pediatric cancer patients. Many chemotherapy agents cause a mild reversible transaminitis. Elevations as high as 10× normal can occur 1 to 3 days after the administration of high-dose methotrexate. Treatment-related transaminitis is usually a laboratory-only finding without any clinical correlate. Transfusion-associated viral transaminitis can also occur in the highly transfused oncology population. The incidence of viral transmission has been reduced by both direct and indirect screening of donor blood. Immunosuppression from treatment can also increase the risk of CMV and EBV. Isolated transaminitis may be noted during an evaluation in the ED but rarely is an indication for a laboratory evaluation.

Mild, reversible elevations in bilirubin are common during cancer treatment and should rarely require an ED evaluation. Such elevations are likely multifactorial and may relate to chemotherapy, transfusion, or subclinical liver injury. Isolated mild hyperbilirubinemia may be noted but rarely needs further testing.

Diarrhea in an oncology patient may be triggered by a variety of causes including radiation injury as noted above. Oncology patients may be at increased risk of Clostridia difficile colitis due to prolonged hospitalizations and/or use of broad-spectrum antibiotics. Irinotecan chemotherapy can cause two forms of diarrhea. The first is an acute effect that occurs during or immediately after infusion. It is mediated via a cholinergic effect and should be treated with loperamide. Prophylaxis with atropine should be given with subsequent cycles. Delayed diarrhea (more than 24 hours after infusion) also occurs and should also be treated with loperamide. Typical dosing regimens use loperamide 4 mg po at onset of diarrhea followed by 2 mg po every 2 hours until resolution of diarrhea. Prophylaxis with subsequent courses includes cefixime to eliminate aerobic gut flora that deglucuronidate the SN-38G metabolite of irinotecan.

Veno-occlusive disease of the liver (VOD) is a rare but important complication to recognize. Risk factors include exposure to actinomycin-D chemotherapy and liver radiation. Manifestations

TABLE 97.9

MANAGEMENT OF CHEMOTHERAPY-INDUCED NAUSEA AND VOMITING (CINV)

Agents with a high therapeutic index

Drug class	Specific drug	Pediatric dosage and frequency (usual adult maximum)	Route	Comment
Serotonin-S3 receptor antagonists	Ondansetron	0.15 mg/kg (8 mg) q 8 h or 0.45 mg/kg (24 mg) q 24 h	IV/PO	There are limited data that there may be incomplete cross-resistance between agents.
	Granisetron	10–40 μg/kg (1 mg) q 24 h	IV/PO	
	Dolasetron	1.8 mg/kg (100 mg) q 24 h	IV/PO	
Steroid	Dexamethasone	10 mg/m^2 (10 mg) q 12–24 h	IV/PO	■ Should not be used in patients with steroid-sensitive malignancies without consultation with oncologist (e.g., ALL, lymphoma ■ Use should be avoided/minimized in patients at high risk of infection or if at increased risk of mucosal toxicity from chemotherapy (e.g., AML, advanced lymphomas, ALL during induction)
NK receptor antagonist	Aprepitant		PO	There are minimal pediatric data with this drug. There are no published data using this drug for established symptoms. Thus, we do not recommend using this drug in the ED setting.
Other	Scopolamine	1.5 mg fixed-dose transdermal patch for patients >40 kg	Transdermal	Avoid concurrent use of anticholinergic drugs such as diphenhydramine

Agents with a low therapeutic index

Drug class	Specific drug	Pediatric dosage and frequency (usual adult maximum)	Route	Comment
Benzodiazepine	Lorazepam	0.05 mg/kg (1 mg) q 6 h	IV/PO	Overdosage may be common with weight-based dosing strategies. Thus, also consider 0.25 mg for <25 kg, 0.5 mg for ≥25–50 kg, and 1 mg for ≥50 kg. More potent as an anxiolytic than as an antiemetic.
Dopamine antagonist	Metoclopramide	0.5 mg/kg q 6 h	IV/PO	■ Children are at high risk of extrapyramidal reactions. □ Must be given with diphenhydramine prophylaxis. □ If more than 1 mg/kg of metoclopramide given in 24 h, recommend diphenhydramine coverage for 24 h after the last dose of metoclopramide.
	Prochlorperazine	Complex dosing guidelines, consult appropriate source.	IV	
	Prochlorperazine		PO	
	Prochlorperazine		PR	
	Thiethylperazine			
	Haloperidol			We do not recommend usage in the ED setting unless the prescriber is experienced with the use of this drug.
Other	Dronabinol	5 mg/m^2	PO	No data in use younger than 5 yr

IV, intravenous; PO, per os; ALL, acute lymphoblastic leukemia; AML, acute myeloid leukemia; NK, neurokinin; ED, emergency department; PR.

include hepatomegaly, transaminitis, thrombocytopenia, and ascites. The thrombocytopenia is frequently more than what would be expected from the chemotherapy alone or may occur at the wrong timing relative to chemotherapy. Once the diagnosis is suspected, a hepatic ultrasound with Doppler assessment of hepatic vein flow should be performed. Reversal of flow in the small hepatic veins establishes the diagnosis in the appropriate clinical setting. Management is supportive until the problem resolves on its own. Most patients will require admission for both observation and support.

For a discussion of typhlitis, see section on "Infectious Complications of Cancer Treatment."

RENAL COMPLICATIONS OF CANCER TREATMENT

Renal injury from cancer treatment is very common and some degree of renal dysfunction is frequently present even in patients with normal creatinine for age. Other patients will have documented renal dysfunction based on elevated creatinine, decreased glomerular filtration rate (GFR), or decreased 24-hour creatinine clearance. Renal complications may also lead to metabolic disturbances (see "Metabolic Complications of Cancer Treatment" section). Contributing factors are listed below.

- Urate-acid nephropathy can occur in patients with very high cell turnover (see "Leukemia" section).
- Drug-induced renal injury is common in oncology patients.
  - Administration of high-dose methotrexate (dosage greater than 500 mg per m^2) very rarely causes acute renal failure, typically manifested as brisk urine output and a rapidly rising creatinine. Onset is usually within 24 hours of treatment. The renal failure itself is usually fully reversible and is managed with supportive care only.
  - High-dose cisplatin given in dosages of greater than 50 mg per m^2 per course causes chronic renal insufficiency manifested as decreased glomerular filtration and tubular wasting. Tubular wasting of magnesium is prominent and many patients require magnesium supplementation both on treatment and for months after completion.
  - Ifosfamide exposure causes renal injury manifested as Fanconi's syndrome with proximal tubular dysfunction and wasting of phosphate, glucose, potassium, and bicarbonate.
- Radiation injury to the kidney may cause renal insufficiency as well as radiation nephritis, 3 to 6 months after treatment. Typical findings include the manifestations of vasculitis with hemolytic-uremic syndrome (HUS). Oncology patients are also at risk for medical renal disease associated with poor perfusion (secondary to sepsis), exposure to multiple nephrotoxic agents, and hypertension.

Since renal injury is common, it is appropriate to check BUN, creatinine, electrolytes, calcium, magnesium, and phosphate in all systemically ill oncology patients. If significant abnormalities are noted, the oncology-specific history should be reviewed to determine specific risk factors or exposures that may help explain the problem. In general, the management of significant abnormalities is not unique to patients with cancer and should follow the guidelines in Chapter 100. Consider the possibility of a decreased GFR (whether known or not) when starting antibiotics and other medications excreted via the kidney.

Genitourinary Complications of Cancer Treatment

The most common form of bladder injury in cancer patients is hemorrhagic cystitis, a potential complication of exposure to cyclophosphamide or ifosfamide. Both of these drugs have an acrolein metabolite that is directly toxic to the bladder mucosa. Prevention of drug-induced hematuria usually includes hydration, frequent voiding, and administration of mesna, a drug that binds the toxic metabolite. Manifestations include dysuria, suprapubic pain, and microscopic or gross hematuria with onset within 24 hours of drug administration. Other causes of toxicity to the GU tract include infection, bladder radiation, tumor resection, or ongoing presence of tumor in the GU tract.

If a patient is complaining of bladder-related symptoms or the urinalysis shows evidence of hematuria, the oncology-specific history should be reviewed to help develop an appropriate differential diagnosis in addition to the usual causes (such as infection) that would be considered in a patient without cancer. Initial management should include initiation of one and one-half times to twice maintenance hydration and frequent voiding. Laboratory evaluation should include a urine analysis, CBC count to look for anemia or thrombocytopenia, and coagulation studies. Any contribution from coagulopathy and/or thrombocytopenia should be corrected. If severe bleeding or bladder outlet obstruction from clots occurs, an urologist should be consulted. A bladder catheter large enough to be used for irrigation should be placed and bladder washing initiated in consultation with urology. Packed red blood cell transfusion may be needed. In very rare cases, bleeding can be life-threatening and bladder sclerosis is indicated. Mesna (2-mercaptoethane sulfonate sodium) has no utility once the offending drug has cleared from the system. Pain management with oxybutynin chloride and narcotics should be initiated as needed.

Skin Complications of Cancer Treatment

Various cancer treatments are known to have cutaneous toxicities.

- High does of cytarabine may cause erythroderma, often limited to the plantar surfaces, with subsequent desquamation. Treatment is supportive.
- Radiation induces dermatitis in the treatment field that can range from mild to severe, based on the total dose and any concurrent radiation sensitizers. The presentation may vary from a mild erythroderma, similar to a sunburn, to severe desquamation in the treatment field. Any topical treatment must be prescribed in conjunction with the treating radiation oncologist because certain topical agents may increase the radiation dose to the skin.
- Drug rashes are very common in oncology patients. Because any one patient tends to be on many drugs at one time, it may be difficult to identify the specific culprit. Management of a drug reaction is not unique to oncology patients. However, consultation with the oncologist may be needed to discuss if alternate treatment is needed.

Infections may be accompanied by cutaneous manifestations (see Chapter 92). Although not unique to oncology patients, certain infections affecting the skin may be more common in

this patient group. Immunosuppressed patients are at increased risk for herpes simplex and herpes zoster. Any skin lesions in a dermatomal distribution, with or without associated pain and whether or not the lesions are "classic," should be considered herpes zoster until proven otherwise. Immunocompromised patients with herpes zoster have an increased risk of disseminated disease and should be placed in respiratory isolation. Evaluation should include chest radiograph and liver function tests. If there is vesicular lesion, it should be scraped and sent for both rapid testing and culture for herpes simplex and varicella zoster. Empiric therapy should be started with either acyclovir or one of its derivatives. Admission for intravenous therapy is indicated for evidence of dissemination, ophthalmologic involvement or failure to respond to oral therapy. Oral home therapy can be considered in consultation with oncology after considering extent of involvement, degree of underlying immunosuppression, likelihood of medication compliance at home, and ability to follow up.

COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANT

Bone marrow transplantation is an increasingly utilized therapy aimed at treating various hematologic, oncologic, metabolic, or immunologic diseases. In hematologic malignancies, allogeneic marrow transplantation may follow initial remission induction or disease relapse. The allogeneic donor may be related, usually a sibling, or unrelated to the recipient. In solid tumors and some lymphomas, patients may receive aggressive chemotherapy and radiation and then have their own stem cells infused as a "rescue" to help reconstitute their immune system following therapy. Knowledge of the type of transplant a patient received (Table 97.1) can help the clinician to anticipate what complications might ensue. In general, patients who have had a stem cell transplant represent a fragile patient population at risk for many complications.

In approaching these patients, substantial immunosuppression should be presumed for at least 6 months following the transplant. For patients still receiving immunosuppressing medications, the period of immune dysfunction may be much longer. Regardless of the WBC and neutrophil counts, immune function following a stem cell transplant can be profoundly impaired.

Graft-versus-host disease (GVHD) may develop in the setting of allogeneic stem cell transplants as newly engrafted immune cells of the donor react against tissue antigens of the recipient that are perceived to be foreign (Table 97.10). The risk of developing GVHD is higher if the degree of HLA (human leukocyte antigen) matching between the donor and recipient was less optimal and if donors and recipients are unrelated. Acute GVHD occurs in the first 100 days post transplant, often when patient is still in hospital, and typically involves the skin, GI tract, or liver. Chronic GVHD presents after 100 days and is accompanied by severe immunologic dysfunction.

The management in the ED of patients with known or suspected GVHD following an allogeneic stem cell transplant begins with a history to explore whether the patient could be dehydrated or anemic due to colitis or whether he/she is experiencing dyspnea due to lung involvement. Physical examination should explore the skin for rash, fibrosis, or jaundice, liver size and tenderness, and oxygen saturation. Assessment should focus on screening for organ dysfunction serious enough to require intervention in the ED. Clinicians should have a low threshold for admitting such patients for inpatient management due to overall fragility of this patient population.

Therapy for GVHD is primarily immunosuppressive using corticosteroids, cyclosporine, and other agents directed against T cells. Specialists in hematopoietic stem cell transplant decide whether to pursue such agents and when. Often a biopsy (skin, bowel, liver, etc.) is required to diagnose GVHD on histopathology.

The management of infectious complications for patients following stem cell transplant is not different from infections in the oncology population overall, but the relevant organisms may vary and the clinician's level of suspicion may need to be higher (Table 97.10). Infections in these patients result from the extreme immunosuppression achieved by myeloablation, cutaneous and mucosal barrier damage intrinsic to the transplant process, and the immunologic immaturity of the transplanted marrow. Exacerbating the risk is the presence of central lines in these patients.

Importantly, the types of infections patients tend to develop after hematopoietic stem cell transplant can vary based on how many days have elapsed since the transplant.

- In the first month after the transplant, as patients are hospitalized and awaiting engraftment of their bone marrow, they are vulnerable to gram-positive and -negative bacteria, anaerobic bacteria, respiratory viruses and reactivation of herpes simplex virus, and fungal infection with candida and aspergillus.
- After engraftment, from day 30 to 100 after the transplant, patients remain at risk for bacterial infections, particularly those related to their central lines. Aspergillus and respiratory viruses continue to be a concern. However, CMV becomes more of a threat at this point as can infections with pneumocystis and toxoplasma.
- More than 100 days after the transplant, patients are at risk for encapsulated bacteria, especially if they are simultaneously affected by GVHD or on ongoing immunosuppression. Aspergillus, pneumocystis, and toxoplasma continue to be a concern. Viral infections with varicella zoster virus, CMV, EBV, and respiratory viruses are also a large threat for these patients.

When patients present to the ED with fever following a hematopoietic stem cell transplant, empiric coverage with antibiotics should be instituted at once while cultures of the blood and urine are pending. While gram-negative organisms have historically been of primary concern, gram-positive bacteria have more recently become more threatening, particularly with the emergence of MRSA in some regions. Antibiotic regimens need to broadly cover gram-positive and -negative bacteria (e.g., piperacillin/tazobactam and gentamicin) as well as MRSA when relevant.

Rarely seen as a complication of stem cell transplant, TTP (thrombotic thrombocytopenic purpura) can present in this patient population manifesting the classic pentad of fever, neurologic symptoms, hemolytic anemia, thrombocytopenia, and renal compromise (Table 97.10). The disorder seems to be associated with immunosuppression with cyclosporine or FK506 in the posttransplant period. In some patients, TTP

TABLE 97.10

COMPLICATIONS OF HEMATOPOIETIC STEM CELL TRANSPLANT

Complication	Clinical findings	Management
Graft versus host Disease (GVHD)	Acute Skin Erythematous rash Classic involvement of palms and soles GI tract Colitis, sometimes bloody diarrhea Abdominal pain Liver Elevated bilirubin, alkaline phosphatase, transaminases Hepatomegaly Right upper quadrant tenderness Chronic Pulmonary Hypoxia Shortness of breath Liver (as above) Eye dryness Mouth dryness Skin Sclerodermatous changes Contractures	Immunosuppressive medications chosen only in consultation with experts in stem cell transplant Aggressive management of infections and fevers given immunosuppression intrinsic to Graft-versus-host disease (GVHD) Hydration as needed for dehydration from colitis Assessment of anemia secondary to bloody diarrhea Caution using drugs metabolized in the liver if hepatic GVHD present
Infection	Bacterial Bacteria Gram positive Gram negative Viral Endogenous Varicella zoster Herpes simplex Epstein-Barr virus Cytomegalovirus Adenovirus Exogenous Influenza Parainfluenza Respiratory syncytial virus Adenovirus Fungal Disseminated candidemia Invasive aspergillosis	Empiric broad spectrum antibiotics for fever All patients to be considered functionally neutropenic and immunocompromised until they have been off all immunosuppressive medications for at least 6 mo Aggressive imaging to follow-up and localizing signs or symptoms elicited through history and physical examination Bacterial and fungal cultures as well as viral studies of blood, urine, sputum Spinal tap not required
Thrombotic thrombocytopenic purpura	Acute form displays classic pentad Fever Hemolytic anemia Thrombocytopenia Renal failure Neurologic symptoms Rarely can evolve into chronic hemolytic-uremic syndrome–like picture	Manage as TTP would be managed outside of the stem cell transplant setting

may evolve into a more chronic picture with abnormal renal dysfunction and a clinical picture more consistent with HUS.

Care of Patients with Advanced Cancer

Pediatric palliative care has seen major changes in recent decades and these developments clearly impact care for children with cancer. Children with incurable cancer may still receive treatment that may be life prolonging and options for managing symptoms related to advanced disease have expanded. Also noteworthy is the increased role for the patient and family members in decisions in the setting of advanced disease. Finally, options for patients to receive care outside of the hospital, either in hospice or at home, have greatly evolved.

Central to the mission of the emergency physician approaching a child with advanced cancer should be establishing the current goals of care. This can occur in two major ways:

- The preferences of the patient and/or family members may already be documented in the medical record. Often, these preferences have been explored during previous hospitalizations or clinic appointments with the patient's primary oncology team. In many cases, the outcome of such discussions may now be written in the form of a Do-Not-Resuscitate (DNR) order, a Seven Wish Document, or an outpatient/home form or order meant to establish limits for resuscitation. The use of these latter orders/forms are increasing in prevalence. Insight into the patient's and family's goals of care may be gained by direct communication with the oncology provider who knows the patient best.
- During the visit to the ED, the clinician should ask the patient/family open-ended questions to allow for an open expression of preferences. During this conversation, if the patient has any documented preferences already expressed in the medical record, the clinician should inquire whether there have been any recent changes to these preferences. Changes sometimes occur and medical staff unacquainted with the patient often feel uncomfortable embarking upon these discussions, even though patients and family members usually welcome the opportunity to communicate in this way.

Approaching patients with advanced cancer requires the clinician to acknowledge that sometimes patient/family preferences do not seem well aligned with those of the health-care team. For example, the physician may encounter a patient who is clearly within hours or days of death but who still "wants everything done," including cancer-directed therapy and aggressive management such as intubation or resuscitation. On the other hand, the clinician may instead face a patient with seemingly good functional status and quality of life who declines further disease-directed treatments. Cases may also exist anywhere in between these two extremes. It is the clinician's responsibility to provide honest and complete information and elicit the patient's beliefs and wishes to facilitate decision making that most reflects the individual wishes of the patient and family. Once decisions are made, it is then the duty of the clinician to help carry out those wishes.

Initiation of a management plan intended to reduce symptoms is always an appropriate step. The kind of intervention best able to reduce symptoms must be chosen based on the goals of care. Patients with advanced cancer have often received large amounts of opioids in the past and may therefore require larger doses of pain medications than routinely administered to children in the ED (see the "Pain" section). It is imperative for the clinician to increase the opioid dose until an efficacious dose is reached. Opioids may also be used to treat shortness of breath or other respiratory symptoms.

Diagnostic workup and specific management beyond symptom control should be undertaken in a manner consistent with the goals of care. If the patient's focus is only on comfort, then a diagnostic workup should be considered only if it will help identify a reasonable strategy to optimize that comfort. Consider, for example, a patient who presents for pain management but who is also cachectic and dehydrated. The clinician may wonder whether checking serum electrolytes and initiating rehydration are indicated. If the stated goals of care are comfort, then these measures should be omitted since electrolyte disturbances rarely cause pain/discomfort and hydration often will prolong the suffering associated with severe pain at the end of life. Indeed, hydration could increase edema or secretions that would actually decrease quality of life. As an additional example, consider a patient presenting with a malignant pleural effusion causing severe respiratory distress. Under other circumstances, the management of a large effusion might be immediate placement of chest tube. In this case, the clinician might instead ask him or herself "how will a chest tube help *this* patient and does it match what he/she wants?" This change in thought process is often extremely hard for health-care providers whose experience and training do not include care of patients with advanced disease but it is an essential element of their care.

Patients with advanced cancer may have clear preferences regarding admission to the hospital. While some patients and families may have adequate services in place to remain in their homes, some will still desire inpatient management as a form of respite.

CHAPTER 98 ■ PULMONARY EMERGENCIES

JOSHUA NAGLER, MD

ACUTE RESPIRATORY FAILURE

Background

Respiratory disease accounts for almost 10% of pediatric emergency department (ED) visits. Most cases are benign and self-limited, requiring no intervention. However, respiratory illnesses also contribute to a significant proportion of morbidity and mortality in pediatrics, including approximately 20% of hospital admissions and 3% to 5% of deaths in children. Importantly, respiratory failure often precedes cardiopulmonary arrest in children, unlike in adults where primary cardiac disease is often responsible. Therefore, prompt recognition and treatment of pediatric patients with pending respiratory failure can be lifesaving.

Many different disease processes can lead to respiratory failure (Table 98.1), including primary pulmonary diseases as well as disorders outside the respiratory tract (see Chapter 68). This section discusses the pathophysiology and clinical manifestations of respiratory failure, as well as a general approach to initiating treatment in the emergency setting. The management of specific disorders can be found in subsequent sections of this chapter, as well as in Chapters 82, 92, and 128, and other areas of the text.

Pathophysiology

By definition, respiratory failure indicates an inability of the respiratory system to provide sufficient oxygen for metabolic needs or to excrete the CO_2 produced by the body. The former can be further categorized as *hypoxemic* respiratory failure and the latter as *ventilatory* failure. Alternatively, causes of acute respiratory failure can be categorized by etiology (Table 98.1), each of which is reviewed here.

The nervous system plays a major role in the control and maintenance of respiration. Therefore, either reversible or irreversible causes of central nervous system (CNS) disease can affect respiratory function. CNS disease may result in depressed respiratory drive or inability to maintain protective airway reflexes. In addition, neurologic disease may directly affect the peripheral nerves or muscles, leading to either airway obstruction or inadequate excursion of the chest wall and diaphragm. The result is inadequate gas exchange and ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch.

Untreated upper airway obstruction in children can also lead to respiratory failure. Pediatric airways are intrinsically small; therefore, further narrowing or collapse can have a profound effect on airflow. Edema from infectious, allergic, or caustic etiologies; foreign material in the airway; or obstruction by enlarged or compressing anatomic structures can contribute to airway obstruction. These may occur in isolation or in combination. For example, patients with severe static encephalopathy or anatomic head and neck problems may have only partial compromise of the airway when well, but they may develop increased obstruction during respiratory infection, a seizure, or other acute medical problems.

Lower airway disease is a common cause of acute respiratory failure. Asthma accounts for the largest percentage of this group, but infections such as bronchiolitis or viral pneumonia are also common and predominantly impact the small airways. Foreign-body aspiration in the lower airway can present acutely with obstruction or may be a delayed diagnosis, following the development of secondary postobstructive atelectasis or pneumonia (Fig. 98.1).

Chest wall deformities and mechanical impairments can play a role in respiratory failure. Inability to fully expand the chest leads to restrictive disease and lowers the vital capacity. The decreased expansion of the thoracic cavity leads to decreased minute ventilation and resultant hypercapnia, while the extra energy expended by the inefficient respiratory pattern can lead to hypoxemia. As with airway obstruction described above, many of these patients are able to maintain near normal respiratory function until additional physiologic compromise occurs, often from illness as minor as an upper respiratory tract infection.

Parenchymal lung disease can lead to acute respiratory failure, most commonly in children younger than 1 year. While the majority of cases do not result in failure, patients with underlying cardiopulmonary disorders [e.g., bronchopulmonary dysplasia (BPD) or congenital heart disease] are particularly susceptible. In such cases, the additional respiratory embarrassment from acute pulmonary infection can induce respiratory failure.

Finally, numerous nonrespiratory conditions may precipitate respiratory failure. Although with varied underlying pathophysiology, the diseases listed in Table 98.1 each alter the balance of O_2 consumption and CO_2 production such that gas exchange cannot be maintained by the respiratory system, leading to secondary respiratory failure.

Clinical Manifestations

Acute respiratory failure represents the severe end of the spectrum of respiratory disease. Although the onset can be hyperacute (e.g., complete airway obstruction from foreign-body aspiration or traumatic injury to the phrenic nerve with complete loss of respiratory effort), respiratory failure more

TABLE 98.1

CAUSES OF ACUTE RESPIRATORY FAILURE IN CHILDREN

Neurologic Disease	
Central nervous system	Status epilepticus
	Severe static encephalopathy
	Acute meningoencephalitis
	Brain abscess, hematoma, tumor
	Brain stem insult
	Arnold–Chiari crisis
	Drug intoxication
	General anesthesia
Spinal/anterior horn cell	Transverse myelitis
	Poliomyelitis
	Polyradiculitis (Guillain–Barré)
	Spinal muscle atrophy type 1 (Werdnig–Hoffmann syndrome)
Neuromuscular junction	Myasthenia gravis
	Botulism (e.g., infantile, food-borne, wound)
	Tetanus
	Myopathy
	Neuropathy
	Drugs (e.g., succinylcholine, curare, pancuronium, organophosphates)
Airway Obstruction	
Upper	Acute epiglottitis
	Laryngotracheobronchitis (croup)
	Bacterial tracheitis
	Foreign-body aspiration
	Adenotonsillar hypertrophy
	Retropharyngeal abscess
	Subglottic stenosis, web, or hemangioma
	Laryngomalacia
	Laryngeal edema
	Congenital anomalies

commonly results from a progression of respiratory illness and distress. Therefore, recognizing the signs and symptoms of *impending* respiratory failure is as important as establishing criteria for failure. By identifying patients (i) at increased risk (e.g., neonates, those with underlying lung or cardiac disease), (ii) who show signs of significant distress (e.g., grunting, gasping, retracting), and (iii) with a worrisome trajectory based on observation and response to therapy over time (e.g., evidence of tiring), aggressive intervention can sometimes avert progression to failure. For those patients whose respiratory compromise is more advanced, clinical, laboratory, and physiologic criteria for respiratory failure are outlined in Table 98.2.

Management

Table 98.3 outlines an approach to management for acute respiratory failure. Resuscitation and basic life support measures are discussed in Chapter 1. Immediate therapeutic interventions aim at increasing oxygen delivery, assisting ventilation, and identifying and treating specific underlying etiologies wherever possible.

All patients in acute respiratory failure should receive supplemental oxygen to improve arteriolar oxygen concentration. For spontaneously breathing patients who do not require assisted ventilation, utilizing high-flow oxygen through a nonrebreather mask will provide maximal oxygen delivery. The goal is to achieve a minimal acceptable Pa_{O_2}, generally greater than 60 mm Hg (Sa_{O_2} greater than 90%). If hypoxemia persists despite passive supplemental oxygen administration, assisted ventilation should be initiated. A mask seal using a flow-inflating resuscitation bag delivers continuous positive airway pressure (CPAP), which can improve oxygen delivery. Importantly, CPAP cannot be delivered though a self-inflating (Ambu) bag. Positive-pressure breaths utilizing either a self-inflating or flow-inflating bag will further increase oxygen delivery. Endotracheal intubation provides the most effective

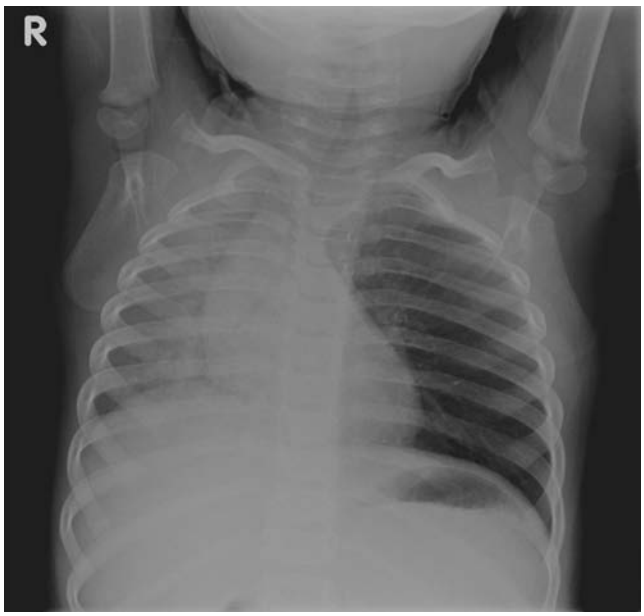

FIGURE 98.1 Foreign body aspiration. This 2-year-old girl presented in significant respiratory distress after choking on a peanut. The chest film shows hyperinflation of the left lung, tracheal deviation and mediastinal shift, and compression atelectasis of the right lung, consistent with air trapping secondary to foreign body aspiration (FBA).

means of increasing Pa_{O_2} and is required for patients with persistent hypoxemia despite other interventions.

In addition to improving oxygen delivery, assisted ventilation may be required to correct alveolar hypoventilation.

TABLE 98.2

DIAGNOSIS OF ACUTE RESPIRATORY FAILURE FROM PULMONARY CAUSES IN CHILDREN

Clinical findings
Vital signs: tachycardia, tachypnea or bradypnea, hypoxemia
General appearance: cyanosis, diaphoresis, confusion, restlessness, fatigue, shortness of breath, apnea, grunting, stridor, retractions, decreased air entry, wheezing
Blood gas abnormalities
$Pa_{CO_2} > 50$ mm Hg with acidosis (pH < 7.25)
$Pa_{CO_2} > 40$ mm Hg with severe distress
$Pa_{O_2} < 60$ mm Hg (or $Sa_{O_2} < 90\%$) on 0.4 F_{IO_2}
Pulmonary function abnormalities
Vital capacity (<15 mL/kg)
Inspiratory pressure (<25–30 cm H_2O)

Adequacy of ventilation should be assessed clinically by chest wall expansion and confirmed with either end-tidal carbon dioxide ($EtCO_2$) or serum Pa_{CO_2}. New recommendations suggest this can often be achieved with a tidal volume of 7 to 10 mL per kg, although this will vary based on lung compliance and underlying disease. Using a manometer within the airway circuit can provide valuable information regarding appropriate airway pressures and help prevent unnecessary barotrauma.

Specific ventilatory strategies will vary based on underlying disease. In children with acute respiratory failure but normal lung function (e.g., CNS depression), standard airway pressures and respiratory rates are adequate. CPAP or positive end-expiratory pressures (PEEP) may be useful where alveolar recruit-

TABLE 98.3

MANAGEMENT OF ACUTE RESPIRATORY FAILURE

Primary hypoxemia	1. High flow supplemental oxygen (e.g., nonrebreather mask), titrate for cyanosis, or by pulse oximetry or Pa_{O_2} 2. Use CPAP or PEEP to further improve oxygenation 3. Consider endotracheal intubation when persistent hypoxemia on $F_{IO_2} > 0.6$ or when decreased lung compliance and $F_{IO_2} > 0.4$ 4. Use assisted ventilation to improve gas exchange (increased inspiratory time, normal respiratory rates, tidal volume: 10–15 mL/kg; pressure cycle ventilation if wt. < 10 kg, volume cycle ventilation if wt. > 10 kg). If inspiratory pressure exceeds 40 cm H_20, consider use of permissive hypercapnia to reduce barotrauma. 5. Treat underlying cause
Primary hypoventilation	1. Supplemental oxygen (as above) 2. Support ventilation a. Oral/nasal pharyngeal tube or endotracheal intubation b. Bag-mask ventilation with high-flow oxygen c. Use assisted ventilation (normal to increased respiratory rates, increased expired time, increased flow rates) d. Use increased tidal volume (pressure) with obstructive airway disease or with atelectasis e. Monitor carefully for side effects of ventilation
Adjunctive therapy	1. Intravenous fluid to achieve normal vascular volume (less fluid for child with interstitial lung disease) 2. Diuretics such as furosemide (1 mg/kg) for acute pulmonary edema or fluid overload 3. Sedatives/analgesics—morphine sulfate (0.1–0.2 mg/kg) every 1–2 h intravenously; midazolam (0.1–0.2 mg/kg every 2–4 h intravenously) 4. Muscle relaxants—vecuronium bromide, starting at 0.1 mg/kg every 1–2 h or alternative 0.1–0.2 mg/kg/h drip

CPAP, constant positive airway pressure; PEEP, positive end-expiratory pressure.

ment is important to improve gas exchange (e.g., atelectasis). By increasing the end-expiratory lung volume or functional residual capacity, PEEP shifts lungs to a position on the pressure–volume curve that improves alveolar ventilation while minimizing the risk of barotrauma. In patients with decreased lung compliance due to either stiff lungs (e.g., fibrosis) or hyperinflation (e.g., bronchiolitis or asthma), higher pressures must be generated to sufficiently ventilate the child. The inspiratory:expiratory (I:E) ratio can also be tailored to the disease process. Increased I:E ratios of 1:5 to 1 should be utilized in alveolar or interstitial disorders to improve oxygenation. A normal or decreased I:E ratio is used in obstructive lower airway disease to extend exhalation time to better allow elimination of CO_2.

Although past practice aimed to achieve normocapnia, recent recommendations suggest that permissive hypercapnia may be advantageous. That is, accepting slightly elevated P_{CO_2} values is acceptable as long as pH is maintained. This may allow for pressure-limited ventilation, which will reduce the risk of barotrauma.

Fluid management is also a key component to tailored therapy in respiratory failure. Patients with increased work of breathing generate high negative intrathoracic pressures, which increase venous return. When these patients are intubated, the transition to positive pressure ventilation rapidly decreases venous return and may precipitate cardiovascular collapse. Therefore, unless clinical circumstances mandate more immediate action, rapid intravascular repletion prior to intubation is prudent. In contrast, for patients with interstitial disease or pulmonary capillary leak, a slightly reduced intravascular volume may improve the mechanics necessary for effective ventilation. As a result, the F_{IO_2} requirement may be decreased and airway pressures minimized. Beyond such circumstances, other clinical indicators should guide fluid management. In general, however, fluids should be titrated to maintain normal intravascular volume as determined by observation of heart rate, blood pressure, peripheral perfusion, and urine output. In severely ill or complex patients, the measurement of central venous pressure may provide a more precise guide for monitoring fluid status.

Sedation is also an important adjunct to efficient assisted ventilation. In neurologically depressed children, sedation may not be required. However in most circumstances, parenteral sedation is utilized to reduce anxiety and to increase tolerance to the presence of a tracheal tube and assisted ventilation. Morphine sulfate dosed 0.1 to 0.2 mg per kg every 1 to 2 hours or as a continuous infusion of 0.1 mg per kg per hour is often used. This is frequently combined with a benzodiazepine, for example, midazolam 0.1 to 0.2 mg per kg every 1 to 2 hours or as a continuous infusion. Muscle relaxants may be helpful to optimally ventilate children with severe respiratory failure. This may be necessary for children with stiff lungs (e.g., severe interstitial pneumonia) or a stiff chest wall (e.g., status epilepticus). Muscle relaxants improve chest wall compliance and reduce oxygen consumption. Vecuronium may be given initially in doses of 0.1 mg per kg every 1 to 2 hours or as a continuous infusion at 0.05 to 0.1 mg per kg per hour (see Chapter 5). Some children, particularly younger infants, will metabolize vecuronium quickly and require either more frequent dosing or a higher infusion rate, titrated to movement.

Beyond the ED, other innovative ventilatory options in respiratory failure that may reduce risk of ventilation-associated barotrauma include use of helium–oxygen (heliox) gas mixtures, prone positioning, high-frequency oscillation, extracorporeal membrane oxygenation (ECMO), nitric oxide, and liquid ventilation. Detailed description of these critical care processes may be found in the references at the end of the chapter.

BRONCHOPULMONARY DYSPLASIA

Background

Bronchopulmonary dysplasia is a cause of chronic respiratory disease in infants and children. BPD is a clinical diagnosis, defined as the need for supplemental oxygen at a prescribed postconceptual or chronologic age, with associated radiographic findings. The specifics of these parameters have changed over time. The current definitions for graded severity of BPD as defined by the National Institute of Child Head and Human Development are presented in Table 98.4.

The etiology of BPD is thought to be multifactorial. While newer data suggest a genetic predisposition, previously defined risk factors include immaturity, supplemental oxygen therapy, positive-pressure ventilation, and inadequate nutrition. Pathophysiologically, the disease process is thought to stem from inflammation and injury to the lung, with resultant arrest of alveolar septation and impaired microvascular development. This occurs most commonly in infants with hyaline membrane disease or other acute perinatal lung disease. Infants with apnea, congenital heart disease, or other illnesses requiring prolonged ventilation in the first weeks of life are also at risk. Utilization of improved ventilation strategies, as well as antenatal glucocorticoids, surfactant, and improvement in nutrition, has improved outcomes. However, with these advances in neonatal care has also come the survival of large number of infants born at earlier gestational age and lower birthweights. As a result, the overall incidence of BPD has not changed significantly over time.

In emergency medicine, BPD becomes important because these patients may present with acute exacerbations of their

TABLE 98.4

DEFINITION OF BPD FOR INFANTS BORN LESS THAN 32 WEEKS' GESTATIONAL AGE[a]

Mild	Room air at 36 weeks postmenstrual age (PMA) or discharge
Moderate	Need for <30% oxygen at 36 weeks PMA or discharge
Severe	Need for ≥30% oxygen and/or positive pressure (ventilation or CPAP) at 36 weeks PMA

BPD, bronchopulmonary dysplasia; CPAP, constant positive airway pressure.
[a]All patients with BPD require supplemental oxygen for the first 28 days of life and have characteristic findings on chest X-ray.

chronic lung disease and because BPD is a risk factor for increased severity of other respiratory illnesses.

Clinical Manifestations

Signs and symptoms of patients with BPD will vary based on severity; therefore, recognizing interim worsening of disease requires an understanding of baseline examination findings and pulmonary function. This is most commonly elicited from parents although referral to findings from prior visits can also be helpful.

Children with BPD are typically tachypneic, with some degree of retractions that worsen with even mild respiratory or febrile illnesses. Findings on auscultation can include crackles, wheezes, or decreased breath sounds. Failure to thrive often results from concomitant nutritional issues, or from increased energy expenditure secondary to chronic increased work of breathing. Chest radiographs (Fig. 98.2) demonstrate varying amounts of hyperinflation; several patterns occur, including cystic areas with signs of fibrosis, which are often confused with congenital lobar emphysema, severe cystic fibrosis, or new infiltrates.

Management

Emergency physicians most often will evaluate children with BPD when their underlying disease is worsened by intercurrent acute respiratory infections. More than 50% of infants with BPD require admission within a year of their diagnosis for respiratory illness. Of particular importance is respiratory syncytial virus (RSV) infection, which typically causes bronchiolitis with fever, tachypnea, crackles, and wheezing. Patients with RSV can also present with apnea, without significant acute pulmonary change, particularly in younger infants and those with a history of prematurity. Patients with BPD who develop RSV bronchiolitis are prone to more severe courses, including higher rates of intensive care unit admission, need for mechanical ventilation, and mortality.

FIGURE 98.2 Bronchopulmonary dysplasia. This 2-month-old child was treated with mechanical ventilation during the first days of life for hyaline membrane disease. The chest film shows generalized overaeration and coarse nodularity with multiple cystlike areas throughout both lung fields.

Pulse oximetry can be beneficial in assessing for hypoxemia. Arterial, venous, or capillary blood gas is indicated when signs and symptoms suggest hypercapnia or when cyanosis, respiratory distress, or deterioration from baseline cannot be easily reversed. Arterial blood gas measurements may be misleading because decreases in Pa_{O_2} may reflect hypoxia from crying or breath-holding during the painful procedure rather than worsening pulmonary function. A chest radiograph is helpful in most episodes; however, given baseline abnormalities, these often need to be compared with prior films.

Management of children with BPD and intercurrent respiratory illnesses is primarily limited to supportive care. Although some patients can be treated as outpatients, care must be taken to first assess the severity of the episode. If the acute exacerbation is mild, outpatient therapy may be indicated with frequent follow-up every 1 to 2 days. In infants with moderate to severe BPD, even mild deterioration may herald early respiratory failure. Ensuring hydration by oral or intravenous (IV) routes, addressing hypoxemia, and, when necessary, providing assisted ventilation for hypercarbia and respiratory acidosis are the mainstays of therapy.

Bronchodilators, inhaled corticosteroids, and diuretics may also be helpful. Most children with BPD have had trials of β-agonist therapy. Although the use of metered dose inhalers for β-agonists is effective in older infants with asthma, the evidence for their use in young infants with BPD is less clear. Although most acute episodes are from viral infection, antibiotic therapy should be considered when the risk of bacterial infection appears higher. Indications for admission include a respiratory rate above 70 to 80 breaths per minute or significant change from baseline, increasing hypoxia or hypercarbia, poor feeding, apnea, or new radiographic infiltrates. Parental fatigue and stress are also important factors to consider.

Prevention of BPD exacerbations is challenging. Although routine viral illnesses may not be avoidable, RSV and influenza are the leading preventable causes of rehospitalization in patients with BPD. Monoclonal antibody against RSV (palivizumab, Synagis®) has largely replaced RSV-IGIV prophylaxis in preventing or lessening disease secondary to RSV. Such immunoprophylaxis is recommended for children less than 2 years of age with BPD who have required medical therapy within 6 months of the start of RSV season. Patients with more severe BPD who continue to require medical therapy may also benefit from prophylaxis during a second RSV season, although supporting data here are limited. Influenza vaccination should also be considered each winter for children older than 6 months of age with BPD. Two doses separated by at least 1 month, ideally prior to December, are recommended for the first immunization season. After the first year, subsequent influenza vaccinations require only one dose.

INTERSTITIAL LUNG DISEASE

Background

Childhood interstitial lung disease (ILD) comprises a heterogeneous group of pulmonary disorders, characterized by diffuse infiltrates and impaired gas exchange. Although data are limited, the overall incidence is a fraction of that seen in the adult population. In addition, while the nomenclature is similar,

TABLE 98.5

CAUSES OF INTERSTITIAL LUNG DISEASE

Environmental irritants	Sarcoidosis
Inorganic dusts	Inherited disorders
Organic dusts (hypersensitivity)	Neurofibromatosis
Noxious gases	Miscellaneous causes
Drugs	Celiac disease
Radiation	Whipple's disease
Collagen vascular disease	Weber–Christian disease
Rheumatoid arthritis	Histiocytosis
Scleroderma	Hermansky–Pudiak syndrome
Systemic lupus erythematosus	

there are significant differences between pediatric and adult ILD with regard to etiology, management, and outcome.

There are numerous causes for the group of conditions that are included as ILD (Table 98.5). Either primary pulmonary diseases or systemic disorders with pulmonary involvement can be responsible. These may be inherited or may result from lung insult, for example, secondary to infection or environmental exposures. Importantly, many of the included entities are distinct to infants and young children. Therefore, adult-based classification schemes may not be fully applicable. As a result, a novel classification system based on etiology and pathology has been introduced for children. It will not be fully reviewed here but can be found in the reference at the end of the chapter.

Idiopathic interstitial pneumonias, defined by their histology, make up an important subgroup of ILD. Although similar nomenclature is used in adults and children, many of these disease processes are quite different. Usual interstitial pneumonia (UIP) is the pathologic correlate of idiopathic pulmonary fibrosis and is a relatively common cause of ILD in adults. Although defined in children, no pediatric case has described the fibroblastic foci, which are thought to be the defining histologic feature. In addition, children reported to have UIP are reported to have a nonprogressive course, different than their adult counterparts. Desquamative interstitial pneumonitis (DIP) also occurs rarely in children. Histology tends to show cellular rather than fibrotic infiltrates. In adults, smoking has been associated, whereas in children gene mutations are felt to be responsible. DIP tends to be responsive to steroids, particular in the adult population. Lymphoid interstitial pneumonia (LIP) has a lymphocytic infiltrate. In children, it is commonly associated with HIV infection, including up to 30% of perinatally transmitted disease (see Chapter 93).

Clinical Manifestations

Congenital ILD may present in infants or young children; however, the pneumonic processes are more likely to manifest in older children. Immunocompromised children are at risk at all ages. Infants may present with tachypnea or hypoxemia, while older children are more likely to complain of chronic cough or dyspnea on exertion. Patients with more severe or advanced cases will frequently have dyspnea even at rest. Systemic symptoms including weight loss, anorexia, and fatigue may also occur. Occasionally, hemoptysis or a "spontaneous" pneumothorax may be the primary clinical event. Physical findings may include tachypnea and tachycardia, often with shallow excursions and bibasilar rales. In severe cases, digital clubbing and cyanosis may be present.

Oxygen saturation or Pa_{O_2} generally correlate with severity; initially they are reduced only during exercise but with disease progression, they eventually become compromised at rest. The Pa_{CO_2} usually remains normal until late in the course. Polycythemia may be present secondary to hypoxemia in severe cases.

Management

Evaluation of patients with suspected ILD should focus on assessing for the primary etiology as well as the extent and severity of disease. A systematic approach that combines historical and examination findings with noninvasive and invasive studies is required. Because the diagnostic workup can be extensive, the child with characteristic history and physical findings will need admission to the hospital and consultation with a pediatric pulmonologist.

Laboratory evaluation is generally limited. A complete blood cell count can detect polycythemia and abnormal white blood cell differentials may suggest immunodeficiencies. Arterial blood gas may be performed to assess Pa_{O_2} if oxygen saturation testing is felt to be inadequate. Focused testing may be performed based on specific concerns, for example, antinuclear antibody and serum immunoglobulins to detect vasculitis and genetic mutations testing, which can identify certain etiologies of ILD.

Noninvasive evaluation can include pulmonary function testing and radiologic imaging. In older children who are able to cooperate, pulmonary function testing with diffusion capacity and exercise testing generally shows a pattern of restrictive lung disease. Specifically, the forced expiratory volume in 1 second (FEV_1) and forced vital capacity (FVC) are both reduced, with a normal FEV_1:FVC ratio. Chest radiographs (Figs. 98.3 and 98.4) typically show a diffuse reticulonodular infiltrate, especially in the lower lobes. As disease progresses,

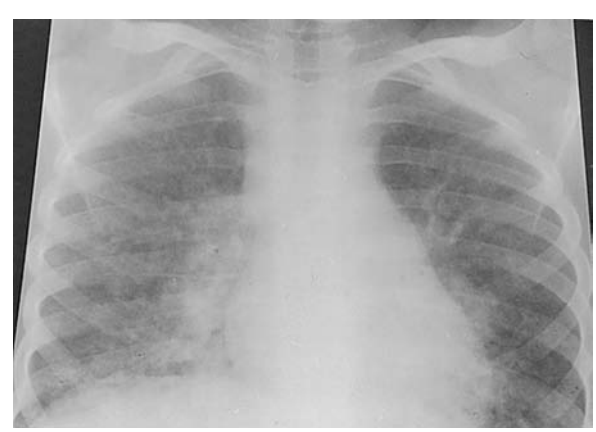

FIGURE 98.3 Sarcoid. A 9-year-old child with hepatosplenomegaly but no pulmonary complaints. The chest film shows interstitial lung disease with hilar adenopathy.

FIGURE 98.4 Idiopathic interstitial pneumonia. An 18-year-old boy with chronic granulomatous disease, after bone marrow transplant, with insidious onset of shortness of breath. The chest film shows bilateral interstitial disease in the lower lung field more on left side.

decreased lung volume and pulmonic changes may result in a cystic "honeycomb" appearance. High resolution computed tomography (HR-CT) has become the primary imaging modality for ILD. It can confirm the diagnosis, characterize findings to help identify underlying etiology, and localize areas amenable to biopsy. A method known as *controlled ventilation HR-CT* can be employed to reduce motion artifact and improve lung detail in tachypneic children.

Invasive testing employed during the evaluation of children with suspected ILD might include bronchoalveolar lavage (BAL) and lung biopsy. Bronchoscopy with BAL can identify cellular and biochemical components of alveolar-lining fluids, which may be helpful in understanding the etiology. For example, lipid-laden or hemosiderin-laden macrophages, alveolar proteinosis, and surfactant deficiency may be suggestive of select diagnoses. Similarly, staining and culture may identify infectious causes, including *Pneumocystis carinii*, in patients with possible LIP in an immunocompromised host or HIV-infected patient. Historically, there has been a reluctance to perform biopsies in children because of the associated morbidity and the low diagnostic yield. However, the acceptance of a thoracoscopic approach to biopsy coupled with better-defined ILD syndromes in children has led to increased willingness to obtain tissue from pediatric patients.

Treatment of the child with suspected or known ILD will vary based on the underlying etiology. Acutely, patients should be evaluated and treated for hypoxemia. Systemic illnesses, for example, systemic lupus erythematosus (SLE) or HIV, should be treated, and antimicrobial therapy initiated when infectious etiologies are of concern. Corticosteroids have also become a mainstay of therapy. Patients with biopsy-proven disease known to be steroid-responsive should be treated. For those who have not undergone biopsy or whose diagnosis remains unclear, an empiric trial of steroids can be considered; however, risks and benefits need to be weighed in such cases. Alternative steroid-sparing immunosuppressants have also been used with some success. Unfortunately, ILD may progress despite aggressive therapy. In such circumstances, lung transplantation may become the only viable treatment option for some patients. Outcomes for transplanted patients have been similar to those for patients with cystic fibrosis and pulmonary hypertension.

ASPIRATION PNEUMONIA

Background

Aspiration of foreign material into the lung can result in inflammation and impaired lung function. Chemical injury to lung tissue, often from sterile gastric contents, results in *aspiration pneumonitis*. Infection following inhalation of foreign material, commonly from the oropharynx, is termed *aspiration pneumonia*. Infectious pneumonia may result from aspiration of viral or bacterial pathogens, as described in Chapter 92; however, the term *aspiration pneumonia* denotes infection following inhalation of foreign material.

Two groups of patients at risk for aspiration pneumonia are those with neurological impairment and those with inadequate gastrointestinal motility. Children with altered consciousness and CNS disorders that impair normal swallowing or protective airway reflexes are at risk for aspiration. This is particularly true for chronically impaired, institutionalized children, although healthy children who are transiently depressed from procedural sedation or during seizures can also aspirate. Likewise, children with decreased esophageal or intestinal motility or delayed gastric emptying are at increased risk of regurgitation of stomach contents and therefore possible aspiration. Dysmotility may be secondary to underlying disease, trauma, or medications such as opiates or those with anticholinergic properties. Similarly, anatomic narrowing or obstruction along the gastrointestinal tract can also increase the risk of aspiration.

Pathophysiology

The pathophysiology of pulmonary disease secondary to aspiration can be classified based on the source of the foreign material. In humans, aspirate contents with a pH of less than 2.5 are considered acidic. Such material causes a severe chemical pneumonitis with direct injury to alveolar-capillary membranes. A hemorrhagic, granulocytic, necrotizing reaction generally follows. Effects from the initial injury can occur within minutes to hours, and may include reflex airway closure, destruction of surfactant resulting in atelectasis, exudation of fluid and protein across damaged membranes creating interstitial and alveolar edema, and alveolar hemorrhage and consolidation.

Aspirates with a pH greater than 2.5 are considered nonacidic. These may come from the oropharynx or from the stomach in patients on H_2 blockers or proton-pump inhibitors. The early pathophysiologic response is similar to that seen with acidic injury, with the exception of reduced alveolar neutrophilic infiltration and necrosis. The extent of lung damage from nonacid aspirates varies depending on the composition of the aspirate; clear liquid aspiration resolves quickly while sizable food particles are likely to lead to a prolonged pathologic response. Repeated aspirations occurring over an extended period may result in radiographic evidence of granuloma formation similar to that of miliary tuberculosis. Aspiration of hydrocarbons is covered separately in Chapter 102.

Most physicians agree that infection plays little role in the initial pulmonary complications that result from aspiration. However, pathogenic bacterial from the oropharynx may

accompany foreign material, resulting in direct inoculation of lung tissue. Alternatively, following acid aspiration, the injured lung is vulnerable and secondary bacterial infection may occur in up to half of these cases.

For those who develop infection, two distinct patterns are possible. A localized necrotizing bacterial pneumonia, abscess, or empyema may result from a heavily infected inoculum. Although opinions vary, anaerobic organisms, either alone or as polymicrobial infection with aerobes, are likely culprits in such cases. The second pattern of infection is that which follows large aspirates, usually of the acidic type. Aerobic rather than anaerobic organisms predominate here; gram-negative organisms, such as *Pseudomonas aeruginosa*, and gram-positive organisms, such as staphylococci, may be isolated.

Clinical Manifestations

Aspiration pneumonia should be considered in any at-risk child who has signs of respiratory distress. Occasionally, an aspiration event will be witnessed or vomitus will be present in the vicinity, suggesting the possibility of this diagnosis. However, not uncommonly, particularly in cognitively compromised children, no triggering episode is witnessed.

The clinical manifestations of pneumonia are discussed in Chapter 92. With aspiration, a very brief latent period occurs before the onset of respiratory signs and symptoms, and more than 90% of patients are symptomatic within 1 hour. Fever, tachypnea, and cough are often seen. Hypoxia is common, whereas apnea and shock are less likely but possible. Sputum production is usually minimal.

The physical findings in patients with aspiration pneumonia are not dissimilar from those in patients with pulmonary infections resulting from community- or hospital-acquired bacterial or viral causes. Focal or diffuse crackles and wheezing are common. Cyanosis appears with progression or more severe disease. Chest radiographs (Figs. 98.5A and B) may show either localized or diffuse infiltrates, which may be unilateral or bilateral. The chest x-ray of a patient who has aspirated may evolve from normal to complete bilateral opacification within several hours.

Management

The suspicion of aspiration should be confirmed with a chest radiograph. Children with significant aspiration pneumonia, diagnosed either by clinical suspicion or radiograph, require admission to the hospital. Table 98.6 outlines therapeutic modalities that may be useful. Some children who aspirate may have relatively normal radiographs early in the course but significant symptomatology. Conversely, radiographs may be significantly abnormal in the face of minimal clinical symptoms in patients with aspiration of hydrocarbon or other volatile agents.

In the acute care setting, children who aspirate require primarily supportive care. Specifically, prevention of further aspiration by gastric decompression, oropharyngeal suctioning, and proper positioning should be utilized. Supplemental oxygen should be administered as needed, based on pulse oximetry or direct measurement of oxygenation with an arterial blood gas. Endotracheal intubation is indicated if airway reflexes are inadequate or for severe cases with impending respiratory failure.

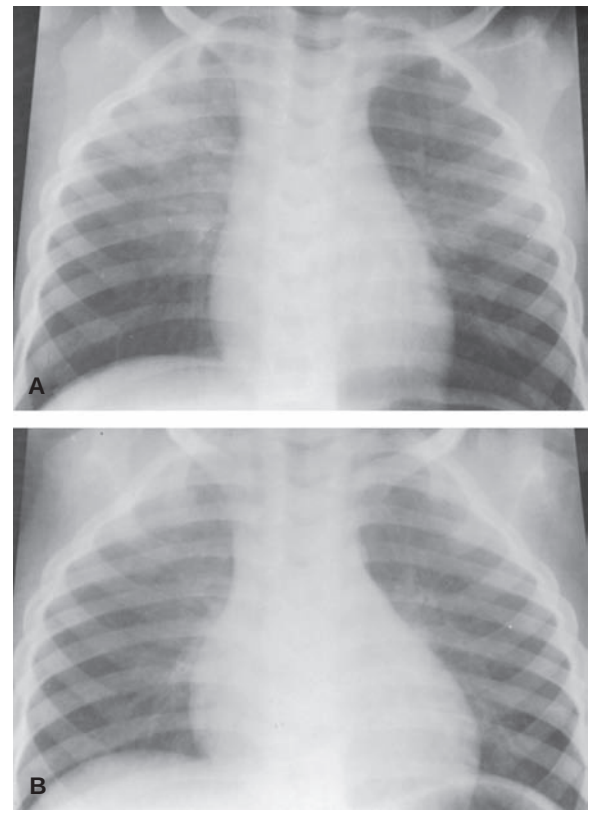

FIGURE 98.5 **A:** Blood aspiration. A 3-year-old boy with tachypnea 1 day after surgery for enlarged adenoids/tonsils. Chest film shows an infiltrate in the right upper lobe and left lower lobe. **B:** Blood aspiration (see **A**). The chest film 2 days later shows clearing of the infiltrate in the right upper lobe and left lower lobe.

The use of corticosteroids in the treatment of aspiration pneumonia is controversial. Because experimental evidence indicates minimal benefit at best and because the concomitant immunosupression may contribute the development of secondary bacterial pneumonia, their administration is not usually indicated in the ED.

The decision whether or not to initiate antibiotic therapy is challenging. There is no strong data to suggest that prophylactic antibiotic therapy will prevent subsequent infection in a patient with chemical pneumonitis. However, fever, purulent sputum, leukocytosis, and pulmonary infiltrates may result from chemical inflammation alone; therefore, the distinction from infectious aspiration pneumonia can be difficult. A reasonable initial approach is to defer antibiotic treatment in

TABLE 98.6

INITIAL TREATMENT OF ASPIRATION PNEUMONIA

Proven measures	Optional modalities
Suction	Corticosteroids
Airway protection	Antibiotics
Oxygen	

favor of careful observation in a well-appearing child and empirically treat only those with a tenuous respiratory status or compelling clinical evidence of infection.

For those who receive antimicrobial therapy, the choice of antibiotics can be guided by both the clinical setting and the results of properly obtained specimens for culture. Aspiration pneumonias developing outside the hospital generally involve anaerobes and are adequately treated with ampicillin or clindamycin, whereas nosocomial infections require broader aerobic and anaerobic coverage. Clindamycin with gentamicin, or ampicillin/sulbactam, are often used. In neurologically impaired children, with either aspiration or tracheostomy-associated pneumonia, antibiotics effective against penicillin-resistant anaerobic bacteria and *P. aeruginosa* have been shown to produce superior clinical and microbiologic responses.

PULMONARY EMBOLISM

Background

Pulmonary embolism (PE) is the partial or complete obstruction of the pulmonary artery or branches from detachment of all or part of a thrombosis from within the systemic venous system. In adults, it contributes to significant morbidity and mortality, with reported incidence of 2% to 5% of the population and up to 300,000 deaths per year. The epidemiology in children is less well defined because of limited available pediatric data, although one series reports an incidence of 0.7 per 10,000 children. This is likely an underestimate, however, as newer diagnostic modalities are increasingly recognizing subclinical disease. In addition, improved survival of children with illnesses and injuries that predispose to PE may also be leading to increased risk of thromboembolic events.

Children with PE very commonly have underlying medical conditions that predispose them to thromboembolic events. Central venous catheters have been identified as the most common precipitant for PE in pediatric patients. Other underlying conditions include malignancy, congenital heart disease, collagen vascular disease, significant trauma/surgery, and severe infection/sepsis. Available data suggest that more than 90% of children diagnosed with PE will have at least one of these risk factors. In addition, a minority of children with PE will be diagnosed with a congenital prothrombotic condition, although data estimating the risk of thrombophilia are varied. Traditional "adult" risk factors, including oral contraceptives, elective abortion, prolonged immobilization, IV drug use, rheumatic heart disease, smoking, and obesity, may also play a role in some older pediatric patients.

Pathophysiology

Virchow identified stasis, venous injury, and hypercoagulabilty as the three factors that contribute to thrombogenesis. A combination of environmental and genetic factors may contribute to each of these. One potential complication of such thromboses is the embolization of all or part of the clot into the pulmonary vasculature. The degree of anatomic obstruction of the arterial vessel will dictate the degree of hemodynamic compromise. Increases in right-sided afterload can lead to pulmonary hypertension or, with comcomitant reductions in left-sided cardiac output, can result in cardiovascular collapse, particularly in patients with preexisting heart or lung disease. In addition to direct vascular obstruction from PE, release of vasoactive and bronchoconstrictive cytokines may also lead to further $\dot{V}/\dot{Q}$ mismatching and intrapulmonary shunting, which may contribute to the hyoxemia seen in more than 80% of cases.

Clinical Manifestations

The challenge in recognizing PE in children stems from the relative infrequency of the condition coupled with the nonspecific signs and symptoms in most patients (Table 98.7). While the presentation of massive PE with severe circulatory compromise in a patient at high risk may be easily recognized, making the diagnosis in a patient with common respiratory complaints may not. Dyspnea, pleuritic chest pain, cough, and hemoptysis are the most common symptoms of PE in both adults and children; however, children with these symptoms are much more likely to have alternative diagnoses. Less frequent symptoms such as apprehension, fever, sweats, and palpitations are similarly nonspecific. Current literature suggests that 25% of adults with PE will be asymptomatic, which further complicates recognition. The extent of asymptomatic disease in children has not been similarly reported; however, this may reflect different methodologies in available pediatric registries and studies, which have not screened for subclinical disease in pediatric populations.

Physical examination findings are often absent with PE. Tachycardia, rales, and tachypnea are the most common signs in those with findings, although again each is nondiscriminating. Significant vascular obstruction that results in pulmonary hypertension may lead to distended neck veins, a prominent S_2, or a ventricular gallop. Similarly, in cases where embolism results in large pulmonary infarction, there may be decreased resonance over the lung fields and a pleural friction rub. Breath sounds may be distant or absent, and crackles may be heard. The presence of hypoxemia not clearly explained by an underlying disease process or clinical state may also suggest the possibility of PE.

To help quantify the risk of PE, clinical prediction scores that combine historical risk factors with physical findings have been created. Both the Wells criteria and the Geneva score have been shown to be useful in categorizing pretest probability for PE in adults and have been integrated into management schemes, as described below.

To supplement an initial assessment based on the history, physical examination, and possible risk factors, additional studies may help qualify the likelihood of PE.

An electrocardiogram (EKG) should be obtained; although similar to history and examination findings, abnormalities are rare and, when present, are nonspecific (Table 98.7). Sinus tachycardia is the most common but least specific finding. Conversely, right axis deviation, right bundle branch block, and the classic "S1, Q3, T3" are all consistent with cor pulmonale, which is usually seen only with massive PE but may also occur in nonembolic disease including pneumothorax.

Arterial blood gases will commonly indicate hypoxemia with a reduced partial pressure of oxygen, which may be

TABLE 98.7

CLINICAL MANIFESTATION OF PULMONARY EMBOLISM

	Nonspecific	Suggestive	Diagnostic
Symptoms	Syncope	Dyspnea out of proportion to degree of abnormal findings

	ST-T wave changes		
	Right bundle branch block		

EKG, electrocardiogram.

supportive but nondiagnostic of PE. In addition, because 15% of patients will have a PaO_2 greater than 80 mm Hg and 5% of patients greater than 90 mm Hg, the negative predictive value of a normal gas may not justify the use of this painful and occasionally difficult procedure in the diagnostic evaluation in children.

The laboratory study, which has traditionally played the most significant role in the evaluation of adult patients with suspected PE, is the D-dimer. Measurement of degradation products produced when plasmin splits cross-linked fibrin is a sensitive marker for intravascular clot. Such biomarkers will be positive as early as 1 hour after thrombus formation, with a circulating half-life of 4 to 6 hours. However, with continued PE fibrinolysis, plasma D-dimer levels are commonly elevated for at least 1 week. Many different enzyme-linked immunosorbent assays (ELISAs) are available to detect D-dimers in the circulation. Newer-generation assays have reported sensitivities of 96% to 98% and reasonable turnaround times. Nonetheless, because of the presence of wide variability in performance of each assay, it is important for practitioners to be aware of the characteristics within their laboratory when incorporating results into their medical decision making. The applicability of D-dimer testing to evaluation and management of pediatric patients with suspected PE is discussed below. Radiographic studies are an important part of the evaluation of patients with possible PE. Chest radiographs are recommended because they are relatively noninvasive although they are rarely diagnostic. The presence of a segmental pulmonary infiltrate with an ipsilateral elevated hemidiaphragm is suggestive of a PE; however, even these radiographic findings are not pathognomonic. Occasionally, however, chest films will uncover an alternative diagnosis for a patient's symptoms, obviating the need for further evaluation in low-risk patients.

For years, $\dot{V}/\dot{Q}$ scans were the mainstay of imaging in patients with concern for PE. For patients without preexisting cardiopulmonary disease, some $\dot{V}/\dot{Q}$ studies can effectively rule in or out the diagnosis. A characteristic pattern of normal ventilation in a poorly perfused area of lung is considered high probability and effectively establishes the diagnosis of PE. Similarly, a normal $\dot{V}/\dot{Q}$ scan essentially excludes the diagnosis. However, many patients have underlying structural lung disease or the scans are reported as low or intermediate probability, making results nondiagnostic. In fact, the majority of patients ultimately diagnosed with embolic disease are classified as low or intermediate rather than high probability, based on $\dot{V}/\dot{Q}$ scanning alone.

In recent years, computed tomography angiography (CTA) has become the most common imaging modality for diagnosis of PE. Compared with $\dot{V}/\dot{Q}$ scanning, it is more rapid, more readily available, and has the advantage of characterizing nonvascular structures as well. Utilizing pulmonary angiography as the diagnostic standard, initial adult studies investigating the utility of spiral CT scanning reported sensitivities of 64% to 93% and specificities of 89% to 100%. The test performance in more recently available multidetector scanners is likely even higher. Still, CTA is likely less sensitive for emboli beyond main, lobar, or segmental pulmonary arteries. Therefore, at present, a negative scan cannot absolutely rule out PE, especially in any patient considered to be at high risk.

Management

Utilizing available data from history and physical examination, as well as adjunctive testing modalities described above, forms the basis for decision making regarding management of

patients with suspected PE. The challenge is to accurately and rapidly identify the minority of presenting patients with the disease from the multitude without PE who present with overlapping nonspecific complaints and findings. Toward these ends, algorithms for adult patients have suggested a dichotomous approach.

Patients deemed to have low pretest probability by Wells criteria or Geneva scores and a negative D-dimer are felt to have a low likelihood of PE and, therefore, may not need further evaluation. This may exempt one-third of presenting adult patients from requiring additional workup and has been shown to have a negative predictive value of 99% in select populations. Patients with high pretest probability or an abnormal D-dimer should have additional imaging performed. On the basis of this protocol, a negative CTA in these patients was found to have an observed risk of missed diagnosis nearly identical to that identified by pulmonary arteriography (less than 2%).

There are a number of differences in PE in children and adults; and therefore, utilizing a similar evaluative approach in children may not be straightforward. While the Wells criteria and Geneva scores may accurately stratify adult patients into risk categories, this may not be true for children. Risk factors in these assessments include age more than 65 years and heart rate more than 100 beats per minute, which are clearly less applicable in pediatrics. In addition, the majority of emboli in children originate in the upper venous system as a result of central venous catheters, which differs dramatically from adults where more than 75% of clots originate in the legs and pelvis, suggesting the need for different weighting for risk factors in children than in adults. In fact, all children in whom PE is being entertained as a diagnosis might need to be considered high risk. Therefore, the prospect of linking pretest probability screening with D-dimer results as an initial screen may not be applicable, as a negative D-dimer in a patient who cannot be considered low risk may still not reliably exclude the possibility of PE. More data are needed before this or any other evaluative algorithm can be used safely in children. Nonetheless, the concept of utilizing available information from multiple sources to determine probability of disease in children is important. When clinical suspicion is low, and all the aforementioned tests are normal and the patient's clinical condition permits, the patient may be discharged with close follow-up. If abnormalities are uncovered, further diagnostic workup (e.g., additional imaging studies such as magnetic resonance angiography/venography (MRA/MRV) or pulmonary arteriography) and admission to the hospital should be considered. Regardless of the results, if the clinical suspicion is high, the patient should be admitted for initiation of definitive treatment.

Initial therapy for patients with presumed or proven PE includes supplemental oxygen, achievement of vascular access, and ventilatory support as indicated. Anticoagulation remains the mainstay of definitive therapy for PE because its onset of action is immediate and it is rapidly metabolized. Although unfractionated heparin has been the traditional approach, low-molecular-weight heparin (LMWH) may be advantageous. It has more predictable dosing and requires minimal monitoring, which is particularly important in children in whom phlebotomy may be challenging and painful. In addition, LMWH has a reduced risk of heparin-induced thrombocytopenia.

Heparin therapy is recommended for a minimum of 5 days. Longer-term anticoagulation can be accomplished either with continuation of LMWH or with oral anticoagulation with warfarin. Oral anticoagulation may be initiated either at the time of initial treatment with heparin or 1 to 2 days thereafter (Table 98.8). The required daily dose varies, depending on concomitant medical illness and other drug ingestion. The dose is adjusted to maintain the INR at 2.0 to 3.0. Anticoagulant therapy is usually continued for 3 to 6 months beyond the time of diagnosis.

For the rare massive PE with hemodynamic compromise, fluid and inotropic support as well as immediate anticoagulation are the mainstays of therapy. Thombolytic therapy may prove helpful in cases of cardiogenic shock; however, the risk of intracranial or other life-threatening hemorrhage is not insignificant and the clinical utility in children is unknown (Fig. 98.6).

TABLE 98.8

TREATMENT FOR FIRST-TIME DVT/PE IN CHILDREN

	First line	Therapeutic goal	Duration	Notes
Immediate Therapy	IV heparin	aPTT corresponding to anti-Factor Xa level 0.3–0.7 U/mL	5–10 days	Longer duration recommended for massive PE or extensive DVT
	Alternatively: LMWH	Anti-Factor Xa level 0.5–1.0 U/mL	5–10 days	
Ongoing Therapy	Warfarin	INR 2.5 (2.0–3.0)	3–6 mo	Minimum 6 mo if thromboembolic event is idiopathic.
	Alternatively: LMWH	Anti-Factor Xa level 0.5–1.0 U/mL	3–6 mo	For CVL-related DVT, following initial 3 mo therapy, continuation of low-dose anticoagulation (INR 1.5–1.8 or anti-Factor Xa levels 0.1–0.3) until catheter is removed

DVT, deep vein thrombosis; PE, pulmonary embolism; IV, intravenous; aPTT, activated partial thromboplastin time; LMWH, low-molecular-weight heparin; INR, international normalized ratio; CVL, central venous line.

PE, pulmonary embolism; V̇/Q̇, ventilation-perfusion; DVT, deep vein thrombosis; PA, pulmonary angiography; EKG, electrocardiogram; bpm, beats per minute. *Note:* This is an updated version of Wells' predictor, presented by the author on May 19, 2002, at a panel discussion in St. Louis during the annual meeting of the Society for Academic Emergency Medicine. The algorithm remains the same as when published in 1998. (From Wells PS, Ginsberg JS, Anderson DR, et al. Use of a chemical model for safe management of patients with suspected pulmonary embolism. *Ann Intern Med* 1998;129:997–1005.)

PULMONARY EDEMA

Background

Pulmonary edema refers to the abnormal accumulation of fluid within the alveolar spaces and bronchioles. In the healthy lung, intravascular and interstitial hydrostatic and plasma oncotic pressures are relatively balanced, resulting in minimal fluid flux into the interstitium and alveoli. However, alterations in these pressures or changes in permeability of fluid-exchanging membranes in the lungs can lead to pulmonary edema.

The differentiation between cardiogenic pulmonary edema, which results from increases in pulmonary capillary hydrostatic pressure and noncardiogenic edema, originates from the adult population where coronary artery disease and resultant pump failure are highly prevalent. In pediatrics, because the etiologies are more varied, it is more effective to categorize the disease by the underlying pathophysiology.

Pathophysiology

Pulmonary edema can result from increased pulmonary vascular hydrostatic pressures. In adults, this most commonly results from left-sided heart failure. In children, this can be secondary to congenital cardiac abnormalities such as hypoplastic left heart syndrome, cor triatriatum, mitral stenosis, severe aortic stenosis, coarctation of the aorta, or acquired myocardial disease. Overcirculation within the pulmonary vasculature secondary to left-to-right vascular shunting is seen in patent ductus arteriosus, ventricular septal defects, and iatrogenic cardiac shunts. These processes increase pulmonary vascular blood flow and can also lead to pulmonary edema. Beyond cardiac disease, increased hydrostatic pressures from overaggressive administration of IV fluids can be causative.

Intracranial pathology or insult can result in neurogenic pulmonary edema. This can be seen with seizure activity or increased intracranial pressure. Although the mechanism is not entirely understood, it likely results also from increased capillary hydrostatic pressures. Experimental evidence supports an acute sympathetic discharge in these patients. The increase in sympathetic tone leads to profound generalized vasoconstriction with increased venous return and simultaneous pulmonary vasoconstriction. The resultant surge in the pulmonary-capillary pressure can lead to pulmonary edema. The possibility of concomitant capillary leak in neurogenic pulmonary edema has also been proposed.

Decreased plasma oncotic pressure is also associated with pulmonary edema. This condition is seen with lowered levels of circulating plasma proteins, such as occurs with nephrosis, protein-losing enteropathies, massive burns, and severe malnutrition.

Any breakdown in the alveolar-capillary barrier can result in accumulation of protein-rich fluid in the interstitium. This is the major and initial manifestation of ARDS. Lung insult leads to targeting of pulmonary vasculature by inflammatory cells, with resultant tissue destruction from chemical mediators such as prostaglandins, histamine, and bradykinin. The damaged endothelial and epithelial cells create increased permeability of the alveolar-capillary membrane.

In addition to ARDS, a variety of other clinical conditions can similarly lead to capillary leak syndromes. Circulating toxins, such as snake venom and endotoxins from gram-negative sepsis, are examples. In addition, altered permeability is the most common pathophysiology behind pulmonary edema from asthma, hypersensitivity pneumonitis, Goodpasture's syndrome, and systemic lupus erythematosus. Inhaled environmental exposures can have a similar effect. Noxious gases from fires, hydrocarbons, oxides from sulfur and nitrogen, and inhalation of some herbicides (e.g., paraquat) can denature proteins and cause cellular damage with development of pulmonary edema.

Postobstructive pulmonary edema, also known as *negative-pressure pulmonary edema*, is associated with upper airway obstruction (Figs. 98.7A, B, and C). It is thought to result from exaggeration of the transmural pulmonary vascular hydrostatic pressure gradient. The highly negative pleural pressures that accompany upper airway obstruction lead to increased venous return, which increases pulmonary vascular volume and may impair cardiac output. In addition, the negative pressures cause highly negative pulmonary interstitial pressures. All of these mechanisms can contribute to transudation of fluid across pulmonary capillaries.

Finally, pulmonary edema can result from travel to high altitudes. This characteristically affects young people who are exposed to altitudes above 2,700 m. It generally occurs soon after arrival and can occur in those who are new to such elevations or those who have returned from time spent nearer to sea level. Although the precise mechanism is unclear, cardiac catheterizations have suggested that the cause is not related to increased hydrostatic pressures.

Clinical Manifestations

The onset of pulmonary edema is variable depending on etiology but can occur rapidly (i.e., flash pulmonary edema). Cough is the most common symptom and may produce frothy, pink-tinged sputum. Patients may also endorse dyspnea, shortness of breath, orthopnea, and chest pain. On physical examination, the child may appear pale or cyanotic and frequently has a rapid pulse. Tachypnea is almost universally present. Grunting often occurs in an effort to stent open small airways and airspaces and prevent lung collapse. Auscultatory findings include decreased breath sounds and moist crackles, particularly at the bases; however, these are often absent with small amounts of edema. Indeed, physical examination and radiographic findings may not manifest until the interstitial and extravascular fluid has doubled or tripled in volume.

Chest radiographs are often diagnostic, although findings may lag behind the acute clinical process. Lymphatic and interstitial fluid accumulations may be visible as Kerley A and B lines (septal lines; Fig. 98.8). These lines represent interstitial edema, tangential to the radiograph beam. The B lines, which lie in the periphery, are often the first findings. Unlike blood vessels, these radiopacities will reach the lung edge. As edema progresses, Kerley A lines near the hilum may occur, and ultimately, a butterfly pattern with a central predominance of shadows can be seen. Although these findings are not specific, transient changes in an appropriate clinical context usually signify edema.

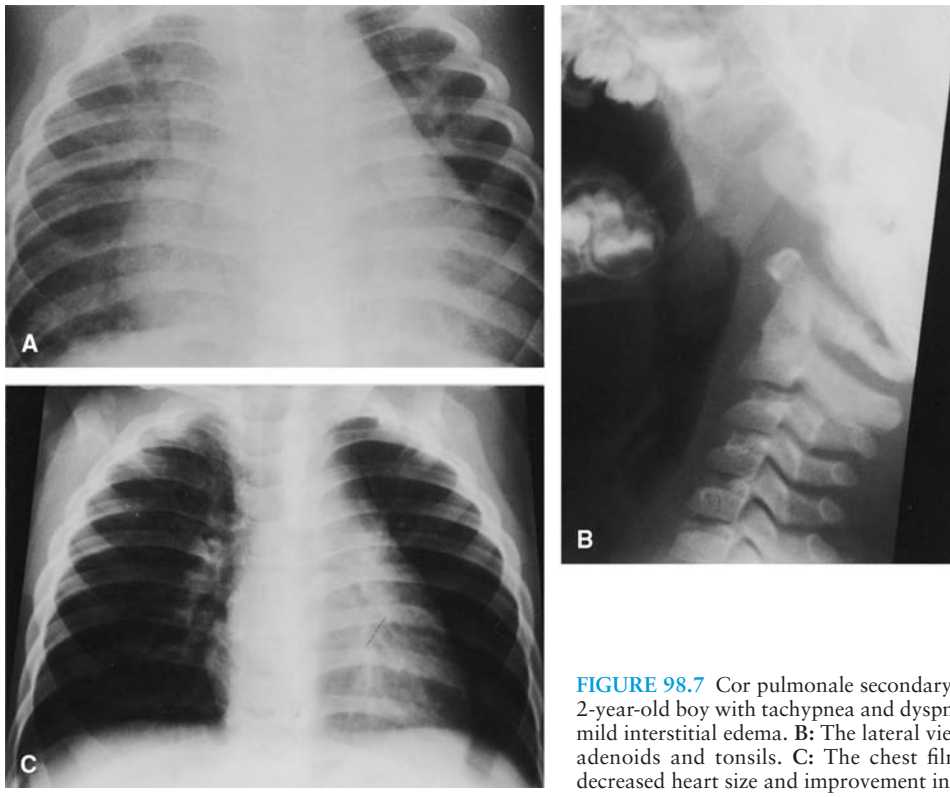

FIGURE 98.7 Cor pulmonale secondary to upper airway obstruction. **A:** This is a 2-year-old boy with tachypnea and dyspnea. The chest film shows a large heart and mild interstitial edema. **B:** The lateral view of the neck shows obstructing enlarged adenoids and tonsils. **C:** The chest film 2 days after adenoidectomy shows a decreased heart size and improvement in interstitial edema.

The distribution, symmetry, and extent of radiographic findings may also provide helpful information regarding possible etiology and severity of edema. Patterns of radiographic findings in particular can be helpful in identifying underlying cause. Cardiac size and increased prominence of pulmonary vasculature may suggest increased hydrostatic pressure or cardiogenic edema. Conversely, presence of air bronchograms, peribronchial cuffing, and increased lung volume may suggest primary lung injury with resultant capillary leak.

It should be kept in mind that if pulmonary edema is superimposed on another pulmonary process, the clinical and radiographic findings may be obscured by those of the primary illness. Similarly, once pulmonary edema is severe enough, it may be difficult to separate edema, atelectasis, and inflammation on the chest film.

FIGURE 98.8 Interstitial fluid from volume overload. This is a 2-year-old child with paraspinal sarcoma removed 6 months earlier. Before chest radiation, he received a large fluid load. The chest film shows interstitial edema with Kerley's lines and small pleural effusions.

Management

The management of patients with pulmonary edema includes supportive therapies and correction of the underlying disorder. Initial efforts (Table 98.9) should be directed toward correction of hypoxemia through the administration of supplemental oxygen. In addition to satisfying the patient's oxygen demands,

TABLE 98.9

TREATMENT OF PULMONARY EDEMA

Oxygen	Afterload reduction
Diuresis	Morphine 0.1 mg/kg IV
Furosemide 1 mg/kg IV	Digitalis (see Table 82.7, for dosage)

IV, intravenous.

reversal of hypoxemia is often useful in relieving chest pain and is important to the metabolism of vasoactive mediators that affect microvascular permeability.

In severe cases, CPAP or mechanical ventilation may be warranted. Assisted ventilation has several beneficial effects for patients with pulmonary edema. It reduces oxygen consumption by decreasing work of breathing. Oxygenation is also improved through prevention of alveolar collapse. In addition, positive intrathoracic pressures decreases pulmonary vascular volume and reduced fluid filtration in the lung.

In healthy lungs, there is a small fluid flux from pulmonary capillaries into the interstitium. This fluid is actively drained by a sodium transporter in the alveolar epithelium and reenters the vascular system as lymph. This process can be actively enhanced and alveolar fluid clearance augmented with β-adrenergic agonists, which may be utilized in some clinical circumstances.

Other therapeutic measures should be tailored to fit the patient's underlying disease process. When ventricular failure is the cause of pulmonary edema, diuretics can be used to decrease plasma volume, and inotropes can improve contractility. Morphine helps physiologically by dilating the venous system and may also relieve anxiety and dyspnea. Afterload reducers such as milrinone may also be helpful.

When decreased plasma oncotic pressure is primary, administration of colloid such as albumin is indicated. Slow infusion and concomitant diuretic use will help minimize resultant increases in pulmonary vascular pressure.

The management of ARDS is beyond the scope of this chapter. Management is focused on addressing underlying illness and supportive ventilatory strategies. Clinical studies have shown that the use of systemic steroids does not improve outcome and may in fact increase the incidence of secondary infections and subsequent mortality.

PULMONARY HEMORRHAGE

Background

Pulmonary hemorrhage, or bleeding into the lung, manifests clinically with hemoptysis. Although relatively uncommon, this can be dramatic and life-threatening. Therefore, early evaluation and treatment is paramount.

The incidence of pulmonary hemorrhage is difficult to ascertain. Underreporting is probably uncommon, given that children with hemoptysis are unlikely to forego medical evaluation. However, the relative frequency of causative etiologies will vary significantly by the population being evaluated, making estimation of incidence of disease difficult.

Table 98.10 provides a differential diagnosis for pulmonary hemorrhage by category. The initial supportive management for the hemoptysizing patient will be similar regardless of etiology; however, subsequent management is tailored to the underlying disease process. Therefore, evaluative efforts are aimed at identifying a specific diagnosis whenever possible.

Clinical Manifestations

Hemoptysis is the most common presentation of pulmonary hemorrhage. It may be necessary to distinguish this from hematemesis or blood from the nose, tonsils, or upper airway. Findings may be mild with blood-streaked sputum, or patients may present with massive blood loss. Hypoxia and shortness of breath sometimes occur. Apprehension is not uncommon in these children as dyspnea is compounded by the visualization of loss of blood. Children with recurrent intrapulmonary

TABLE 98.10

CAUSES OF PULMONARY HEMORRHAGE IN CHILDREN

Primary	Associated with other organ dysfunction	Secondary	Airways	Parenchymal	Nonlung sources
Cow's milk allergy Hiener's syndrome	Goodpasture's	Congestive heart failure	Bronchitis	Trauma (including nonaccidental)	Hematemesis/GI bleeding

Acute idiopathic pulmonary hemorrhage (AIPH) among infants	Henoch–Schönlein purpura	Clotting disorders	Airway anomalies	Infarction	Factitious hemoptysis
	Systemic lupus erythematosus (SLE) and collagen vascular disease	Malignancy	Vascular anomalies, (hemangioma and arteriovascular malformation (AVM's))	Neoplasm	
		Alveolar injury (e.g., drugs, radiation, smoke, acid aspiration)	Foreign body	Cavitary lesion	

Modified from Boat TF. Pulmonary hemorrhage and hemoptysis. In: Chernick V, Boat TF, eds. *Kendig's disorders of the respiratory tract in children*, 6th ed. Philadelphia, PA: WB Saunders, 1998:624.

bleeding are more likely to be anemic. As a result, they may also present with fatigue and poor weight gain.

Examination findings are often nonspecific and include: tachypnea, tachycardia, and hypoxia. Crackles may be appreciated over the affected area, although isolating the location of the bleeding by auscultation is rare. For older patients, identifying the affected area may be best accomplished by asking the patient where they feel changes. Other signs on examination may be helpful in elucidating an underlying diagnosis, such as abnormal cardiac sounds with heart failure, rash or joint involvement with collagen vascular disease, or external signs of thoracic injury in trauma patients. Cardiorespiratory decompensation can occur in children with severe anemia or shock from severe hemorrhage.

Characteristic laboratory findings include a microcytic, hypochromic anemia in patients with recurrent hemorrhage. Elevated reticulocytes may be present except in hyperacute cases and if not suppressed by underlying disease or reduced iron stores. Chronically affected patients may develop secondary restrictive lung with subsequent retention of CO_2. Additional laboratory findings will vary based on underlying disease, such as eosinophilia with immune-mediated disease or elevated inflammatory markers with vasculidities. Coagulation and hematologic studies will be abnormal in patients with bleeding diatheses.

Radiographs (Fig. 98.9) will vary depending on etiology. Alveolar infiltrates may be transient localized processes or diffuse and chronic. In idiopathic pulmonary hemosiderosis, diffuse alveolar changes are usually symmetric and spare the apices and costophrenic angles.

Because most children swallow their sputum, a presumptive diagnosis can be made by finding hemosiderin-laden macrophages in nasogastric washings; these macrophages will stain blue with the Prussian blue reaction. More definitive diagnosis, however, requires bronchoscopy and BAL. Finding similar macrophages from BAL is diagnostic, and direct visualization of the airways provides an opportunity to potentially localize the site and assess the activity of bleeding. Lung biopsy is required only for patients with recurrent bleeding in whom no diagnosis can be made on a clinical basis and alternative systemic diseases cannot be excluded.

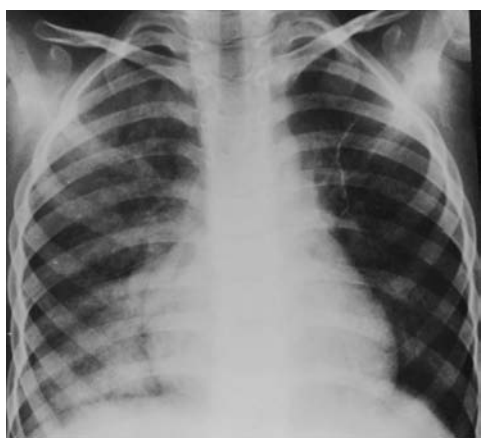

FIGURE 98.9 Idiopathic pulmonary hemosiderosis. A 5-year-old child with repeated bouts of pulmonary hemorrhage. The chest film shows diffuse radiopacities throughout both lungs (more on right side), with a well-defined alveolar opacity in the right lower lobe. Note the surgical sutures in left upper lobe.

Pulmonary function testing may reveal an obstructive pattern secondary to bronchial irritation from blood. Chronically, however, patients with systemic disease frequently develop scarring and fibrosis and may develop a restrictive or mixed pattern.

Management

Immediate management of any patient with presumed pulmonary hemorrhage is supportive. Supplemental oxygen to correct hypoxia and intravascular volume repletion should be initiated. For those with chronic disease or large acute blood losses with resultant anemia, anticipating the need for blood transfusions is important. Occasionally, pulmonary hemorrhage is so severe that it causes respiratory insufficiency or hypotension. Aggressive fluid resuscitation followed by positive-pressure ventilation with PEEP is the preferred treatment in this situation. In these severe cases, platelets and fresh-frozen plasma can also provide volume replacement and help with hemostasis.

Bronchoscopy can be diagnostically useful, usually to determine infectious causes rather than to localize a source of bleeding and control it, which is unusual. Occasionally, for brisk bleeding in a patient with a known or likely source, such as in bronchiectasis from cystic fibrosis or a known vascular malformation, embolization of vessels may be employed to rapidly stop the hemorrhage.

Additional treatment is tailored to the underlying etiology of disease. In allergic, vasculitic, and idiopathic hemorrhage, the administration of methylprednisolone (2 mg per kg per day IV divided in three to four divided doses) is indicated. When hemorrhage is caused by infection, especially tuberculosis, antimicrobial therapy should be instituted and steroids avoided. Admission is necessary until the cause of the bleeding has been determined and the hemorrhage has been controlled.

PLEURITIS

Background

Pleuritis or *pleurisy* refers to inflammation of the pleural membranes, resulting from primary pleural, adjacent pneumonic, or systemic disease. This inflammation may be associated with minimal or considerable accumulation of fluid in the pleural space. Specific references to the incidence of pleural effusions in various respiratory infections are made in Chapter 92, and the surgical approach to pleural effusions is reviewed in Chapter 128.

There exist a wide spectrum of illnesses and injuries that lead to pleural inflammation (Table 98.11). Infectious etiologies are most common and may include viruses (e.g., Coxsackie virus, Epstein-Barr virus, herpes zoster), mycoplasma, bacteria (e.g., *Staphylococcus aureus, Streptococcus pneumoniae, Haemophilus influenzae,* group A streptococcus, *Mycobacterium tuberculosis*), and fungi (e.g., histoplasmosis, coccidioidomycosis). Infections from pulmonary, subdiaphragmatic, or more distant sites may all eventually involve the pleura.

Neoplastic involvement may also be primary or metastatic. When oncologic lesions obstruct the lymphatic drainage, accumulation of pleural fluid can occur. PE may cause pleural inflammation with or without effusion as a result of focal parenchymal necrosis. Trauma, both accidental and following diagnostic and therapeutic procedures in the chest, can irritate the pleura and lead to secondary infection. Pleuritis with or without effusion is seen in more than half of patients who have a systemic vasculitis such as systemic lupus erythematosus or sarcoidosis.

Pathophysiology

The pleura is a double-layered, thin membrane that separates the lung from the chest wall, diaphragm, and mediastinum. The outer parietal pleura is adherent to the chest wall, and the inner visceral pleura completely covers the lungs except at the hili. In the healthy child, the two layers of pleura are apposed, separated by only a thin physiologic layer of serous fluid. This pleural fluid is constantly being turned over, entering from the parietal pleura and exiting via the lymphatics and vasculature of the visceral pleura.

Abnormal pleural fluid accumulation can result from changes in hydrostatic or oncotic pressures or diseases of the pleural surface that alter capillary permeability or affect lymphatic reabsorption. The underlying pathophysiology will determine if an effusion will be transudative or exudative. Transudates occur as a consequence of increased capillary hydrostatic pressure such as congestive heart failure or decreased oncotic pressure such as hypoproteinemic states. Exudates result from diseases of the pleural surface that produce increased capillary permeability or lymphatic obstruction, such as pleural infection or tumor.

The determination of the nature of pleural fluid may be helpful from a diagnostic perspective (Table 98.11). Light's criteria for classifying pleural fluid is the most reliable for distinguishing exudative from transudative effusions. These criteria include a pleural fluid:serum protein ratio greater than 0.5, a pleural fluid:serum lactate dehydrogenase (LDH) ratio greater than 0.6, and a pleural LDH concentration more than two-thirds the normal upper limit for serum. If any one of these values is exceeded, the effusion is classified as exudative. Recent efforts at utilizing additional markers such as pleural C-reactive protein and adenosine deaminase levels have also shown promise, although their clinical use is not yet widespread.

In adult populations, where the high frequency of congestive heart failure, cirrhosis, and renal disease make transudative effusions common, differentiating effusion type is helpful. In pediatrics, however, because the majority of effusions are exudative, classification focuses instead on whether pleural fluid collections are infectious or noninfectious.

Clinical Manifestations

The hallmarks of pleural disease are pain, shortness of breath, fever, and an abnormal chest radiograph. Pain with respirations, or pleuritic chest pain, is the most characteristic symptom with pleural inflammation. Most patients also describe some degree of dyspnea. Additional symptoms vary depending on the primary cause. In "dry" pleurisy, which is usually caused by a minor pulmonary infection, the patient is often febrile with an irritating, nonproductive cough. With oncologic etiologies, weight loss, night sweats, and fatigue may be present.

On examination, pressure over the involved area may elicit tenderness, and a coarse vibration may sometime be appreciated on palpation. A pleural friction rub is most apt to be heard when pleural inflammation is associated with little or no

effusion. The sound has been described as low pitched, sometimes with a grating or squeaking quality. It is usually loudest on inspiration, but often it may also be audible during expiration. Sometimes, the rub is confused with low-pitched rhonchi, produced by secretions partially blocking the airway. A vigorous cough will eliminate these secretions and sounds but will not affect the pleural friction rub. Grunting may occur, although related to pain rather than respiratory distress in most patients with dry pleurisy.

For patients with pleural effusions, characteristic physical findings include restriction of movement of the chest wall on the affected side, dullness to percussion, diminished to absent tactile and vocal fremitus, and decreased or absent breath sounds. These signs are similar to patients with large areas of atelectasis or collapse, although pleural effusions decrease the available space within the hemithorax, causing the trachea to deviate away from the diseased side. Conversely, atelectasis causes the trachea to deviate toward the diseased side.

Radiographs may be used to evaluate for pleural thickening or pleural effusion, as well as to help determine underlying etiology. Pleural inflammation alone can be difficult to appreciate on chest films. Instead, effusion is the most common radiographic manifestation of pleural disease. The first radiographic sign of a pleural effusion is usually blunting of the costophrenic angles, producing wedgelike menisci that extend upward along the lateral chest wall. Similar collections can be seen in the posterior costophrenic angles on lateral views. Larger effusions may be seen to extend up the entire lateral chest wall or retrosternally.

Pleural effusions may alternatively present with apparent prominence or thickening of the interlobar fissures or by wedge-shaped accumulations of fluid at either end of these fissures. The latter may be mistaken for focal infiltrates or segmental atelectasis on some views.

Although small effusions are easily overlooked on radiograph, with proper technique, collections as small as 25 mL have been identified. In adults, pleural effusions are visible on lateral chest radiographs at a volume of approximately 50 mL. At a volume of 200 mL, the meniscus can be identified on the posteroanterior radiograph, whereas at a volume of 500 mL, the meniscus obscures the hemidiaphragm.

Management

The management of pleural disease is aimed at determining the cause, treating the primary disorder, and relieving associated functional disturbances. When no effusion is present, relief of chest pain is the most pressing issue. Antiinflammatory therapy and rest are indicated. Pleurisy can be significant in some children, and constant aggravation with respiration can be frustrating. Irritability and restlessness can result, and mild sedatives may be helpful.

For patients with increased accumulation of pleural fluid, pain is usually less significant; however, respiratory compromise is more likely. Thoracentesis is indicated when fluid accumulation is extensive enough to cause dyspnea and/or for diagnostic purposes (Fig. 98.10). Sonographic guidance is not mandatory but can simplify and enhance the success of this procedure, particularly with small or loculated effusions. Complications of thoracentesis include pneumothorax, hemothorax, reexpansion pulmonary edema, and, rarely, air embolism. The recommended technique for thoracentesis is provided in Section VII, and details of management of fluid in the pleural space are reviewed in Chapter 128.

Additional means of draining pleural fluid are also available. Thoracostomy using small "pigtail" tubes placed by Seldinger technique is minimally more invasive than needle thoracentesis and allows for ongoing drainage as needed. Again, ultrasound guidance can be utilized at the bedside, or the location of maximal fluid can be marked prior to drainage. Image-guided catheter drainage is most effective in patients with short duration of symptoms, free-flowing or unilocular effusions, absence of thick pleural peel, and fluid collections that can be easily reached. Other approaches for more advanced disease include surgical tube thoracotomy; video-assisted thoracosopic surgery, which allows directed chest tube placement and debridement; and minithoracotomy with open pleural decortication.

Diagnostic tests of pleural fluid should include gross and microscopic examination; Gram stain; protein, glucose, LDH, and pH determinations; and cytology if malignancy is known or suspected. Gross examination can be suggestive of fluid content. For example, frank pus can be diagnostic of empyema, chylous effusions are milky white, and exudative fluid with high content of protein and cells is usually turbid. However, oftentimes, classification of pleural fluid by visual appearance alone will not be feasible or accurate. Therefore, concomitant blood and pleural fluid protein and LDH determinations are required.

For patients with exudative effusions, pleural fluid pH measurement is helpful in guiding decisions regarding drainage. In adult patients, pH values of greater than 7.2 to 7.3 are generally found in sterile pleural fluid that does not require further drainage. One exception is *Proteus mirabilis* infection, which causes an elevated pleural fluid pH. In contrast, a pH of less than 7.0 is seen only in empyema, collagen vascular disease, or esophageal rupture. Therapeutically, a pleural fluid pH of less than 7.2 suggests that the effusion will likely require chest tube drainage.

A pleural fluid:serum glucose ratio less than 0.5 has a similar differential diagnosis as low pleural fluid pH. In animal studies, both leukocytes and bacteria have been shown to use glucose anaerobically, resulting in reduced glucose concentration. Diseases associated with low pleural fluid glucose (less than 60 mg per dL) include infectious causes, collagen vascular diseases, malignancies, and esophageal rupture.

Although pleural fluid white blood cell count is routinely obtained, rarely will findings influence management. While blood cell counts are generally higher in children with purulent effusions than in those with transudative effusions, values overlap considerably. In large series of both adult and pediatric patients, pleural fluid white blood cell counts have not been helpful in narrowing the differential diagnosis or in determining the need for or duration of chest tube drainage.

OBSTRUCTIVE SLEEP APNEA

Background

Sleep-disordered breathing refers to the group of respiratory disorders that occur or are exacerbated by sleep. These include

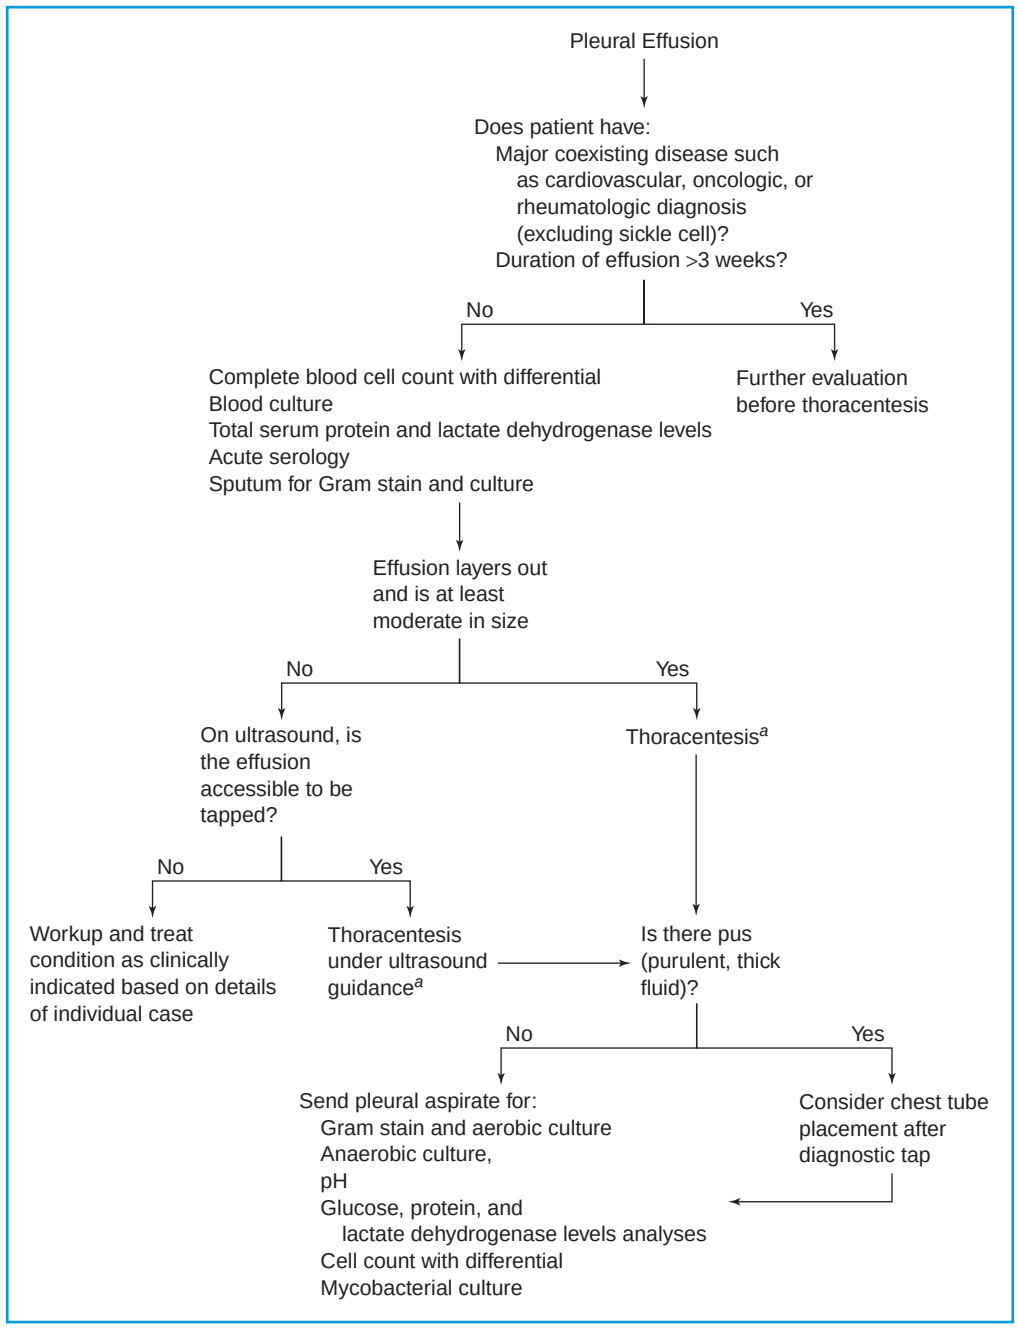

FIGURE 98.10 Approach to pleural effusion. [a]Consider simultaneous placement of small gauge (8F to 10F) chest tube by Seldinger technique for large, free-flowing effusions.

those disease processes that result in central or obstructive apnea or hypoventilation. Of those with obstructive etiologies, primary habitual snoring is the most common, but also the least worrisome. On the other end of the spectrum is obstructive sleep apnea syndrome (OSAS), which can have long-term consequences, including neurocognitive deficits and cardiovascular morbidities.

Obstructive sleep apnea was first described nearly a century ago when William Osler coined the term *Pickwickian*, referring to obese hypersomnolent patients. Subsequent accounts of sleep apnea associated with obesity emerged. For years, however, confusion in nomenclature and incomplete understanding of the overlapping pathophysiology of these reported disorders prevented the recognition of a unified syndrome. In 1996, the American Thoracic Society defined OSAS in children as a disorder of breathing during sleep, characterized by prolonged upper airway obstruction or intermittent complete obstruction that disrupts normal ventilation during sleep and normal sleep patterns.

Although the reported incidence varies depending on the data collection methodology and inclusion criteria, most studies suggest that OSAS occurs in 1% to 5% of children. It is more common in boys than in girls. The peak incidence is in children between 2 and 8 years of age, paralleling the prominence of

growth of lymphoid tissues around the airway. However, OSAS can occur in any age. Craniofacial anomalies and neurological disorders affecting upper airway structure and tone predispose infants to OSAS, while obesity is often a factor in the development of the syndrome in older children.

Pathophysiology

The exact pathophysiology of OSAS is unclear. Available data suggest that upper airway resistance, from either anatomic or dynamic airway obstructions, leads to variable and abnormal breathing patterns during sleep. Complete or partial obstruction leads to limited airflow that prompts electrocortical arousal and autonomic activation. This response stimulates an increased respiratory effort and tachypnea in an effort to maintain normal gas exchange. Collectively, the result is disordered sleep patterns that have downstream consequences on the cardiovascular system and on daytime behaviors.

In the majority of cases, adenotonsillar hypertrophy is the major precipitant of airway obstruction. Obesity has become another precipitant, particularly given the growing epidemic of childhood obesity in this country. Of note, obese patients with OSAS tend to require less tonsillar hypertophy to become symptomatic than do their younger, thinner counterparts.

Children with craniofacial anomalies are also at higher risk for obstruction, oftentimes beginning shortly after birth. In children whose craniofacial anomalies reduce the size of the nasal cavity, nasopharynx, or oropharynx, the normal pharyngeal tissues or minimal hyperplasia of the lymphoid tissue of Waldeyer's ring can cause varying degrees of obstruction. This obstruction can result in OSAS.

Children with neuromuscular diseases are also prone to obstruction and sleep apnea. In these children, impaired pharyngeal tone allows posterior soft tissues to collapse into the airway during sleep. Such children with neuromuscular disorders are likely to also have chronic pulmonary disease and impaired ability to clear pharyngeal secretions, which further complicates their evaluation and management.

Clinical Manifestations

Snoring and difficulty breathing are the most common complaints in children (and parents) with OSAS. The snoring is described as loud, often with interspersed pauses, snorts, or gasps. Retractions are frequently noted while the child is sleeping. Episodes of obstruction may be witnessed, many of which are terminated by gasping, movement, or awakening. Children will frequently appear restless throughout the night, naturally repositioning themselves to promote airway patency. Increased autonomic tone frequently results in nighttime diaphoresis and may contribute to enuresis. Chronic nighttime cough may also be observed as a result of intermittent aspiration of small amounts of pharyngeal secretions.

Although symptoms including nasal voice and mouth breathing may be noticeable during the daytime, many children exhibit no evidence of airway compromise when awake. However, because of disrupted sleep, children with OSAS may demonstrate excessive somnolence, although this is much less common in younger children than in teens and adults. Behavioral and neurocognitive changes are relatively common, however, resembling symptoms seen in patients with attention deficit hyperactivity disorder. Other commonly associated behavioral abnormalities include fighting with peers, crying easily, withdrawal behavior, and rapid fluctuations in alertness. Older children may also experience decreased school performance, especially with regard to language acquisition. These changes may result from disrupted sleep as well as chronic, intermittent hypoxemia.

Abnormal physical findings on examination are unusual. Tonsillar enlargement may be noted; however, it is often mild to moderate rather than marked. A normal oropharyngeal examination does not exclude OSAS, given the potential for other soft tissue structures or dynamic changes to cause the airway obstruction. Other nonspecific signs might include delayed growth or impaired weight gain, from chronic increased work of breathing, intermittent hypoxia, and limited caloric intake secondary to difficulty eating and breathing comfortably at the same time. Alternatively, obesity is a risk factor for disease and may be noted particularly in older patients with OSAS. Abnormal facies or systemically decreased tone may be found as etiologies, and a loud S_2 can occur in patients with long-standing disease who have developed pulmonary hypertension as a result.

Initial screening for snoring should occur at routine health care maintenance visits. If a history of nightly snoring is elicited, or a child has other symptoms concerning for OSAS, a comprehensive history and physical examination should be performed. A detailed account of labored breathing during sleep, observed apnea, restless sleep, diaphoresis, enuresis, cyanosis, excessive daytime sleepiness, and behavior or learning disorders should be obtained. Formal questionnaires are available, although differentiating OSAS from primary habitual snoring based on self- or family-reported results may be difficult.

Soft-tissue radiographs of the lateral neck taken with the child lying on his/her back can be helpful but are not a definitive method of diagnosis. Much as with physical examination of the pharynx, static images cannot replicate potential dynamic changes that may occur during sleep. Standardized recordings of breathing sounds, videotaping of a child while sleeping, or continuous overnight pulse oximetry can occur either in the hospital or in the patient's home. Evidence suggests that these screening tools can have reasonable positive predictive value; however, absence of abnormal findings cannot exclude OSAS.

Polysomnography is the current gold standard and the diagnostic test of choice for evaluating apnea and should be performed on children with historical and physical findings associated with OSAS. It can distinguish primary snoring from OSAS and can determine the severity of OSAS. Although polysomnography can be performed satisfactorily in children of any age, it requires appropriate equipment and appropriately trained staff. Therefore, availability is often limited. Abbreviated or nap polysomnography in the hospital or unattended home polysomnography have been utilized in place, but as with other screening tools, these have limited negative predictive value.

Management

Children with concern for significant apnea may warrant hospitalization until a diagnosis and severity can be determined.

Historical clues will be most important in making this determination, as children with OSAS do not usually appear in extremis during wakeful periods. However, some well-appearing children may be at risk for repeated apnea and subsequent hypoxemia while sleeping. During hospitalization, airway obstruction should be managed according to basic life support protocols, with airway maneuvers such as repositioning, jaw thrust, and head-tilt chin lift to open the upper airway as necessary. Nasal trumpets may also be helpful.

Supplemental oxygen therapy is sometimes recommended to alleviate nocturnal hypoxemia. However, it does not prevent sleep-related upper airway obstruction, sleep fragmentation, or increased work of breathing. In addition, patients with long-standing disease may chronically retain CO_2; therefore, aggressive correction of hypoxia may depress respiratory drive and potentially worsen hypoventilation. Assessing a serum HCO_3 or blood gas level may be helpful in identifying such patients.

In addition to a thorough general medical evaluation, children with OSAS will usually require otolaryngologic consultation for airway evaluation and, if needed, planning for relief of obstruction.

Numerous methods of management of OSAS have been suggested and studied. Patients with hyperplasia of the tonsils and adenoids as the primary cause for obstruction may be trialed on high-dose nasal steroids, although those who improve may not have sustained benefit. Most of these patients will have dramatic relief of symptoms following surgical resection. Postoperative polysomnography shows resolution of OSAS in 75% to 100% of patients. Patients with craniofacial anomalies and with neuromuscular disorders also usually have significant improvement after adenotonsillectomy or other targeted surgical procedures.

Patients with obesity-hypoventilation syndrome (Pickwickian syndrome) may benefit from maintained weight reduction. Unfortunately, weight loss in these patients is often either difficult to achieve or only temporarily successful. Because many obese children will be adequately treated with adenotonsillectomy, it is generally the first-line therapy for these patients.

Oral appliances have been shown to improve snoring and reduce apnea and hypopnea in adults by modifying the upper airway by changing the posture of the mandible and tongue. Although some tolerate such devices well, oral discomfort probably decreases compliance rates, which may be as low as 50% in adults and would likely be even lower in children. For some OSAS patients, nasally administered CPAP successfully alleviates hypoventilation, although again this may be less well tolerated in pediatric population. Rarely, patients require artificial airway placement and/or supplemental ventilation.

SARCOIDOSIS

Background

Sarcoidosis is a rare, chronic, granulomatous disease of unknown cause. Lungs are the most affected organs although joints, skin, eyes, lymph nodes, liver, spleen, muscle, and brain can all be involved. Involved organs have accumulations of T lymphocytes and mononuclear phagocytes, noncaseating epithelioid granulomas, and derangements of normal tissue architecture. Although the exact cause of sarcoidosis is unknown, evidence suggests a multifactorial etiology; both environmental and genetic factors result in an exaggerated cellular immune response to an unclear antigen.

The incidence of sarcoidosis varies with age, race, and geography. The majority of those affected are adults between the ages of 20 and 40 years. Although cases of patients less than 1 year of age have been reported, most pediatric cases present in the second decade. The disease is often acute or subacute and self-limiting. However, in many, it is chronic, with waxing and waning symptoms over many years.

Clinical Manifestations

The most common initial symptoms in children and young adults are nonspecific and may include malaise, fatigue, fever, and weight loss. Organ-specific symptoms vary by age. Children younger than 5 years most commonly have skin, eye, and joint involvement, whereas older children are more likely to report symptoms related to lung involvement or enlarged lymph nodes. The presence of cough and dyspnea usually indicates pulmonary involvement. However, extensive pulmonary disease can be present without clinical findings. Hoarseness, dyspnea, and dysphagia can result from laryngeal involvement. Arrhythmia or congestive heart failure can also present as initial findings of cardiac disease. Other symptoms vary depending on affected systems and may include bone and joint pain, visual acuity impairment, ocular swelling or pain, parotid gland enlargement, headache, and unexplained fever.

On physical examination, lymph node enlargement is the most frequently detected abnormality. Intrathoracic nodes including hilar, paratracheal, or mediastinal chains are enlarged in 75% to 90% of patients. When present, hilar adenopathy is usually bilateral and symmetric. Peripheral adenopathy is also common, particularly in cervical, axillary, and inguinal regions. Affected lymph nodes are firm, nontender, mobile, and nonulcerative. Some patients have a skin rash that is similar in appearance to erythema nodosum. Plaques, subcutaneous nodules, and maculopapular eruptions can also be seen. Uveitis is present in up to 25% of patients. Small yellow nodules are frequently found on the conjunctiva in these patients. Hepatosplenomegaly and joint effusions can also be present.

Laboratory test abnormalities in patients with sarcoid tend to be nonspecific. Hyperproteinemia, elevated erythrocyte sedimentation rate, hypercalciuria, eosinophilia, and rarely hypercalcemia can be seen. Although not pathognomonic, an elevated serum angiotensin-converting enzyme level in patients in whom sarcoid is suspected is strongly supportive. On chest radiograph, between 40% and 60% of symptomatic children will have hilar adenopathy alone or in combination with parenchymal infiltrates. Pulmonary function testing usually reveals restrictive lung disease.

Diagnosis of sarcoid in children is challenging because it is extremely rare and oftentimes findings are subtle. For pediatric patients with multisystem complaints, however, sarcoid should be considered. In particular, pulmonary disease associated with rash, uveitis, or arthritis is suggestive. However, because lung disease can remain clinically silent, respiratory complaints need not be present at the time of initial presentation.

Alternatively, unexplained intrathoracic adenopathy may prompt further investigation, leading to the diagnosis.

The diagnosis is ultimately made histologically. Biopsy of a lymph node or other easily accessible organ will demonstrate noncaseating epithelioid cell granulomas. These findings may need to be further differentiated from other rheumatologic or infectious diseases that can have similar histopathology.

Management

Glucocorticoid treatment is the most commonly used therapy for sarcoidosis. However, because the disease resolves spontaneously in a substantial proportion of patients, there is often debate about who requires steroids. Patients with significant lung or eye lesions are most commonly treated. In addition, those with cardiac, CNS, or multiorgan system involvement usually warrant therapy. Corticosteroids seem to be effective as acute therapeutic agents but have little effect on permanent organ derangements, including chronic lung disease.

For many, the prognosis in sarcoidosis is favorable, although clinical and genetic factors are important factors. Most patients with an acute presentation improve gradually over months and are left with no sequelae. However, some develop progressive cystic emphysema, bronchiectasis, or severe restrictive pulmonary disease with exercise-induced hypoxemia. Younger children and those with multiorgan system involvement tend to have less favorable outcomes. In addition, all patients require close monitoring during and after treatment because relapses are not uncommon.

SEVERE ACUTE RESPIRATORY SYNDROME

Background

An epidemic of a newly defined respiratory illness, severe acute respiratory syndrome (SARS), occurred in 2002/2003. Index cases in Hong Kong appeared to transport the illness to Singapore, Vietnam, Canada, Ireland, and the United States, resulting in widespread infection, totaling more than 3,000 cases with 10% mortality reported throughout 27 countries. Laboratory and epidemiologic studies revealed SARS-associated coronavirus as the etiologic agent. The small droplets, which serve as vectors for transmissibility, allowed for easy spread, even in relatively protected environments.

Clinical Presentation

In adults, clinical features include fever, cough, shortness of breath, and varying degrees of respiratory distress. Associated laboratory findings may include leukopenia, thrombocytopenia, liver function abnormalities, and coagulation abnormalities. Patients with more significant disease have bilateral pulmonary infiltrates on radiographs and may progress to ARDS and multiorgan system failure.

Pediatric patients diagnosed with SARS tend to have less severe illness, although most adolescents require more aggressive therapy than do younger children. Similar to adults, pediatric patients with confirmed SARS-associated coronavirus infection present most commonly with fever, cough, malaise, coryza, and other nonspecific symptoms. Some children show no evidence of lower respiratory tract infection, yet others have clinical signs such as inspiratory crackles, chest radiographs suggestive of alveolar infiltrates, or occasionally CT findings confirming parenchymal lung involvement. The most common laboratory abnormalities tend to be mild and may include leukopenia; thrombocytopenia; elevated alanine aminotransferase, aspartate aminotransferase, and lactate dehydrogenase levels; and prolonged aPTT (activated partial thromboplastin time).

Because the signs and symptoms of SARS are nonspecific and immediately available laboratory testing could be supportive but not diagnostic, incorporation of careful investigation into potential exposures was crucial during the epidemic. Evaluation of symptomatic patients required investigation for SARS as well as more common etiologies for community-acquired pneumonia. Nasopharyngeal swab for PCR for coronavirus, serum antibody to SARS-CoV (SARS coronovirus), and clinical specimen for isolation in cell culture are all acceptable testing methodologies.

Little is known about the potential transmission from child to child. However, of greater importance was the reduction of potential spread from children to higher risk adults by isolation during the viremic phase.

Management

In addition to supportive therapy with supplemental oxygen, nutrition, and symptomatic therapy, ribavirin was used in a number of cases. The benefits are unclear, although there exists a theoretical benefit in treatment of RNA viruses such as coronavirus. Many patients received pulse steroids for 3 to 5 days, particularly those with radiographic findings and hypoxemia.

There have been no recurrent epidemics of SARS since 2003. Depending on future epidemiology, more may be elucidated regarding this particular pulmonary infection in pediatrics. For now, however, the SARS outbreak serves as an example of the important interaction between epidemiologic and clinical investigation during the development of new, severe illnesses in children and the general population.

CHAPTER 99 ■ EMERGENCIES IN CYSTIC FIBROSIS

EVA LEDER, MD, AND HENRY L. DORKIN, MD

INTRODUCTION

Cystic fibrosis (CF), previously known in Europe and first described in the American literature by Anderson, is a relatively common recessive genetic disease, predominantly seen in the Caucasian population. The basic defect, an abnormal cystic fibrosis transmembrane conductance regulator (CFTR) protein, was not elucidated until 1989. In the late 1970s, 50% expected survival was in the 16- to 18-year-old range. However, with the advent of new therapies directed at the pulmonary and gastrointestinal (GI) manifestations of the disease, survival has dramatically improved. Currently, of the approximately 24,000 CF patients listed in the Registry of the Cystic Fibrosis Foundation (CFF), 45% are older than 21 years, with the 50% expected survival now at 39 years of age in the United States. The improved survival, coupled with opportunities for leisure travel and college enrollment far away from their usual health-care providers, means that the presentation in the emergency department (ED) of acute illness in CF patients is likely to increase. While some of these encounters are manifestations of common complaints applicable to the general pediatric population, the setting in the CF patient changes the paradigm. An understanding of the disease and its emergent presentations is important to address these issues and avoid complications arising from unappreciated aspects of CF. Where treatment varies little from that of the same complaint in the non-CF patient, the reader may refer to the appropriate chapters elsewhere in this textbook.

The common emergency presentations can be grouped as systemic, pulmonary, or GI processes. Some of these are single events, while other complaints are recurrent (with similar findings on representation). Knowledge of successful treatment for a previous episode can be quite instructive in understanding how to manage a repeat event.

BACKGROUND

CF, an autosomal, recessively inherited disease, results from genetic mutation on the long arm of chromosome 7. This code for a 1,479 amino acid protein, is the CFTR. The first defect identified was a deletion of phenylalanine at the 508th position (df508). Since that discovery more than 1,500 different defects, variably represented in various ethnic groups, have been elucidated. In addition, modifier genes have been proposed that accentuate or mitigate the expression of the major CF genes, thus possibly explaining phenotypic variability beyond that conveyed by the CF genotype. These defects have maximal impact on cells lining the respiratory tract, the pancreatic exocrine system, the sweat glands, and the intrahepatic biliary epithelium. The defect leads to impaired chloride transport, with resultant altered water movement across the epithelial boundaries. In the respiratory and GI tracts, this leads to dehydrated secretions that are difficult to mobilize. In the sweat duct, it produces highly concentrated sweat. The former leads to inflammation and (in the respiratory tract) chronic infection. The latter results in the loss of electrolyte-concentrating abilities causing excessive electrolyte loss and dehydration.

SYSTEMIC PRESENTATIONS

Hyponatremic, hypochloremic dehydration, while more common in the era before widespread environmental temperature control, still occurs. The mechanism is the loss of electrolyte with sweat, where concentrations of sodium and chloride can be as high as 130 to 140 mEq per L (as compared with 10 to 30 mEq per L in non-CF patients). In the heat of the summer, infants and athletes are most at risk, although such dehydration can occur at any age. It has, in fact, also presented in swaddled babies in the wintertime. Exclusively breastfed infants, whose sodium chloride (NaCl) intake may be lower than that of formula-fed infants, may be even more susceptible. In an earlier era before newborn screening, dehydration was commonly the first presentation of CF and should still raise suspicion of the diagnosis whenever encountered in patients not known to have CF. Signs of dehydration (loss of skin turgor, dry mucus membranes, tenting, irritability, etc.) are usually seen and respond appropriately to standard fluid resuscitation. For those patients without a previous CF diagnosis, it is imperative that electrolyte normalization be achieved before considering diagnostic testing with pilocarpine iontophoresis. Sweat chlorides may not be in the diagnostic range in the setting of electrolyte depletion and may render false results below the diagnostic range. Modest NaCl supplementation can prevent recurrence and is usually given as ~1/7th level teaspoon of salt daily, distributed in an infant's feeds over the course of the day. Older children can be given salt containing foods and educated that the salt intake restrictions that the non-CF population use as part of good health diets must not be applied to them.

RESPIRATORY/CHEST PRESENTATIONS

Chest Pain

Chest pain is a common complaint in patients with CF and can stem from a variety of underlying processes (Table 99.1). When evaluating such a patient in the ED, it is important to formulate

TABLE 99.1

CHEST PAIN IN CYSTIC FIBROSIS PATIENTS

Common	Uncommon	Rare
Costochondritis Pleurisy/pleuritis Pneumothorax Esophagitis Minor trauma	Rib fracture Pulmonary embolism	Cardiac disease

a differential diagnosis based on age, disease severity, and associated symptoms. As always, the underlying cause should be treated rather than simply masking the pain with analgesics. Where such analgesia is needed, care must be taken to avoid untoward side effects. CF patients, through years of aminoglycoside exposure and other nephrotoxic therapies, may not have normal renal function. Renally excreted analgesics therefore should not be used long term without assessment of renal function. Furthermore, narcotic analgesics can cause decreased GI motility. This may, in turn, lead to constipation and bowel obstruction, which can have other implications (vide infra).

Pneumothorax

Spontaneous pneumothorax is a well-known complication in CF patients and is far more common than in the general population. Occasionally a first presentation of CF, it occurs in approximately 1:167 patients yearly; nearly 3.5% of all CF patients will experience a pneumothorax at some point in their lives. Risk of recurrence, on both the ipsilateral and contralateral sides of the hemithorax, is also significantly increased at 20%.

The principal risk factor is the severity of disease, with a mean age of first pneumothorax in the late teens to early 20s. Mucous plugging and air trapping impose increased intrapulmonary air pressure differentials on fibroelastic lung structures weakened from chronic inflammation. Classic symptoms include sudden or subacute onset of sharp chest pain, often referred to the shoulder. Depending on the size of the pneumothorax as well as the patient's respiratory reserve, there can be varying degrees of dyspnea, tachypnea, hypoxemia, and cyanosis. Large pneumothoraces can be appreciated by visual assessment of the chest wall, with differential hyperexpansion of the affected hemithorax. Auscultation for all but small pneumothoraces will demonstrate decreased breath sounds. In the absence of loculation, the altered auscultation will be most evident high in the axilla and in the supraclavicular region. Listening alternately from one hemithorax to the other is the best way to appreciate this physical finding.

Confirmation should be sought with a chest radiograph (CXR), which should include frontal and lateral views (Fig. 99.1). If age is appropriate, inspiratory and expiratory views can also be helpful to define the extent of the extraaveolar air collection. Supine films should be avoided as they are more likely to miss less than a moderate or severe pneumothorax.

While consensus guidelines are currently being developed by the CFF, at present, every CF patient with a newly diagnosed, first pneumothorax should be hospitalized and

FIGURE 99.1 Chest radiograph showing pneumothorax.

observed for a minimum of 24 hours. A minimally asymptomatic patient with a small pneumothorax (less than 1 cm from apex to parietal pleural surface) and no increase in the size of the pneumothorax, auscultatory asymmetry, or pain/dyspnea over the next 24 hours can then be followed as an outpatient until spontaneous resolution. If the patient is symptomatic or the pneumothorax appears to be more than 1 cm from apex to parietal pleural surface, a chest tube should be inserted. The tube may be a pigtail catheter, placed over a guide wire. Negative pressure of up to −20 cm of water should be applied. Very large pneumothoraces are best managed by applying modest suction initially and letting the lung reexpand slowly to avoid reinflation pulmonary edema of the affected tissue (admittedly a rare occurrence).

After chest tube insertion, a new CXR should be obtained to confirm placement and at least partial resolution of the extraalveolar air. There are no current data to support the use of 100% oxygen via face mask to increase the rate of pneumothorax reabsorption in CF patients. Supplemental oxygen should therefore only be used as needed to optimize oxygenation and patient comfort, avoiding excess oxygen exposure in those patients with advanced disease and hypoxic ventilatory drive.

Needle aspiration is indicated only when patients are severely compromised upon presentation and require immediate intervention (e.g., tension pneumothorax). This should be followed by chest tube insertion. In recurrent or persistent cases, the patient should be evaluated for pleurodesis, by personnel from the CF center. While this may prevent recurrence, such intervention may have implications for lung transplant eligibility and should be discussed with physicians having experience in either CF or lung transplantation.

Daily CF therapies, such as chest percussion and postural drainage, oscillatory percussive vest therapy, other airway

clearance techniques (e.g., positive expiratory pressure (PEP) mask, flutter valve), inhalation of dornase alfa, and pulmonary function testing, should be suspended transiently to avoid exacerbating the pneumothorax. Where needed, inhalational therapy with bronchodilators and/or inhaled corticosteroids may be continued with nebulization. The usual inhalational maneuvers with metered dose inhalers probably should be avoided until the pneumothorax is no longer an issue. Timing for reimplementation of the other therapies is determined by observation of pneumothorax resolution/extension and discussion with the patient's CF physician.

Gastroesophageal Reflux Disease

While many patients with CF are on acid suppression [e.g., H2 blocker or protein pump inhibitor (PPI)] for enhancement of exogenous pancreatic enzyme function, the incidence of gastroesophageal reflux disease (GERD) in children with CF is actually as high as 55% in some studies. Acute exacerbations of reflux can cause symptoms of gastritis and esophagitis including significant chest pain in the epigastrium and retrosternal regions. Medications, such as nonsteroidal antiinflammatory drugs (NSAIDs), recent dietary changes and stress and ethanol may exacerbate preexisting GERD. Clinical entities such as hiatal hernia or pulmonary hyperinflation may also predispose the patient to reflux. An empiric trial of acid control may be warranted, but all patients with recurrent symptoms of GERD, including regurgitation and chest pain, should be followed closely after ED discharge. In refractory cases, this leads to referral of the patient to a gastroenterologist for a formal evaluation including upper GI series, pH/impedance probe study, and/or endoscopy with biopsy.

Costochondritis

Costochondritis can be a common cause of chest pain in CF patients with increased intensity and frequency of cough or with certain viral infections with focal, inflammatory effects. The pain is described as sharp, exacerbated by coughing, and readily elicited either by palpation of the costochondral joints directly or by compression of the chest wall/sternum in an anteroposterior or lateral dimension. There is no curative therapy for this self-limited entity. A short course of analgesia can be considered, but care should be taken to inquire about baseline bowel and renal function, as concomitant CF medications may (synergistically with the analgesic) affect these organ systems.

Pleuritis

Pleuritic chest pain can present in CF patients during acute/subacute bacterial exacerbations of CF lung disease or with concomitant viral infection and, where possible, should be differentiated from costochondritis. Such pain is phasic with respiration. It is caused by pleural irritation secondary to inflammation of underlying lung tissue, with visceral pleura rubbing against the parietal pleural surface. The pain usually improves with antibiotic treatment of the underlying infectious process (if bacterial) and oral analgesia, the latter only necessary until the underlying infectious/inflammatory cause is resolving.

Cardiac Pain

Chest pain of cardiac origin is rare in the pediatric CF population, although they are as susceptible as any pediatric patient to entities such as viral pericarditis. While cardiac pain is more common outside the pediatric patient age group, the rare pediatric CF patient with severe pulmonary disease, nonpulmonary pain, and borderline secondary right heart dysfunction should be evaluated with a careful cardiac examination, electrocardiogram, CXR, and echocardiogram. Such patients with chest pain should be admitted for appropriate evaluation and management in consultation with a cardiologist.

Pulmonary Embolism

There is no current literature to suggest an increased incidence of pulmonary embolism (PE) in CF patients. As in any other patient with chest pain, shortness of breath, tachypnea, and possibly pleural effusion, one should entertain this etiology in the differential diagnosis. Depending on the extent of the underlying CF lung disease, even the use of PE protocol computed tomography (CT) scanning may not allow one to unequivocally confirm or refute this entity. Coupled with the propensity of CF patients to have hemoptysis, the risks in using anticoagulation or thrombolytic therapy with more than mild pulmonary disease are not trivial, and these therapies should always be performed in the inpatient setting. Once confirmed, standard management of pulmonary embolism is appropriate (while considering the confounders noted above).

Trauma/Rib Fracture

Schoolyard play and sports can lead to mild thoracic trauma or musculoskeletal injury as in children without CF. However, in patients with malnutrition, rib fracture can occur secondary to predisposing osteopenia. This can also happen in CF patients with overly aggressive chest percussion and postural drainage. Superficial ecchymoses, point tenderness along the rib margin, and evidence for scant subcutaneous fat tissue are suggestive of this entity. Diagnosis can be confirmed radiologically. Treatment is complicated by the need to at least temporarily limit airway clearance, which can lead to increasing airway obstruction. History of fracture or suspicious behavior should also raise the question of child abuse.

Shortness of Breath and Cough in the Absence of Chest Pain

As CF is characterized by impaired mucociliary clearance with concomitant chronic bacterial colonization and infection, recurrent bronchitis/pneumonia is common. Current standard of CF care is to use early maintenance airway clearance coupled with frequent culturing of the airway secretions and appropriate antibiotic therapy. However, most patients have difficulty fully clearing pathogens from the airways and experience chronic, recurrent pulmonary infections and chronic inflammation despite their daily maintenance therapies. An increase in a symptom such as cough or shortness of breath may simply be the sign of an acute viral respiratory tract infection but can also be caused by several other etiologies [e.g., acute exacerbation of progressive CF bacterial lung disease, allergic bronchopulmonary aspergillosis (ABPA), asthma].

Viral Respiratory Tract Infection

Simple viral respiratory infections, as common in the CF patient as in the general population, are often the inciting event for a pulmonary exacerbation. CF patients will be more

likely to suffer increased/prolonged symptoms due to impaired mucociliary clearance and decreased respiratory reserve. It is important to check baseline oxygen saturation and (depending on findings from physical examination) obtain a CXR. Ideally the CXR should be compared with prior studies to differentiate new infiltrates from chronic changes. Even in patients with stable vital signs, oxygenation, and CXR, one may consider a short outpatient course of oral antibiotics if there is suspicion of exacerbation of the underlying CF lung disease (vide infra). It should be explained that such therapy is not directed at the viral infection but only at the superimposed chronic bacterial colonization, so that the parents do not automatically expect an antibiotic with any viral presentation.

Pulmonary Exacerbations of CF Bacterial Lung Disease

The pathophysiological triad of CF lung disease with inflammation, impaired mucociliary clearance, and subsequent chronic airway infection is the starting point for all pulmonary exacerbations. These events are usually associated with decline of lung function and acute worsening of respiratory symptoms. Clinical features of an exacerbation may include any or all of the following: increased cough, change of sputum quality or quantity, shortness of breath, increased work of breathing, loss of appetite, fatigue, and low-grade fever. On examination, the presence of new crackles/wheezes, increased tactile fremitus, and increased hyperinflation may be present. Lung function test changes usually associated with an exacerbation are decrease in forced vital capacity (FVC) and/or forced expiratory volume in 1 second (FEV_1) as compared with the patient's best values in the previous 12 months. In the ED setting, basic vital signs, including pulse oximetry, CXR, and sputum cultures, as well as baseline chemistries and blood counts should be obtained. Oxyhemoglobin saturation is often decreased from baseline values. Frequently, there is leukocytosis. CXR should ideally be compared with prior studies to assess for new infiltrates.

Treatment varies from oral/inhaled antibiotics to parenteral antibiotic treatment, either route being coupled with an increase in aggressive airway clearance. Other medications used chronically for maintenance of lung health may be continued or even increased during treatment of an acute exacerbation of pulmonary disease. Depending on the severity of symptoms, treatment options range from home therapy to hospital admission. Candid assessment of the family's ability to provide the increased care at home must be made. It is important to consider the recent overall course, home situation/adherence, and nutritional history in addition to the acute presentation.

In the case of a mild exacerbation, the patient can be managed at home with a 10- to 14-day course of antibiotics covering the usual organisms affecting CF patients. Here, the knowledge of organisms recovered from the patient in the CF center maintenance program may allow a choice of antibiotics directed against known pathogens specific to the individual patient. Common CF pathogens such as *Haemophilus influenzae* and *Staphylococcus aureus* (including methicillin-resistant *S. aureus*), *Pseudomonas aeruginosa*, *Stenotrophomonas maltophilia*, *Achromobacter xylosoxidans*, and *Burkholderia cepacia* complex require oral, inhaled, or combination therapy. It is important to ensure that the patient has a good airway clearance regimen in place at home, as antibiotics alone will not necessarily achieve the desired improvement.

In the case of a severe exacerbation, intravenous (IV) antibiotics should be initiated and the patient admitted either for a stabilizing period before home therapy completion or for the duration of intense treatment. Antibiotic coverage should be based on prior respiratory culture results and should include double coverage for *Pseudomonas* to limit the chance for the development of drug resistance to a single agent. An increased airway clearance regimen should be initiated. Special attention should be given to the patient's nutritional status and caloric requirements, both of which may deteriorate during acute illness. In patients with endocrine pancreatic insufficiency and CF-related diabetes, blood glucose levels can be more difficult to control during acute exacerbations. While dehydration is to be avoided, judicious fluid use is necessary to avoid mild pulmonary edema, which can easily occur in the setting of hyperinflation, poor oncotic pressure, and multiple IV administrations. Where possible, antibiotics should be concentrated to the smallest volume necessary for administration.

Whether in the ED or in the hospital, care must be given to infection control. Cross infection with various organisms has been demonstrated in many studies, and policies of the CFF have been promulgated to decrease the chance for such transmission. Early acquisition of organisms such as *Pseudomonas* have led to more rapid decline in lung function, and chance acquisition from another patient in the ED would be most unfortunate. Gown and gloves are the minimum standard precautions for CF patient care, with mask added as required for droplet precautions in suspected viral settings.

Wheezing

Wheeze on expiration is a common presentation in the pediatric ED, with acute viral processes, asthma, foreign bodies, and extrinsic airway compression from enlarged nodes/masses high in the differential diagnosis. With the CF patient, the list must include ABPA. ABPA occurs in 1% to 15% of patients with CF. ABPA is an exaggerated type I hypersensitivity reaction to the ubiquitous organism *Aspergillus fumigates*. CD4+ Th2 cells are activated and excess IgE and IgG1 are produced, all of which drive an inflammatory response in the airways. Clinically, patients present with (i) chronic wheeze that is difficult to control, (ii) decline in lung function, (iii) chronic cough, and (iv) transient infiltrates on CXR. Symptoms typically respond well to oral steroids. Any CF patient with recurrent wheezing and cough as well as changes on CXR and decline in lung function not responsive to antibiotic therapy and airway clearance should be evaluated for ABPA. Diagnostic criteria for CF patients include elevated total serum IgE level, positive skin reactivity to *Aspergillus*, and positive specific serum antibodies to *Aspergillus*. Treatment consists of a prolonged course of oral steroids (prednisone or prednisolone), usually starting at a dose of 2 mg per kg per day, with subsequent taper and close follow-up. IgE levels should be followed at regular intervals both as indication of response to therapy and as a warning of reexacerbation. There are no current studies to suggest a clear benefit of antifungal therapy along with steroids, although some physicians use concomitant oral itraconazole therapy in the hope that the course of oral steroids may be shortened.

Hemoptysis

Mild Hemoptysis

Blood streaking of the sputum is common in CF patients and requires no specific treatment other than observation to resolution. Persistent streaking may indicate the onset of a pulmonary exacerbation requiring antibiotic treatment. Other factors such as chronic use of medications with antiplatelet function activity (e.g., aspirin) or coagulopathy secondary to decreased vitamin K levels should be ruled out and treated accordingly. Other sources of bleeding, such as posterior epistaxis or hematemesis, should be ruled out as they require different approaches.

Moderate/Severe Hemoptysis

The CFF's Guidelines for Management of Hemoptysis define hemoptysis as mild (less than 60 cm^3 daily), moderate (more than 60 and less than 240 cm^3 daily), and severe (more than 240 cm^3 daily or more than 100 mL per day for more than 2 days). Severe episodes can be life-threatening due to asphyxiation from airway obstruction, hypotension to the point of overt shock, chronic anemia, and/or chemical pneumonitis. Approximately 1% of CF patients experience an episode of major bleeding per year, the majority of patients being 16 years or older. The bleeding usually originates from enlarged and tortuous bronchial arteries, two-thirds of which arise from the ventral surface of the aorta. The remaining third come from the internal mammary and intercostals arteries. Onset is often unheralded. After initial stabilization of the patient, it is essential to differentiate true hemoptysis from extrathoracic upper airway tract or GI tract bleeding. A history may help to localize a pulmonary bleed as many CF patients notice localized gurgling or other unusual sensation in specific sites. Physical examination may reveal new, localized pulmonary findings or bleeding from an upper airway site such as the nasopharynx. Placing a nasogastric tube or performing endoscopy may become necessary in differentiating GI from pulmonary sources. A CXR can help determine localized changes from previous chest studies, as well as other unusual findings which could explain the bleeding (e.g., a new thick-walled cystic lesion suggesting infection with atypical mycobacterium). Unfortunately, often the CXR is not helpful in localizing the affected site.

The following laboratory tests should be obtained: complete blood cell count/differential, prothrombin time, partial thromboplastin time, liver function tests, arterial blood gas levels, emergency type and cross match, and sputum culture. Bronchoscopy may be necessary to localize the site of bleeding. However, not only can the procedure destabilize the patient further but also it is not always successful. Often, either the patient has stopped bleeding or massive hemorrhage prevents adequate visualization of the main stem/segmental bronchi. The majority of severe pulmonary bleeds in CF are self-limited and can be dealt with by using intensive care unit (ICU) monitoring, vitamin K, blood products, and antibiotics. Nonemergent bronchoscopy is indicated when bleeding appears to be progressive or persistent, and either surgery or local vascular therapy with arterial embolization will be necessary. In that situation, both rigid and flexible bronchoscopy should be available during the procedure in the operating room or ICU.

Ongoing management after hemodynamic stabilization is aided by reassuring and calming the patient. Drugs that could interfere with coagulation including aspirin, NSAIDs, inhaled drugs such as N-acetylcysteine, dornase alfa, and aerosolized antibiotics should be discontinued. Coagulation defects should be corrected with Vitamin K, fresh frozen plasma, or specific factors as indicated. Acute blood loss should be corrected with transfusions as clinically indicated, keeping in mind that patients with severe lung disease may be awaiting lung transplantation at some future date. Care should be taken when possible to obtain blood products prepared in a manner to minimize the risk of posttransplant complications.

As a majority of major bleeds are associated with pulmonary exacerbations, treatment with IV antibiotics may need to be initiated. Placing the lung that appears to be bleeding in the dependent position may help to prevent aspiration into the as yet uninvolved lung. IV therapies to halt bleeding, such as pitressin or octreotide, should be discussed with the pulmonologist or intensivist who will be accepting the admission. Local airway treatment may be indicated in acutely life-threatening situation, such as therapies including endobronchial tamponade, selective double lumen intubation, and iced saline lavage. Timely embolization or access to surgery needs to be organized. When a patient with major hemoptysis is admitted, a surgeon and interventional radiologist should be notified and should be readily available. If that is not possible, referral to another center should be considered.

Respiratory Failure

Thickened airway secretions with bacterial infection, mucus hypersecretion, bronchoconstriction, mucosal edema, inflammation, and fibrosis contribute to respiratory muscle fatigue and can lead to the development of respiratory failure in CF. Patients will present with hypoxia and/or hypercapnia associated with obstructive airway disease. The goal of treatment is to correct gas exchange and acid–base status, which are most likely occurring in the setting of concomitant pulmonary hypertension and cor pulmonale. The initial therapeutic approach should include intensification of antibacterial and airway clearance therapy. The patient should also be evaluated for comorbidities (e.g., atypical infections, ABPA, pneumothorax), which can be precipitating events for acute or subacute decompensation.

Long-term supplemental oxygen therapy should be initiated for patients with chronic hypoxemia. Usually noted first by desaturation while asleep, patients with daytime hypoxia (Pa_{O_2} less than 55 torr or ~88%) need continuous supplemental oxygen therapy to limit development of pulmonary hypertension and right heart failure. Patients with daytime oxygen saturation of more than 88% but less than 92% or early signs of pulmonary hypertension with/without right heart failure should be evaluated for nocturnal desaturation. In any event, supplemental oxygen therapy needs to be introduced with caution in patients with chronic CO_2 retention, to avoid suppressing hypoxic ventilator drive. Initiation of Continuous Positive Airway Pressure or Bi-level Positive Airway Pressure via mask can be helpful in situations of acute decompensation or chronic fatigue and can be very effective when overnight relief is needed. Intubation with assisted ventilation is appropriate when there are reversible causes of respiratory

failure, such as infection, or when lung transplantation is imminent. CF patients with progressive respiratory failure who are not lung transplant candidates and have been aggressively treated with standard therapy in a CF center have very poor chances of survival after intubation and mechanical ventilation is initiated and should be counseled accordingly.

ABDOMINAL PRESENTATIONS

GI problems account for a significant number of primary and secondary problems in patients with CF. Even in this era of CF prenatal diagnosis and neonatal screening, newborn meconium ileus may be the first symptom that leads to the diagnosis of CF. Similarly, in the young child, rectal prolapse or failure to thrive may first bring a patient to medical attention, and these may be first noted in the ED. In older children, recurrent bowel obstructive symptoms may lead to repeated ED visits and hospitalization. Despite the high incidence of CF-specific GI symptoms in this patient population, it is important to maintain a high suspicion for other etiologies such as appendicitis or intussusceptions (vide infra).

Abdominal Pain

Appendicitis

Appendicitis is often difficult to diagnose in patients with CF. Symptoms may be mild or severe, and the presentation may be altered concurrent with respiratory infection antibiotic use. Other etiologies are often considered first and lead to delay in diagnosis. This in turn may lead to an increased incidence of complications such as perforation and periappendiceal abscess formation (Table 99.2). Appropriate attention to the rectal examination and the widespread availability of abdominal CT scan (Fig. 99.2) in the ED makes earlier determination of appendicitis possible in this patient population.

Constipation/Meconium Ileus/Distal Intestinal Obstructive Syndrome

Constipation can be an intermittent or chronic problem in CF patients with pancreatic insufficiency. The earliest manifestation is meconium ileus, which may present to the ED in infants discharged too early (e.g., before passing a stool) from the birthing hospital. Abdominal distension, irritability, and failure to feed in a neonate raise the possibility. More likely, however, this will present in an older infant with a history of stooling, possibly with frequent diarrhea and other manifestations of CF that had not yet been diagnosed.

TABLE 99.2

ABDOMINAL PAIN IN CYSTIC FIBROSIS PATIENTS

Common	Uncommon	Rare
Malabsorption Constipation GERD DIOS Pancreatitis	Appendicitis Cholecystitis	Intussusceptions Inflammatory bowel disease

GERD, gastroesophageal reflux disease; DIOS, distal intestinal obstruction syndrome.

FIGURE 99.2 Radiograph showing constipation.

The consistency of the stool in CF constipation is not that of "rock hard" inspissated stool. Rather, it is a sticky, tenacious material that is very adherent to the bowel wall. Some stool may actually pass by the initial intermittent obstruction, so history of recent stooling should not deter one from considering this diagnosis. In addition, the softer consistency of the stool is such that more frequently than not, no stool is palpable on examination. Thus, a soft abdomen does not rule out constipation and stool retention.

Diagnosis is best made with supine and upright abdominal films (Fig. 99.3), although it should also be evident on CT scan. Localization of the stool retention will help guide therapy (vide infra). In the more advanced case, air–fluid levels, marked distension, and severe abdominal pain may denote the presence of DIOS, or distal intestinal obstruction syndrome. This latter represents a more extensive constipation event and invariably leads to admission despite any initial improvement in the ED.

First treatment should include adequate (although not excessive) hydration. If the stool is predominantly in the descending or transverse colon, a simple enema in the ED may begin removal of the obstruction. After distal stool removal, or in the face of a predominantly ascending colon obstruction, a poorly absorbable hypertonic solution such as GoLYTELY® should be administered. While some older children will drink this, the most reliable method is to pass an nasogastric tube for administration as clearance is much more gradual if the rate of administration is too slow. N-acetylcysteine enemas may be

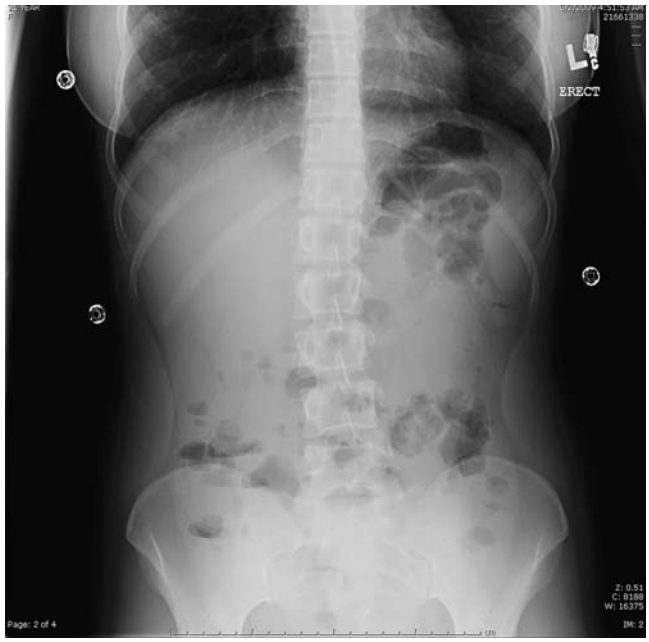

FIGURE 99.3 Radiograph showing distal intestinal obstructive syndrome.

beneficial in some patients. For patients with DIOS, a retrograde, hyperosmolar contrast enema under fluoroscopic guidance from the radiologist may be needed. In this setting, it may be prudent to notify the abdominal surgeon of the case so that in the (unlikely) event of perforation, surgical resources may be mobilized rapidly.

Depending on the degree of obstruction and the rapidity of response, the patient may need to be admitted. Refeeding before complete clearance of stool from the KUB (plain frontal supine radiograph of the abdomen) radiograph may lead to reaccumulation of feces and the need to start the process all over again. It is important to try and determine what led to the obstruction. Did the patient fail to take their oral enzymes? Are the enzyme supplements outdated or damaged (exposed to excessive heat)? Has there been an alteration in diet to more constipating foods? Have sports or summer heat led to relative dehydration or limited access to toilet facilities? Does the patient need the intermittent use of stool-hydrating agents or cathartics? Failure to appreciate such etiologies may lead to representation to the ED a few days or weeks later.

Pancreatitis

Historically, it was thought that acute pancreatitis only occurred in CF patients who were clinically pancreatic insufficient (PI). We now appreciate, however, that even the presence of one CF allele predisposes to a statistically higher incidence of pancreatitis in the general population, and that pancreatitis can occur in PI patients with enough functioning pancreatic tissue to become obstructed and inflamed. Precipitating events are not very different from those of non-CF patients, and this is complicated by the fact that CF patients are often on high-fat diets to promote weight gain. Elevations of amylase and lipase levels are usually noted, although because of preexisting pancreatic insufficiency, the levels reached may be lower than expected in non-CF pancreatitis. As patients age and have recurrent episodes of pancreatitis, both the intensity of symptoms and the levels of lipase/amylase elevation decline. Eventually, the exocrine pancreas is completely destroyed to the point where the patient no longer has enough functioning tissue to be symptomatic from pancreatitis.

Gastroesophageal Reflux with Esophagitis

Reflux, often clinically asymptomatic, has been recognized in CF patients since the early 1980s. It is not surprising, given the hyperinflation, increased coughing with resultant elevated intraabdominal pressures, and use of agents that may decrease lower esophageal tone. When pain presents, it will be either as chest pain or as subxiphoid pain. It is usually not influenced by phase of respiration but can be excruciating. If considered, one can treat with an antacid preparation to see if there is transient relief. Assuming no GI bleeding is active at the time of presentation, appropriate management with H2 blockers or PPIs can be started. At the present time, many CF patients are already on such agents because of the improvement in exogenous pancreatic enzyme supplement function. Routinely, if CF patients require higher doses of supplemental enzymes to resolve their steatorrhea and gain weight, such agents are added to alkalinize the duodenal environment. Presence of such an agent in the patient's medication list should not of itself remove the diagnosis from consideration. Some patients are not as consistent in taking these medications as they should be, and not all specific PPIs work well in individual CF patients. Sometimes several different PPIs have to be tried before the desired response is noted.

Cholecystitis

Thirty percent of all CF patients have a small, hypotrophic gall bladder filled with sludge. This is due in part to the intrahepatic biliary epithelium defect for CFTR transport, the same defect seen in airway and pancreatic cells. The stones are often difficult to visualize and may require discussion with the radiologist as to how best to visualize them. In older patients (both with and without CF), medical treatment is only symptomatic and frequent manifestation of cholecystitis often leads to cholecystectomy.

Other Causes of Abdominal Pain

Patients with CF are no more, and no less, likely to develop adhesions postoperatively than are others. Occasionally, patients with a history of meconium ileus surgery earlier in life may develop signs of intestinal obstruction either without stool retention or unresponsive to therapy directed at such a cause. Abdominal CT scan may be useful in ascertaining whether this or other less common causes of CF abdominal pain (intussusception, inflammatory bowel disease, etc.) may be etiologic. Treatment, either medical or surgical as indicated, does not differ from that of the non-CF population.

GI Bleeding

Although not common in CF patients, GI bleeding can occur in a subset of the patient population. Because of malabsorption of vitamin K, some patients do not have normal clotting function. While this usually manifests as either frequent ecchymoses or airway hemorrhage, a few patients may have minor bleeding from GI sources (e.g., esophagitis). However, a small

fraction of CF patients have cirrhosis and develop bleeding varices or hemorrhoids. The etiology is the CFTR defect in the intrahepatic biliary epithelium, which leads to bile stasis and fibrosis. Onset of CF liver disease can be subtle and missed despite CFF mandated quarterly abdominal examinations and yearly phlebotomy. Sometimes the first presentation is an enlarging spleen, or even a GI bleed.

Such hemorrhage can be quite significant, and any evaluation of GI bleeding for common causes has to include evaluation for cirrhosis with varices. Any CF patient with GI bleeding needs to have the cause elucidated, and in the ED, this may require complete blood cell count/differential, prothrombin time, partial thromboplastin time, fat-soluble vitamin levels (to evaluate absorption in general), and either CT scan or abdominal ultrasound. Standard approaches for blood replacement and hemodynamic stabilization with admission to the ICU are appropriate. Immediate and long-term follow-up with the gastroenterologist/hepatologist, if not already part of the patient's care profile, should be in place. Endoscopy, either investigative or for treatment of esophageal varices, is often necessary.

FOLLOW-UP CARE

The majority of CF patients in the United States are followed in CFF approved and supported CF centers. All centers' contact information is available at the CFF Web site (http://www.cff.org). Close contact between emergency physicians and the CF center team caring for this patient population facilitates continuity of care and hopefully diminishes representation to the ED for recrudescence of the presenting problem. Transmission of radiographs, laboratory results, and evaluation summaries will be much appreciated by the CF care team. At the same time, CF center physicians are on call and always available to provide information about their patients to the physicians in the ED providing acute care.

CHAPTER 100 ■ RENAL AND ELECTROLYTE EMERGENCIES

NANCY M. RODIG, MD

DEHYDRATION/HYPOVOLEMIA

Background

Clinically significant hypovolemia occurs more commonly in children than in adults, and this is predicted given characteristics specific to the pediatric patient. Predisposing factors include a higher frequency of acute gastroenteritis (AGE) in children when compared to adults, a higher surface area-to-volume ratio in children with proportionally higher insensible losses, and the inability to access adequate fluids to replenish losses given developmental limitations. Volume depletion will develop as fluid lost from the extracellular space is inadequately replaced. Losses may ensue from the gastrointestinal tract, skin, or kidneys. Far less frequently, volume depletion may result when fluid intake is inadequate to provide maintenance requirements necessitated by caloric intake without excessive losses, which may occur in those who are supported with enteral tube feedings.

Gastrointestinal loss is the most common cause of pediatric hypovolemia, and viral AGE accounts for the majority of cases. Database analysis studying disease burden in the United States and Europe reveals that diarrhea was associated with approximately 4% of emergency department visits. Rotavirus-positive AGE is generally more severe than rotavirus-negative AGE, resulting in more significant dehydration and increased need for emergency room assessment and hospitalization. Rotavirus-associated diarrhea has been estimated to be associated with 4% to 5% of all childhood hospitalizations.

Clinical Manifestations

The initial assessment of a child with hypovolemia will include history and thorough physical examination. A careful history should establish the cause of hypovolemia, duration of illness, and approximate volume and composition of fluid taken in and retained. Inquiries regarding urine production, one indication of intravascular volume, should be made. Potential causes of increased insensible losses, such as fever and tachypnea, should be accounted for.

The physical assessment should include an accurate weight, and the weight should be remeasured if ongoing losses are significant and difficult to quantify. A change in weight from a recent healthy baseline, if available, would provide an objective account of the degree of depletion. Assessment of intravascular volume should include the pulse quality and rate, blood pressure, hydration of mucous membranes, skin turgor, mental status, and activity. Mild hypovolemia (3% to 5% volume loss) may be associated with minimal or absent clinical signs. Moderate hypovolemia (6% to 9% volume loss) will have clinical signs apparent, which may include tachycardia, fall in blood pressure with orthostatic accentuation, dry mucous membranes, and delayed capillary refill time. A systematic review of published data reported by Steiner et al. revealed that the most useful individual signs for predicting 5% hypovolemia in children were delayed capillary refill time, abnormal skin turgor, and deep respiratory pattern. A combination of examination signs provided the best predictive data. In the setting of severe dehydration (greater than or equal to 10% volume loss), evidence of shock may be apparent. Severe hypovolemia requires immediate attention with aggressive isotonic fluid resuscitation and the reader is referred to Chapter 3 to review the management of shock. Clinical dehydration scales have been published and recently validated for children with AGE.

Though laboratory assessment has been shown to be less useful than physical findings when predicting the degree of volume depletion, laboratory testing can identify associated electrolyte and acid–base abnormalities. Classification of the type of hypovolemia based upon the serum sodium (Na) may impact subsequent fluid therapy and monitoring. The serum Na concentration is determined by the ratio between total body solutes and total body water (TBW). Solute is primarily composed of sodium salts in the extracellular fluid (ECF) and potassium salts in the intracellular fluid (ICF). The presenting serum Na in the child with hypovolemia results from the loss of solute relative to water during the illness. Determinants of the serum Na include the type of fluid lost, the composition of fluid provided prior to presentation, and the ability to excrete water during the illness.

Hyponatremic hypovolemia (serum Na less than 135 mEq per L) reflects the net loss of solute in excess of water. Solute is never lost in excess of water in any physiologic fluid, as losses can never be hypertonic to plasma. Hyponatremia results when water taken in is retained due to the effect of antidiuretic hormone (ADH), which is secreted due to the stimulation of volume receptors for ADH release. Additional stimuli of ADH secretion identified in children with gastroenteritis include vomiting, hypoglycemia, and stress. Isonatremic hypovolemia (serum Na 135 to 145 mEq per L) results when solute is lost in proportion to water, and hypernatremic hypovolemia (serum Na greater than 145 mEq per L) reflects net loss of water in excess of solute. The sodium plus potassium concentration of diarrheal fluid in viral gastroenteritis is typically less than 100 mEq per L, representing relatively hypotonic losses. Despite the

relatively dilute losses, the majority of cases of hypovolemia caused by viral gastroenteritis are isonatremic.

Other biochemical abnormalities that may develop during hypovolemia include disorders of potassium homeostasis, acid–base abnormalities, and increased blood urea nitrogen and creatinine, reflecting a decline in glomerular filtration rate (GFR). Though hyperkalemia may result, hypokalemia is more commonly seen in children with gastroenteritis given the loss of potassium in diarrheal fluid and urine. Urine losses of potassium may be generous and driven by aldosterone. The effect of aldosterone is to conserve urinary sodium to maintain effective intravascular volume and promote potassium excretion. Alternatively, marked acidosis may favor the development of hyperkalemia due to transcellular shift of potassium ions. During acidosis hydrogen ions enter the intracellular space to be buffered, and potassium moves to the extracellular space to maintain electroneutrality. If a child presents with hypovolemia and acidosis, one may expect that the serum potassium will fall with correction of the acidosis. Therefore, if hypokalemia and acidosis are concurrent abnormalities at presentation, hypokalemia may worsen with resolution of acidosis, or hypokalemia may develop despite initial normal serum potassium concentration. Physicians should be prepared to provide supplemental potassium if appropriate. If the patient is oligoanuric or renal function is significantly compromised, excessive potassium supplementation may cause hyperkalemia.

Management

The treatment of children with dehydration should be guided by the following inquiries: (i) Is there need for emergent fluid therapy? (ii) Is there an abnormality of the serum Na? (iii) Should fluid be provided by the oral or intravenous route? The aims of treatment are to restore perfusion and maintain adequate volume in the face of ongoing losses. Approaching fluid management with a plan for initial repletion therapy followed by ongoing maintenance therapy may be useful. The repletion phase may require emergent fluid resuscitation, and therefore may be considered in two phases if necessary—emergent repletion and ongoing repletion.

Oral therapy, when tolerated, is recommended by the American Academy of Pediatrics as the preferred treatment of fluid and electrolyte losses in children with mild to moderate diarrhea. The following will focus on intravenous fluid therapy, and the reader is referred to Chapter 17 for more extensive discussion regarding recommendations for oral rehydration therapy (ORT). In general, limitations to ORT include severe dehydration, altered mental status, abdominal ileus or disorders that limit intestinal absorption, severe and persistent vomiting, excessive stool losses and severe electrolyte abnormalities.

Emergent Fluid Repletion

Patients who have moderate or severe hypovolemia will have compromised effective circulating volume, and rapid volume resuscitation is required to restore perfusion and avoid tissue damage. Emergent intravenous fluid therapy should be provided with a rapid infusion of 20 mL per kg of isotonic crystalloid, such as 0.9% sodium chloride (NS) or NS with 5% dextrose (D5% NS). Assessment of the patient's perfusion during and at completion of the intravenous bolus is imperative in order to determine if additional bolus therapy is indicated. Isotonic crystalloid fluid is the only solution recommended for emergent fluid repletion, and the use of hypotonic or hypertonic crystalloid solutions in emergent resuscitation is not recommended. Currently, there is inadequate data to support the use of colloid-containing solutions during resuscitation in the general population. However, patients with decreased oncotic pressure due to illnesses such as nephrotic syndrome or cirrhosis may benefit from a colloid solution if they present with hypovolemia. In these patients, initial bolus therapy with 5% albumin may be beneficial. In addition to monitoring the physical exam for evidence of adequate perfusion, establishment of urine flow would be reassuring. The urine flow in response to therapeutic interventions should be clearly documented.

Ongoing Repletion and Maintenance Therapy

Once effective circulating volume has been adequately restored, the second phase of fluid therapy corrects persistent deficits, replaces ongoing losses, and provides maintenance fluids. In cases of hypotonic or isotonic hypovolemia, there are various approaches to this phase of therapy, including the traditional "deficit" therapy for which the composition of the fluid is based upon estimates of depletion and therapy based upon isotonic intravenous fluid. Deficit therapy is a method of replacing previous fluid losses while providing the expected maintenance requirements for water and electrolytes. The water deficit may be estimated by the fall in body weight, and this estimate is most accurate if a recent baseline weight is known. The Na deficit can be estimated by the following equation using the serum Na concentration and estimates of TBW:

$$\text{Na deficit} = [\text{TBW(n)} \times 140\ \text{mEq/L}] - [\text{TBW(c)} \times \text{serum Na}]$$

In this calculation, TBW(n) is the estimated normal TBW, TBW(c) is the estimated current TBW, and serum Na is the serum Na concentration. The normal TBW in term neonates, toddlers, and older or pubertal children is approximately 75% to 80%, 65% to 70%, and 60% of body weight, respectively. The current body water is estimated by considering the degree of dehydration. For example, if a healthy child's TBW content is approximately 60% of weight, then in the setting of severe dehydration, the current body water may be 50% of weight. The maintenance requirement for water in children is based upon the estimated caloric expenditure of hospitalized children at bed rest as described in Holliday and Segar's landmark paper published in 1957. The calculations based upon this are outlined in Table 100.1 and can serve as a starting point to provide maintenance needs.

TABLE 100.1

WEIGHT-BASED DAILY MAINTENANCE FLUID FOR CHILDREN

Body weight (kg)	Daily fluid requirements
3.5–10 kg	100 mL/kg/day
11–20 kg	1,000 mL + 50 mL/kg (for each kg >10), maximum 1,500 mL/day
>20 kg	1,500 mL + 20 mL/kg (for each kg >20), typical maximum 2,400 mL/day

Though common practice has been to provide hypotonic maintenance fluids based upon deficit calculations and maintenance requirements, recent reports have highlighted the potential risks of acquired hyponatremia. Of note, some reports pointing to this risk have included postoperative patients. A group of children who presented to a tertiary pediatric hospital with hypovolemia due to presumed gastroenteritis were randomly assigned to receive hypotonic (0.45% NS with 2.5% dextrose) or isotonic fluid (0.9% NS with 2.5% dextrose). Hyponatremia was a common finding, noted in 36% of patients at presentation. Of the children presenting with hyponatremia, the serum Na was unchanged with hypotonic solution and increased from approximately 132 to 134 mEq per L with isotonic solution after 4 hours of rehydration. Of the children who presented with isotonic hypovolemia, the serum Na fell approximately 2 mmol per L after hydration with hypotonic fluid and was unchanged after hydration with isotonic solution. Nonosmotic stimuli for ADH release would predispose to positive water balance and hyponatremia. Some have proposed that isotonic fluid be continued in the ongoing repletion and maintenance phase of therapy with periodic assessment of serum Na to determine if further adjustment in fluid composition is warranted. The risks of sodium excess, inadequate free water provision during ongoing hypotonic losses, and hypernatremia must be considered. Rapid rehydration schemes have been put forth for cases of moderate or severe hypovolemia and recommend expanding the ECF with 40 mL per kg over 1 to 2 hours utilizing lactated Ringer's solution or normal saline. Additional isotonic therapy of 20 to 40 mL per kg over 1 to 2 hours is provided if warranted by physical assessment of perfusion. The potential benefits of rapid rehydration include restoration of the ECF with improved gastrointestinal and renal perfusion. Improved gastrointestinal perfusion may allow earlier oral hydration. Currently there are inadequate data to support the use of isotonic solution as the new "standard of care" for ongoing fluid repletion and maintenance therapy in hypovolemia. Further studies are needed to compare the efficacy and safety of differing fluid regimens.

Of importance is the recognition of potential potassium deficit when planning fluid therapy. Potassium is the principal cation of the ICF and contributes to the maintenance of intracellular tonicity. The ICF contains approximately 98% of the body potassium, and the serum potassium concentration does not adequately reflect total body stores. There is no practical means of calculating the potassium deficit. When calculating the Na deficit as outlined above, this actually reflects *total cation* (Na^+ and K^+) deficit lost from the extracellular and intracellular compartments. The majority of patients with hypovolemia will present after a brief illness, which typically has persisted for less than 1 week. If the illness has been ongoing for less than 3 days, historical estimates suggest that 75% to 100% fluid losses arise from ECF (primarily sodium loss). As the duration of the illness lengthens to beyond 3 days, a greater proportion of fluid is lost from the ICF (primarily potassium loss) with approximately 60% to 75% lost from the ECF.

The following tables (Tables 100.2 through 100.4) provide examples of isonatremic, hyponatremic, and hypernatremic hypovolemia and outline an approach to fluid therapy. The examples assume that the duration of illness has been brief, and therefore, potassium losses from the ICF are relatively small compared to sodium losses from the ECF. For illnesses of longer duration, 20% to 40% of the total cation deficit may be potassium and would require less sodium and more potassium repletion. For the examples of isotonic and hypotonic hypovolemia, the deficit is corrected over the first 24 hours. Traditional schemes of replacing one half of the remaining deficit over the first 8 hours and the remainder over the next 16 hours for isotonic hypovolemia and replacing about two thirds of the deficit in the first 24 hours for isonatremic hypovolemia may be applied.

TABLE 100.2

ESTIMATED DEFICITS AND INTRAVENOUS THERAPY: 10 kg CHILD WITH 10% HYPOVOLEMIA AND SERUM SODIUM 140 mEq/L

Water and sodium (Na) deficits
Water deficit: 10 kg × 10% = 1 L
Na deficit: 1 L × 140 mEq/L = 140 mEq

Emergent fluid repletion with NS or D5% NS
20 mL/kg × 10 kg = 200 mL (200 mL water and ≈30 mEq sodium)

Ongoing repletion and maintenance requirements
Remaining water deficit: 1,000 mL − 200 mL = 800 mL
Daily maintenance water requirement: 100 mL/kg/day × 10 kg = 1,000 mL/day
800 mL + 1,000 mL = 1,800 mL/24 h = 75 mL/h
Remaining Na deficit: 140 mEq − 30 mEq = 110 mEq
Maintenance sodium requirement: 3 mEq/100 mL water × 1,000 mL/day = 30 mEq/day
110 mEq + 30 mEq = 140 mEq/24 h
140 mEq/1,800 mL ≈ 0.45% sodium chloride (½ NS)
Maintenance potassium requirement: 3 mEq/100 mL water × 1,000 mL/day = 30 mEq/day
30 mEq/1,800 mL ≈15–20 mEq/L
Intravenous fluid based upon deficit calculations:
D5% 1/2 NS with 20 mEq/L KCl at 75 mL/h

Ongoing losses
Extrarenal losses should be replaced mL-for-mL if volumes are significant.
The sodium content of the fluid lost should be estimated or measured in order to select the appropriate replacement fluid.

Isonatremic Hypovolemia

Table 100.2 outlines the estimated deficits and therapeutic approach of a 10-kg child with isotonic hypovolemia. In this example, the isotonic deficit is corrected by an initial bolus of isotonic saline followed by ongoing repletion. The traditional approach of deficit calculation and therapy is outlined. Replacement of ongoing extrarenal losses should be provided if the volume of losses is significant and increased free water provision may be necessary should ongoing gastrointestinal losses be significant in order to avoid hypernatremia. The importance of strict monitoring of fluid balance is emphasized and repeated assessment of the serum Na may be indicated on the basis of losses and duration of intravenous therapy.

TABLE 100.3

ESTIMATED DEFICITS AND INTRAVENOUS THERAPY: 10 kg CHILD WITH 10% HYPOVOLEMIA AND SERUM SODIUM 125 mEq/L

Water and sodium deficits
Water deficit: 10 kg × 10% = 1 L
Sodium deficit: [TBW(n) × 140 mEq/L] − [TBW(c) × 125 mEq/L]
TBW(n) = 10 kg × 65% = 6.5 L
TBW(c) = TBW(n) − water deficit = 6.5 L − 1 L = 5.5 L
Sodium deficit: (6.5 L × 140 mEq/L) − (5.5 L × 125 mEq/L) ≈ 220 mEq

Emergent fluid repletion with NS or D5%NS
20 mL/kg × 10 kg = 200 mL (200 mL water and ≈30 mEq sodium)

Ongoing repletion and maintenance requirements
Remaining water deficit: 1,000 mL − 200 mL = 800 mL
Daily maintenance water requirement: 100 mL/kg/day × 10 kg = 1,000 mL/day
800 mL + 1,000 mL = 1,800 mL/24 h = 75 mL/h
Remaining sodium deficit: 220 mEq − 30 mEq = 190 mEq
Maintenance sodium requirement: 3 mEq/100 mL water × 1,000 mL/day = 30 mEq/day
190 mEq + 30 mEq = 220 mEq
220 mEq/1,800 mL ≈120 mEq/L
Maintenance potassium requirement: 3 mEq/100 mL water × 1,000 mL/day = 30 mEq/day
30 mEq/1,800 mL ≈15–20 mEq/L KCl
Intravenous fluid based upon deficit calculations:
D5% with 120 mEq/L NaCl and 20 mEq/L KCl at 75 mL/h
Given the availability of standard solutions in emergency departments, D5%NS *with added potassium* could be provided for the initial half of the total volume and completed with D5%1/2 NS *with added potassium*.

Ongoing losses
Extrarenal losses should be replaced mL-for-mL if volumes are significant.
The sodium content of the fluid lost should be estimated or measured in order to select the appropriate replacement fluid.

TABLE 100.4

ESTIMATED DEFICITS AND INTRAVENOUS THERAPY: 10 kg CHILD WITH 10% HYPOVOLEMIA AND SERUM SODIUM 155 mEq/L

Water and sodium deficits
Total water deficit: 10 kg × 10% = 1 L
TBW(c) = TBW(n) − 1 L = (10 kg × 65%) − 1 L = 5.5 L
Free water deficit: TBW(c)[(155/140) − 1] = 5.5[(155/140) − 1] = 0.59 L
Isotonic deficit = total water deficit − free water deficit = 0.41 L
Sodium deficit: 0.41 L × 140 mEq/L ≈ 60 mEq

Emergent fluid repletion with NS or D5%NS
20 mL/kg × 10 kg = 200 mL (200 mL water and ~30 mEq sodium)

Ongoing repletion and maintenance requirements
Remaining total water deficit: 1,000 mL − 200 mL = 800 mL, plan to replace over 36–48 h or 400 mL/day × 2 days
Daily maintenance water requirement: 100 mL/kg/day × 10 kg = 1,000 mL/day
1,000 mL + 400 mL = 1,400/24 h or ≈60 mL/h
Remaining sodium deficit: 60 mEq − 30 mEq = 30 mEq
Maintenance sodium requirement: 3 mEq/100 mL water × 1,000 mL/day = 30 mEq/day
Total sodium requirement: 30 mEq + 30 mEq = 60 mEq
60 mEq/1,400 mL or ≈0.225% sodium chloride
Maintenance potassium requirement: 3 mEq/100 mL water × 1,000 mL/day = 30 mEq/day
30 mEq/1,400 mL ≈20 mEq/L KCl
D5% 1/4 NS with 20 mEq/L KCl at 60 mL/h for ~36–48 h

Ongoing losses
Extrarenal losses should be replaced mL-for-mL if volumes are significant.
The sodium content of the fluid lost should be estimated or measured in order to select the appropriate replacement fluid.

Hyponatremic Hypovolemia

Children with mild to moderate hyponatremia should be provided isotonic or near-isotonic fluids to both complete the repletion phase and continue the maintenance phase of intravenous fluid therapy. Providing hypotonic fluid in the setting of persistent decreased intravascular volume and acute illness with osmotic and nonosmotic stimuli for ADH secretion may perpetuate or worsen hyponatremia. Isotonic saline will correct the volume depletion and raise the serum Na concurrently. When intravascular volume is restored, the volume stimulus for ADH secretion will be removed and will allow the renal excretion of free water. The therapy of asymptomatic hyponatremia requires gradual correction of the serum Na with a target increase of less than 10 to 12 mEq per L per day.

Table 100.3 estimates the sodium and water deficits and outlines a plan for fluid management of a child with hyponatremic hypovolemia and serum Na of 125 mEq per L. As in the previous example, the deficits are replaced by an initial bolus and then completed over the next 24 hours. Of note, the composition of the intravenous fluid based upon deficit calculations with added potassium chloride (120 mEq per L Na^+ + 20 mEq per L K^+) is an isotonic fluid. Potassium is osmotically active, and infused potassium will move to the intracellular space in exchange for sodium to the extracellular space, promoting an increase in the serum Na concentration. Therefore, if the rate of rise of the serum Na is greater than targeted (10 to 12 mEq per L per day), the concentration of sodium in the intravenous fluids should be reduced. The need for serial assessment of serum Na concentration in order to make appropriate adjustments to fluid composition is again emphasized.

For children with severe hyponatremia (i.e., serum Na less than 125 mEq per L) and hypovolemia, volume resuscitation should proceed with isotonic solution to restore effective circulating volume. However, given mechanisms of cellular adaptation to maintain normal cell volume in brain cells, rapid correction of the serum Na should be avoided. The therapy of severe hyponatremia or symptomatic hyponatremia is discussed further in the section "Hyponatremia."

Hypernatremic Hypovolemia

In children who present with hypernatremic hypovolemia, the total fluid deficit is composed of both a free water deficit and an isotonic deficit. A pure water deficit is consistent with dehydration. Hyperosmolality initially promotes water movement out of the cells, including brain cells. Over several days, idiogenic osmols are generated within the brain cells, prompting water movement into the intracellular space and restoring normal brain volume. Once cerebral adaptation has occurred, rapid correction of the serum Na can result in cerebral edema and severe neurologic consequence. The goal of therapy in children with a serum Na concentration above 150 mEq per L is to correct the hypernatremia at a rate of less than 10 to 12 mEq per L in 24 hours. The total fluid deficit can be inferred by the estimated weight loss. Calculation of the free water deficit is based upon the serum Na and estimated current body water,

$$\text{Free water deficit} = \text{TBW(c)} \times [(\text{serum Na}/140) - 1]$$

The difference between the total fluid deficit and the free water deficit is the estimated isotonic deficit. After the patient has received the initial isotonic fluid bolus to emergently restore intravascular volume, subsequent therapy should correct the remaining isotonic deficit, free water deficit, ongoing losses, and maintenance requirements. Depending on the acuity and severity of the process, the free water deficit should be replaced gradually to allow judicious correction of the serum Na at the desired rate. Table 100.4 estimates the sodium and water deficits and outlines a plan for fluid management of a child with hypernatremic hypovolemia and serum Na of 155 mEq per L. The Na deficit is calculated on the basis of the isotonic deficit. Alternatively, the Na deficit can be calculated using the serum Na and estimates of TBW as previously reviewed.

ELECTROLYTE DISORDERS

Disorders of Sodium Homeostasis

Sodium salts are the predominant solutes in the extracellular space. The serum Na concentration is directly related to the total body solute content and inversely related to the TBW. Given this relationship, the plasma sodium concentration will vary depending on changes of the either total body sodium or TBW. All body compartments are freely permeable to water, and water will move along an osmotic gradient. Sodium is cell membrane permeable, though remains predominantly in the extracellular space due to the action of Na^+–K^+-ATPase.

Hyponatremia

Background. Hyponatremia is commonly defined as a measured serum Na concentration less than 135 mEq per L. When approaching a patient with hyponatremia, it is necessary to estimate the patient's total body sodium and water based on history and physical exam. Gastroenteritis is a common cause of hyponatremia presenting for pediatric urgent or emergent care, which would be a state of total body sodium deficiency relatively greater than TBW deficiency. However, as outlined in Table 100.5, there are numerous causes of hyponatremia associated with normal or increased total body sodium, including states of impaired water excretion such as renal failure and the syndrome of inappropriate antidiuretic hormone (SIADH) secretion. It is critical to assess for underlying causes associated with increased total body sodium and water, as in the edema-forming states. In these clinical circumstances, providing supplemental sodium would aggravate the state of volume excess.

Appropriate evaluation to determine the cause of hyponatremia begins with a thorough physical examination in order to estimate the child's volume status. History may reveal obvious sources of sodium loss or raise the concern for water intoxication. Laboratory tests should include serum electrolytes, osmolality, and assessment of renal function. Concomitant urine studies should include osmolality, urine sodium, and urinalysis. In children with hyponatremia and concentrated urine, the urine sodium may distinguish between states of decreased effective circulating volume and euvolemic hyponatremia, such as the SIADH. In the setting of decreased effective circulating volume, the urine sodium concentration is generally less than 25 mEq per L, which is an appropriate renal response to maintain perfusion. Patients with SIADH have impaired free water excretion, though urine sodium handling is intact and dependent on sodium intake. In patients with SIADH, the urine sodium concentration is generally greater than 40 mEq per L. Further studies to investigate the underlying cause of hyponatremia are guided by clinical assessment and consideration of the differential diagnosis.

TABLE 100.5

CAUSES OF HYPONATREMIA BASED UPON TOTAL BODY SODIUM CONTENT

Low total body sodium	Normal total body sodium	High total body sodium
Diarrhea	SIADH	Congestive heart failure
Vomiting	Adrenal insufficiency	Nephrotic syndrome
Ostomy losses	Hypothyroidism	Liver failure (cirrhosis)
Bleeding	Acute renal failure	Multiorgan dysfunction
Diuretic use	Water intoxication	
Mineralocorticoid deficiency	Psuedohyponatremia	
Salt wasting renal disease		
Cystic fibrosis		
Marathon running		

Clinical Manifestations. The symptoms attributable to hyponatremia are primarily neurologic and due to water movement into brain cells. The symptoms mirror the severity of cerebral edema, which in turn is related to the degree of hyponatremia and the acuity of the process. The mechanisms of cellular adaptation include movement of intracellular electrolytes to the extracellular space, which can occur within minutes. Over hours to days, organic solutes move to the extracellular space. Given the ability for cerebral adaptation, the degree of cerebral edema and neurologic symptoms are less severe in chronic hyponatremia. Early neurologic symptoms include nausea and malaise, and may be seen when the serum Na concentration falls below 125 mEq per L. With progressive derangement of cerebral cell volume, symptoms of headache, altered mental status, lethargy, ataxia, and psychosis may ensue. Signs of severe cerebral edema include seizures, coma, and respiratory depression.

Management. For children with hyponatremia associated with hypovolemia, isotonic solutions should be provided to restore intravascular volume. In cases of severe hyponatremia (i.e., serum Na less than 125 mEq per L), symptoms of neurologic dysfunction due to cerebral edema may evolve. Children with symptomatic hyponatremia require urgent treatment to avoid progressive neurologic complications. Symptoms are more likely to develop if hyponatremia evolves rapidly, as water will move along an osmotic gradient from the extracellular space to the intracellular space. Given the effect of cell volume regulatory mechanisms, an important goal is to control the rate of rise in serum Na to prevent rapid fluid shifts into the extracellular space and avoid the development of osmotic demyelination. The general recommendation for a child with severe hyponatremia is to increase the serum Na no more rapidly than 12 mEq per L in the first 24 hours or an average of 0.5 mEq per L per hour. An exception to this guideline would be symptomatic hyponatremia and evolving cerebral edema. Symptomatic hyponatremia would call for a more aggressive initial correction of the serum Na of approximately 2 mEq per L per hour for 2 to 3 hours, which should result in clinical improvement. This can be achieved with hypertonic or 3% saline (513 mEq per L of sodium). As an example, the calculation for the dose of sodium required to increase the serum Na by 4 mEq per L in a symptomatic patient is

$$\text{Na (mEq)} = \text{TBW(c)} \times 4 \text{ mEq/L}$$

Once the dose of sodium is estimated, the volume of 3% saline can be calculated as each mL contains approximately 0.5 mEq of sodium. After the initial correction is achieve, the goal for the daily correction remains approximately 12 mEq per L in the first 24 hours (including the initial emergent correction). Frequent assessment of serum Na is necessary to avoid rapid correction, which may lead to the osmotic demyelination syndrome.

Patients who have asymptomatic hyponatremia and euvolemia do not require urgent intervention. The care of these patients should be carefully planned and based upon the underlying diagnosis with the aim of gradual correction. If hyponatremia is associated with an edema-forming state, providing supplemental sodium will worsen the state volume excess, and the goal of therapy would be to achieve negative water balance in excess of negative sodium balance. To achieve this effectively, the underlying pathophysiology must be considered, though initial water restriction is generally indicated. Sodium restriction and diuretic therapy may also be warranted. The treatment of SIADH begins with water restriction, though this may be insufficient. Some cases of SIADH require the administration of salt supplements and loop diuretics to achieve the desired negative water balance. Loop diuretics interfere with the countercurrent concentrating mechanism in the loop of Henle and impair the renal responsiveness to ADH.

Hypernatremia

Background. Hypernatremia is defined as a serum Na greater than 145 mEq per L. An increase in the serum Na can result from an increase in the total body solutes, a decrease in body water, or a reduction of body water relatively greater than a concurrent reduction in total body solutes. Protective mechanisms to prevent the development of hypernatremia include the stimulation of thirst and the ability to excrete concentrated urine, thereby minimizing free water loss. For these mechanisms to be effective, there must be adequate access to and the ability to retain free water. Given the potential for limited access to water, infants and the elderly are predisposed to hypernatremic dehydration. The causes of hypernatremia based on total body sodium are outlined in Table 100.6. Hypernatremia due to isolated water deficit is termed dehydration. If both salt and water deficits are present, this condition is termed hypovolemia.

Diarrhea is a common cause of hypernatremia in the urgent or emergent care setting. Though the degree of Na deficit may vary, generally children who present for care have

TABLE 100.6

CAUSES OF HYPERNATREMIA BASED UPON TOTAL BODY SODIUM CONTENT

Low total body sodium	Normal total body sodium	High total body sodium
Diarrhea	Increased insensible losses	Salt poisoning
Vomiting	Fever	Inappropriately mixed formula
Ostomy losses	Prematurity	Salt water drowning
Osmotic diuresis	Phototherapy	$NaHCO_3$ given with CPR
Immature renal conservation (prematurity)	Radiant warmers	
	Tachypnea	
	Nephrogenic DI	
	Central DI	

$NaHCO_3$, sodium bicarbonate; CPR, cardiopulmonary resuscitation; DI, diabetes insipidus.

true hypovolemia. Though hypernatremia due to salt excess is rare, this can occur with the improper mixing of infant formulas or iatrogenic administration of a salt load. The latter can result after sodium bicarbonate infusion during cardiopulmonary resuscitation or during therapy of refractory metabolic acidosis. Hypernatremia secondary to nearly pure water loss may develop if replacement of insensible water loss from the skin and respiratory tract is inadequate. Central diabetes insipidus is due to insufficient release of ADH from the hypothalamic nuclei, and nephrogenic diabetes insipidus is due to a renal resistance to the effect of ADH. Most children affected with these disorders have normal thirst and free access to water and are able to maintain acceptable water balance. However, infants who do not have free access to water and children with intercurrent illness precluding adequate intake of free water are at risk for the development of hypernatremic dehydration.

The cause of hypernatremia is usually evident from the presenting history. In formula fed infants, an accurate account of formula preparation should be pursued to evaluate for inappropriate mixing, which would result in increased renal osmotic load. Inquiries of urine volume should also be made, as the production of significant urine in a child who presents with apparent hypernatremic dehydration would be suggestive of diabetes insipidus. The physical examination should assess weight, perfusion, and mental status. During hypernatremic hypovolemia, water moves from the intracellular to the extracellular space. Given the relative preservation of the extracellular volume, this may delay the objective signs of volume depletion typically noted by clinicians. Laboratory studies should include serum electrolytes, serum osmolality, BUN, and renal serum creatinine. If the underlying diagnosis remains in question, urine studies may be informative. Urine osmolality should be compared to serum osmolality and would be elevated if renal concentrating mechanisms are intact. If the urine osmolality is inappropriately low when compared to the serum osmolality, then central or nephrogenic diabetes insipidus should be considered. The urine sodium concentration may also assist diagnosis. During hypernatremic hypovolemia, the urine sodium is generally less than 25 mEq per L due to the effect of aldosterone to maintain perfusion. If hypernatremia is due to salt excess, the appropriate renal response is to excrete sodium, and the urine sodium concentration would be elevated.

Clinical Manifestations. Similar to hyponatremia, the clinical manifestations of hypernatremia are primarily neurologic. The rise in the plasma osmolality causes water movement out of the brain. The decrease in brain volume may lead rupture of the blood vessels contained in the membranes that tether the brain to the overlying skull and elsewhere. Early clinical manifestations can include lethargy, weakness, fever, and irritability. More severe manifestations include seizures and coma. Symptoms are more likely if the disturbance is acute and rapid. If hypernatremia evolves more slowly, there is cerebral adaptation to protect brain cell volume. Adaptive mechanisms include movement of cerebrospinal fluid into the brain, uptake of sodium and potassium into the cells, followed by intracellular accumulation of osmolytes.

Management. During sustained hypernatremia, cerebral adaptation occurs over several days to restore brain cell volume. Rapid correction of the serum Na after cerebral adaptation occurs results in osmotic movement of water into the brain and cerebral edema. Data suggest that the plasma sodium concentration should be lowered by less that 0.5 mEq per L per hour and no more than 12 mEq per L per day. In children with hypernatremia due to salt loading, treatment should facilitate renal excretion of sodium. This is typically achieved with salt restriction and free water and may be facilitated with diuretics. If intravenous fluids are required, the sodium plus potassium concentration of the fluid provided should be less than the sum of these electrolytes in the urine, and the fluid should be given at a rate sufficient to achieve positive water balance. Adequate intravascular volume should be assured to allow renal excretion of sodium. The therapy of children with hypernatremic hypovolemia (sodium and water deficit) was previously reviewed. In summary, children with clinical signs of decreased effective circulating volume should be provided isotonic saline to restore perfusion. Once intravascular volume is restored, hypotonic fluids should continue to allow judicious restoration of the estimated free water deficit. If hypernatremia is due to nearly pure water deficit (hypernatremic dehydration), replacement of free water should be provided at a rate to allow correction of the serum Na at an acceptable rate.

Disorders of Potassium Homeostasis

Potassium is the most abundant intracellular cation in the body with only approximately 2% of total body stores present in the extracellular space. Among a variety of vital cellular functions, high cytosolic potassium concentration is required for growth, metabolism, cell division, and protein synthesis. Maintenance of the cytosolic potassium concentration and transcellular gradient is dependent on the function of the basolateral cell membrane enzyme, Na^+–K^+-ATPase. This enzyme is physiologically regulated by insulin, thyroid hormone, catecholamines, aldosterone, and plasma potassium concentration. Hormonal and metabolic dysregulation may result from conditions present in ill children and result in abnormalities of potassium homeostasis.

Hypokalemia

Background. Hypokalemia is defined as a measured serum potassium concentration below 3.5 mEq per L. Hypokalemia may result from total body deficit, transcellular shift of potassium to the intracellular space, or a combination of both processes. There are numerous causes of hypokalemia including renal loss, extrarenal loss, and increased cellular uptake, which are outlined in Table 100.7. The common causes of hypokalemia seen in pediatric emergency departments are due to gastrointestinal loss, diuretic use, and diabetic ketoacidosis (DKA).

Loss of gastric or intestinal secretions from any cause will predispose a child to the development of hypokalemia by both direct and indirect mechanisms. The potassium concentration of lower intestinal fluids is relatively high, ranging from 20 to 50 mEq per L, and diarrhea may result in significant potassium loss. The potassium content of gastric fluid is lower at approximately 5 to 10 mEq per L, and hypokalemia associated with vomiting is not primarily due to enteral loss but increased renal excretion of potassium. Gastrointestinal losses resulting in volume contraction will stimulate the secretion of aldosterone,

TABLE 100.7

CAUSES OF HYPOKALEMIA

Decreased potassium intake
Increased renal excretion
- Diuretics
- Metabolic alkalosis (chloride deficient)
- Diabetic ketoacidosis
- Increased mineralocorticoid effect
- Nonreabsorbable anions
- Renal tubular acidosis (type 1 and type 2)
- Bartter's syndrome
- Gitelman's syndrome
- Magnesium depletion

Increased gastrointestinal losses
- Diarrhea
- Laxatives
- Ostomy losses

Increased cellular uptake (redistributive)
- Acute alkalosis
- Insulin therapy
- Elevated β-adrenergic activity
- Increase in bone marrow cell production
- Hypokalemic periodic paralysis

which promotes sodium conservation and increased potassium excretion in the distal nephron. Gastric losses associated with metabolic alkalosis will increase the delivery of sodium and water to the aldosterone-sensitive site and facilitate this exchange. Metabolic alkalosis will also promote transcellular shift of potassium to the intracellular space to maintain electroneutrality. For every approximately 0.1 U rise in blood pH, the anticipated reduction of extracellular potassium concentration of approximately 0.4 to 0.6 mEq per L.

Potassium homeostasis is complex and dynamic in the setting of DKA. Urinary losses of potassium are high due to osmotic diuresis, hypovolemia-induced hyperaldosteronism, and the presence of β-hydroxybutyrate in the glomerular filtrate. β-Hyroxybutyrate is a nonreabsorbable anion and obligates cation loss, which includes both sodium and potassium. Patients with DKA generally have total body potassium depletion at presentation. However, the combination of insulin deficiency, which reduces the activity of the Na^+–K^+-ATPase, and hyperosmolality, which draws water and potassium out of the cells, may result in normal or elevated serum potassium at presentation. Hypokalemia in child who presents with DKA would suggest significant potassium depletion and need for supplementation with close monitoring.

The cause of hypokalemia may be inferred after a careful history is obtained. This should include a thorough account of medications taken, such as diuretics, laxatives, and beta agonists. The laboratory assessment of hypokalemia should include serum electrolytes, magnesium, calcium, serum bicarbonate, renal function, and glucose. In addition to urinalysis and urine pH, urine electrolytes and osmolality should be submitted to assess the renal response to hypokalemia. If the urine potassium concentration is less that 15 mEq per L, this would suggest extrarenal losses, though would be misleading if the child was polyuric. Calculation of the transtubular potassium gradient (TTKG) estimates the tubular potassium concentration at the end of the cortical collecting duct, permitting estimation of the aldosterone effect. This calculation is relatively accurate as long as the urine sodium concentration is greater than 25 mEq per L and the urine osmolality is greater than the plasma osmolality:

$$\text{TTKG} = [(\text{urine K/serum K}) \div (\text{urine osmolality/serum osmolality})]$$

If the TTKG is less than 3, this would be consistent with low urine excretion and extrarenal cause of hypokalemia.

Clinical Manifestations. The clinical manifestations of hypokalemia are generally proportionate to the severity and duration of the disorder and result from hyperpolarization of the cell membrane. Unless the serum potassium falls rapidly or is associated with digitalis use, symptoms are typically not apparent until the serum level is below 2.5 mEq per L. Symptoms may also vary dependent on the concentration of other ions, including calcium, magnesium, and hydrogen. Clinically relevant signs and symptoms of hypokalemia relate to abnormal neuromuscular function and cardiovascular effects, and monitoring of muscle strength and electrocardiogram (EKG) are indicated to assess the functional consequences of hypokalemia. Neuromuscular dysfunction typically manifests as skeletal muscle weakness in an ascending pattern with worsening hypokalemia. Lower extremity muscles are initially affected with progression to the trunk and upper extremities. Respiratory weakness may develop and lead to respiratory failure. Smooth muscle dysfunction can lead to nausea, vomiting, constipation, and voiding dysfunction with urinary retention. Significant hypokalemia produces characteristic changes on the EKG. As the plasma K drops, T-wave amplitude declines, U waves develop, and ST segment depression may result. With more profound hypokalemia the QRS complex may widen and the PR interval may prolong. Supraventricular and ventricular dysrhythmias may develop, the likelihood being greater for patients taking digitalis and in patients with congestive heart failure and coronary ischemia. Renal effects of hypokalemia include a defect in the ability to concentrate urine, an acquired form of nephrogenic diabetes insipidus.

Management. The therapeutic approach to hypokalemia must take into consideration numerous factors including severity, acuity, associated clinical signs, comorbid conditions, and the expectation for ongoing loss. In general, potassium replacement is indicated when there has been potassium loss. If hypokalemia is redistributive in nature but associated with either severely depressed levels or clinical signs, supplementation may be required. However, supplementation during a redistributive process should proceed with close monitoring given the risk of rebound hyperkalemia. In cases when potassium has been lost, there is no strict correlation between serum level and total body stores, and potassium deficit can only be approximated. In clinical scenarios when potassium loss is accompanied by acid–base disturbance, a redistribution effect should be factored when losses are estimated. Magnesium supplementation is indicated in hypokalemia associated with hypomagnesemia. In all cases of significant hypokalemia, monitoring for EKG changes and muscle strength is imperative, and if abnormalities are present, immediate replacement is warranted.

The choice of oral or intravenous replacement will depend on the severity of the disorder and the ability to tolerate enteral salts. If the child is clinically well, oral therapy is preferable and can be provided two to four times per day as potassium chloride. Dosing may start at 2 to 5 mEq per kg per day and be adjusted on the basis of serial laboratory assessment. If there is concurrent metabolic acidosis, potassium citrate or bicarbonate can be provided. If the child is unable to take oral medications or is symptomatic, intravenous potassium should be provided. If the child is not symptomatic, potassium can be added to the maintenance fluids. If intermittent infusion is indicated, this can begin with an intravenous dose of 0.5 to 1 mEq per kg (typical maximum 30 to 40 mEq per dose). In order to avoid insulin secretion, which promotes transcellular shift of potassium into the intracellular space, potassium should be provided in a dextrose-free solution. Potassium chloride or potassium phosphate may be used, though the use of phosphate salt is typically limited to the treatment of DKA or documented severe hypophosphatemia. The reader is referred to Chapter 86 for further discussion regarding potassium replacement in the setting of DKA. Potassium acetate or its equivalent should be used if there is metabolic acidosis. The infusion rate for clinically stable patients should provide 0.25 mEq per kg per hour, though emergent conditions may warrant the maximal rate of 0.5 to 1 mEq per kg per hour (maximum 15 to 40 mEq per hour depending on local policy) with continuous EKG monitoring.

Hyperkalemia

Background. Hyperkalemia is typically defined as serum potassium concentration exceeding 6 mEq per L in neonates or 5.5 mEq per L in children or adults. Serum potassium concentration is determined by the interplay of potassium intake, distribution between the intracellular and extracellular space, and renal excretion. In normal subjects, ingestion of a large potassium load is initially handled by cellular uptake driven by increased activity of the Na^+–K^+-ATPase. The activity of this enzyme is increased by insulin and β_2-adrenergic stimulation. Potassium is subsequently excreted by incremental increase in serum potassium concentration and increased aldosterone effect, which promotes potassium excretion in the distal nephron. This effect of aldosterone is dependent on the delivery of sodium and water to the distal secretory site, which may be compromised in states of decreased intravascular volume. Hyperkalemia can therefore result from excessive load, transcellular shift, decreased renal excretion, or a combination of these factors.

If hyperkalemia develops, both endogenous and exogenous sources of potassium should be considered. Potential sources of exogenous potassium include large volume packed red blood cell transfusion, medicines with significant potassium content, such as Penicillin G potassium (1.7 mEq K per 1 million units), and potassium salt infusions. Given improvements in blood bank procedure, hyperkalemia is less common with transfusion of red cells. Endogenous sources of potassium may result from tissue damage, including burns, trauma, rhabdomyolysis, hemolysis, tumor lysis, and gastrointestinal bleeding with enteral reabsorption. Clinical scenarios associated with extracellular shift include metabolic acidosis, hyperosmolarity, insulin deficiency, and the use of β-adrenergic receptor antagonists. Reduced renal excretion of potassium may occur in acute or chronic renal insufficiency, hypovolemia, mineralocorticoid deficiency, inherited or acquired renal tubulopathy, and due to the use of certain medications (Table 100.8).

TABLE 100.8

MEDICATIONS ASSOCIATED WITH HYPERKALEMIA

NSAIDs
ACE inhibitors
Angiotensin II receptor blockers
Amiloride
Spironolactone
Eplerenone
Tacrolimus
Cyclosporine
Propranolol
Digitalis

Evaluation begins with a thorough history with specific inquiries regarding injuries, muscle pain, history of renal disease, and medications taken. Laboratory studies should include serum electrolytes, calcium, phosphorus, bicarbonate, and renal function. Serum creatinine kinase should be submitted if there is suspicion for rhabdomyolysis. Urine electrolytes and osmolality should be obtained to calculate the TTKG to estimate the aldosterone effect. The TTKG would be greater than 10 to 11 in a normal subject provided a potassium load, reflecting appropriate aldosterone effect. A value below 5 to 7 would be suggestive of hypoaldosteronism. An EKG should be obtained to monitor for cardiac effect.

Clinical Manifestations. The clinical features associated with hyperkalemia are a consequence of altered cellular transmembrane potassium gradient, which reduces the resting membrane potential. Initially this increases membrane excitability, which is followed by a sustained reduction in excitability. Unless the rise is rapid, symptoms or signs generally do not become apparent until the serum potassium concentration exceeds 7.0 mEq per L. Clinical features predominantly involve cardiac conduction and neuromuscular disturbance. Cardiac dysrhythmias are the most serious consequence, and toxicity is exacerbated by a rapid rise in potassium concentration, acidosis, hyponatremia, and hypocalcemia. Early EKG changes include narrow peak T waves with shortened QT interval, which is followed by progressive lengthening of the PR interval and widening of the QRS complex. There may be loss of P-wave amplitude and eventual "sine wave" pattern when the QRS merges with the T wave. This is typically followed by ventricular fibrillation or standstill. Neuromuscular effects are rarely evident at potassium concentrations less than 8 mEq per L and include paresthesias, skeletal muscle weakness, and ascending flaccid paralysis. Respiratory muscles are typically spared.

Management. Strategies to prevent complications from hyperkalemia include (i) removing potassium from the body, (ii) shifting potassium to the intracellular space, and (iii) antagonizing the cell membrane effects of hyperkalemia (Table 100.9). The urgency of care should be based upon the degree of hyperkalemia and evidence of cardiac or neuromuscular effect. Should there be EKG changes consistent with hyperkalemia,

TABLE 100.9

THERAPIES FOR HYPERKALEMIA

Intravenous calcium to stabilize cardiac membrane
Calcium gluconate 10% solution, 50–100 mg/kg (0.5–1 mL/kg); typical adult dose 1,000 mg, max 2,000–3,000 mg
Infuse over 2–5 min, central access is preferred, may repeat in 10 min if needed
Patient must be on cardiac monitor
Effect is immediate in onset though transient (~30 min)

Measures to redistribute potassium into the intracellular space
Insulin and dextrose:
Give dextrose 1 g/kg and provide insulin 0.2 U/g of dextrose
Monitor blood glucose
Time to onset is ~15–30 min, duration is 2–6 h

β_2 Agonists:
2.5–5 mg nebulized albuterol
Time to onset is 20–30 min, duration 2–4 h

Sodium bicarbonate:
1–2 mEq/kg IV over 5–15 min
Minimal effect if the child is not acidemic
Time to onset ~15–30 min, duration ~2 h

Measures to remove potassium from the body
Cation exchange resins:
Sodium polystyrene sulfonate 1 g/kg orally or per rectum, may repeat dose after 4 h
Do not give retention enema with sorbitol
Do not give if within 1 wk of surgery (postoperative ileus)
Time to onset is 1–2 h

Loop diuretics:
1–2 mg/kg furosemide IV, higher doses may be required in renal insufficiency
To avoid hypovolemia, provide appropriate non-potassium–containing fluids
Time to onset 15–60 min

Dialysis:
To be employed if conservative measures fail after discussion with nephrology consultant

the patient should be placed on cardiac monitor and intravenous calcium should be provided to stabilize cardiac membranes. It has been recommended that calcium is indicated only in instances of significant EKG changes, such as widening of the QRS or loss of the P wave but is not indicated in isolated peaked T waves. The effect of calcium is nearly immediate but also transient and should be coupled with other measures to shift potassium to the intracellular space and remove potassium from the body. Calcium gluconate (10% solution) 50 to 100 mg per kg IV or calcium chloride (10% solution) 20 mg per kg IV infused over 2 to 5 minutes with continuous cardiac monitoring. The usual adult dose of calcium gluconate is 1,000 mg and calcium chloride is 500 to 1,000 mg. Calcium is irritating to veins and can result in tissue necrosis; therefore, central vein access is preferable for both the gluconate and chloride salts and strongly recommended if calcium chloride is infused. In patients taking digitalis, an immediate cardiac consultation should be obtained prior to administration if possible as calcium therapy may precipitate other dysrhythmias.

Several therapies are aimed at shifting potassium into the intracellular space and are outlined in Table 100.6. Increasing the effect of insulin enhances the activity of the Na^+–K^+-ATPase in skeletal muscle, driving the K^+ into the cell. Enzyme activity can be increased by intravenous dextrose infusion, though a greater effect is anticipated with the combination of insulin and dextrose. The time of onset is 15 to 30 minutes, peak effect at approximately 60 minutes, and duration of several hours. Providing sodium bicarbonate raises the systemic pH and promotes hydrogen movement out of the cells accompanied by potassium movement into the cells. This is most effective in patients with metabolic acidosis. The time of onset is approximately 15 to 30 minutes and persists for several hours. β_2-adrenergic agonists increase Na^+–K^+-ATPase activity and promote transcellular shift, and therefore, nebulized albuterol may provide further benefit.

Though slower in onset than measures applied to shift potassium into the intracellular space, efforts to remove potassium are necessary. This is essential in cases of total body potassium excess. Sodium polystyrene sulfonate (Kayexalate®) is a commonly used ion exchange resin. Within the intestinal lumen, the resin takes up potassium in exchange for sodium. To a lesser extent, the resin will also exchange for calcium and magnesium, and therefore, electrolytes should be monitored with frequent or prolonged dosing. Oral doses may be provided in sorbitol, which tends to precipitate osmotic diarrhea and augments enteral potassium loss. The pediatric oral dose is 1 g per kg provided every 4 to 6 hours as necessary. Adults are typically provided 15 to 30 g orally. Rectal doses of 1 g per kg every 2 to 6 hours may be given without sorbitol, though the dose must be retained for 15 to 30 minutes to be effective. Kayexalate should not be provided to patients within 1 week of surgery due to risk of intestinal necrosis. In patients who have acceptable renal function, providing isotonic saline and loop diuretics may increase potassium excretion. Isotonic expansion may be particularly effective in patients who are hypovolemic with decreased effective renal perfusion. In cases of hypovolemia, diuretics should only be provided once volume status is restored to avoid prerenal insult. Thereafter, close monitoring of volume balance will allow appropriate adjustment of fluid rate and diuretic dosing. In those patients with significantly impaired renal function, dialysis may be indicated. Hemodialysis provides more rapid clearance of potassium, though peritoneal dialysis may be more practical depending on the size of the child, center preference, and comorbidities such as cardiovascular instability or congenital heart disease.

Disorders of Calcium Homeostasis

Calcium is the most abundant cation in the body with approximately 99% of calcium present in the skeleton in the form of hydroxyapatite. The small fraction remaining in the soft tissue and ECF compartment plays a pivotal role in cellular processes. The intracellular calcium concentration (approximately 10^{-7} mmol per L) is very low when compared to ECF concentration (approximately 1.25 mmol per L), and this concentration gradient is maintained by activity of calcium ATPase. A well-regulated ECF calcium concentration is critical for cell function and survival. The ECF calcium is approximately 40% bound to plasma proteins, approximately 12% complexed with other

ions, such as phosphate and citrate, and approximately 48% free or ionized. It is the ionized fraction of calcium that exerts physiologic effect and is under physiologic regulation. Of note, the fraction of calcium bound to plasma proteins is affected by the extracellular pH. During acidemia, hydrogen ions will displace calcium from proteins and increase ionized calcium levels, and alkalemia will promote the opposite effect.

Calcium homeostasis is dependent on endocrine control of three primary organ systems: intestines, kidneys, and the skeletal system. The parathyroid gland allows for the rapid regulation of ionized calcium concentration via the calcium-sensing receptor (CaSR). The CaSR is highly expressed in the parathyroid gland and is activated by low concentrations of ionized calcium, thereby stimulating parathyroid hormone (PTH) secretion. PTH will increase serum calcium levels through several mechanisms: (i) mobilize calcium from the bone, (ii) increase calcium reabsorption in the distal renal tubule, (iii) stimulate the conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D, the active metabolite of vitamin D. 1,25-Dihydroxyvitamin D promotes calcium and phosphorus absorption from the gastrointestinal tract and reabsorption from the renal tubules. Calcitonin is a hormone produced by the parafollicular cells of the thyroid when calcium levels are high. Calcitonin inhibits osteoclastic activity and promotes movement of calcium from the blood into the skeletal system.

Hypocalcemia

Background. Hypocalcemia has many causes, which include PTH deficiency or resistance, vitamin D deficiency or resistance, extravascular deposition, and abnormal magnesium metabolism (Table 100.10). Abnormal serum calcium should be confirmed by repeat measurement and if confirmed, ionized serum calcium should be measured. As approximately 90% of protein-bound calcium is bound to albumin, the serum albumin concentration should also be determined. For each 1 g per dL reduction in serum albumin, the total calcium concentration will be lowered by approximately 0.8 mg per dL. Hypoalbuminemia does not effect the ionized calcium concentration, which is under hormonal regulation. If available, previous calcium levels should be reviewed to determine if this is an acute or chronic process. Though results will not be available during an urgent or emergent assessment period, a serum PTH level must be performed in all patients with confirmed hypocalcemia. Measurement of serum phosphate, magnesium, and creatinine should also be performed. Hyperphosphatemia increases the risk for calcium phosphate precipitation in tissues and may lead to hypocalcemia. Magnesium is required for PTH release, and hypomagnesemia results in hyporesponsiveness to the effect of PTH in target organs. Hypocalcemia is common in renal failure and is due to phosphate retention and insufficient production of 1,25-dihydroxyvitamin D. As timely serum PTH levels may not be available for review, urine calcium, phosphate, and creatinine should be submitted to assess renal tubular handling, which may suggest the PTH effect. Vitamin D metabolites should be performed in selected patients if clinically indicated.

CAUSES OF HYPOCALCEMIA

Precipitation or altered binding
Hyperphosphatemia
Metabolic alkalosis
Citrated products
Pancreatitis
Vitamin D deficiency
Nutritional
Malabsorption
Impaired synthesis
Hepatic dysfunction
Renal dysfunction
Impaired metabolism
Vitamin D–dependent rickets
Hypoparathyroidism
Impaired synthesis
DiGeorge Syndrome
Activating mutations of the calcium-sensing receptor
Psuedohypoparathyroidism
Other
Hypomagnesemia
Hungry bone syndrome
Fluoride poisoning

Clinical Manifestations. The clinical manifestations of hypocalcemia are dependent on the severity of the abnormality, the rate of decline in serum calcium, and the chronicity of the underlying process. Other factors affecting the development of symptoms include acid–base balance and hypomagnesemia. Classic acute manifestations of hypocalcemia include neuromuscular instability or tetany, which effects both sensory and muscular function. Early or mild symptoms include paresthesias of the perioral region, hands and feet, and muscle cramps. More severe symptoms include seizure, laryngospasm and bronchospasm. Classic physical findings in patients with neuromuscular instability include Trousseau's sign and Chvostek's sign. A positive Trousseau's sign is the precipitation of carpopedal spasm by inflation of a sphygmomanometer above systolic blood pressure for 3 minutes. A positive Chvostek's sign is contraction of the ipsilateral facial muscle induced by tapping of the facial nerve in front of the ear. Of note, Chvostek's sign may be present in up to 10% of normal subjects. In addition to neuromuscular findings, acute hypocalcemia may result in significant cardiovascular disturbance, including hypotension, congestive heart failure, prolonged QT interval, and dysrhythmias. Papilledema may also be present and resolves with correction of hypocalcemia.

Management. Numerous forms of calcium salts are available, and therefore, attention to the salt form is critical when dosing to determine the elemental calcium dose. Calcium may be provided by either oral supplementation or intravenous solution. The appropriate choice is guided by pertinent clinical findings. In general, intravenous calcium is indicated if the patient has prolonged QT, significant symptoms (tetany, seizures, carpopedal spasm), or acute decrease in serum corrected calcium to less than or equal to 7.5 mg per dL regardless of symptoms. Oral supplementation is more appropriate when symptoms are absent or mild and corrected calcium is greater than or equal to 7.5 mg per dL. In patients with asymptomatic chronic hypocalcemia associated with chronic kidney disease (CKD), oral calcium supplementation is preferred with concomitant

replacement of 1,25-dihydroxyvitamin D. If hypocalcemia is associated with metabolic acidosis, correction of the acidosis will reduce the ionized calcium level. Therefore, if metabolic acidosis is not causing clinical compromise, priority should be given to increasing the serum calcium. If hypocalcemia is associated with severe hyperphosphatemia, the provision of calcium may result in the precipitation of calcium and phosphate in the tissues, a disorder known as calciphylaxis. In patients with associated hypomagnesemia, magnesium supplements should be provided, as persistent hypomagnesemia will hinder the correction of hypocalcemia.

Prompt treatment of symptomatic or severe acute hypocalcemia should be initiated intravenously with either calcium chloride or calcium gluconate. Central access is necessary for calcium chloride infusions, though emergent situations may indicate peripheral infusion. Central access is preferred for calcium gluconate, though this salt can be infused peripherally via a large vein. The use of calcium gluconate is usually favored as it is less likely to result in tissue damage if extravasation occurs. As concentrated forms are irritating to veins, calcium salts should be diluted in dextrose and water or saline. The final concentration of calcium gluconate should be 50 mg per mL, and calcium chloride should be diluted to 20 mg per mL. Calcium should not be prepared or infused with fluids containing phosphate or bicarbonate given the risk of precipitation of insoluble salts. The dose for intravenous bolus of calcium gluconate in the setting of cardiac disturbance is 50 to 100 mg per kg per dose infused over 3 to 5 minutes and for tetany is 100 to 200 mg per kg per dose infused over 5 to 10 minutes. Intravenous calcium should not be infused more rapidly given the risk for cardiac arrhythmia, bradycardia, and arrest. Cardiac monitoring and serial monitoring of the serum calcium level should be performed. Repeat boluses should be provided until the symptoms resolve, and then a slower infusion should be continued.

For patients with either chronic hypocalcemia or milder degrees of acute hypocalcemia without severe symptoms, oral calcium is preferred. Numerous forms of oral calcium salts are available. Calcium carbonate is readily available and well tolerated. If either hypoparathyroidism or vitamin D deficiency is suspected, vitamin D replacement should be provided to optimize enteral absorption. The overall management goal of chronic hypocalcemia is to achieve acceptable serum calcium while avoiding hypercalcemia and excessive hypercalciuria.

Hypercalcemia

Background. Hypercalcemia results when the influx of calcium into the extracellular space exceeds the rate of deposition into bone or renal capacity for excretion. This may occur due to excessive absorption from the gastrointestinal tract, accelerated bone resorption, or decreased renal excretion. Excessive exposure to vitamin D will increase intestinal calcium and phosphate absorption and would be associated with a depressed PTH level. In addition to exogenous sources of vitamin D, granulomatous disorders may be associated with unregulated activity of monocytic 1-α-hyroxylase with conversion of 25-hydroxyvitamin D to the more active 1,25-dihydroxyvitamin D and promote absorptive hypercalcemia. Accelerated bone resorption would be anticipated in primary, secondary, and tertiary hyperparathyroidism. Jansen's syndrome, a genetic disorder of the PTH receptor, renders the receptor constitutively active. Children with Jansen's syndrome present with hypercalcemia, undetectable levels of PTH, and skeletal changes consistent with hyperparathyroidism. Immobilization, particularly in rapidly growing adolescents, may result in significant bone resorption and hypercalcemia. Malignancy is a rare cause of hypercalcemia in children. Decreased renal excretion occurs in familial hypocalciuric hypercalcemia (FHH), an autosomal dominant disorder affecting the CaSR. FHH is characterized by mild, asymptomatic hypercalcemia, increased tubular reabsorption of calcium, and inappropriately normal PTH. Medications associated with hypercalcemia include thiazide diuretics and lithium.

The evaluation of hypercalcemia begins with a thorough assessment of symptoms, diet, medication, medical history, and family history. Laboratory evaluation should include ionized calcium, electrolyte, phosphorus, magnesium, renal function, serum albumin, and acid–base assessment. Review of previous laboratory studies, if available, should be performed. Though results will not be available to the emergency department physicians, PTH level is critical to ultimately differentiate the underlying cause. If the PTH is not elevated, vitamin D metabolites should be submitted. Assessment of urine calcium excretion via random urine calcium to creatinine ratio may also be informative. Calcium excretion is high in hyperparathyroidism but low in FHH and with thiazide therapy.

Clinical Manifestations. Hypercalcemia is associated with a number of signs and symptoms depending on the acuity and severity of the disorder. Patients with mildly elevated calcium (less than 11.5 to 12 mg per dL) are often asymptomatic, especially if the elevation is chronic in onset. Patients with moderate hypercalcemia (12 to 14 mg per dL) may experience anorexia, irritability, abdominal pain, constipation, and weakness. An important renal manifestation of hypercalcemia is polyuria due to an inability to concentrate urine, an acquired form of nephrogenic diabetes insipidus. Should polyuria be associated with gastrointestinal symptoms and decreased fluid intake, dehydration will ensue and aggravate the existing hypercalcemia by reducing renal excretion of calcium. If hypercalcemia is severe, progressive weakness, confusion, seizures, and coma may develop.

Management. When hypercalcemia is mild, no specific therapy is warranted and efforts should focus on identifying the underlying condition. Chronic moderate hypercalcemia (12 to 14 mg per dL) may be well tolerated and not require immediate intervention, though thorough evaluation should be pursued. If hypercalcemia is severe (greater than 14 mg per dL) or associated with clinically significant symptoms, prompt intervention is warranted. Given the gastrointestinal and renal manifestations associated with hypercalcemia, patients may present with hypovolemia. Initial efforts should focus on restoring adequate intravascular volume with isotonic intravenous fluids, which will increase GFR and increase renal excretion of calcium. Once intravascular volume is restored, attempts to promote continued calcium excretion with intravenous saline and loop diuretics (furosemide 1 to 2 mg per kg) should be employed. Loop diuretics inhibit tubular reabsorption of calcium and enhance excretion, an effect that is optimized when adequate tubular sodium is present. The rate of intravenous fluid will depend upon the urine flow rate and volume status, and meticulous attention to fluid balance and serial assessment of weight is

warranted. If renal function and urine flow are preserved, hydration at a rate of 2,000 to 3,000 mL per m^2 per day will likely be well tolerated. If the patient is in renal failure or efforts with saline diuresis are not sufficient, contacting a pediatric nephrology or endocrinology consultant is advised. Therapeutic options for cases not responsive to conventional therapies include calcitonin, bisphosphonates, and renal replacement therapy (RRT), if clinically indicated.

Disorders of Acid–Base Homeostasis

When compared to the extracellular sodium ion concentration, normally ranging between 135 and 145 mEq per L, the extracellular hydrogen ion (H^+) concentration is precisely maintained within narrow limits to achieve a concentration of 40 nanoEq per L or 0.00004 mEq per L. This underscores the impact of H^+ concentration on cellular function. Once a derangement of H^+ concentration occurs, several homeostatic responses are activated in a stepwise fashion to restore normal acid–base balance. Within minutes chemical buffers begin to neutralize the derangement, followed by an appropriate adjustment in pulmonary ventilation, and finally renal mechanisms are activated to adjust acid–base excretion. The effect of pulmonary ventilation and renal control of acid–base excretion on systemic pH can be predicted by applying the Henderson-Hasselbalch equation,

$$pH = 6.10 + \log([HCO_3^-] \div [0.03 \times pCO_2]).$$

Metabolic Acidosis

Background. Metabolic acidosis is a process that tends to lower extracellular pH and results from either a net gain of H^+ ions or a net loss of bicarbonate (HCO_3^-) ions. Acidemia is a state of low extracellular pH. The two classes of physiologic acids are volatile acids and nonvolatile acids. The excretion of volatile acid is achieved by pulmonary ventilation, and the elimination nonvolatile acid is achieved by renal excretion. Children typically produce 2 to 3 mEq per kg per day of nonvolatile acids, primarily sulfuric acid derived from the metabolism of sulfur-containing amino acids. Nonvolatile acids are initially buffered by bicarbonate in the extracellular space and by proteins and phosphates in the intracellular space. The net effect is a fall in serum HCO_3^-, which is restored by renal excretion of the daily acid load. There are two basic steps involved in this process: (i) reabsorption of the filtered HCO_3^- and (ii) tubular secretion of H^+ ion, which combines with either titratable acid (primarily phosphate) or ammonia to generate ammonium. The net effect of secreting a H^+ is the generation of a HCO_3^- ion. The secreted H^+ ion is derived from the breakdown of water and generates a hydroxyl ion (OH^-). OH^- combines with carbon dioxide (CO_2) within the cell and generates a new HCO_3^- ion, which is returned to the systemic circulation and replaces the HCO_3^- ion loss in the initial buffering reaction. When there is a significant increase in the daily acid load, the kidney compensates largely by increasing ammonium excretion.

Clinical Manifestation. The clinical manifestations of metabolic acidosis are variable and will depend on the underlying etiology and severity. Children may be asymptomatic or present with a variety of acute or chronic manifestations such as tachypnea, abdominal pain, vomiting, lethargy, neurologic abnormalities, and failure to thrive. Inquiries regarding the presence and duration of symptoms such as diarrhea, polyuria, and poor growth should be included in the historical assessment. The physical examination should include an assessment of perfusion and measurement of growth parameters to determine if growth has been impaired.

Evaluation of metabolic acidosis ideally begins with an assessment of the arterial or venous blood gas, which defines systemic pH, pulmonary compensation, and may identify the presence of complex acid–base disorders (mixed acid–base disorders). The serum bicarbonate is typically measured indirectly by blood gas or directly by adding a strong acid to venous blood and observing the amount of CO_2 generated. Once metabolic acidosis is diagnosed, assessment of respiratory compensation can be performed. The arterial partial pressure of CO_2 (pCO_2) normally falls an average of 1.2 mmHg for every 1 mEq per L reduction in the serum HCO_3^- to a minimum pCO_2 of 10 to 15 mmHg. The Winter's formula can also approximate the expected arterial pCO_2,

$$\text{Arterial } pCO_2 = (1.5 \times \text{measured } HCO_3^-) + 8 \pm 2$$

If the fall in pCO_2 is significantly different than the expected value, a mixed acid–base disorder is likely present.

Patients with metabolic acidosis can be classified in two groups based on the serum anion gap (AG), and this determination may facilitate the diagnosis of the underlying cause. Serum electrolytes should be obtained to calculate the AG using the following formula:

$$AG\ (mEq/L) = Na^+ - (Cl^- + HCO_3^-)$$

The normal AG typically ranges between 7 and 13 mEq per L, and an AG greater than 14 to 16 mEq per L is elevated. In normal subjects, the AG is primarily due to negative charges from plasma proteins, particularly albumin. An elevated AG is most often due to an unmeasured anion, though can also result from a low concentration of serum cations (K^+, Ca^{2+}, Mg^{2+}). A low AG can result from an increase in serum cations or low serum albumin. For every 1 g per dL reduction in serum albumin level, the AG would be expected to be reduced by approximately 2.5 mEq per L. The causes of metabolic acidosis based on elevated or normal AG are outlined in Table 100.11. In addition to serum electrolytes and serum albumin, initial laboratory studies should include serum glucose, BUN, creatinine, and urinalysis with urine pH. A higher than expected urine pH in the setting of acidosis may suggest renal tubular acidosis (RTA). Further studies are based upon clinical suspicion.

Management. The management of metabolic acidosis should focus on the identification and treatment of the underlying cause and to ensure adequate perfusion. The immediate therapy of metabolic acidosis in the emergency department generally depends on the severity of the disorder. In children with severe acidemia (serum pH less than 7.10), bicarbonate therapy is generally indicated. The basis for correcting severe acidosis is the negative impact severe acidemia has on cardiac function, including impaired cardiac contractility and increased risk for cardiac arrhythmias. An exception would include metabolic acidosis in patients with DKA, as lower thresholds for pH are allowed before bicarbonate is provided given the expected

TABLE 100.11

CAUSES OF METABOLIC ACIDOSIS WITH RESPECT TO THE ANION GAP

Elevated anion gap
- Lactic acidosis
  - Hypoperfusion
  - Inborn errors of carbohydrate metabolism
  - Mitochondrial disorders
- Diabetic ketoacidosis
- Inborn errors of metabolism
  - Organic acidemias
  - Fatty acid oxidation defects
- Ingestions
  - Methanol, ethanol, ethylene glycol, salicylates
- Renal failure

Normal anion gap
- Renal tubular acidosis
- Diarrhea
- Enteric fistulae
- Ureterosigmoidostomy
- Early renal failure

Alkali therapy

Contraction alkalosis
- Loop or thiazide diuretics
- Cystic Fibrosis
- Congenital chloridorrhea

Intracellular movement of hydrogen
- Hypokalemia

metabolism of ketoacid into bicarbonate with insulin and fluid repletion. The reader is referred to Chapter 86 for further discussion regarding emergent treatment of DKA. The role of alkali therapy remains controversial in hypoperfusion lactic acidosis and is yet to be resolved. The aim of treatment in hypoperfusion lactic acidosis is to restore intravascular volume and perfusion in a timely fashion, which will allow metabolism of lactate anions to bicarbonate. The potential complications of alkali therapy in metabolic acidosis include hypercarbia, hypernatremia, transcellular shift of potassium ion into the intracellular space resulting in hypokalemia, and alkalosis. Furthermore, alkalosis or an increase in blood pH may precipitate tetany by promoting binding of calcium to albumin, which reduces the ionized calcium concentration.

When bicarbonate therapy is to be given, estimating the necessary dose may prove to be challenging. The apparent bicarbonate space reflects total body buffering capacity, which includes extracellular bicarbonate, intracellular proteins, and bone carbonate. The bicarbonate distribution space rises from 50% of body weight to 100% of body weight with progressive acidemia. Given the difficulty in accurately estimating the bicarbonate deficit, bicarbonate can be given at an initial dose of 0.5 to 1 mEq per kg if clinically indicated with the aim of increasing the systemic pH to more than 7.20. Further alkali therapy will depend upon the response and subsequent disease course. If the patient is asymptomatic, the underlying process can be controlled (e.g., diarrheal dehydration), and tissue perfusion can be assured, alkali therapy may not be required. In the setting of asymptomatic chronic metabolic acidosis, such as RTA and CKD, consultation with an appropriate specialist would be reasonable to guide oral therapy and avoid complications such as electrolyte derangements and volume excess.

Metabolic Alkalosis

Background. Metabolic alkalosis is characterized by a rise in the plasma bicarbonate concentration, and causes include hydrogen loss from the gastrointestinal tract or kidneys, volume contraction around a relatively constant amount of extracellular bicarbonate (contraction alkalosis), and the administration of bicarbonate. Given the renal capacity to excrete excess bicarbonate, clinical circumstances must be present that impair bicarbonate excretion and sustain the disorder. Therefore, when approaching the patient with metabolic alkalosis, identification of both the inciting cause and the clinical factors allowing persistence of the disorder must be pursued.

Though there are many causes (Table 100.12), metabolic alkalosis in children most commonly results from diuretic therapy and H^+ loss from gastrointestinal secretions. Diuretics are prescribed to children for a variety of chronic and acute disorders. Renal acid excretion requires adequate delivery of both sodium and water to the distal tubule and is promoted by the effect of aldosterone. By increasing Na^+ reabsorption in the distal nephron, aldosterone creates a lumen-negative potential difference and favors H^+ movement into the lumen. Furthermore, aldosterone directly stimulates the H^+-ATPase, enhancing H^+ secretion into the tubular lumen. Loop and thiazide diuretics increase distal delivery of both sodium and water and predispose to volume contraction, thereby stimulating aldosterone secretion. Gastrointestinal causes of metabolic alkalosis include vomiting or nasogastric suction. Gastric secretions have high concentrations of hydrogen chloride and a lesser amount of potassium chloride (5 to 10 mEq per L), and gastric losses will predispose to the development of metabolic alkalosis. In addition, if gastrointestinal losses are significant and inadequately replaced, intravascular depletion may ensue with resultant increase in aldosterone secretion.

In normal subjects, the renal capacity to excrete bicarbonate prevents the development of metabolic alkalosis. The persistence of metabolic alkalosis implies a limitation of renal bicarbonate excretion, and the most common perpetuating cause is effective circulating volume depletion. A central mechanism to preserve intravascular volume is renal tubular reabsorption of Na^+, stimulated by aldosterone as described above. To maintain electroneutrality, bicarbonate will be reabsorbed with Na^+. During sustained volume depletion, the

adaptive tubular reabsorptive capacity for bicarbonate will increase steadily and may exceed 35 mEq per L.

In addition to volume depletion, chloride depletion will also limit renal bicarbonate excretion and is associated with gastric fluid loss and diuretic therapy. Low renal tubular concentration of chloride favors both bicarbonate reabsorption and decreases bicarbonate excretion. Distal bicarbonate secretion is dependent upon the Cl^-–HCO_3^- exchanger located in the luminal membrane, which transports chloride into the intercalated cells of the cortical collecting tubule and excretes bicarbonate into the tubule lumen. A fall in the tubular lumen chloride will diminish the favorable gradient for ion exchange and bicarbonate excretion. Hypokalemia also directly increases bicarbonate reabsorption, which is in part due to intracellular acidosis induced by the entry of H^+ into the cell in exchange for K^+ movement out of the cell. Intracellular acidosis induces renal acid excretion and promotes net bicarbonate reabsorption.

Management. The cause of metabolic alkalosis is generally evident from the history. The evaluation of metabolic alkalosis should include a thorough history to identify gastrointestinal losses and an account of medications taken, specifically diuretics and antacids. Serum studies should include assessment of renal function and electrolyte balance to evaluate for concurrent abnormalities such as hypokalemia, hypercalcemia, and abnormalities in serum magnesium, which may support a renal tubulopathy such as Gitelman's syndrome. Urine electrolytes may also be informative. In patients with metabolic alkalosis and volume contraction, the urine sodium and chloride concentrations may be dissociated. If the serum bicarbonate exceeds the renal capacity to conserve, some of the excess bicarbonate will be excreted with sodium and potassium. This loss of cations will worsen the Na deficit and may lead to potassium depletion. Despite metabolic alkalosis, the conservation of chloride is intact, and a urine chloride concentration less than 25 mEq per L would be consistent with volume depletion. A urine chloride concentration greater than 40 mEq per L in the setting of metabolic alkalosis would be consistent with disorders such as primary mineralocorticoid excess, Bartter's syndrome, Gitelman's syndrome, or continued diuretic therapy.

The treatment of metabolic alkalosis is supportive, and reversible underlying cause should be addressed. The focus of therapy should aim at restoring adequate circulating volume and correcting chloride and potassium deficits. Providing isotonic sodium chloride will restore intravascular volume, remove the stimulus for sodium retention, and increase distal chloride delivery. Once these results have been achieved, there will be decreased bicarbonate reabsorption, increased bicarbonate excretion, and correction of the metabolic alkalosis. Potassium chloride should be provided if depletion is suspected with close monitoring to avoid excessive replacement. Though the extracellular concentration of K^+ may be low during metabolic alkalosis due to transcellular shift to the intracellular space, true potassium depletion may be present. Potassium can be lost due to impaired renal absorption from diuretic therapy, aldosterone effect associated with volume depletion, and obligatory wasting of cations (Na^+ and K^+) associated with bicarbonate excretion. In patients with metabolic alkalosis and edematous states, providing sodium chloride may be hazardous. Therapy should take into account the underlying condition and planned in concert with appropriate subspecialty care if possible.

ACUTE KIDNEY INJURY

Background and Pathophysiology

Previously termed acute renal failure, acute kidney injury (AKI) defines an abrupt decrease in GFR with impairment of nitrogenous waste product excretion. Depending on the severity of the injury, there may be altered water and electrolyte excretion and disturbance of metabolic and acid–base regulation. In mild cases, nonoliguric AKI may be asymptomatic and only detected when serum laboratory studies are performed. When severe, oliguric AKI may result in profound derangements of electrolyte and volume balance and necessitate the initiation of RRT.

Due to various definitions, the incidence and prevalence of AKI in the pediatric population is difficult to ascertain. However, the incidence appears to be rising and causation changing with the advancement of medical and surgical practice. This trend is most apparent in tertiary care centers and was illustrated in a retrospective study from a large pediatric tertiary center, which reviewed the course of AKI in approximately 250 children. Approximately two thirds of these children had underlying comorbid conditions, and only 7% of cases of AKI were due to primary renal disease. The most common causes of AKI were renal ischemia (21%), nephrotoxic agents (16%), and sepsis (11%). Infants with congenital heart disease requiring cardiopulmonary bypass and recipients of stem cell transplants appear to be particularly vulnerable populations. In contrast to the underlying causes of AKI in tertiary centers, primary renal disease is more likely to cause AKI in community hospital and less developed countries. In 2004, the Acute Dialysis Quality Initiative proposed a consensus definition for AKI: the RIFLE criteria. This was modified and validated in pediatric patients and renamed the pediatric RIFLE criteria. These criteria define five levels of AKI based upon degree of creatinine elevation, urine output, and requirement for dialysis. As a research tool, this standardized definition will advance our understanding of AKI with respect to incidence and outcome and potentially allow the identification of modifiable risk factors.

AKI may be classified as prerenal, intrinsic renal, and postrenal. Prerenal AKI may result from intravascular volume depletion or reduced effective circulating volume. Uncontrolled bleeding, gastrointestinal losses, diuretic therapy, osmotic diuresis, and cutaneous losses are potential causes of intravascular depletion. Intravascular volume depletion also develops when fluid shifts out of the vascular space into the interstitial space and occurs with hypoalbuminemia and during systemic inflammatory response syndrome (SIRS). Decreased effective circulating volume may be present in heart failure and during systemic vasodilation. Intrinsic renal disease may result from insults to the renal vasculature, glomeruli, interstitium, and tubular mass. Of note, a sustained prerenal state may result in acute tubular necrosis (ATN), an intrinsic renal disease not immediately reversible with restoration of effective intravascular volume. Causes of postrenal AKI include bilateral ureteral obstruction (stones, masses), unilateral obstruction in a solitary kidney, and functional or anatomic bladder outlet obstruction. Posterior urethral valves are the most common cause of postrenal failure

and commonly detected during gestation given the routine practice of fetal ultrasounds during prenatal care.

Management

A thorough physical exam and history is a necessary starting point to reveal the underlying etiology of AKI. Prerenal physiology is not an uncommon finding in emergency departments and often due to gastrointestinal losses. A detailed history of fluid balance should be obtained, and the physical exam should assess hydration status and perfusion. An account of medications taken prior to presentation should also be performed to identify the potential for drug-induced nephrotoxicity. Important classes of medications increasing the risk for AKI include nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, angiotensin II receptor blockers (ARBs), and calcineurin inhibitors. Physical exam may also reveal signs of systemic vasculitis associated with nephritis, such as rashes or arthritis. Any patient who presents with anuria should have a thorough abdominal exam to assess for palpable bladder or masses, which may be compressing the urinary tract.

Laboratory assessment of AKI should serve two purposes. First, it should determine the severity of renal dysfunction and identify associated metabolic or hematologic abnormalities, which may require urgent intervention. Second, a focused investigation should begin to elucidate the underlying cause of AKI. For any child who presents with AKI, initial serum laboratory studies should include serum creatinine, electrolytes, and complete blood cell counts. Serial assessment of renal function and electrolytes will be required to determine the disease course and to monitor for the development of electrolyte derangements. Other laboratory tests should be considered based on the clinical presentation of the patient and should be pursued at a tempo reasonable for the clinical course. In cases of suspected glomerulonephritis, serum complements, antistreptococcal antibodies, and antinuclear antibodies should be considered. If there is rapid deterioration of renal function consistent with rapidly progressive glomerulonephritis (RPGN), antineurophil cytoplasmic antibodies (ANCA) and anti–glomerular basement (GBM) antibodies should be submitted. RPGN would necessitate prompt evaluation by a pediatric nephrologist.

Initial urine studies submitted during the evaluation of AKI must include urinalysis with microscopic assessment. An elevated urine-specific gravity may be consistent with prerenal physiology. Results of the urine dipstick may reveal nitrite or leukocyte esterase, a sign of urinary tract infection. Detection of large heme by dipstick is found in glomerulonephritis and pigment nephropathy, and differentiation between these two disorders relies upon the presence or absence of red blood cells in the urine sediment, respectively. Heavy proteinuria by dipstick, which detects albumin excretion, would be suggestive of glomerular disease and should be followed by a quantitative urine protein to creatinine ratio (normal less than 0.2, nephrotic range greater than 2 to 3). Microscopic examination of the urine sediment may be normal or nearly normal, consistent with prerenal AKI and some cases of ATN. ATN may also be associated with granular, muddy brown, and/or tubuloepithelial cell casts. The finding of red blood cell casts is pathognomonic of glomerulonephritis, and concomitant white blood cells or white blood cell casts would be consistent with an exudative nephritis such as postinfectious glomerulonephritis or renal vasculitis. The urine sediment associated with acute interstitial nephritis (AIN) varies and include microscopic hematuria, sterile pyuria, and white blood cell casts. The degree of proteinuria associated with AIN is also variable, though is typically not severe. A notable exception is NSAID-induced AIN, which may be associated with nephrotic range proteinuria. If interstitial nephritis is suspected, urine eosinophils should be submitted, though sensitivity and specificity of urine eosinophilia is limited.

An assessment of urine chemistries may also be useful in distinguishing prerenal AKI from ATN, and initial studies to consider include urine electrolytes and urine creatinine. The fractional excretion of sodium (FENa) is calculated as follows:

$$\text{FENa (\%)} = (\text{urine sodium} \times \text{serum creatinine} / \text{serum Na} \times \text{urine creatinine}) \times 100$$

A value below 1% suggests prerenal disease and reflects reabsorption of almost all of the filtered sodium to maintain intravascular volume, an appropriate response to decreased renal perfusion. A value greater than 2% is consistent with ATN or other tubular disorders. Of note, the FENa may be less than 1% in normal subjects and reflects normal tubular handling of sodium in the setting of relatively low sodium intake. The fractional excretion of urea is similarly calculated as the FENa with substitution of urine urea nitrogen and blood urea nitrogen and is generally less than 35% in prerenal states. Diuretics increase urine sodium excretion, though have less effect on urea excretion. Therefore, the FENa may be less reliable and the fractional excretion of urea more informative if diuretics have been provided prior to the collection of urine.

Radiographic assessment should be considered in all patients with AKI of unclear etiology. This is most certainly true in those who present with acute anuria, as urinary tract obstruction is a possible etiology and would require intervention. Given its safety and general availability, ultrasonography of the kidneys and urinary tract should be considered in all children with AKI. Ultrasound provides timely and valuable data, including assessment of renal parenchymal mass and may identify conditions of acquired or congenital obstruction of the urinary tract. Doppler investigation of the renal vessels should be performed if there is concern for vascular compromise or thrombosis, though further imaging may be necessary, given the limitations of this modality.

The initial management of AKI in the emergency department is largely supportive and aimed at addressing fluid or electrolyte abnormalities and avoiding further renal insult. If prerenal physiology is suspected, appropriate volume resuscitation with isotonic fluids should be provided with frequent assessment of perfusion and urine flow. Normal saline bolus therapy provided at 5 to 10 mL per kg is warranted with reassessment to determine if further resuscitation is indicated. Though prerenal physiology should be corrected, prevention of fluid overload should be emphasized. This balance is most challenging in those patients who present critically ill with sepsis associated with capillary leak and in those with heart failure and ineffective circulating volume. Potassium supplementation should be withheld until urine flow is established and results of serum electrolytes are available. Electrolyte and acid–base disturbances should be addressed as previously reviewed.

TABLE 100.13

ESTIMATION OF GFR BY THE SCHWARTZ FORMULA

$C_{cr} = k \times L/S_{cr}$

C_{cr} = creatinine clearance in mL/min/1.73 m^2

k = proportionality constant

L = length (cm)

S_{cr} = serum creatinine (mg/dL)

k values

Low birth weight infants during the first year of life = 0.33
Full term babies during first year of life = 0.45
Children and adolescent girls = 0.55
Adolescent boys = 0.7

Adapted from Schwartz GJ, Feld LG, Langford DJ. A simple estimate of glomerular filtration rate in full-term infants during the first year of life. *J Pediatr* 1984;104:849–854; Schwartz GJ, Gauthier B. A simple estimate of glomerular filtration rate in adolescent boys. *J Pediatr* 1985;106:522–526; Schwartz GJ, Haycock GB, Edelmann CM Jr, et al. A simple estimate of glomerular filtration rate in children derived from body length and plasma creatinine. *Pediatrics* 1976;58:259–263.

If AKI is associated with oligoanuria, the child may present in a state of volume excess. If severe, hypertension and pulmonary edema may be present and would warrant a trial of diuretic therapy. Intravenous furosemide given at a dose of 1 to 2 mg per kg should be provided if volume excess is causing cardiopulmonary compromise. Hypertension can be treated with either oral or intravenous agents. Oral calcium channel blockers and hydralazine are well tolerated and would not worsen renal function, unlike ACE inhibitors and ARB therapy. If intravenous agents are required, intermittent doses of hydralazine or labetalol are often effective. If the child remains oligoanuric despite diuretic challenge and has clinical evidence of volume excess, a pediatric nephrologist should be consulted given the potential need for RRT and ultrafiltration. If medications are indicated, such as antibiotics, the need for dose adjustment based on decreased renal function must be considered. The Schwartz formula allows estimation of the GFR based on serum creatinine and patient length and has gained widespread clinical use in North America (Table 100.13). This formula tends to overestimate GFR, and this overestimation increases with decreasing GFR.

Rhabdomyolysis

Background

Rhabdomyolysis accounts for approximately 3% of all cases of AKI in children and causes include both traumatic and nontraumatic. Traumatic etiologies include crush injuries, vascular occlusions, and acute lower extremity compartment syndrome. Nontraumatic causes include extreme exertion, prolonged seizure, malignant hyperthermia, DKA, hypokalemia, hypophosphatemia, and metabolic myopathies. Rhabdomyolysis has also been associated with a variety of infections, including influenza A and B, parainfluenza, Coxsackie virus, Epstein-Barr virus, herpes simplex virus, varicella zoster, human immunodeficiency virus, and sepsis. Both prescribed and illicit drugs can cause rhabdomyolysis and include lipid lowering drugs (primarily statins), colchicines, alcohol, cocaine, ecstasy, and amphetamines. In a retrospective study of approximately 190 children presenting to the emergency department of a tertiary pediatric hospital, the most common causes of pediatric rhabdomyolysis were viral myositis (38%) and trauma (26%). Of this group, none of the children with urinary heme dipstick of less than 2+ developed acute renal failure. In general, if the serum creatinine kinase level is less than 15,000 to 20,000 U per L at presentation, the risk for AKI is relatively low but not negligible. Clinical factors increasing the risk for AKI at lower concentrations of serum creatinine kinase include dehydration, metabolic acidosis, and sepsis.

Clinical Manifestations

The classic symptoms of rhabdomyolysis include myalgias, weakness, and red or brown discolored urine, though these findings are not consistently reported by those affected. The serum studies reflect the release of myocyte contents and include elevated serum creatinine kinase. Unlike hemoglobin, myoglobin is a monomer and is freely filtered into the urine. The severity of rhabdomyolysis ranges from asymptomatic elevations in serum muscle enzymes to oliguric renal failure associated with life-threatening electrolyte abnormalities. Electrolyte abnormalities include hyperkalemia and hyperphosphatemia, which result from the endogenous load released from damaged muscle cells and limited excretion if renal function is impaired. Hypocalcemia may also develop due to calcium phosphate precipitation into injured muscle tissue. AKI during rhabdomyolysis is often multifactorial, and insults include prerenal physiology, tubular cell damage, and tubular obstruction. Decreased intravascular volume and prerenal physiology develop secondary to fluid sequestration within damaged muscle and intrarenal vasoconstriction. Tubular cell injury results from tubular obstruction with heme pigment casts and lipid peroxidation from hydroxyl radicals generated by heme and free iron. The urine sediment may reveal pigmented granular casts and a red to brown discoloration of the urine supernatant.

Management

The mainstay of therapy for rhabdomyolysis includes early vigorous hydration to ensure adequate intravascular volume and promote urine flow. The benefit of high urine flow is the removal of obstructing, pigmented casts, which initiate the cytotoxic insults. Children should be provided isotonic saline to ensure adequate renal perfusion, and intravenous fluids should continue to optimize urine flow. The intravenous fluid rate will depend on urine flow rate and should be reevaluated regularly to avoid volume excess. Guidelines for adults suggest targeting urine flow rate at approximately 3 mL per kg per hour. Should the urine flow be low despite adequate volume status, a trial of furosemide 0.5 to 1 mg per kg IV would be reasonable and should be continued (i.e., every 6 to 8 hours) if effective. If diuretics are used, meticulous attention should be given to volume balance and perfusion to avoid prerenal insult. Some have advocated the use of a forced alkaline or mannitol diuresis, though the clinical benefits are not proven. Should metabolic acidosis develop, this should be treated with addition of bicarbonate to intravenous fluids. The risk of providing bicarbonate is excessive alkalinization and reduction of ionized

calcium in patients with evolving hypocalcemia. For those with severe AKI associated with oligoanuria and electrolyte disturbance, dialysis may be required until renal recovery is achieved.

GLOMERULAR DISEASES

Glomerular diseases encompass a variety of disorders, including both acute and chronic processes. Moreover, they may be due to a primary renal disorder or reflect renal involvement in a systemic disease or infection. The differential diagnosis of glomerular disease is broad, and Table 100.14 lists some of the more common forms of glomerular disease seen in the pediatric population. Depending on the underlying disorder, the clinical course may be mild and self-limited with full recovery or severe with progression to renal insufficiency. Glomerulonephritis is the leading cause of acquired chronic renal failure during childhood. The following will review the clinical presentations and management of postinfectious glomerulonephritis, Henoch-Schönlein purpura (HSP), and hemolytic uremic syndrome (HUS).

Postinfectious Glomerulonephritis

Background

Postinfectious glomerulonephritis is the leading cause of glomerulonephritis in children and has been associated with a host of bacteria, viruses, and parasites. In children, however, nephritogenic strains of group A β-hemolytic streptococci are the most frequently implicated organisms. Currently nephritis-associated streptococcal plasmin receptor and streptococcal pyrogenic exotoxin B are considered the major putative nephritogens. The classic preceding illnesses are streptococcal pharyngitis and cellulitis. The latent period from pharyngitis and cellulitis to acute poststreptococcal glomerulonephritis (APSGN) averages 10 days and 21 days, respectively. APSGN may be sporadic or occur during an endemic and more commonly affects school age children. During an epidemic of pharyngitis, the incidence of clinically detectable APSGN is approximately 5% to 10%. In recent decades, the prevalence of APSGN has declined in most industrialized nations, though persists at high rates in some developing countries.

TABLE 100.14

GLOMERULAR DISEASES IN CHILDHOOD

Primary
- IgA nephropathy
- Focal segmental glomerulosclerosis
- Membranoproliferative glomerulonephritis
- Membranous glomerulonephritis

Associated with systemic disease
- Henoch-Schönlein purpura
- Hemolytic uremic syndrome
- Systemic lupus erythematosus
- Wegner granulomatosis
- Goodpasture syndrome
- Microscopic polyarteritis

Infectious
- Poststreptococcal glomerulonephritis
- Hepatitis B and C associated nephritis
- Shunt nephritis
- Subacute bacterial endocarditis

Inherited
- Benign familial hematuria
- Alport syndrome

Clinical Manifestations

The clinical presentation of APSGN may vary from asymptomatic microscopic hematuria to an abrupt onset of the nephritic syndrome, which can be associated with gross hematuria, proteinuria, oliguria, edema, and hypertension. Hypertension can be severe and evolve into hypertensive emergency, which typically affects the central nervous system (CNS) in children and manifests as seizure activity. Given the potential morbidity, hypertension at presentation would be an indication for admission. In a small minority of children (less than 1%) the course will be consistent with RPGN and warrant renal biopsy. Generally, the clinical symptoms of ASPGN begin to improve after 1 to 2 weeks. If reduced renal function and edema are evident at presentation, renal function begins to normalize and diuresis ensues within this several week period. Gross hematuria will fade rapidly, though microscopic hematuria may persist for 6 months or longer. Proteinuria typically improves quickly and resolves within 6 months.

Laboratory studies during a typical episode of ASPGN reflect a nephritic process with activation of the alternative complement pathway. Subendothelial immune deposits with activation of complement will result in an influx of inflammatory cells, leading to a proliferative glomerulonephritis. The urine sediment will demonstrate glomerular erythrocytes and leukocytes, and may contain red cell casts. Proteinuria is not uncommon, though not typically in the nephrotic range. Serum studies may demonstrate reduced renal function. Associated electrolyte abnormalities include hyponatremia, reflecting inability to excrete water, and hyperkalemia. The majority of patients will have a low total hemolytic complement, low C3 complement, and a normal C4 complement. The C3 level typically recovers in 6 to 8 weeks. Serologic testing to document recent streptococcal infection is helpful but does not prove causation, as a significant number of children are asymptomatic carriers. In addition, it is important to recognize that antibiotic therapy may blunt the increase in antibody titers. Serologic tests available include antistreptolysin O, antideoxyribonuclease B, and hyaluronidase. If the C3 remains depressed after 3 months or the C4 is low, diagnostic considerations include chronic forms of glomerulonephritis, including membranoproliferative glomerulonephritis (MPGN) and lupus nephritis. If the complement levels are normal at presentation, this would make ASPGN less likely, and IgA nephropathy would be a consideration.

Management

Therapy for APSGN is largely supportive. Given the underlying glomerular inflammation and generally intact tubular function, there is a propensity for salt and water retention leading to edema and increased blood pressure. Therefore, weight should be measured daily and blood pressure checked regularly during the early acute illness. Children with hypertension or decreased renal function should be considered for admission. If edema or hypertension is present, salt and fluid restriction should be initiated and diuretic therapy considered. Furosemide can be provided at doses of 0.5 to 1 mg per kg

once to four times daily to optimize fluid balance. If the child is hypertensive, short or long acting calcium channel blockers can be initiated while awaiting recovery. If the blood pressure is significantly elevated, intravenous hydralazine 0.1 mg per kg can be given every 4 to 6 hours with appropriate dose adjustment until other supportive measures are effective. If a child demonstrates persistent hypertension and proteinuria and if his renal function has been stable, ACE inhibitors or ARBs can be considered with close monitoring of serum creatinine and potassium. In a child whose course is consistent with RPGN, an immediate renal biopsy is warranted to provide histologic diagnosis and guide therapy.

In the absence of RPGN, the prognosis for complete recovery from the initial episode is good, which is true even for those who presented with renal insufficiency or hypertension. However, studies evaluating the long-term prognosis reveal residual signs of chronic kidney damage in some patients decades after the initial course. Late complications include proteinuria, hypertension, and decreased renal function. This underscores the importance of routine monitoring of blood pressure and urinalyses as part of health maintenance in those who have a history of ASPGN.

Henoch-Schönlein Purpura

Background

HSP is a multisystem IgA-mediated vasculitis predominantly affecting the skin, joints, gastrointestinal tract, and kidneys. Despite concerted research efforts, the exact pathogenesis of HSP remains unclear. Though HSP can occur at any age, most cases affect children between 3 and 15 years with a peak incidence at 4 to 7 years of age. In pediatric cases, there has been a male predominance noted with reported male-to-female ratio as high as 1.8:1. Presentation during adolescence or adulthood may predict a worse prognosis. The disease is more prevalent during autumn, winter, and early spring. The onset is usually sudden and frequently preceded by an acute illness, often involving the mucosal upper respiratory tract.

Clinical Manifestations

The clinical manifestations of HSP reflect the small-vessel vasculitis of affected organs. The hallmark signs and symptoms include nonthrombocytopenic purpuric rash, arthralgias, nonerosive arthritis, abdominal pain, and nephritis. The rash, often the most distinctive feature of the disease, characteristically involves the buttocks and extensor surfaces of the lower extremities. Purpura and joint pain are the most common presenting symptoms, though studies have revealed that abdominal symptoms may precede the rash in as many as 15% to 35% of cases. Overall, gastrointestinal symptoms occur in approximately half of children with HSP, and the most common abdominal symptoms are periumbilical pain, vomiting, diarrhea, and hematochezia. Surgical emergencies develop in 1% to 5% of patients and include intussusception and bowel perforation. The intussusception is confined to the small bowel in the majority of cases. The acute morbidity of HSP typically stems from severe gastrointestinal manifestations.

Though the acute illness may be overshadowed by gastrointestinal symptoms, the long-term prognosis for children with HSP depends upon the extent of the renal involvement. The exact prevalence of HSP nephritis is unknown, though rates as high as 54% have been reported. If nephritis develops, 90% of cases present within 6 weeks after the onset of systemic symptoms, and it is rare for nephritis to develop later than 6 months after presentation. Generally, if the urinalyses remain normal during the initial 6-month period, there is no need to screen for renal disease thereafter. Most children who develop nephritis will have relatively mild renal involvement. Signs of mild renal involvement include asymptomatic hematuria, mild proteinuria, and preserved or mildly and transiently impaired renal function. These patients are expected to have a favorable long-term prognosis. A subset of children will develop more severe renal involvement and develop nephritic syndrome or combined nephritic-nephrotic syndrome. Severe disease can be associated with decreased renal function, hypertension, hypoalbuminemia, and edema, and severe acute involvement would increase the risk for long-term renal sequelae. Histologically, children with severe clinical disease are more likely to have extensive involvement, such as crescentic changes in the majority of the glomeruli sampled.

Management

Most patients with HSP and associated nephritis receive supportive care, which includes ensuring hydration and comfort. If hypertension is present, short or long acting calcium channel blockers can be used. If the patient has significant nephritis, ACE inhibitors or ARB therapy should be used with caution as these agents may result in decreased renal function, which would be difficult to distinguish from a progressive case of HSP nephritis. Patients with HSP nephritis should undergo regular evaluation to screen for signs of progressive renal disease, such as worsening proteinuria, decreasing renal function, and hypertension.

Once HSP has developed, there are conflicting reports regarding the efficacy of early prednisone therapy to prevent significant nephritis. More recently, two randomized controlled studies have been performed to evaluate the effect of glucocorticosteroids on changing the risk of developing renal involvement with HSP. The first study included 40 children followed for 1 year. The treatment group received prednisone 2 mg per kg daily for 1 week followed by weaning doses over the second week. At 1 year there was no difference in the rate of renal involvement. The second study included 171 children who were followed over a 6-month period. The treatment group received 1 mg per kg daily of prednisone for 2 weeks followed by weaning over the subsequent 2 weeks. Prednisone did not prevent renal involvement, though appeared to improve the course of the nephritis with resolution of renal symptoms more rapidly when compared to the placebo group. This effect was most apparent in children older than 6 years who developed renal symptoms early in the course. However, spontaneous resolution also occurred in the placebo group and most children did well long-term with or without any steroid therapy. Further studies are required to determine if there is a role for steroids in HSP nephritis, either provided early in the acute course to reduce the incidence of renal involvement or prescribed after nephritis manifests to impact the course of renal involvement. The relatively infrequent occurrence of HSP nephritis and the overall favorable renal outcome has hindered research efforts, especially those involving medications such as steroids with significant clinical sequelae.

The optimal treatment of children with extensive renal disease remains controversial. Prior to initiating therapy, a renal biopsy should be obtained to determine the extent of crescent formation, as this appears to be the best indicator of prognosis. Cases with greater than 50% crescentic change have a guarded prognosis. Though data are limited given the rarity of severe HSP nephritis, aggressive therapy may be beneficial in patients with severe disease. Numerous uncontrolled trials have shown benefit when patients are treated with steroids with or without other agents such as azathioprine, cyclophosphamide, and anticoagulants. However, controlled trial of oral cyclophosphamide for 6 weeks without steroids did not demonstrate a difference in outcome after a mean follow up of nearly 7 years.

The short-term outcome of childhood HSP nephritis is favorable with 94% of children demonstrating complete recovery at a mean follow up of nearly 20 months. Recurrence of HSP is common and occurs in up to one third of patients and may not predict worse long-term outcome. The long-term outcome depends on the extent of renal involvement. A longitudinal study of 270 children with HSP followed over a mean of more than 8 years reported an optimistic outcome. Fifty-five children were found to have initial evidence of HSP nephritis at presentation and two thirds had mild renal disease (isolated hematuria or hematuria with mild proteinuria). Of those affected by mild disease, all recovered completely and had no evidence of persistent kidney disease at follow up. Of those with more severe nephritis, all had normal renal function and less than 20% had persistent urinary abnormalities at follow up. Other studies have demonstrated a guarded prognosis for those with severe HSP nephritis as evidenced by nephritic syndrome, combined nephritic-nephrotic syndrome, or more than 50% crescent formation on biopsy. Long-term follow-up of these patients reveal chronic renal sequelae such as hypertension or CKD in as many as 44% of patients.

Hemolytic Uremic Syndrome

Background and Pathophysiology

HUS is characterized by the clinical triad of microangiopathic hemolytic anemia, thrombocytopenia, and AKI. HUS can be broadly divided into typical forms associated with prodromal diarrhea or atypical cases distinguished by the absence of diarrhea. Typical HUS accounts for approximately 90% of pediatric cases and is frequently due to infection with enterohemorrhagic *Escherichia coli* (EHEC), which produce Shiga toxin. Atypical HUS is a heterogenous disorder and may be precipitated by numerous triggers, including drugs, bone marrow transplantation, and nonenteric infections such as those due to *Streptococcus pneumoniae* and human immunodeficiency virus. Evidence for a pathologic role of the alternative complement pathway has been revealed, and an increasing number of genetic mutations associated with atypical HUS have been described. Given that the majority of cases of HUS in children follow diarrhea, the subsequent discussion will focus on typical or diarrhea-associated HUS.

Typical Hemolytic Uremic Syndrome

Although outbreaks of diarrhea-associated HUS are dramatic and draw considerable public attention, only approximately 10% of cases in children arise from epidemics. A variety of organisms have been implicated in the pathogenesis, including *Shigella dysenteriae* type 1, *Salmonella*, and *Yersinia*. However, EHEC that produce a Shiga toxin accounts for the majority of cases, and *E. coli* serotype O157:H7 has been isolated in more than 80% of cases in the United States. EHEC may be carried in the intestines of asymptomatic cattle, and higher carriage rates have been noted in the summer months and early fall, mimicking the seasonal variation of human disease that peaks from June through September. Ground beef, vegetables, unpasteurized milk or juice, and water all serve as possible vectors of disease via contamination with bovine feces. Rarely, human-to-human transmission occurs via oral-fecal contamination. Although children of all ages can develop typical HUS, this principally affects children younger than 5 years. Approximately 10% to 15% of children who develop culture confirmed *E. coli* O157:H7 gastroenteritis progress to HUS. Measures to prevent progression to postdiarrheal HUS have been unsuccessful, and the use of antibiotics and antimotility agents appear to increase the risk of subsequent HUS.

Pathophysiology. Central to the pathogenesis of typical HUS is microvascular endothelial cell injury induced by Shiga toxin. Once the integrity of the intestinal mucosal barrier is disrupted by the inciting pathogen, cytotoxin gains access to the circulation and extragastrointestinal sites. After binding to the cell surface receptor glycosphingolipid globotriosyl ceramide, which is highly expressed on renal endothelium, a subunit of the toxin inactivates the 60S ribosome and suppresses protein synthesis leading to cellular dysfunction. The hematologic abnormalities reflect the underlying microangiopathic process and microthrombi formation.

Clinical Manifestations. The clinical manifestations of HUS are generally apparent 5 to 10 days after the onset of colitis. The colitis begins with watery diarrhea and evolves to hemorrhagic colitis in the majority of patients. The intestinal involvement may be associated with vomiting and severe abdominal pain and mimic other diseases such as ulcerative colitis, regional enteritis, intussusception, and appendicitis. Gastrointestinal complications include bowel wall necrosis, toxic megacolon, intussusception, and rectal prolapse. HUS generally becomes apparent as the diarrhea is resolving, and the evolution of the clinical signs may be abrupt. The child may present pale and listless with laboratory studies showing microangiopathic anemia and thrombocytopenia. Jaundice is present in approximately one third of patients. Given symptoms of severe diarrhea and vomiting, the child may present with hypovolemia. Alternatively, if oral intake has been maintained in the face of oliguric renal failure, signs of volume excess may be apparent, including edema and hypertension.

Laboratory studies show decreasing hemoglobin, increased reticulocytes, increased lactate dehydrogenase, and thrombocytopenia. Assessment of the blood smear demonstrates fragmented erythrocytes and schistocytes. Coagulation studies are generally normal, distinguishing HUS from sepsis and disseminated intravascular coagulation. The indirect and direct Coomb's test should be negative.

The severity of the renal involvement in typical HUS varies widely. AKI may be mild and self-limited, associated with microscopic hematuria, mild proteinuria, and preserved renal function. When renal microangiopathy is severe, fulminant

oligoanuric renal failure may ensue and necessitate RRT. In a retrospective review of typical HUS in Utah over a 20-year period, 60% of children experienced anuria or oliguria lasting a median of 6 days, and dialysis was performed in 43% of cases. Age less than 2 years, anuria before admission, and leukocytosis on admission predicted more severe disease. Hypertension was present in two thirds of children but was mild and typically resolved at the time of discharge.

Microangiopathic injury of organs other than the kidneys and intestine may occur. Pancreatic involvement can be associated with transient or rarely permanent diabetes mellitus. Liver injury manifests as hepatomegaly and elevated transaminases. Clinical evidence of microangiopathy of the myocardium or lung is not usually apparent, though cases of circulatory collapse due to decreased ventricular function have been reported. Involvement of the CNS can result in significant morbidity and is the most common cause of death in children. The majority of children demonstrate some degree of encephalopathy as irritability and somnolence. More significant manifestations are apparent in up to 20% of children with typical HUS and include seizures, coma, stroke, hemiparesis, and cortical blindness. Seizures and cerebral infarct occur in 10% and 4% of children, respectively and predict a poorer prognosis.

Management. The mainstay of therapy for typical HUS is meticulous supportive care. As children often present after several days of gastrointestinal losses and poor oral intake, intravascular volume may be depleted, increasing the risk for prerenal AKI to compound the microvascular disease. Fluid resuscitation with isotonic saline should be provided with repeated assessment of volume status. Once the intravascular volume status has been restored, further fluid management should be guided by renal function and urine flow. If oligoanuria is present, a trial of furosemide (1 to 2 mg per kg per day) may be provided to establish urine flow. If oligoanuria persists, fluids should be provided at a rate to ensure adequate intravascular volume but avoid volume excess. Both intravenous and oral intake should match the total of measurable output (urine and gastrointestinal losses) and insensible water losses, estimated at 300 mL per m^2 per day. Frequent monitoring of fluid balance, weight, and vital signs is essential. If hypertension develops and is sustained, therapy should be provided. Vasodilators such as hydralazine or calcium-channel blockers are effective and preferred over ACE inhibitors and ARBs given ongoing kidney injury.

The anemia associated with typical HUS can be fulminant. Packed red blood cell transfusions should be provided for symptomatic anemia or vigorous hemolysis with anticipated or actual hematocrit less than 18% to 20%. If the patient is oligoanuric, this should be performed while on dialysis to avoid volume excess and hyperkalemia. During microangiopathy, transfused platelets will be consumed quickly and not result in sustained increase in the platelet count. Platelet transfusion is only indicated in patients with active bleeding or when a surgical procedure is intended.

Approximately 40% to 60% of children with typical HUS will require RRT. Indications for dialysis include progressive azotemia, clinically significant volume overload, and hyperkalemia or acidosis that is refractory to conservative medical therapy. Dialysis is also indicated to safely provide blood products and nutritional support in the setting of persistent oligoanuria. The modality of dialysis depends on the expertise of the center. However, if there is a severe abdominal complication requiring surgical intervention, hemodialysis will be necessary as peritoneal dialysis will be contraindicated. Plasma exchange can be considered in children with severe CNS involvement such as stroke and seizures based upon reported benefits in adults with thrombotic thrombocytopenic purpura and severe neurologic dysfunction.

Nephrotic Syndrome

Background and Pathophysiology

Nephrotic syndrome results when there is increased permeability across the glomerular filtration barrier and is characterized by massive proteinuria exceeding 50 mg per kg per day leading to hypoproteinemia, edema, and hyperlipidemia. Nephrotic syndrome is the clinical expression of a variety of glomerular diseases and can be classified as primary or secondary. Primary nephrotic syndrome includes idiopathic nephrotic syndrome and nephrotic syndrome associated with primary glomerulonephritis. Idiopathic nephrotic syndrome is typically associated with bland urine sediment and no significant glomerular inflammation on renal pathology, and underlying causes include minimal change disease (MCD) and primary focal segmental glomerulosclerosis (FSGS). Nephrotic syndrome associated with primary glomerulonephritis, such as IgA nephropathy and MPGN, is generally associated with an active urine sediment and inflammation on renal pathology. Secondary nephrotic syndrome is associated with systemic disorders such as infection with the human immunodeficiency virus, systemic lupus erythematosus, and HSP. Intrauterine infections with syphilis, toxoplasmosis, and other organisms have been associated with congenital nephrotic syndrome.

In children younger than 16 years, the annual incidence of nephrotic syndrome is approximately 2 per 100,000. Presentation within the first year of life is uncommon, and nephrotic syndrome within the first 3 months of life should raise the suspicion for congenital nephrotic syndrome. Idiopathic nephrotic syndrome is the most common form of childhood nephrosis. Children typically present between the ages of 2 and 6 years, and the reported ratio of boys to girls who are diagnosed at a younger age is as high has 2:1. The gender ratio is closer to 1:1 in those who present later in childhood or as adolescents. When children with primary nephrotic syndrome underwent renal biopsy at presentation during the 1960s and 1970s as part of the International Study of Kidney Disease in Children, it was revealed that MCD was the most common histopathology accounting for 77% of cases. MPGN and FSGS accounted for 8% and 7%, respectively. Other pathologies included proliferative nephritis, mesangial proliferation, and membranous glomerulonephropathy. Contemporary data have documented an increased incidence of FSGS, a disorder less responsive to glucocorticoid therapy and more likely to progress to renal failure.

Most patients with MCD (greater than 90%) will respond to glucocorticoid therapy. Clinical findings at presentation suggestive of MCD include age younger than 6 years; normal renal function, blood pressure, and complement levels; and benign urine sediment. Given the high frequency of MCD as the cause of idiopathic nephrotic syndrome and the favorable response of MCD to glucocorticoid therapy, an empiric trial of

glucocorticoid therapy without confirmatory pathology is often provided to prepubertal children with suggestive clinical characteristics. Adolescents are also considered for empiric therapy, though obtaining a renal biopsy prior to therapy or after a defined period of glucocorticoid therapy without response would be reasonable given the increased occurrence of FSGS, MPGN, and membranous nephropathy in this age group. Patients with idiopathic nephrotic syndrome are further classified on the basis of their response to glucocorticoid therapy: glucocorticoid-responsive, glucocorticoid-dependent, and glucocorticoid-resistant nephrotic syndrome. Patients with responsive disease have a favorable long-term prognosis, and those with resistant pattern have a more guarded prognosis.

Nephrotic syndrome diagnosed within the first 3 months and first year of life is termed congenital nephrotic syndrome and infantile nephrotic syndrome, respectively. Most of these children have a genetic basis for the renal disease with mutations affecting nephrin (NPHS1), podocin (NPHS2), WT1, and laminin beta-2 (LAMB2). Nephrin is a key component of the slit diaphragm, and podocin is a protein that interacts with nephrin at the slit diaphragm. WT1 encodes a protein involved in kidney development, and LAMB2 encodes a component of the glomerular basement membrane. In a European study analyzing these genes in 89 children and 80 families with nephrotic syndrome in the first year of life, it was found that approximately 85% of the families with congenital onset and 44% of those with infantile onset were explained by known mutations. Mutations in nephrin and podocin were by far the most common. As predicted by their structural or developmental roles, infants with causative mutations in any of these four genes did not respond to glucocorticoid therapy. Congenital nephrotic syndrome may also be due to intrauterine infection, such as congenital syphilis, toxoplasmosis, cytomegalovirus, human immunodeficiency virus, and other organisms. Evaluation should be pursued for these treatable infectious diseases.

Clinical Manifestations and Complications

Edema is one of the major clinical manifestations of nephrotic syndrome and represents excessive salt and water retention. Periorbital edema is often the initial finding and may be misdiagnosed as signs of allergy. Prominent upper eyelid edema should prompt evaluation for nephrotic syndrome. The edema is gravity dependent and therefore will vary in location based on patient position and activity. Upon awakening, edema may be more marked in the face and then shift to the lower extremities with ambulation. Anasarca, or generalized and massive edema, may develop and is characterized by marked peripheral edema, vulvar or scrotal edema, ascites, abdominal distention, and pleural effusions with respiratory compromise.

Two major processes have been proposed to be the cause of edema formation: arterial underfilling because of low oncotic pressure (hypoalbuminemia) and primary renal sodium retention. Evidence has supported both mechanisms, and it is likely that both processes contribute to varying degrees in individual patients. To be able to determine which is most relevant may impact clinical care. Diuretic therapy would be effective in reducing edema and indicated if the primary process is renal sodium retention. However, if hypoalbuminemia leads to decreased plasma volume via movement of fluid from the vascular space to the interstitium, diuretic therapy may aggravate arterial underfilling. As it may be difficult to determine intravascular volume in patients with nephrotic syndrome, clinical characteristics that may predict intravascular volume status include GFR and serum albumin level. Patients with reduced GFR and higher plasma albumin concentrations (greater than 2 g per dL) may be more likely to have elevated intravascular volume and tolerate diuretics with less risk of precipitating clinically significant arterial underfilling. Patients who are more likely to have underfilling are those with severe hypoalbuminemia (less than 1 g per dL) or those with rapid onset of nephrosis.

In addition to volume excess, complications resulting from nephrotic syndrome include infection, thromboembolism, and hypovolemia. Children with nephrotic syndrome are at increased risk of developing serious bacterial infection, particularly infections with encapsulated bacteria, given urinary losses of immunoglobulins and alternative complement pathway factor B and factor D. Children who are treated with immunosuppressive agents will have additional risks. Furthermore, ascites and pleural effusions will increase the risk for peritonitis, pneumonia, and empyema. The reported rates of peritonitis are approximately 2% to 6%. Other infections include sepsis, meningitis, cellulitis, urinary tract infection, upper respiratory tract infection, and severe AGE. A retrospective review of 24 episodes of peritonitis in children with idiopathic nephrotic syndrome prior to the current practice of vaccination with pneumococcal vaccine revealed *Streptococcus pneumoniae* was the most common isolated pathogen (50%). *Escherichia coli* was also commonly isolated, accounting for 25% of cases. Children with nephrotic syndrome who are receiving immunosuppression may also develop life-threatening viral infections, and varicella may result in significant morbidity and mortality.

Thromboembolic complications are reported in approximately 2% to 3% of children with nephrotic syndrome and may occur in either the arterial or venous circulation. The risk may be higher in children with steroid-resistant disease and persistent of nephrotic syndrome. Nephrotic syndrome results in a hypercoagulable state due to urinary losses of antithrombin, protein S, and plasminogen. Additional risk factors include hemoconcentration, thrombocytosis, infection, and immobility. Though many embolic events are silent, as has been documented by ventilation-perfusion scan abnormalities detected in asymptomatic subjects, pulmonary embolism and renal vein thrombosis may result in significant morbidity. Though a much less frequent occurrence in children than in adults with nephrotic syndrome, renal vein thrombosis should be suspected in cases of sudden onset macroscopic hematuria and flank pain.

Though children with nephrotic syndrome and edema have total body sodium and water excess, some will present with evidence of intravascular depletion. This is more likely to occur in those with severely depressed serum albumin and will be exacerbated by diuretic use, gastrointestinal losses, and restricted intake. Signs of decreased effective circulating volume include tachycardia, peripheral vasoconstriction, and oliguria. Laboratory studies may demonstrate renal insufficiency, which may be acute and transient due to intravascular depletion, secondary to the underlying renal pathology, or due to a combination of these factors.

Management

The initial assessment of a child with nephrotic syndrome should focus on the adequacy of intravascular volume and perfusion, respiratory status, and assess for evidence of infection.

As some patients with nephritis will have concomitant nephrotic syndrome (secondary nephrotic syndrome), accurate measurement of blood pressure should be documented to screen for associated hypertension. There should be a thorough assessment of recent fluid balance, with specific inquiries to diuretic use, urine output, and gastrointestinal losses.

The intent of laboratory investigation should include confirmation of nephrotic syndrome, identification of associated electrolyte abnormalities, and a determination if the disorder is associated with glomerulonephritis or systemic disease. The serum albumin should be less than 2.5 g per dL to fulfill the criteria for nephrotic syndrome and may be profoundly depressed (less than 1 g per dL). A freshly obtained urine sample should confirm heavy proteinuria by dipstick and be inspected for the presence of macroscopic hematuria, which may suggest glomerulonephritis. Nephrotic range proteinuria in children is defined as protein excretion greater than 50 mg per kg per day, though this would depend upon a timed 24-hour urine collection, which is prone to inaccuracies and may not be feasible in a young child. Alternatively, a urine protein to creatinine ratio can be submitted on a spot urine sample to quantify the degree of proteinuria. A normal ratio is less than 0.5 in children younger than 2 years and less than 0.2 in older children and adults. Generally, a ratio more than 2 to 3 is consistent with nephrotic range proteinuria. Serum electrolytes may reveal hyponatremia, which is not uncommon and secondary to decreased intravascular volume and stimulation of ADH release. Hyponatremia in the edematous child does not reflect total body sodium depletion but water excess greater than sodium excess. Renal function studies may be abnormal and reflect decreased intravascular volume or the underlying renal disease. Complete blood cell counts may demonstrate elevated hemoglobin and hematocrit due to hemoconcentration. Studies to distinguish the cause of nephrotic syndrome should be considered based on the patient's presentation. Serum complements may identify disorders associated with complement consumption such as postinfectious glomerulonephritis, MPGN, and lupus nephritis. Additional studies to be considered include serum antinuclear antibodies, antibodies to double-stranded DNA, and hepatitis B and C serologies.

Children with nephrotic syndrome who present to the emergency department with the primary complaint of edema are generally provided supportive care. Therapy of edema and volume excess should begin with sodium restriction. Optimally, children are restricted to approximately 2 to 3 mEq per kg per day of sodium or up to a maximum of 2,000 mg per day in older children and adolescents. Edematous children who have adequate intravascular volume and mild to moderate hyponatremia should not be provided supplemental sodium, as they are in a state of sodium excess. Water restriction should be initiated, given the release and action of ADH resulting in dilutional hyponatremia. Though diuretics are commonly provided to adults with nephrotic syndrome, the risks of aggravating intravascular volume depletion in children should be considered and discussed with a pediatric nephrologist if possible. Children who present with severe edema should be admitted and may be treated with furosemide and salt-poor albumin (e.g., 25% albumin) to achieve diuresis. Albumin (0.5 to 1 g per kg) infused over 4 hours with one to two doses of furosemide (0.5 to 1 mg per kg per dose) should result in fluid mobilization. Providing albumin will bolster the intravascular oncotic pressure and safeguard against volume depletion during fluid mobilization. The effect of albumin and furosemide will be transient given ongoing urinary losses of albumin and should be coupled with sodium restriction and education. Should renal function be diminished, albumin infusions may result in hypertension and pulmonary congestion due to limited ability to excrete salt and water despite improved intravascular volume, and these risks must be considered.

Children with nephrotic syndrome who present with evidence of inadequate intravascular volume should be provided isotonic intravenous fluid. Due to the increased risk of infection, any evidence of sepsis physiology should be addressed promptly. Normal saline can be infused as bolus therapy to restore perfusion. If readily available, 5% albumin would provide the additional benefit of oncotic support should the serum albumin be severely depressed. Once the intravascular volume is adequately restored, sodium and water restriction should be tailored to the individual need in order to avoid progressive volume excess and respiratory compromise. Admission for close volume management should be strongly considered if evidence of hypovolemia is apparent at presentation or uncontrolled fluid loss is anticipated (i.e., gastroenteritis) given the risk for thromboembolic complications and prerenal kidney injury.

Children with nephrotic syndrome are at increased risk for infectious complications, and overwhelming infection carries a mortality rate of 1.5%. As these children are predisposed to infections with *Streptococcus pneumoniae* and gram-negative bacterial infections, appropriate antibiotic coverage should be provided. Pneumococcal vaccination with the 23-valent and heptavalent conjugated pneumococcal vaccine is recommended, though data do not support the routine use of prophylactic antibiotics. Children with nephrotic syndrome who require immunosuppressive therapy are also at increased risk for developing severe varicella infection. Prophylactic treatment with varicella zoster immune globulin (VZIG) is recommended in cases of exposure to nonimmune children with nephrotic syndrome who are taking immunosuppressive treatments and should be administered within 96 hours of the exposure. In addition, acyclovir can be considered an adjunctive measure to VZIG in exposed patients on immunosuppressive therapy. Acyclovir should be initiated promptly in any patient exhibiting any signs of varicella infection. Varicella vaccine should be administered to children with nephrotic syndrome, if not immune. Ideally, it should be administered when the child is on alternate day or off corticosteroid therapy and should not be given within 5 months of VZIG.

Though children with nephrotic syndrome are at risk for thromboembolic complications as discussed above, most clinicians do not give prophylactic therapy initially given the lack of randomized controlled clinical trials supporting this practice. Some, however, will treat high-risk patients based on their coagulation profile with warfarin, low-dose aspirin, or dipyridamole. Supportive measures to reduce the risk of thromboembolism include mobilization and avoiding intravascular volume depletion (hemoconcentration). If thrombosis does occur, heparin is provided with the expectation that infusions of antithrombin III may be required to be effective. In children with a history of thrombotic complications and ongoing nephrosis, warfarin should be initiated to prevent future events.

In addition to the management of acute complications of nephrotic syndrome in emergency care settings, management of chronic complications requires regular outpatient visits and monitoring. Therapy for hyperlipidemia, persistent proteinuria, chronic hypertension, and dietary guidance is provided, though full discussion is beyond the scope of this chapter.

Urolithiasis

Background

Urolithiasis accounts for 1 in every 1,000 to 7,600 admissions to pediatric hospitals annually throughout the United States, which is approximately one fiftieth to one seventy-fifth of that reported in adults. Furthermore, the incidence over the last decade may be increasing. In the United States, urolithiasis occurs more commonly in the southeastern region, and Caucasian children are most often affected. Boys may demonstrate an increased risk for renal stone formation when compared to girls, with reported male-to-female ratios of 1.4:1 to 2:1. In 75% to 85% of children affected, an identifiable risk factor is revealed. The most common underlying factors are metabolic predisposition and structural urinary tract abnormalities, accounting for approximately 50% and 32% of cases, respectively. The most common metabolic risk factors are hypercalciuria, hypocitraturia, and hyperoxaluria. Renal and urinary tract anomalies associated with urinary stasis include neurogenic bladder, ureteropelvic junction obstruction, medullary sponge kidneys, and autosomal dominant polycystic kidney disease. As in adults, the majority of stones in children are calcium based with approximately 45% calcium oxalate and approximately 25% calcium phosphate reported at analysis.

Clinical Manifestations

Flank pain and hematuria due to renal colic are commonly experienced in adults who present with nephrolithiasis. Though many children present with classic symptoms, approximately 15% to 20% are asymptomatic at presentation, and these tend to be younger children. In one series, 94% of adolescents presented with pain or hematuria. In children from birth to 5 years, 56% presented with these symptoms. The age-related difference in the symptoms may be due to stone location. Young children are more likely to have renal rather than ureteral stones. Ureteral stones causing obstruction would produce renal colic, whereas renal stones may be asymptomatic and found incidentally. Gross hematuria has been reported in up to 55% of children and can occur with pain or in isolation. Dysuria and urgency has also been reported and may be due to mechanical irritation of the lower urinary tract or concomitant urinary tract infection. Urease-producing bacteria are strongly associated with urolithiasis. Hydrolysis of urea will produce ammonium and bicarbonate ions and increases the risk for magnesium ammonium phosphate (struvite) stones. Urease-producing bacteria include *Proteus*, *Klebsiella*, *Providencia*, *Pseudomonas*, *Enterobacter*, and *Ureaplasma urealyticum*.

The evaluation of a child with urolithiasis includes a thorough personal and family history. Inquiries regarding previous urolithiasis, recurrent urinary tract infections, and underlying urologic abnormalities should be pursued. Given the high proportion of children with and underlying metabolic predisposition, specifically hypercalciuria, the history should account for periods of immobilization, vitamin D supplementation, and treatment with loop diuretics. Children with fat malabsorption are at risk for increased enteric absorption of oxalate and hyperoxaluria, and therefore, gastrointestinal history should include symptoms consistent with inflammatory bowel disease, pancreatic insufficiency, and history of bowel resection. Patients with cystic fibrosis have numerous potential risk factors for calcium oxalate stones, including pancreatic disease, vitamin D supplementation, altered bowel flora, and low urine volume. Physical examination should include documentation of temperature, careful abdominal exam, and growth measurements. Poor growth may be a sign of chronic renal disease, such as distal RTA, which may be associated with urolithiasis.

Management

The initial laboratory evaluation should include urinalysis with urine pH and assessment of the urine sediment, which may reveal crystals. Urine culture should be submitted to evaluate for urinary tract infection, especially in children with known abnormality of the urinary tract given the risk for chronic urinary tract infection. Serum studies should include measurement of electrolytes, including calcium and phosphorus, bicarbonate, magnesium, uric acid, and creatinine. Depending on the results of the initial laboratory screen, other studies to be considered include PTH and vitamin D metabolites. Given the frequency of metabolic predisposition, urine studies to be performed in the nonurgent setting include a timed 24-hour assessment of urinary solutes (e.g., calcium, oxalate, uric acid, citrate, magnesium, cystine), urine creatinine, and urine volume. This should also be pursued in children with known urologic tract abnormalities, as approximately 35% of children with urologic malformation and urolithiasis were found to have metabolic risk factors. If the child's age or development is not permitting for a daily collection, assessment of solute excretion based upon random urine samples should be submitted. If the stone is available, this should be submitted for analysis, which may guide future preventative therapy.

Diagnostic imaging techniques available to evaluate for urolithiasis include abdominal plain radiography, ultrasonography, and noncontrast helical computed tomography (CT). Abdominal radiograph may detect radiopaque stones (e.g., calcium, cysteine, and struvite stones) though will not reveal radiolucent stones (e.g., uric acid stones). Plain radiograph may miss small stones and stones overlying bony structures, and one center reported a sensitivity of 57%. Furthermore, radiograph will not assess the urinary tract for obstruction. Ultrasonography is widely available, avoids radiation, and will assess for urinary obstruction. Ultrasonography can detect radiolucent stones, though may not identify small papillary, calyceal, or ureteral stones. Noncontrast helical CT scan is the most sensitive modality to detect urolithiasis, especially ureteral or small calculi and provides the most anatomic detail of the urinary tract. Performance of CT scan will result in radiation exposure, and this must be considered. However, adjustments of scanning technique appropriate for the size and weight of the child can be made to reduce radiation exposure.

The management of urolithiasis will be based on the severity of symptoms and likelihood of spontaneous passage of the stone. Children with significant acute renal colic, urinary tract obstruction, and potentially infected stones should be evaluated

in concert with a urologist. Children with smaller stones (less than 5 mm) and mild symptoms may be appropriately managed as an outpatient with hydration and NSAIDs. Hydration will increase urine flow and may facilitate passage. Increased hydration may also minimize stone growth and decrease the risk for recurrent stone disease. In adults, medications prescribed to facilitate the passage of ureteral stones include antispasmodic agents, calcium channel blockers, and alpha blockers. Studies evaluating these therapies in children are not currently available. Instructions to strain the urine should be provided, and any retrieved fragments should be submitted for analysis. Reliable follow up should be assured. Children with significant pain, vomiting, or concern for urinary tract infection should be admitted for appropriate care.

Urologic intervention may be required and indications include unremitting severe pain, persistent obstruction despite conservative management, urolithiasis in a solitary kidney with obstruction or risk of obstruction, larger stones that are unlikely to pass spontaneously (e.g., greater than 5 mm), renal insufficiency, and urosepsis. Though open surgical repair remains an option, other procedures have been adapted for use in children and have reduced the need for surgical intervention. These procedures include extracorporeal shock wave lithotripsy (ESWL), percutaneous nephrostolithotomy, and ureterostomy. The procedure utilized is determined by the experience of the clinician, the stone size and location, and anatomic abnormalities. Stone composition, if known, is also considered. Stones of harder composition, such as cystine and calcium oxalate monohydrate, are less likely fragmented with ESWL.

Recurrence of urolithiasis in children and adolescents is common with reported rates of 30% to 65%, underscoring the need for referral to a pediatric urologist or nephrologist for metabolic evaluation and appropriate preventive care. Children with an identified metabolic abnormality are at the highest risk for recurrence. Preventive measures should be pursued in all children with urolithiasis to reduce the risk of recurrence. The importance of increased fluid intake to increase the urine flow rate and lower urine solute concentration must be emphasized. Recommended fluid intake is based upon age and desired 24-hour urine volume (Table 100.15). For children with hypercalciuria, additional measures should include low-sodium diet and avoidance of supplemental vitamin D. Low sodium intake enhances renal tubular absorption of both sodium and calcium, thereby reducing calcium excretion. Dietary calcium should meet the RDA but not be excessive. Limiting calcium intake was found to increase oxalate excretion in adults. If the response to supportive measures is insufficient based upon repeat assessment of urinary solutes or recurrent disease, thiazide diuretics to reduce calcium excretion should be considered. For patients with hypocitraturia, supplemental potassium citrate can be provided. Citrate inhibits stone formation by forming a soluble complex with calcium. Specific preventive measures for other disorders, including hyperoxaluria, hyperuricosuria, and cystinuria should be pursued, though discussion is beyond the scope of this chapter. Monitoring should include imaging to follow the size of existing stones and to identify the development of new stones. Ultrasonography is generally the favored modality given the lower radiation exposure and availability.

TABLE 100.15

UROLITHIASIS: TARGET DAILY URINE VOLUME BASED ON AGE

Infants	>750 mL/day
Children <5 yr	>1,000 mL/day
Children 5–10 yr	>1,500 mL/day
Children >10 yr, adolescents, adults	>2,000 mL/day

CHRONIC KIDNEY DISEASE

Background

The definition of CKD is based upon persistent structural or functional abnormalities, which may be associated with reduced or normal GFR. When reviewing registry data of children with CKD, the most common primary diseases were congenital and included obstructive uropathy (20.7%); renal aplasia, hypoplasia, and dysplasia (17.3%); and reflux nephropathy (8.4%). FSGS, which is an acquired glomerulopathy, accounted for 8.7% of diagnoses. The natural history of CKD is variable and depends upon the severity of the underlying kidney damage. When kidney damage is significant, there is progressive loss of functioning nephron mass leading to end-stage renal disease (ESRD). In 2002, the National Kidney Foundation Kidney Disease Outcomes Quality Initiative put forth definition criteria and a classification scheme to define the stages of CKD in patients older than 2 years (Table 100.16). Emphasis is placed on early detection and intervention, as measures to retard the progression of renal dysfunction include treating hypertension and reducing proteinuria when it is significant. For children who progress to ESRD, therapies include chronic hemodialysis, peritoneal dialysis, and renal transplantation. Renal transplantation is recognized as the preferred treatment for children with ESRD, as restoration of normal renal physiologic function can greatly improve the child's quality of life.

Clinical Manifestations

The clinical presentation of CKD will depend upon the severity of the renal dysfunction and the underlying cause. Children with mild CKD (stage 1 and 2) and no other comorbidities may be asymptomatic. Children with more severe CKD are at increased likelihood for associated symptoms and signs such as fatigue, anorexia, and poor growth. Furthermore, these children may present for emergent care with a variety of complaints directly related to renal dysfunction including hypertension, volume excess, anemia, and severe electrolyte or acid–base abnormalities. They may also present with illness attributable to the underlying disorder, such as urinary tract infection in those with complex urologic disease and symptoms of systemic inflammation in those with systemic vasculitis. Children with CKD have limited renal reserve and are susceptible to AKI

TABLE 100.16

STAGES OF CHRONIC KIDNEY DISEASE

Stage	Description	GFR (mL/min/1.73 m^2)
1	Kidney damage with normal or increased GFR	≥90
2	Kidney damage with mildly decreased GFR	60–89
3	Moderately decreased GFR	30–59
4	Severely decreased GFR	15–29
5	Kidney failure	<15 (or dialysis)

Chronic kidney disease is defined as either kidney damage of GFR <60 mL/min/1.73 m^2 or ≥3 mo. Kidney damage is defined as pathologic abnormalities or makers of damage, including abnormalities in blood or urine tests or imaging studies.
Adapted from Hogg RJ, Furth S, LemLey KV, et al. National Kidney Foundation's Kidney Disease Outcomes Quality Initiative clinical practice guidelines for chronic kidney disease in children and adolescents: evaluation, classification, and stratification. *Pediatrics* 2003;111:1416–1421.

superimposed on chronic insufficiency, which will increase the risk for metabolic derangements and volume excess.

Though many children with CKD who present for emergent care have a known history of renal disease, some will present with newly diagnosed CKD. For those with a new diagnosis, the physician should inquire about previous episodes of urinary tract infection and signs of concentrating defect or urologic disease, such as polyuria, polydipsia, and enuresis. To evaluate for signs consistent with chronic glomerulonephritis, history of gross hematuria, edema, unusual rashes, or evidence of systemic inflammation should be sought. A review of the family history should include inquiries of urologic disease, vesicoureteral reflux, progressive kidney disease, cystic kidney disease, and early onset hypertension.

Management

The initial evaluation of a child with CKD must include accurate assessment of blood pressure, cardiopulmonary exam, volume status, and growth parameters. Initial laboratory studies should be guided by the presenting complaint and history, though assessment of blood counts, electrolytes (including calcium and phosphorus), acid–base status, and renal function should be performed. The GFR may be estimated by using the Schwartz formula (Table 100.13), which takes into account the serum creatinine and the patient's height and gender. This formula is convenient for use at the bedside, though tends to overestimate GFR due to the tubular secretion of creatinine. This overestimation increases with decreasing GFR, and newer equations are being developed but need validation. Urinalysis should also be submitted as it may provide useful clinical data. Most patients with congenital dysplasia or reflux nephropathy will have bland urine sediments and modest amounts of proteinuria. Significant hematuria, heavy proteinuria, and active urine sediment with glomerular hematuria and cellular casts would be consistent with glomerular disease. Further laboratory studies should be guided by the presentation of illness and clinical suspicion.

For all children with newly diagnosed CKD of unknown etiology and for many children with known urologic disease, a renal ultrasound is indicated. This is a safe and readily available radiographic study and can provide valuable assessment of the renal parenchyma and the urologic tract. Ultrasound can detect such disorders as renal dysplasia, renal cortical thinning consistent with reflux nephropathy, cystic kidney disease, urinary tract obstruction, and screen for renal vascular disease. If the kidneys appear relatively normal but enlarged, this is more suggestive of an acute or reversible process. Small kidneys would be consistent with a chronic process and parenchymal scarring. Of note, the use of gadolinium has been associated with nephrogenic systemic fibrosis (NSF), a recently identified severe fibrosing disorder found only in patients with renal failure. Gadolinium should be avoided in patients with acute or chronic renal failure, and this includes those patients on hemodialysis and peritoneal dialysis. If gadolinium is thought to be necessary, then the risks and benefits should be discussed, the lowest possible dose of gadolinium should be provided, and consideration should be given to the preparation of gadolinium as some may result in increased risk for the development of NSF. Furthermore, hemodialysis immediately after gadolinium exposure may reduce the risk of NSF, though this is not proven effective.

The treatment of children with CKD can range from routine care to intensive management. If a child with CKD presents to the emergency department with a significant illness, treatment should be coordinated with a pediatric nephrologist when possible. The initial approach should identify reversible causes of decreased renal function, such as intravascular volume depletion and use of nephrotoxic medications (i.e., NSAIDs). Children who have decreased effective circulating volume should be provided intravenous isotonic fluid if oral hydration is expected to be insufficient or not well tolerated. Bolus intravenous fluid can be provided at 5 to 10 mL per kg and should be followed by repeated assessment to determine if further intravenous fluid is warranted. Subsequent fluid rates should be provided on the basis of ongoing losses and urine flow to ensure adequate perfusion and avoid volume excess.

With severe decline in GFR, sodium and water retention may develop and lead to clinical signs if volume overload. Children with CKD may present with edema, hypertension, and pulmonary congestion. Diuretic therapy should be trialed for treatment of clinical volume overload, though may not be adequately effective. Furosemide at a dose of 1 to 2 mg per kg intravenously may be given, recognizing that higher doses may be required to achieve the desired effect for those with more severe renal dysfunction. For children with sustained hyper-

tension, therapy will depend on the degree and the chronicity of elevation. Severe hypertension with end-organ dysfunction or concern for impending end-organ dysfunction should be treated with short acting intravenous antihypertensive medications, and commonly used agents include hydralazine and labetalol. The aim of therapy is to lower the blood pressure by 20% to 30% or to a range that is not acutely dangerous within the first 2 to 3 hours. Blood pressure can then be controlled gradually over the next several days or longer. ACE inhibitor and ARB therapy are generally well tolerated in early stages of CKD and may slow the progression of CKD over time, especially in those with proteinuria. However, in more severe CKD, these agents may result in unacceptable elevations in serum potassium and decreased GFR. For those children with CKD and on ACE inhibitor or ARB therapy chronically, these agents may need to be temporarily held during periods of acute deterioration of renal function.

Electrolyte and acid–base abnormalities are common in CKD and include hyperkalemia, hypocalcemia, hyperphosphatemia, and metabolic acidosis. The therapy of these electrolyte and acid–base disturbances were previously discussed. Of note, the metabolic disturbances associated with CKD generally develop gradually, and therefore, immediate correction may not be warranted and may, in fact, be deleterious. Given the potential for cardiac dysrhythmias, hyperkalemia should be addressed urgently. In clinically stable patients with concurrent hypocalcemia and acidosis, the potential risk for tetany with alkali therapy should be considered. If clinically reasonable, hypocalcemia should be treated initially, and this can be achieved with oral calcium if the patient is asymptomatic.

For some children with severe CKD or AKI superimposed on CKD, supportive medical management will be insufficient and RRT will be required. Accepted indications for RRT include severe fluid overload, refractory hyperkalemia, and severe uremia. Modalities of dialysis include continuous renal replacement, intermittent hemodialysis, and peritoneal dialysis. The modality utilized will depend on the clinical circumstances, local resources, and clinician preference.

CHAPTER 101 ■ RHEUMATOLOGIC EMERGENCIES

AMY L. WOODWARD, MD, MPH, AND ROBERT P. SUNDEL, MD

Pediatric rheumatologic conditions are relatively rare, affecting less than 0.5% of children in the United States. Further, pediatric autoimmune diseases are most commonly chronic conditions with an indolent onset rather than acute conditions likely to bring a child to the emergency department (ED). Nonetheless, arthritis, lupus, and vasculitis [especially Kawasaki disease (KD)] may have acute and life-threatening manifestations requiring rapid initiation of appropriate therapy. These plus the conditions that must be distinguished from them are quite prevalent; for example, up to 20% of urgent visits to pediatricians involve musculoskeletal complaints. Thus, arthritis, vasculitis, and other inflammatory and autoimmune conditions of childhood must be considered if clinicians are to recognize and treat the far more common infectious and traumatic complaints likely to bring children to their attention. Finally, treatment of rheumatologic disorders is becoming more sophisticated and more specialized, involving combinations of antiinflammatory, immunosuppressive, and biologic agents with a wide spectrum of intended and undesired effects. For all of these reasons, familiarity with rheumatologic conditions and their treatments is essential if children are to receive high-quality emergency care.

JUVENILE RHEUMATOID ARTHRITIS

Background

Juvenile rheumatoid arthritis (JRA) is now the most common pediatric rheumatologic disease in the developed world, having replaced acute rheumatic fever. JRA occurs in all races and ethnic groups, with a reported prevalence that varies from 30 to 400 per 100,000 children depending upon the population studied and the diagnostic techniques used. In the United States alone, JRA affects at least 100,000 children.

Arthritis is a clinical finding of persistent joint swelling or restriction of joint movement by pain. A variety of different classification systems exist, but in the absence of a clear-cut understanding of the pathogenesis of arthritis, these systems do not differ practically. Accordingly, we will continue to use the American College of Rheumatology criteria used in previous editions of this textbook. Persistent unexplained arthritis of one or more joints lasting more than 6 weeks in children younger than 16 years of age will be referred to as JRA (Table 101.1). The differences from other nomenclature systems are largely irrelevant to ED evaluations (Table 101.2). In all cases, because there are no laboratory abnormalities specific for JRA, the diagnosis is made clinically after exclusion of other infectious, inflammatory, and traumatic conditions.

Pathophysiology

The etiology of JRA is not known. It may be triggered by infections including borrelia, parvovirus, or Epstein-Barr virus (EBV), or by trauma, but most cases develop without identifiable precipitants. The presence of rheumatoid factor (RF) in the serum of some children with JRA, a lowered level of complement in the synovial fluid, and activated lymphocytes in the synovial tissue suggest that immunologically mediated injury plays a role in the pathogenesis of this disease. There may also be genetic factors, as suggested by the association of JRA with particular histocompatibility antigens and cytokine alleles.

It is useful conceptually to divide the pathogenesis of JRA into an initiating phase and a perpetuating phase. Various events, particularly viral infections, may trigger articular inflammation. For a variety of reasons related to both the host and the inciting event, a process that is self-limited in most children leads to ongoing inflammation in others. This inflammation is characterized by abnormal tissue and circulating levels of proinflammatory cytokines [including interleukin (IL)-1, IL-6, tumor necrosis factor (TNF), and interferon-γ] leading to activation of lymphocytes and infiltration of synovium. In fact, conditions labeled as JRA most likely represent a final common pathway for many different types of synovitis in view of the widely disparate characteristics of the different subtypes of JRA.

Pathologically, synovial vasculitis is prominent in early lesions. In established cases of arthritis, light microscopy of the synovium shows fibrin deposits, hyperplasia and hypertrophy of synovial lining cells, and an inflammatory cell infiltrate. Increased secretion of synovial fluid results in joint effusions. In uncontrolled and persistent arthritis, synovial villi project into the joint, so-called pannus formation. Fronds of synovium may spread from the edges of the joint and overgrow the cartilage, causing damage to the articulation and eventually to the underlying bone.

Clinical Manifestations

JRA is characterized by wide demographic and clinical variety, so the condition has been divided into subtypes based on these factors and on the pattern of the disease during the first 6 months following onset (Table 101.1). These varieties, in turn, are treated in different ways, and are associated with different complications. While the term JRA will likely be familiar to practitioners in the United States, a classification scheme with the umbrella term juvenile idiopathic arthritis (JIA) has become widely used in the rheumatologic literature. Until better means of classifying and distinguishing these subtypes of JRA become available, what is likely to be several discrete

TABLE 101.1

SUBGROUPS OF JUVENILE RHEUMATOID ARTHRITIS

Subgroup	At onset % of JRA	Gender ratio	Age at onset	Joints affected	Serologic and genetic test[a]	Extraarticular manifestations	Prognosis
Rheumatoid-positive polyarticular	15	90% female	Late childhood	Any joints, especially hands, wrists	ANA 75% RF 100%	Low-grade fever, anemia, malaise, rheumatoid nodules	>50% Severe arthritis
Rheumatoid-negative polyarticular	20	70% female	Younger onset	Any joints	ANA 50%	Low-grade fever, mild anemia, malaise, growth retardation	20%–40% Severe arthritis
Type 1 pauciarticular	45	80% female	Early childhood	Few large joints (hips and sacroiliac joints spared)	ANA 50%	Few constitutional complaints, chronic iridocyclitis in 50%	Severe arthritis uncommon; 10%–20% ocular damage from iridocyclitis if untreated
Type 2 pauciarticular	5	90% male	Late childhood	Few large joints (hip and sacroiliac involvement common)	ANA negative, HLA-B27 75%	Few constitutional complaints, acute iridocyclitis in 5%–10% during childhood	Clinically similar to spondyloarthritis
Systemic onset	15	50% female	Any age	Any joints	ANA negative, RF negative	High fever, rash, organomegaly, polyserositis, leukocytosis, growth retardation	30% Severe arthritis

ANA, antinuclear antibody; RF, rheumatoid factor; HLA-B27, histocompatibility antigen-B27.

TABLE 101.2

CLASSIFICATION SYSTEMS FOR JUVENILE ARTHRITIS

Comparison of current classification systems for chronic arthritis in children, showing differing names for similar types of arthritis in parallel columns.

ACR	ILAR	EULAR
Juvenile rheumatoid arthritis	Juvenile idiopathic arthritis	Juvenile chronic arthritis
Systemic onset	Systemic arthritis	Systemic onset
Polyarticular onset	RF-negative polyarthritis	Polyarticular onset
	RF-positive polyarthritis	Juvenile rheumatoid arthritis
Pauciarticular onset	Oligoarthritis	Pauciarticular onset
Type 1	Persistent	
	Extended	
	Psoriatic arthritis	Juvenile psoriatic arthritis
Type 2	Enthesitis-related arthritis	Juvenile ankylosing spondylitis
	Undifferentiated arthritis	

ACR, American College of Rheumatology; ILAR, International League of Associations for Rheumatology; EULAR, European League Against Rheumatism.

conditions will continue to be grouped on the basis of purely clinical features. The remainder of this chapter will utilize the traditional JRA classification scheme.

Pauciarticular arthritis, synovitis involving four or fewer joints, is the most common subtype of JRA and accounts for approximately half of all cases. Type 1 pauciarthritis occurs more often in young girls, typically causing swelling, pain, and limitation of movement in one or more large joints. Antinuclear antibodies (ANAs) are detectable in the sera of more than 50% of these children, and their presence correlates with a higher risk for developing iridocyclitis. Type 2 pauciarticular JRA occurs more often in preadolescent boys. Although they are often classified as having JRA, the predilection for axial involvement is more typical of spondyloarthritis. In fact, some of these children may develop ankylosing spondylitis on long-term follow-up. Typical of spondyloarthritis, the risk for developing chronic iridocyclitis is negligible, but 5% to 10% of these children may develop acute anterior uveitis.

Polyarticular arthritis (both RF positive and RF negative) occurs more commonly in girls. It is characterized by the insidious onset of symmetric synovitis in both large and small joints, accompanied by low-grade fever, morning stiffness, and malaise (Fig. 101.1). The presence of antibodies to native immunoglobulins in the serum (RF) corresponds to an increased risk of severe, erosive arthritis, as well as to the development of vasculitic complications and subcutaneous nodules. Cervical spine involvement occurs in approximately 30% to 50% of patients with this variety of arthritis, resulting in neck pain, stiffness, and torticollis. Unlike pauciarticular JRA, in which ocular involvement is the cause of the most significant morbidity, polyarticular disease may result in severe musculoskeletal disability. Thus, involvement of the temperomandibular joint may result in restricted ability to open the mouth, involvement of the hips may permanently affect ambulation, and small joint arthritis of the hands may compromise manual dexterity.

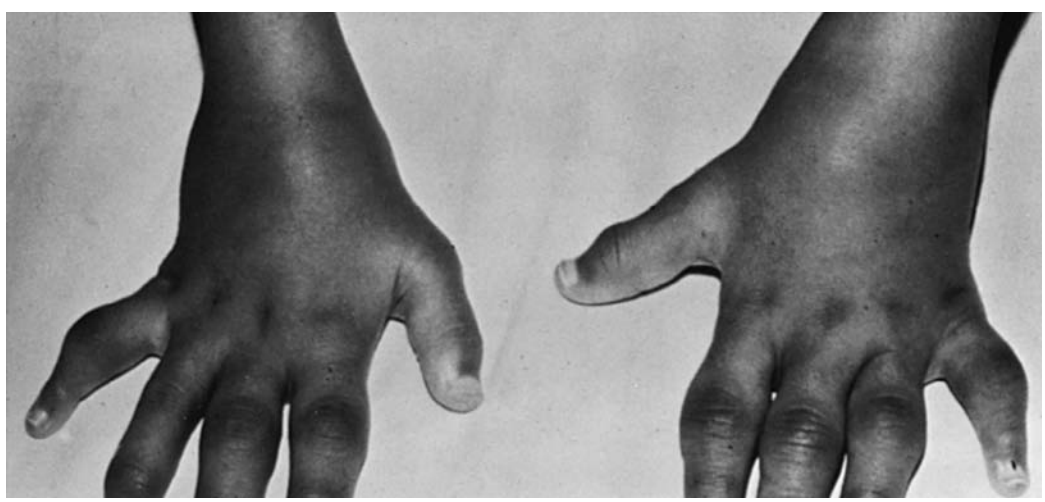

FIGURE 101.1 Symmetric involvement of large and small joints of the hands in a child with polyarticular arthritis.

FIGURE 101.2 Macular rash in a child with systemic type of juvenile rheumatoid arthritis.

The least common subtype of JRA is systemic-onset or Still disease. This subtype occurs most often in boys younger than 5 years of age, although it has been reported even in adults. Clinically, these children often present with a fever of unknown origin; they may have high spiking temperatures (39°C to 41°C) for several weeks or months. Although the child often feels stiff and does not move normally, arthritis may not be a prominent feature at the onset of the disease. Diagnosis therefore generally involves excluding infectious and malignant conditions, especially sepsis, leukemia, and neuroblastoma. A characteristic salmon-pink evanescent maculopapular rash (Fig. 101.2), diffuse lymphadenopathy, and hepatosplenomegaly may also be present in the early stages, offering clues to the diagnosis. Arthralgias and myalgias are common, and pericarditis occurs most typically in this subtype of JRA. With time, systemic features of the disease become less prominent, and polyarticular arthritis becomes the major focus of management.

Laboratory and Radiologic Features

No laboratory test is diagnostic of JRA. Rather, it is a clinical condition diagnosed on the basis of characteristic findings on history and physical examination, although some laboratory studies may be suggestive of the diagnosis. In polyarticular JRA, one subgroup shows RF in the serum; no other pediatric rheumatologic disease typically has this marker. Mild to moderate anemia is common in all subtypes, particularly the systemic type. The white blood count is often elevated, again most typically in the systemic type, in which leukemoid reactions may be seen. Platelet counts are often elevated, and urinalysis is usually normal. There is elevation of levels of acute-phase reactants in the serum, often in proportion to the number of joints involved, and most prominently in systemic-onset disease. Complement levels may be normal or elevated, but immunoglobulins are typically increased, leading to a reversal of the albumin:globulin ratio.

FIGURE 101.3 Radiograph showing features of juvenile rheumatoid arthritis, including soft-tissue swelling, bony overgrowth, and periarticular osteopenia adjacent to affected joints.

Radiographic features of JRA include soft-tissue swelling and periarticular osteopenia adjacent to affected joints (Fig. 101.3). Later, narrowing of the joint spaces, bony cysts, erosions, subluxations, and ankylosis may be seen. In rare children in whom physical examination is difficult or inconclusive, ultrasonography may confirm the presence of a joint effusion, and magnetic resonance imaging (MRI) with gadolinium enhancement may show both synovial proliferation and increased fluid in the joint space.

Management

General Management

The major goal of therapy in children with JRA is to help both the child and the family maintain as normal a life as possible.

Emotional support, including the information that most children with this disease are able to lead a normal life with few long-term problems, provides reassurance. Simple measures, such as warm tub baths and the use of electric blankets at night, help control morning stiffness. For children with minimal joint involvement, regular daily activities, including participation in physical education classes, are to be encouraged, although direct impact on inflamed joints should be avoided. In the presence of muscle wasting, weakness, or restricted range of motion in any joint, an active physical therapy program is indicated. Splinting may be used to rest actively inflamed, painful joints and to prevent worsening of deformities, though complete disuse should be avoided in order to minimize atrophy and loss of motion.

Medications. The pharmacologic management of JRA has changed dramatically over the past two decades due both to therapeutic advances and improved understanding of the natural history of synovitis. Contrary to old teachings, children do not tend to "outgrow" JRA. Rather, in the absence of therapy, most children continue to have active synovial inflammation for decades, often leading to disruption of normal growth and compromised functioning of involved joints. Accordingly, modern therapy aims not only for relief of symptoms of pain and stiffness, but also for joint protection through suppression of synovial inflammation. Although the regimen necessary for disease control varies from child to child, the trend is for more children to receive a broader spectrum of medications. Consequently, physicians caring for these children must be familiar with the intended and unintended effects of a wide variety of drugs.

Nonsteroidal antiinflammatory drugs (NSAIDs) are the initial agents used in most children with JRA. Aspirin, formerly the preferred agent, has fallen into disfavor because of concerns about Reye syndrome and the need for doses every 4 to 6 hours. Other NSAIDs that are approved for use in children include naproxen, ibuprofen, tolmetin sodium, and meloxicam (Table 101.3). COX-2 inhibitors such as celecoxib are antiinflammatory drugs that are specific for the inducible isotype of the cyclooxygenase enzyme. This specificity results in fewer gastrointestinal (GI) side effects than traditional mixed COX-1 and COX-2 inhibitors. One long-acting COX-2 inhibitor, rofecoxib, was withdrawn from the market in 2004 after it was associated with an increased relative risk of cardiovascular events in middle-aged men. No such effect has been seen in children, however, and in fact celecoxib was approved by the FDA in 2006 for use in JRA patients age 2 years and older. This medication should be avoided in children sensitive to sulfonamides, in whom it may precipitate Stevens-Johnson syndrome.

For children who respond inadequately to NSAIDs, so-called disease-modifying antirheumatic drugs (DMARDs) must be added to control symptoms and prevent long-term complications of the arthritis. Several agents are available, including sulfasalazine, hydroxychloroquine, leflunomide, and methotrexate (Table 101.4). Practitioners choose among these agents based on a child's age, the severity of the synovitis, and the subtype of arthritis. Sulfasalazine is most often used in children with inflammatory bowel disease and spondyloarthropathies, but it also has a role in milder cases of JRA. It is typically administered 40 to 70 mg per kg per day divided in two or three doses. Neither sulfasalazine nor hydroxychloroquine, an antimalarial agent with mild immunomodulatory effects, can prevent joint damage in aggressive disease. Doses of hydroxychloroquine should never exceed 7 mg per kg per day, in order to minimize the risk of potentially irreversible ocular toxicity.

Methotrexate is the most commonly used second-line agent in JRA, and the first shown to prevent erosive changes. Doses of 0.5 to 1.0 mg per kg given once per week are usually employed in arthritis. This is several orders of magnitude lower than chemotherapeutic doses, so most of the toxicity generally associated with this agent in patients with cancer is not seen in children with JRA. Leflunomide inhibits de novo pyramidine synthesis, especially in activated lymphocytes. It is taken as a 10- or 20-mg tablet once daily. The side effects of

TABLE 101.3

NSAIDs USED IN THE TREATMENT OF ARTHRITIS IN CHILDREN

Drug	Doses/day	Dose (mg/kg/day)	Side effects
Ibuprofen (Motrin, Advil, Pediaprofen)	3–4	30–40 (maximum 2,400 mg/day)	Gastric irritation, chemical hepatitis
Naproxen (Naprosyn, Aleve)	2	10–20 (maximum 1,000 mg/day)	Gastric irritation, behavioral changes, headache, photosensitivity
Meloxicam (Mobic)	1	0.25 (maximum 15 mg/day)	Gastric irritation, headache, fever
Indomethacin (Indocin)	3	1.5–3 (maximum 200 mg/day)	Gastric irritation, headache, chemical hepatitis
Celecoxib (Celebrex)	2	10–25 kg: 50 mg/dose (maximum 100 mg/day) >25 kg: 100 mg/dose (maximum 200 mg/day) >40 kg: 200 mg/dose (maximum 400 mg/day)	Gastric irritation, cough, rash (including Stevens-Johnson syndrome)

NSAIDs, nonsteroidal antiinflammatory drugs.

TABLE 101.4

DMARDs USED IN THE TREATMENT OF JRA

Drug	Dosing schedule	Dose	Side effects
Methotrexate	Weekly	10–15 mg/m^2 (maximum 25 mg/wk)	Nausea, hair loss, chemical hepatitis, hypersensitivity, pneumonitis
Leflunomide	Once a day	<20 kg: 5 mg >20 kg: 10 mg (maximum 20 mg/day)	Nausea, diarrhea, chemical hepatitis
Sulfasalazine	Twice a day	30–50 mg/kg/day (maximum 3 g/day)	Gastric irritation, photosensitivity, behavioral changes, hypersensitivity reaction, neutropenia
Hydroxychloroquine	Once a day	<7 mg/kg/day (maximum 400 mg/day)	Abdominal pain, diarrhea, retinitis

DMARDs, disease-modifying antirheumatic drugs; JRA, juvenile rheumatoid arthritis.

leflunomide are similar to those of methotrexate. It is teratogenic, and in view of the prolonged half-life of its active metabolite, women of childbearing age should allow sufficient washout time (potentially up to 2 years) before conceiving.

The newest agents in the arthritis armamentarium are the biologic response modifiers, medications that specifically target inflammatory cytokines, cellular receptors, and adhesion molecules, but which are generally more immunosuppressive than conventional DMARDs. The most widely used biologic agents are TNF inhibitors. Etanercept, a TNF-receptor fusion protein, was the first biologic approved for the treatment of JRA, particularly polyarticular disease inadequately controlled with methotrexate. The route of administration is via subcutaneous injection once per week or in two divided doses, depending on the size of the child. The most common side effects reported with etanercept are generally mild, including injection site reactions, upper respiratory tract infections, and abdominal complaints. Adalimumab, an anti-TNF monoclonal antibody, has also been approved for use in JRA. This, too, is given by subcutaneous injection, generally every 1 to 2 weeks. Infliximab is a third TNF inhibitor, a chimeric mouse–human monoclonal antibody. While it is not FDA approved in JRA, it is used widely in children. Infliximab is administered via intravenous (IV) infusion rather than fixed-dose injection so the potential dosing range is broader, but it carries the risk of infusion reactions. Additional anti-TNF monoclonals currently undergoing review include certolizumab, a pegylated antibody, and golimumab. Both were recently approved by the FDA for treatment of adult RA.

Newer biologic response modifiers target other components of the immune response. Abatacept is a fusion protein consisting of the extracellular domain of cytotoxic T lymphocyte–associated antigen 4 linked to the Fc portion of human IgG1 (CTLA4-Ig). It is a costimulatory inhibitor that interferes with T-cell activation. Abatacept has been FDA approved for use in polyarticular JRA patients age 6 years and older. Rituximab, a B cell–depleting agent, is approved for use in adult RA, though data concerning a potential role in JRA are minimal. With all of these agents, major concerns involve an increased risk of developing infection, as well as a possibility of increased risk of malignancy. Abatacept may also pose particular risk for patients with chronic obstructive pulmonary disease (COPD), while adults receiving rituximab rarely have developed progressive multifocal leukoencephalopathy, an invariably fatal slow viral infection of the central nervous system (CNS).

Corticosteroids must be employed judiciously in JRA due to the significant toxicity associated with their use. Systemic steroids are typically reserved for children with severe systemic symptoms, pericarditis, or pleuritis, during brief flare-ups of severe arthritis, or while waiting for slower-acting agents to take effect. Topical steroids are also effective for localized manifestations of JRA. Intraarticular steroids may be used in patients with pauciarthritis, or in children with polyarticular disease in whom selected joints require particularly aggressive management. Ocular steroids are the lynchpin of therapy for iridocyclitis.

Drug Toxicity. Almost all drugs used for the treatment of JRA have the potential for serious toxicity. If a child with JRA on treatment develops a new symptom, drug toxicity must always be considered as a possible cause. Tables 101.3 and 101.4 list the common adverse reactions reported with NSAIDs and DMARDs typically used in the treatment of JRA. Though new medications are more targeted in their effects on the immune system, most advanced therapies for arthritis cause at least a mild degree of immunosuppression. Accordingly, physicians caring for children with JRA should be particularly vigilant for evidence of infections.

For the nonsteroidal antiinflammatory agents, GI toxicity is the most common side effect. Nonetheless, significant NSAID gastropathy is unusual in children, and gastric or intestinal perforations, a significant problem in older adults, are rare. Antacids and H_2-blockers do not reduce the risk of GI complications. They may actually delay diagnosis of gastritis or ulceration by ameliorating symptoms. Prostanoids, on the other hand, do provide a degree of gastroprotection for children on NSAIDs, and the COX-2–specific agent celecoxib also appears to carry less risk of GI toxicity.

NSAIDs may also cause various other side effects. Reversible CNS complaints, particularly headaches, dizziness, and fatigue, occur in about 5% of children. Hepatotoxicity, manifested primarily as elevation of transaminases, and nephrotoxicity, including proteinuria and renal papillary necrosis, are rare but potentially dangerous if overlooked. Friability of the skin and a porphyria-like blistering of sun-exposed areas may be seen with these agents, especially naproxen when used in fair-skinned children.

Unlike salicylates, NSAIDs rarely cause tinnitus or hyperventilation. Reye syndrome, although far less common than with salicylates, has been reported in children receiving NSAIDs; therefore, it is prudent to consider suspension of these agents in children with influenza or varicella. Salicylates must be carefully avoided in children who are even exposed to these viruses. In any child using salicylates or other NSAIDs, development of pernicious vomiting and/or alteration in mental status warrants consideration of Reye syndrome.

Each of the second-line agents used in the treatment of JRA also has the potential to cause specific forms of toxicity. As methotrexate is now the most commonly used advanced medication for JRA, questions of potential side effects are most likely to involve this drug. Doses used for JRA are much lower than those employed for treating malignancies, typically 0.3 to 1 mg per kg per week, and the degree of immunosuppression appears to be minimal. Live viral vaccines are nonetheless generally avoided in children receiving methotrexate, but reported cases of opportunistic or unusually severe infections are rare.

Despite its favorable therapeutic profile, methotrexate is an antimetabolite with the potential to cause oral ulcers, nausea, and abdominal pain. These adverse effects may be minimized by supplementation with folic acid. Children must be monitored regularly for evidence of hepatic toxicity; persistent elevation of hepatic transaminases identifies those at risk for hepatic fibrosis or cirrhosis. Methotrexate may also cause lymphopenia, especially with prolonged use, or even pancytopenia due to bone marrow suppression. Ten percent of children receiving methotrexate for arthritis may develop mild hypogammaglobulinemia, but there is no evidence that this is clinically significant. Concurrent use of other dihydrofolate reductase inhibitors, such as trimethoprim–sulfamethoxazole (Bactrim®), potentiates these risks and should be avoided.

Rarely, use of methotrexate is associated with the development of pulmonary hypersensitivity. This most commonly occurs during the first 6 to 12 months of use and may be marked by dyspnea, cough, fever, and fluffy infiltrates on chest x-ray. Although such symptoms may be conclusively distinguished from viral pneumonitis only by lung biopsy, suspicion of this complication necessitates discontinuation of methotrexate and institution of treatment with systemic corticosteroids. Failure to stop the drug, or rechallenge with methotrexate, may cause fatal respiratory failure.

The newest pharmaceuticals used to treat arthritis are the biologic response modifiers. Agents of this class are generally well tolerated, but as with all medications that target the immune response as a way of controlling inflammation, biologics are immunosuppressive. Although these effects are more limited than those of traditional cytotoxic agents, defenses against various infections are definitely impaired. The infectious risk appears to increase significantly with use of more than one biologic agent at a time, so use of combinations of biologics should be avoided. Although most people note only an increased frequency of mild upper respiratory tract illnesses, treatment with TNF inhibitors also increases susceptibility to potentially serious mycobacterial, bacterial, fungal, and herpes viral infections. Patients should therefore be screened with a purified protein derivative (PPD) before initiating anti-TNF therapies. Screening for histoplasmosis in endemic areas is also recommended. Doses of TNF inhibitors should be withheld during febrile illnesses. In addition, as with methotrexate, live viral vaccines are generally avoided while children are receiving biologic agents.

MedWatch screening suggests that use of TNF-inhibitors increases the risk of developing malignancies, and they now carry a black box warning to this effect. Current FDA mandated postmarketing surveillance programs should provide more precise information concerning infectious and malignant risks of these agents within the next few years.

The long-term effects of altering the immune response with anti-TNF medications are not known. In adults, new autoantibodies may develop [including ANA and anti–double-stranded DNA (anti-ds DNA)], and rarely patients may develop multiple sclerosis–like CNS abnormalities. These associations should be kept in mind if a patient on anti-TNF therapy develops new neurologic or rheumatologic complaints.

Sulfasalazine is a sulfa drug, and its most severe side effects are typical of this class of medications. Headache and GI upset—especially with preparations that are not enterically coated—occur most commonly. Although rare, more concerning are bone marrow suppression, agranulocytosis, photosensitive eruptions, and hypersensitivity reactions, including Stevens-Johnson syndrome. Sulfasalazine is contraindicated in children with known intolerance of sulfa drugs, as well as in children younger than 2 years of age, in whom neurotoxicity may occur.

Antimalarial agents such as hydroxychloroquine must be administered judiciously because of their ability to cause irreversible ocular toxicity at high doses. Even at lower doses, children may develop rashes, gastric upset, or reversible visual disturbances secondary to altered accommodation. Finally, children with glucose-6-phosphate deficiency who receive hydroxychloroquine may develop hemolytic anemia, especially during intercurrent infections.

The long list of potential side effects of systemic corticosteroids is enumerated elsewhere. In the acute setting, immunosuppressive effects of systemic steroids are most salient. It is important to remember that these agents dramatically increase susceptibility to herpes viruses (especially disseminated varicella) and intracellular pathogens, such as mycobacteria and listeria. Although they have little effect on susceptibility to other bacterial pathogens, their antiinflammatory effects tend to mask clinical signs of infection, accentuating the need for attentiveness on the part of clinicians.

Various other agents are rarely used in the United States, although occasional patients receiving intramuscular or oral gold, or D-penicillamine, may present for evaluation. The major side effects from gold compounds are skin rash, bone marrow suppression with cytopenias, and proteinuria. D-penicillamine may cause skin rash, bone marrow suppression, nephrotoxicity, myasthenia gravis, and Goodpasture syndrome. In view of their low benefit-to-risk ratios and prolonged duration of action, these agents should be discontinued whenever toxicity is suspected. If subsequent investigations identify another explanation for an apparent drug reaction, the drug may be restarted.

Management of Complications and Emergencies (Table 101.4)

Fever. Marked elevation of body temperature is characteristic of systemic JRA, whereas a lower-grade fever often accompanies polyarticular disease. The diagnosis of systemic JRA is

one of exclusion and fever is a common symptom, so diligent efforts should be made to rule out infectious diseases and malignancies. This may require hospitalization for a diagnostic evaluation, particularly in infants and young children. Appropriate cultures should be obtained, including cultures of cerebrospinal fluid (CSF) if indicated. A bone marrow examination to rule out malignancy is necessary in many patients with systemic JRA because acute lymphoblastic leukemia may cause joint pain and swelling, fever, lymphadenopathy, and hepatosplenomegaly that are indistinguishable from findings in JRA.

In a patient being treated for known systemic JRA, the appearance of fever is always of concern. Fever may represent recurrence of JRA, or it may be because of an intercurrent infection. Fevers in Still disease typically follow the classic double quotidian pattern, with two peaks above 39°C daily, as well as periods at or below normal without use of antipyretic medications. If there are no localizing signs of infection, if the complete blood cell (CBC) count shows the leukocytosis, thrombocytosis, and anemia typical of JRA, and if the urinalysis is normal, the child may be treated for a presumed JRA flare-up. On the other hand, a child with evidence of a specific infection (e.g., otitis media or urinary tract infection), should receive appropriate antibiotics. Children being treated with immunosuppressive medications may require empiric antibiotics or observation in the hospital until negative culture results allow infections to be excluded. If the patient has received more than 20 mg of prednisone daily for more than 6 weeks within the previous 12 months, appropriate coverage with stress dosages of steroids (three times the physiologic dose) is indicated while the infection is being treated.

Fever in systemic JRA, especially within 6 months of disease onset, occasionally may be caused by macrophage activation syndrome (MAS). This life-threatening complication is characterized by disseminated intravascular coagulopathy with diffuse microthromboses, hemophagocytosis causing cytopenias, hepatic inflammation, and CNS changes progressing to seizures or coma. The cause of MAS is unknown, but it does occur more commonly during intercurrent viral illnesses, as well as in children receiving NSAIDs or DMARDs (particularly sulfasalazine) as treatment. Differentiation from sepsis or a flare-up of JRA may be difficult, although a sudden rise in hepatic enzymes, ferritin, and triglycerides or a sudden drop in platelets, red blood cells, or erythrocyte sedimentation rate (ESR) (due to consumption of cellular elements and fibrinogen) are suggestive. Early diagnosis and a high level of suspicion are essential. Treatment with pulse-dose methylprednisolone (30 mg per kg, maximum 1.5 g) and/or cyclosporine, as well as general support measures for disseminated intravascular coagulation (DIC), often lead to full recovery. Delayed diagnosis, in contrast, is accompanied by a reported mortality rate of 20% to 50%.

Pericarditis, Myocarditis, and Cardiac Tamponade. Cardiac involvement is an important feature of systemic-onset JRA but is uncommon in other subtypes of juvenile arthritis. Pericarditis, like other systemic manifestations of Still disease, most often occurs during the first 2 years of the illness. Common symptoms are fever, chest pain, dyspnea, and inability to lie flat in bed, although at times pericardial effusions may be asymptomatic. On physical examination, a parasternal pericardial friction rub may be heard over the left second and third intercostal spaces, especially with the patient supine. If the child has a moderate to large effusion (Fig. 101.4), one may not hear the friction rub but should look for the following signs of pericardial fluid: edema, tachycardia, weak pulse, distended neck veins, distant heart sounds, palpation of the apical impulse within the border of cardiac dullness, and hepatomegaly. Occasionally, the effusion may be massive, as suggested by a pulsus paradoxus of more than 20 mm Hg. Fortunately, pericardial effusions in JRA rarely lead to cardiac tamponade.

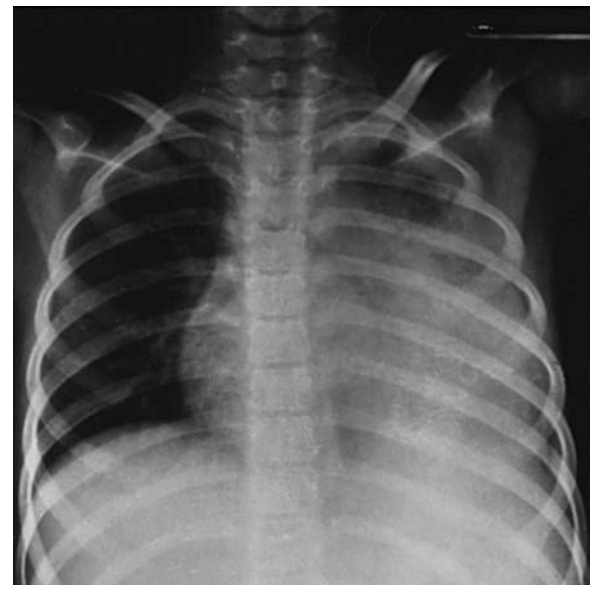

FIGURE 101.4 Pericardial and pleural effusions in a child with systemic type of juvenile rheumatoid arthritis.

Other types of cardiac involvement are unusual. Valvulitis is not typical of JRA and should suggest the possibility of acute rheumatic fever or bacterial endocarditis. Myocarditis is rare but may be seen. Tachycardia out of proportion to the elevation of temperature, arrhythmias, and congestive heart failure (CHF) are the usual clinical indicators of myocarditis.

If pericarditis or myocarditis is suspected, the child should be admitted and observed closely. Diagnostic studies should include electrocardiogram (EKG), chest x-ray, and echocardiogram. Typical EKG changes that may be noted in children with pericarditis or myocarditis include tachycardia, elevated ST segment, and arrhythmias. Radiographs of the chest may show straightening of the left border of the heart and cardiac enlargement. Echocardiogram should be performed to confirm the presence of a pericardial effusion, as well as to quantify ventricular function, particularly if cardiac tamponade or myocarditis is suspected.

Bed rest and therapy with an NSAID should be adequate for the treatment of mild to moderate pericarditis due to JRA. Corticosteroids (prednisone 1 to 2 mg per kg per day, maximum 60 to 80 mg) are indicated for the treatment of noninfectious myocarditis, for massive pericarditis causing compromise of cardiac output, or if significant symptoms persist despite therapy with NSAIDs. In the presence of tamponade or progressive deterioration, pericardiocentesis provides temporary

relief, whereas antiinflammatory medications are used to prevent reaccumulation of fluid. If the child is acutely ill, requiring IV fluid support, care should be taken to avoid fluid overload, and diuretics should be added to the regimen.

Pulmonary Emergencies. Pleural effusions are a recognized manifestation of systemic JRA (Fig. 101.4). Other pleuropulmonary complications include pneumonitis, diffuse interstitial disease, lymphoid bronchiolitis, and pulmonary arteritis. Occasionally, pleural fluid collections may be massive, resulting in respiratory distress. The usual clinical features of pleural effusion are chest pain, cough, and dyspnea. On physical examination, there is dullness to percussion and diminished breath sounds on auscultation over the area of fluid. Chest x-rays, including lateral decubitus views (involved side down), may be used to document the extent of the effusion. Thoracentesis is indicated for diagnostic purposes, especially to rule out infectious processes, and in severe cases, removing pleural fluid may help relieve respiratory compromise. Otherwise, treatment is aimed at the underlying disease process, primarily involving control of inflammation with NSAIDs or corticosteroids. Children with pleural effusions often require admission in order to address the overall severity of systemic features of the disease, if not to ameliorate the cardiopulmonary effects of the pleural effusion.

Iridocyclitis. Iridocyclitis (inflammation of the iris and ciliary body) occurs in approximately 10% to 20% of all children with JRA. This can be of acute or chronic onset. The chronic type of iridocyclitis occurs primarily in young children with pauciarticular JRA, and it is virtually universal in girls with pauciarthritis and a positive ANA. In contrast, acute iridocyclitis occurs most often in older boys with pauciarticular disease.

The onset of chronic iridocyclitis is insidious and asymptomatic. Late signs are decreased visual acuity, unequal pupils, and band keratopathy. These reflect irreversible damage to the eye and so represent a missed opportunity for prevention. Therefore, all children with JRA, particularly those at high risk for iridocyclitis, should have a routine eye examination as soon as the diagnosis is made and at frequent (3- to 6-month) intervals thereafter. The physician in the ED may be able to recognize evidence of established iridocyclitis, such as posterior synechiae or cataracts using a +8 or +10 diopter lens in the ophthalmoscope. Early anterior chamber inflammation due to chronic uveitis, however, cannot be identified without a slit-lamp examination.

Acute iridocyclitis, in contrast, is characterized by sudden onset of redness, tearing, pain, and photophobia, and urgent management may be required to preserve vision. Consultation with an ophthalmologist is essential. The usual treatment includes topical corticosteroids and mydriatics.

Flare-up of a Single Joint in a Patient with JRA. In a patient known to have JRA and receiving antiinflammatory medication, acute swelling with pain and limitation of range of movement of a single joint raises a common management problem. Potential causes of such an acute monoarthritis include a flare-up of JRA versus infectious arthritis, and careful attention to physical examination and historical features are essential to avoid misdiagnosis.

Physical findings characteristic of infection of a joint are extreme pain, tenderness, erythema, and warmth over the joint. The affected joints of JRA, while often swollen, warm, and stiff, are rarely red. There is usually pronounced splinting of an infected joint due to pain; the slightest movement may cause muscle spasm. In contrast, some range of motion is usually possible even with severely inflamed joints of JRA. If the patient is taking an immunosuppressive medication, physical findings of inflammation and/or infection may be masked.

If infection cannot be excluded with confidence, joint fluid must be aspirated, and the fluid sent for cell count, Gram stain, and culture. Synovial fluid is bacteriostatic and some fastidious organisms, such as *Kingella*, may be particularly difficult to culture, so joint fluid samples should be inoculated into blood culture bottles to optimize sensitivity. If there is any doubt about the diagnosis, it is best to also obtain a blood culture (which increases diagnostic yield, as the organisms causing septic arthritis are generally spread hematogenously) and then to initiate treatment for septic arthritis.

For the acute swelling and pain in a single joint caused by a JRA flare, resting the involved extremity for 2 to 3 days may be adequate. After infection has been excluded, local injection of the joint with a topical steroid preparation such as triamcinolone hexacetamide (1 mg per kg, maximum 40 to 60 mg) may provide rapid and sustained relief.

Ruptured Popliteal Cyst. There are six bursae around the knee joint. Of these, the gastrocnemius-semimembranosus bursa is the one that most often communicates with the synovial space. Consequently, in the presence of effusion in the knee joint, fluid may enter the bursa and produce a popliteal cyst (Baker cyst). Patients with popliteal cysts have a palpable and visible enlargement in the popliteal area, best seen while the patient is standing with knees extended.

Rupture of a popliteal cyst with drainage of fluid into the calf muscles may present as an emergency. Affected patients complain of sudden pain in the calf associated with swelling in the leg. On physical examination they have induration, erythema, warmth, and tenderness of the calf, as well as ankle edema. An effusion in the knee joint and evidence of synovial thickening are often present. Homan sign may be positive, but other signs of venous thrombosis, including palpable venous cords, dilation of collateral veins, or arterial spasm, are usually absent.

Differentiation of a ruptured popliteal cyst from thrombophlebitis may be difficult, though the latter are very rare in otherwise healthy children, and the former relatively common in children with arthritis. Elevated D-dimers and other evidence of a consumptive coagulopathy characterize venous thrombosis, while most children with systemic JRA do not have such abnormalities. Ultimately, ultrasonographic or MRI imaging may be needed to establish the diagnosis. Intraarticular administration of steroids (triamcinolone hexacetamide, 1 mg per kg) is the recommended initial treatment for a ruptured Baker cyst. If there is an inadequate response or if the syndrome is chronic, surgical excision of the cyst may be necessary.

Cervical Spine Involvement. This complication usually is seen in children with established severe polyarticular JRA. Although cervical spine involvement is known to occur in 30% to 50% of patients with JRA, subluxation of the

atlantoaxial (AA) joint or the lower cervical spine are less common in children than adults. Clinical evidence of pressure on the spinal cord is seen in 23% to 65% of adults with radiologic evidence of AA subluxation. Similar figures are not available for children.

Neck stiffness that is worst in the morning is the most common symptom of cervical spine involvement in JRA. Occasionally, torticollis may be the presenting manifestation of cervical arthritis. Severe pain in the neck and referred pain over the occipital and retro-orbital areas also may occur. The pain has a dull, aching quality and is often aggravated by neck movement. On physical examination, torticollis and/or loss of lordosis of the cervical spine, as well as limitation of range or movement of the neck, are the typical findings.

Paresthesia of the fingers is the most common symptom of spinal cord compression. Weakness of the arms and legs and inability to control the bladder are other complaints that should suggest spinal cord compression. During the initial stages, exaggerated deep tendon reflexes and an extensor plantar reflex are noted. Chronic myelopathy results in muscle atrophy and loss of deep tendon reflexes. Lateral radiographs of the neck in flexion and in extension are required for complete evaluation of the cervical spine. The patient should be asked to actively and slowly flex and extend the neck to tolerance without discomfort; care should be taken not to force these movements. Tomograms and an open-mouth view of the odontoid process may be helpful. On some occasions, computed tomography (CT) or MRI may be indicated.

The distance between the anterior surface of the odontoid and the posterior surface of the anterior arch of atlas when measured in a lateral flexion film is usually 4 mm or less. In the presence of AA subluxation, this may be as wide as 10 to 12 mm (Fig. 101.5). Other radiologic abnormalities characteristic of cervical spine involvement in JRA include loss of curvature, osteoporosis, erosions and sclerosis of joints, disc space narrowing, and altered height-to-width ratio of the vertebral bodies.

Although most children with AA subluxation do not have evidence of spinal cord compression, the physician must be wary of its occurrence with excessive movement, as occurs during endotracheal intubation. Regular use of a light plastic cervical collar is often all that is required to relieve pain and prevent excessive anterior flexion, particularly during automobile rides. In the presence of spinal cord compression with muscle weakness and atrophy, surgical stabilization may be required.

Cricoarytenoid Arthritis. The cricoarytenoid joint is a diarthroidal joint with a synovial membrane. In patients with known polyarticular JRA, cricoarytenoid arthritis rarely may lead to acute airway obstruction. Clinical features of cricoarytenoid arthritis include stridor and hoarseness. The inspiratory stridor may wax and wane, and may be present only when the patient is asleep. Some of these patients also may complain of pain in the throat while swallowing, and pain in the ears. Many of these symptoms and signs are similar to those of severe acute laryngotracheobronchitis, which at times may be excluded only by direct laryngoscopy. Redness and swelling of the arytenoid eminences may be observed in cricoarytenoid arthritis, rather than the airway inflammation of croup.

FIGURE 101.5 Atlantoaxial sublocation in a child with juvenile rheumatoid arthritis. (The distance between the anterior arch of the atlas and the odontoid process in the original radiograph was 5 mm.)

Increasing airway obstruction with severe inspiratory retractions demands urgent treatment with respiratory support. Large doses of corticosteroids (methylprednisolone, 2 mg per kg per day IV) may control acute inflammation of the joints, avoiding emergency tracheostomy. If significant obstruction occurs, intubation should be attempted to establish an airway until swelling decreases; occasionally, emergency tracheostomy may be necessary. Even if tracheostomy is done, corticosteroid therapy is indicated so the tracheostomy may be closed as quickly as possible.

SYSTEMIC LUPUS ERYTHEMATOSUS

Background

Systemic lupus erythematosus (SLE) is a multisystem disease that is both pleomorphic in its presentation and variable in its clinical course. In many ways, it is the archetypal autoimmune disease, with antibodies to cellular constituents causing immune-mediated attack on various organs. The diagnosis of SLE is based on classification criteria established by the American College of Rheumatology (ACR). The 1971 preliminary criteria were revised in 1982 to include the presence of ANA and antibodies to native DNA; in 1997, a subcommittee

of the ACR also recommended inclusion of antiphospholipid antibodies. Table 101.5 lists the revised criteria and definitions. A patient should meet (any) 4 or more of the 11 criteria, simultaneously or in sequence, during any period of clinical follow-up to be diagnosed as having SLE. It is nonetheless important to remember that these criteria are intended for classification, not diagnosis, so patients may have SLE and not fulfill criteria, or they may meet criteria despite having another illness.

Although SLE is often considered a disease of adulthood, up to 20% of lupus patients are diagnosed during the first two decades of life. The annual incidence of this disease is about 6 per 100,000, with approximately 10,000 to 15,000 children in the United States carrying the diagnosis. Women between the ages of 15 and 64 years (1 in 700), particularly black women (1 in 245), are at highest risk of developing lupus. SLE in children is often a more severe disease than it is in adults. Although adult lupus patients are more likely to die of complications, children and adolescents with lupus are more likely to succumb earlier, during the acute stages of the disease. Delayed diagnosis and treatment are strong risk factors for morbidity and mortality in pediatric lupus. In view of the fact that cumulative disease activity over time correlates with damage from the disease, expedient diagnosis and appropriately aggressive treatment is particularly critical for children. Thus, pediatricians need to maintain a high index of suspicion for lupus, and physicians experienced in the care of children with SLE should participate in the diagnosis and management of all pediatric lupus patients.

Pathophysiology

The great variety of manifestations of SLE suggests that several discrete conditions may fall within the overall diagnostic category. A 7-year-old boy with arthritis, positive ANA, photosensitive eruption, and oral ulcerations appears to have little in common with a multiparous woman with seizures, pericarditis, renal failure, and high-titer anti-ds DNA antibodies. In fact, several different animal models for SLE have been developed, and they vary both in their clinical characteristics and in the underlying immunologic perturbation. The final common pathway unifying all cases of SLE is abnormal production of autoantibodies directed against various antigens, including double-stranded DNA. The resultant circulating and in situ immune complexes activate the complement cascade within tissues. Release of activation products of complement, such as C5a, as well as other chemotactic, opsonic, and proinflammatory mediators, ultimately leads to tissue damage.

Current concepts of the pathogenesis of SLE invoke an interplay of environmental and genetic factors. Exposure to sunlight, to certain drugs (e.g., procainamide), or to various types of infections (especially EBV), precipitates or exacerbates SLE in a predisposed host. That predisposition, in turn, is evidenced in family clusters of SLE, and in the association of lupus-like syndromes with certain complement deficiencies. The net result of these factors is functional abnormalities of both T and B cells, including diminished T-cell proliferative and stimulatory responses, polyclonal B-cell activation, defects in lymphocyte apoptosis, immunoglobulin isotype derangements, and defective cytokine production and response.

TABLE 101.5

CRITERIA FOR CLASSIFICATION OF SYSTEMIC LUPUS ERYTHEMATOSUS

Criterion	Definition
Malar rash	Fixed erythema, flat or raised, over the malar eminences, tending to spare the nasolabial folds
Discoid rash	Erythematosus raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as a result of unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral or nasopharyngeal ulceration, usually painless, observed by a physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis—convincing history of pleuritic pain or rub heard by a physician or evidence of pleural effusion *or* Pericarditis—documented by EKG, rub, or evidence of pericardial effusion on echocardiography
Renal disorder	Persistent proteinuria >0.5 g/day or >3% if quantitation not performed *or* Cellular casts—may be red cell, hemoglobin, granular, tubular, or mixed
Neurologic disorder	Seizures *or* psychosis—in the absence of offending drugs or known metabolic derangements (uremia, ketoacidosis, or electrolyte imbalance)
Hematologic disorder	Hemolytic anemia—with reticulocytosis *or* Leukopenia—<4,000/mm^3 total on two or more occasions *or* Lymphopenia—<1,500/mm^3 on two or more occasions *or* Thrombocytopenia—<100,000/mm^3 in the absence of offending drugs
Immunologic disorders	Positive antiphospholipid antibody *or* Anti-DNA—antibody to native DNA in abnormal titer *or* Anti-Sm—presence of antibody to Sm nuclear antigen *or* False-positive serologic test for syphilis known to be positive for at least 6 mo and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
Antinuclear antibody	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

EKG, electrocardiogram.

Histopathology of affected tissues reflects these mechanisms. In the skin, lesions vary from nonspecific perivascular infiltrates in maculopapular rashes of SLE, to deeper lesions showing thinning of the epidermis, disruption of the dermal–epidermal junction, edema of the dermis, lymphocytic infiltration, and fibrinoid degeneration of the connective tissue. On immunofluorescent staining, localization of immunoglobulins and complement in the dermal–epidermal junction of the skin is seen in more than 75% of patients, although these findings may also be present in other collagen vascular diseases.

Joints affected by arthritis show synovitis with fibrinoid degeneration of connective tissue but no pannus formation or cartilage destruction. Histologic features of lupus nephritis, even in the absence of clinical renal involvement, include cellular proliferation and crescent formation, leukocyte and mononuclear cell infiltrates, and hyaline thrombi, as well as more chronic changes such as interstitial fibrosis and glomerular sclerosis. Analogous lesions in the CNS include microinfarcts with perivascular lymphocytic infiltrates, as well as true vasculitis with inflammatory cells damaging vessel walls.

Clinical Manifestations

The onset of SLE may be insidious or acute. The initial presentation usually includes constitutional features, such as fever, malaise, and weight loss, in addition to manifestations of specific organ involvement such as rash, pericarditis, arthritis, or seizures. Because virtually any part of the body may be affected by SLE, patients may present with a bewildering variety of signs and symptoms. Although many of these are nonspecific, the examiner's level of suspicion for possible SLE should increase as the number of involved organ systems increases. Further, although SLE is indeed a protean disease, the majority of pediatric cases present with a recognizable constellation of complaints due to musculoskeletal, cutaneous, renal, and hematologic involvement.

Arthritis in SLE is usually symmetric, involving both large and small joints. Swollen joints may be quite painful, but they are usually not erythematous. Patients may lose function due to tendon involvement, but the erosive synovial proliferation seen in JRA is uncommon. Cutaneous lesions are present in more than 85% of patients with SLE. The typical malar erythematous rash with butterfly distribution is present at diagnosis about half the time. Discoid lesions are less frequent in children but when seen are characteristic of SLE (Fig. 101.6, see also color plate). Vasculitic skin lesions over the extensor surface of the forearm and on the fingertips are reported in about 20% of patients. These lesions are tender and may ulcerate. Nodules are less common. Mucosal lesions (macular and ulcerative) may involve the nose or the mouth, particularly the palate (Fig. 101.7) and are usually painless. Rarer types of mucocutaneous lesions in SLE include livedo reticularis, urticaria, erythema multiforme, and alopecia.

Evidence of renal disease is present in approximately 50% of children with SLE at the time of presentation, with nearly 90% developing some degree of renal involvement during the course of their disease. This is significantly higher than in adult patients, in whom renal disease develops in about half. Lupus nephritis is usually asymptomatic, although close questioning often reveals nocturia due to impaired renal concentrating mechanisms. Edema or hypertension may be clues to involvement of the kidney. Despite significant improvements in treatment, the extent of renal involvement remains the single most important determinant of prognosis in SLE. Thus, most children with lupus have a renal biopsy to more precisely characterize the pathology and help optimize the therapeutic regimen.

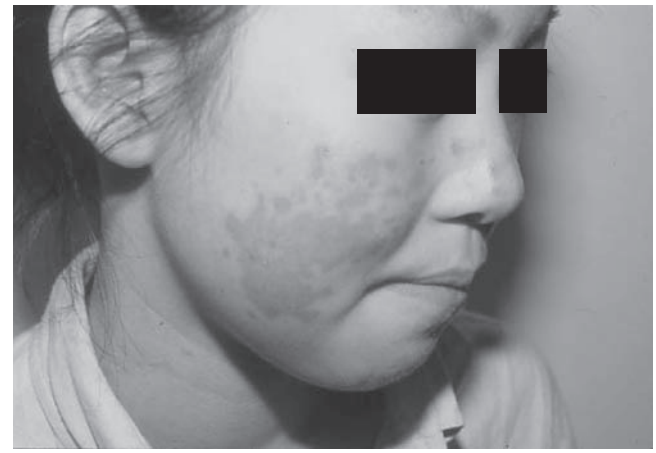

FIGURE 101.6 Adolescent girl with discoid lesions in malar distribution.

Clinical evidence of CNS involvement may occur at onset or later in the disease course. Symptoms and signs referable to the CNS include headache, seizures, polyneuropathy, hemiparesis/hemiplegia, and ophthalmoplegia. Particularly in the ED setting, the clinician should be aware of the risk of stroke (both thrombotic and hemorrhagic) and of sinus vein thrombosis in children with lupus. Chorea is the most common movement disorder and may be a presenting sign; Lyme disease (LD) and rheumatic fever must also be considered in such cases. Cranial nerve palsies most commonly involve the optic nerve, trigeminal nerve, and nerves controlling the extraocular muscles. Myasthenia gravis should be excluded if any extraocular muscles are involved. Neuropsychiatric manifestations include mood disorders, hallucinations, memory alterations, and psychosis; rarely, psychiatric symptoms may be the first clinical manifestation of childhood lupus.

FIGURE 101.7 Mucosal lesions (macules and ulcers) of the palate in an adolescent girl with active lupus.

Pericarditis is the most prevalent form of cardiopulmonary involvement in SLE. Myocarditis occurs less frequently but is seen more often in SLE than in JRA. Heart murmurs caused by valvular lesions are not common, but asymptomatic vegetations on valve leaflets are seen at autopsy in most patients (Libman-Sack endocarditis). These provide a potential nidus for bacterial superinfection, explaining the fact that patients with SLE are at increased risk of developing subacute bacterial endocarditis. Abnormal exercise thallium myocardial perfusion scans have been described in pediatric patients with no history of coronary symptoms, and myocardial infarctions are reported in children with lupus. Thus, the possibility of myocardial ischemia should be kept in mind if a child with lupus develops acute chest pain. Lupus patients are also at risk for early atherosclerosis, with a resultant increased risk of cardiac disease.

Pleuropulmonary involvement occurs in greater than 50% of cases of SLE. Chest pain, dyspnea, productive cough, or fever may be the initial manifestation of respiratory pathology due to lupus. Pleural rub is the most common physical finding. Unilateral or bilateral pleural involvement may occur, with or without pleural effusion, suggested by the presence of chest dullness to percussion and/or diminished breath sounds on auscultation. Pulmonary hemorrhage, although uncommon, also occurs in children with SLE. Pulmonary function testing (PFT) demonstrating an elevated DLCO offers a readily available, noninvasive technique for identifying blood in the lungs. Pulmonary embolus, particularly in children with antiphospholipid antibodies, also must be considered in children with the acute onset of chest pain. For any SLE patient with pleuropulmonary manifestations, disease-related involvement must be distinguished from intercurrent infection, CHF, aspiration pneumonia, and renal failure.

Common GI manifestations include nausea, vomiting, and anorexia. Persistent localized abdominal pain should suggest specific organ involvement, such as pancreatitis or gastric ulcer, both of which may occur from the disease or secondary to medical therapy. Malabsorption syndrome may be a manifestation of SLE. When accompanied by melena, it suggests poorly controlled disease complicated by GI vasculitis. This is associated with a 50% mortality rate without expeditious evaluation and treatment. Of course, abdominal pain in SLE is not always related to the underlying disease but may stem from other causes, including appendicitis, ruptured ovarian cyst, or pelvic inflammatory disease. Further complicating evaluation is the fact that manifestations of any of these conditions may be masked or altered by the corticosteroids most patients receive.

Laboratory Studies

Mild to moderate anemia is common in SLE. Hemolytic anemia associated with a positive Coombs' test is most characteristic. An acute decrease in the hemoglobin or hematocrit should alert the physician to the possibility of internal hemorrhage or massive hemolysis. Autoimmune thrombocytopenia, even in the absence of offending drugs, is commonly seen in SLE; up to 20% of adults initially diagnosed with idiopathic thrombocytopenic purpura (ITP) progress to full-blown lupus over the ensuing years. Leukopenia and lymphopenia are additional hematologic abnormalities characteristically seen in SLE; apart from viral infections and drug toxicity, few other conditions cause children's lymphocyte counts to fall to less than 1,000 per mm^3.

Circulating antibodies to specific clotting factors, deficiencies of one or more clotting factors, and abnormal platelet function, often lead to abnormal hemostasis in SLE. A specific circulating anticoagulant, the "lupus anticoagulant," has been described in up to 10% of patients with SLE. The antibody is so named because in vitro assays of coagulation are prolonged in its presence. In vivo, this antibody predisposes to arterial or venous thrombosis.

Proteinuria, hematuria, and cellular casts are the usual urinary abnormalities. Renal failure is suggested by decreased urine output, elevated levels of blood urea nitrogen (BUN) and creatinine, and reduced creatinine clearance. Nephrotic syndrome is best documented by a 24-hour urine collection for quantitation of protein excretion, although a spot urinary protein:creatinine ratio is a useful screening tool for proteinuria.

The most important single test in children suspected of having SLE is measurement of ANA titers. Up to 2% of normal children have low to intermediate titers of ANA at any time; in most cases, these antibodies are transient by-products of a viral infection. In SLE, the ANA titer is typically quite high—significant levels are greater than 1:512—and often it is accompanied by antibodies to double-stranded DNA, a more specific marker for lupus. Nonetheless, it must be remembered that SLE may only be diagnosed in the presence of evidence of multiple organ system involvement, so no laboratory study is pathognomonic.

Total serum hemolytic complement (CH50) is often decreased in patients with active disease, and so may aid in differentiating disease flares from intercurrent illnesses. An elevated level of anti-ds DNA antibody with hypocomplementemia particularly correlates with active renal disease. Acute-phase reactants are elevated in the serum when inflammatory manifestations of the disease, such as arthritis, are flaring. The hypergammaglobulinemia characteristic of lymphocyte activation in lupus nonspecifically elevates the ESR, so measurement of the C-reactive protein (CRP) more reliably reflects systemic inflammation.

Management

General Management

There is no specific treatment for SLE. Rather, therapy consists of immunosuppression, the type and intensity of which are dictated by the particular organ systems affected. Patients with mild disease (fever and/or arthritis) without nephritis generally receive one of the NSAIDs (e.g., naproxen sodium 15 to 20 mg per kg per day, maximum 1,000 mg) (Table 101.3). Severe systemic features, on the other hand, usually require treatment with oral or IV corticosteroids, with doses divided three or four times daily in the most florid cases. As disease activity subsides, steroids may be carefully weaned; tapering too rapidly often results in a flare of the lupus. Steroids are generally first consolidated into a single morning dose, and then the total daily dose is gingerly decreased over weeks to months. When possible, patients are weaned to alternate-day therapy in an attempt to minimize side effects.

TABLE 101.6

IMMUNOMODULATORY AGENTS FOR THE TREATMENT OF SLE IN CHILDREN

	Biologic effects	Dose	Principal toxicities	Monitor
Hydroxychloroquine	Blocks lysosome processing of autoantigens	≤7 mg/kg/day po, max 400 mg, divided once or twice daily	Retinopathy, nausea, rash, agranulocytosis	Ophthalmology evaluation every 6 mo, CBC count, LFTs every 3–6 mo
Azathioprine	Precursor of 6-MP; blocks purine synthesis	1–3 mg/kg/day po	Bone marrow suppression, infection (especially zoster), nausea, hepatitis, rash	CBC count, lymphocyte count, LFTs
Mycophenolate mofetil	Blocks purine synthesis	600 mg/m^2/dose bid, max 1.5 g bid	Bone marrow suppression, infections, nausea, diarrhea	CBC count, lymphocyte count
Cyclophosphamide	Alkylates DNA leading to cytotoxicity	IV: 500–1,000 mg/m^2 divided every 2–4 wk (max 1.2 g) po: 50–100 mg/m^2/day	Bone marrow suppression, opportunistic infections, nausea, alopecia, bladder toxicity, infertility, cardiotoxicity	WBC, UA, BUN/Cr
Rituximab	Chimeric anti-CD20 monoclonal antibody that depletes B-cells	250–600 mg/m^2 1–4 times every 6–12 mo	Tumor lysis syndrome, anaphylaxis, hypogammaglobulinemia, opportunisitic infections	IgG level, lymphocyte count

SLE, systemic lupus erythematosus; CBC count, complete blood cell count; LFT, liver function test; 6-MP, 6-mercaptopurine; DNA, deoxyribonucleic acid; WBC, white blood cells; UA, urinalysis; BUN/Cr, blood urea nitrogen/creatinine; CD20, B lymphocyte surface marker; IgG, immunoglobin G.

Patients with life-threatening disease, particularly those with severe renal or CNS involvement, may require so-called "pulsed" doses of corticosteroids (IV methylprednisolone, 30 mg per kg per day, maximum 1.5 g), plasmapheresis, or an immunosuppressive agent (especially mycophenolate mofetil, azathioprine, rituximab, or cyclophosphamide) (Table 101.6). Symptomatic management may be necessary for the treatment of seizures, psychosis, or acute renal failure. With rare exception, patients should also receive hydroxychloroquine, which has been shown to prolong disease-free remissions once signs and symptoms of active lupus are controlled. In any event, close follow-up is mandatory to detect clinical and serological evidence of disease flares, and to monitor drug toxicity.

Management of Complications and Emergencies (Table 101.7)

Infections in SLE. Management of emergencies in patients with SLE first and foremost involves distinguishing primary disease manifestations from secondary complications. Infection is the major cause of mortality in childhood SLE. Gram-negative bacilli (especially *Salmonella*), *Listeria*, *Candida*, *Aspergillus*, *Cryptococcus*, *Toxoplasma*, *Pneumocystis*, and varicella-zoster virus are some of the organisms associated with severe infections in SLE. Patients with SLE who are receiving corticosteroids or cytotoxic drugs are at even higher risk for developing viral, mycotic, and other opportunisitic infections. The majority of these infections are diagnosed at autopsy, so clinicians must maintain a high level of suspicion in all children with SLE.

All patients with lupus and suspected infection do not need to be admitted to the hospital. However, acutely ill children, those with an absolute neutrophil count of less than 1,000 per mm^3, and those with pneumonia or the possibility of meningitis, require hospitalization for IV antibiotics while awaiting culture results. Patients with minor infections who are not acutely ill or neutropenic may be treated with appropriate antibiotics given orally along with close follow-up. The dose of corticosteroids should also be increased to provide stress coverage (at least three times the physiologic need) in any acutely ill child who has received more than 20 mg of prednisone daily for more than 6 weeks within the previous 12 months.

Fever. Each febrile episode in a child with SLE represents a potential emergency. It is often difficult to determine whether the fever is secondary to infection, to a flare-up of the primary disease, or to a combination of both. A complete physical examination should be performed. A CBC count, including total and differential white blood cell counts and platelet count, urinalysis, and quantitative CRP provide a rapid and general overview of the patient's well-being. CH50 (or C4), C3, ANA, and anti-ds DNA antibody titers should be obtained in order to assess the degree to which the patient's SLE is active. Cultures of blood and urine are mandatory, and clinicians should have a low threshold for obtaining a chest x-ray (especially in a tachypneic child), and for culturing CSF and other fluids when indicated. These cultures are particularly critical if no source of fever is apparent after a complete physical examination. In most cases, children with SLE who develop fever without a readily apparent source should be

TABLE 101.7

COMPLICATIONS OF SYSTEMIC LUPUS ERYTHEMATOSUS

	Symptoms and signs	Laboratory	Treatment[a]
Fever	Malaise	CBC, urinalysis, ESR, anti-DNA antibodies CH_{50}, C3 Cultures (blood, urine, CSF, stool and appropriate secretions) Chest radiograph Gallium scan	Prednisone 1–2 mg/kg/day
Infection	Fever, headache, seizure, cough, sputum, skin lesions, arthritis, disease flare, weight loss	Same as above	Intravenous antibiotics (broad spectrum) Reevaluate prednisone dose
Renal disease	Dehydration, fever, weight gain, hypertension, decreased urine output	Urinalysis, urine culture, 24-h urine protein Serum creatinine Creatinine clearance Anti-DNA CH_{50}, C3, C4 CBC, ESR, platelets Electrolytes, BUN	Prednisone "pulse therapy" (as needed) Cytotoxic agents (azathioprine PO or cyclophosphamide IV) Plasmapheresis
Hemolytic anemia	Fatigue, malaise, pallor, dyspnea, edema	CBC, Coombs', reticulocyte count, haptoglobin Peripheral smear Total bilirubin	Prednisone 2 mg/kg/day Transfusion, if acute emergency
Central nervous system	Seizures, coma, cranial nerve palsies, papilledema, hypertension psychosis	EEG, MRI, CT scan CSF—opening pressure, cell count, Gram and special stains, cultures	ICU admission Prednisone 2 mg/kg/day or pulse therapy Plasmapheresis Cytotoxic agents
Pleural effusion	Fever, chest pain, dyspnea, decreased breath sounds, splinting	Chest radiograph Thoracentesis—cell count, Gram stain, protein, glucose, culture, cytology	Thoracentesis, if indicated Oxygen, prednisone, cytotoxic agents
Peritonitis	Abdominal pain, fever, vomiting, diarrhea, tenderness, rigidity, hypoactive bowel sounds, melena	Radiograph (abdominal flat plate, cross-table, upright and/or lateral decubitus) Peritoneal aspiration—cell count, special stains, cultures CBC, electrolytes, ESR, ANA Test for occult blood in gastric contents and stool, nuclear scan	Surgical consult, NPO, IV hydration, NG tube, antacids, transfusion Prednisone Interventional radiology (if available)
Pancreatitis	Same	Serum amylase Amylase clearance ratio	IV hydration, NPO, adjust steroid dose, hyperalimentation
Pericarditis	Fever, chest pain, distended neck veins, decreased heart sounds, hepatomegaly	Chest radiograph, EKG Echocardiogram-2D CBC, ESR, blood culture, ANA	NSAIDs Perdnisone 2 mg/kg/day Pericardiocentesis as needed
Raynaud's phenomenon	Triple color change of fingers and/or toes; pain, swelling in digits	CBC, ESR, ANA, cryoglobulins Doppler flow studies	Protection from cold, biofeedback, analgesia, prednisone Calcium channel blockers Sympathetic ganglion block
Ocular	Blurring or loss of vision, headache	Funduscopic examination CT scan	Lumbar puncture (caution), prednisone
Traverse myelitis	Paraplegia, paraparesis, pain, sensory level	CT, MRI, LP (once epidural abscess excluded), antiphospholipid antibody, lupus anticoagulant	Pulse dose methylprednisolone, cytotoxic agents, anticoagulation

[a]Treatment regimens (except for infectious category) assume that an infectious etiology has been excluded. CBC, complete blood count; ESR, erythrocyte sedimentation rate; CSF, cerebrospinal fluid; BUN, blood urea nitrogen; PO, orally; IV, intravenously; EEG, encephalogram; MRI, magnetic resonance imaging; CT, computed tomography; ICU, intensive care unit; ANA, antinuclear antibody; NPO, nothing by mouth; NG, nasogastric; EKG, electrocardiogram; NSAIDs, nonsteroidal antiinflamatory drugs; LP, lumbar puncture.

given antibiotics pending culture results; abnormal splenic function places them at increased risk of rapid development of bacteremia and overwhelming sepsis.

Renal Complications. Renal disease is a major cause of morbidity in SLE, so it is important to establish its presence and severity at the time of diagnosis, and to regularly monitor renal function thereafter. Clinical manifestations of lupus nephritis are often minimal. Gross hematuria or headache resulting from hypertension may be warning signs. In the presence of nephrotic syndrome, the child may be edematous. Laboratory evidence of renal disease includes proteinuria, hematuria, hyposthenuria, casts, and elevated levels of BUN and creatinine. The presence of these findings in a patient with known SLE requires a more thorough investigation that should include estimation of the protein in a 24-hour urine collection; creatinine clearance; measurement of C3, ANA, and anti-ds DNA antibodies; as well as renal biopsy. In a patient with SLE and documented renal disease, hospitalization is necessary in the presence of rapidly worsening renal status, hypertensive crisis, or severe complications of therapy.

Treatment of renal disease is aimed at preserving renal function while minimizing medication toxicity. Selection of therapeutic agents depends on biopsy results and classification of renal involvement according to the World Health Organization classification. Active disease often may be managed with pharmacologic doses of corticosteroids (prednisone 1 to 2 mg per kg per day). In the presence of progressive renal failure, the patient should be hospitalized for more aggressive therapy. This generally includes divided doses of IV corticosteroids with or without an immunosuppressive agent such as cyclophosphamide. "Pulse" therapy with methylprednisolone (30 mg per kg in 50 mL of 5% dextrose in water, 1,500 mg maximum) may be indicated in the presence of rapidly progressive renal disease. Plasmapheresis has been used in the treatment of severe lupus nephritis, especially in patients who fail to respond to conventional therapy with corticosteroids and cytotoxic agents. Although this modality appears to have little effect on long-term outcome, acute disease flare-ups may be rapidly controlled by removing pathogenic autoantibodies, immune complexes, and cytokines. Such therapy may be associated with significant toxicity, so its use should be limited to centers experienced in the care of acutely ill children with SLE.

Hematologic Complications. Anemia is common in SLE and may have many causes. Most typically, patients have a nonspecific normocytic, normochromic anemia of chronic disease. Microcytic anemia, in contrast, may be caused by GI blood loss secondary to vasculitis or gastritis. These patients often have symptoms of GI distress and occult blood in the stool. They require further investigation, with the urgency dependent on the severity of the bleeding and the patient's overall well-being. Hemolytic anemia in SLE may be related to the disease itself (antierythrocyte antibodies) or to medications. Patients with hemolytic anemia often present with pallor, fatigue, jaundice, splenomegaly, and dark-colored urine. Occasionally, these patients develop symptoms of cardiorespiratory distress and CHF after severe hemolysis and a rapid fall in hemoglobin.

Laboratory investigation of anemia in SLE should include CBC count, reticulocyte count, and examination of the blood smear for red cell size and shape, nucleated red cells, and fragmented red cells. Serum levels of iron, iron-binding capacity, haptoglobin, and bilirubin may be helpful when the anemia is more severe or otherwise more concerning. The antibody responsible for autoimmune hemolytic anemia is of the "warm" variety, most commonly of the IgG type; IgM-type antibody is present in only a small percentage of cases. These red cell–bound antibodies may not be demonstrated by the standard Coombs' test, so more sensitive assays may have to be employed.

Mild to moderate anemia of any etiology may be managed using oral iron preparations and by treatment of the primary disease. Children with a hematocrit of less than 20% or compromised cardiac function often require admission to the hospital. Corticosteroids are the most effective agents for the control of autoimmune hemolytic anemia in SLE. Prednisone at 2 mg per kg per day is the initial treatment of choice.

Transfusion may be needed for children with a rapidly dropping hemoglobin concentration or CHF due to hemorrhage. In the case of hemolytic anemia, additional therapy is also mandatory to ensure that red blood cells are not lysed as rapidly as they are infused.

Leukopenia occurs in about 50% of patients with SLE. It may be caused by a reduction in granulocytes, lymphocytes, or both. Granulocytopenia may be secondary to drugs used in the treatment of SLE or less commonly to disease-related destruction of granulocytes. As with all cases of neutropenia, febrile children with absolute granulocyte counts of less than 1,000 per mm^3 are at higher risk of severe infections and should be admitted for empiric antibiotic coverage pending results of further studies.

Thrombocytopenia occurs in approximately 25% of patients with SLE; conversely, more than 5% of children presenting with ITP eventually develop SLE. The usual causes of thrombocytopenia are circulating antibodies to platelets or drug-induced bone marrow suppression. Infection should always be considered as a possible cause, so the presence of purpura and ecchymoses requires immediate investigation. Significant hemorrhage, a sudden drop in hemoglobin, and platelet counts of less than 20,000 per mm^3 are the usual indications for admission to the hospital. Studies should include CBC count, examination of the peripheral blood smear, and appropriate cultures. At times, bone marrow examination and testing of serum for antiplatelet antibodies may be helpful in determining the cause of reduced platelet counts. Patients with SLE are at risk of bleeding from any mucosal surface due to vasculitic ulceration, impaired hemostasis, thrombocytopenia, or a combination of these factors. Patients with life-threatening *epistaxis* may require local packing and platelet replacement in addition to high-dose corticosteroids. Severe *pulmonary hemorrhage* may necessitate general supportive measures such as transfusions, ventilatory assistance, and bronchial lavage. Once infections have been excluded, treatment of the underlying condition with high-dose corticosteroids, immunosuppressive agents, and/or plasmapheresis is essential. Treatment of GI hemorrhage is described in the "Gastrointestinal Complications" section.

Although less common than in systemic JRA, DIC associated with MAS may occur in SLE, with or without an associated infection. Therefore, patients with thrombocytopenia and severe bleeding should be investigated with prothrombin time, partial thromboplastin time (PTT), fibrin split products, and

examination of the peripheral smear. Lupus also appears to predispose to a particularly malignant form of thrombotic thrombocytopenic purpura. Reported mortality rates are extremely high, despite general support in ICUs and aggressive treatment with pheresis and immunosuppression. Outcomes are optimal when the diagnosis is suspected early and treatment is initiated rapidly.

The presence of a circulating *lupus anticoagulant* does not lead to a bleeding diathesis unless associated with significant thrombocytopenia; on the contrary, these patients are at increased risk of deep venous or arterial thrombosis. Prolongation of PTT and chronic false-positive serologic tests for syphilis are the usual clues to the presence of these autoantibodies. Specialized studies such as mixing assays and the Russell viper venom test may confirm the diagnosis. Significant thrombosis or pulmonary embolus in a child with SLE is an indication for immediate anticoagulation with heparin, followed by oral warfarin or subcutaneous low-molecular-weight heparin, pending assays for these circulating anticoagulants.

Neurologic Complications. *Seizures* (see Chapter 69) and altered states of consciousness (see Chapters 12 and 96) are the most common manifestations of CNS involvement in SLE. Other possible causes of seizures in patients with SLE include hypertension (from the disease itself or as a complication of corticosteroid therapy), infection (meningitis, encephalitis, or abscess), and uremia. Coma is not a primary manifestation of SLE but may result from meningitis or CNS hemorrhage secondary to thrombocytopenia. Therefore, patients with SLE who develop seizures or altered states of consciousness require admission for evaluation. They should have repeated examinations with special attention to blood pressure and neurologic findings, as well as the following investigations: CBC count with differential and platelet counts, PT/PTT, electrolytes, BUN, creatinine, and urinalysis. Once space-occupying lesions have been excluded, lumbar puncture (including measurement of opening pressure) should be performed, with CSF sent for routine studies as well as special stains to look for opportunistic organisms such as fungi and acid-fast bacilli.

No study is perfectly sensitive for detecting lupus cerebritis. Measurement of the IgG index [(CSF IgG/serum IgG)/(CSF albumin/serum albumin)] may allow estimation of IgG synthesis within the blood–brain barrier. Although this is increased in various chronic infections, it also typically rises in active CNS lupus. In addition, an electroencephalogram (EEG), MRI study, and CT scan with contrast may facilitate elucidation of the cause of CNS signs in children with lupus. Patients with CNS lupus also demonstrate abnormalities on single photon emission CT scanning, but a potential role for this modality in diagnosis and management is not proven.

IV lorazepam (0.1 mg per kg) is the drug of choice for the initial management of seizures, followed by phenytoin or fosphenytoin (20 mg per kg) for maintenance of seizure control. Phenytoin is preferred over phenobarbital because the latter may alter mental status acutely. If CNS manifestations are considered secondary to active vasculitis, IV corticosteroid therapy should be initiated. In the presence of deteriorating mental function, "pulse" methylprednisolone (30 mg per kg in 50 mL of 5% dextrose in water, 1.5 g maximum), IV cyclophosphamide, or plasmapheresis may be beneficial.

Other manifestations of CNS involvement, such as psychosis, also may need inpatient evaluation. *Listeria monocytogenes* may cause indolent meningitis that is clinically indistinguishable from organic brain syndromes. Similarly, it may be difficult to determine whether psychosis is secondary to corticosteroid therapy; steroids are most likely to induce an altered sensorium in patients with underlying psychiatric disease. Clinicians should not hesitate to aggressively pursue a diagnostic evaluation, including lumbar puncture and imaging procedures, so appropriate therapy may be instituted as expeditiously as possible. When psychosis due to SLE is suspected, psychotropic drugs (e.g., haloperidol 0.025 to 0.05 mg per kg per day in divided doses) may be used along with large doses of corticosteroids for 1 to 2 weeks. If there is no improvement, the steroid dose may be reduced gradually in an attempt to rule out steroid-induced psychosis.

Transverse myelitis is a rare complication of SLE believed to result from vascular compromise of the spinal cord. Patients note acute onset of pain and weakness, and they may develop incontinence. Physical examination is remarkable for weakness or flaccid paralysis below the level of the functional transection. In a high percentage of cases, the process is associated with a circulating lupus anticoagulant or antiphospholipid antibodies. Prognosis is related to the duration of symptoms prior to initiation of therapy, and favorable outcomes are only possible with urgent intervention. Thus, once infection, epidural abscess, and hematoma are excluded with appropriate imaging procedures and lumbar puncture, pulse doses of IV methylprednisolone (30 mg per kg over 1 to 2 hours), plus anticoagulation with IV heparin, are begun. Immunosuppressive agents such as cyclophosphamide, 500 to 750 mg per m^2 IV, must be added in short order.

Pulmonary Complications. *Pleural effusion* is the most common pulmonary manifestation of SLE. However, pulmonary infections and hemorrhage present more acute management issues. Pleural effusion is often bilateral and small, although occasionally it may be massive. The child is often ill with acute manifestations of systemic disease, such as fever, fatigue, and poor appetite. Symptoms may be minimal (cough, chest pain, and mild tachypnea) or absent. Chest pain aggravated by deep breathing or coughing is suggestive of pleurisy, although pain may be absent. In the presence of a moderate or large effusion, the patient may have dyspnea and tachypnea. The presence of fluid is easily demonstrated clinically (diminished breath sounds and dullness to percussion), and radiographs of the chest establish the extent of the effusion.

If the child has a previous history of pleurisy and there are no concerns about infection, hospitalization may not be necessary. Increasing the corticosteroid dose or adding an NSAID such as indomethacin (0.5 to 2 mg per kg per day) may be adequate therapy, but arrangements must be made for close follow-up. Thoracentesis is often necessary (i) to relieve symptoms, (ii) for diagnosis, or (iii) to reveal any underlying lesions obscured by the effusion. Pleural effusions caused by SLE usually are exudative, with elevated protein levels and cell counts and decreased levels of lactic dehydrogenase. Patients with large effusions should be admitted to the hospital for further observation and management.

Pulmonary hemorrhage is a potentially catastrophic complication of SLE, particularly in the pediatric age group. Early

recognition and treatment are critical. A hemorrhage may be related to the disease itself (e.g., pulmonary vasculitis), to the treatment (e.g., drug-induced thrombocytopenia), or to an infection (e.g., aspergillosis). Clinical features of patients with pulmonary hemorrhage include hemoptysis, tachypnea, tachycardia, and dyspnea; respiratory function may deteriorate rapidly if the process is not controlled.

Evaluation of patients with unexplained respiratory symptoms should include a chest x-ray. In cases of pulmonary hemorrhage, this shows fluffy infiltrates resembling pulmonary edema. CBC counts often reveal a dramatic drop in hemoglobin and a low platelet count. Diagnosis of a pulmonary hemorrhage may be confirmed by PFT, including DLCO. Intraalveolar blood increases CO absorption, making it one of the few conditions that results in an abnormally high DLCO. Bronchoalveolar lavage or lung biopsy still may be needed in some patients in whom *Pneumocystis* or *Aspergillus* infection remains a concern.

Management should include support with blood products as needed, plus high doses of IV corticosteroids. If bleeding is related to thrombocytopenia, platelet transfusion is indicated. Tracheal lavage with epinephrine, oxygen therapy, and intubation with positive end-expiratory pressure ventilation may be necessary, depending on the severity and progression of the process.

Occasionally, children with lupus may develop interstitial pneumonitis. Such patients are often ill with high fever, chest pain, cough, and dyspnea. On examination, rales may be heard throughout the chest. Radiographs show a diffuse alveolar infiltrate, unilateral or bilateral, with or without effusion. Cultures of the blood and respiratory secretions, bronchial washings, transtracheal aspirate, or lung biopsy may be necessary to exclude opportunistic infections. Supportive therapy should include increased concentrations of oxygen, adequate pulmonary toilet, and antipyretic drugs. Measures employed to control other manifestations of SLE, including corticosteroids or immunsuppressive agents, may lead to dramatic improvement once infections have been excluded.

Gastrointestinal Complications. Peritonitis and GI hemorrhage are emergencies associated with SLE. Drug-induced gastric ulcer and pancreatitis also occur. Often it is difficult to determine the nature of an intraabdominal catastrophe. Plain radiographs of the abdomen, ultrasonogram, MRI, CT scanning, peritoneal aspiration, and rarely even exploration, may be required to distinguish between possible etiologies.

Peritonitis may be a feature of the disease itself (serosal inflammation) or may be caused by secondary infection or visceral perforation. Patients with SLE and peritonitis should be admitted to the hospital at once. Symptoms and signs associated with peritonitis are pain in the abdomen, fever, vomiting, diarrhea, abdominal distension, diffuse tenderness, rigidity of the anterior abdominal wall, and hypoactive or absent bowel sounds on auscultation. It is important to remember, however, that these findings of peritoneal irritation may be masked by corticosteroid therapy.

A radiograph of the abdomen may show dilatation of intestinal loops with edema of the wall of the intestines, free air in the peritoneal cavity, or evidence of ileus or obstruction. Aspiration of the peritoneal fluid under strict aseptic conditions is essential if the cause of the peritoneal effusion is in doubt. The fluid should be sent for Gram stain and culture. Cell counts higher than 300 per mm^3 should be considered indicative of infection. Peritonitis secondary to GI perforation should be treated aggressively with surgery and IV antibiotics. Peritonitis due to serositis, a feature of SLE, may be treated with one of the NSAIDs; corticosteroids may be added if there is an inadequate response to the antiinflammatory medication or if there is additional evidence of active systemic disease. Prolonged use of both NSAIDs and corticosteroids should be avoided, however, as it increases the risk of GI irritation and/or ulceration.

An *acute abdomen* in SLE may be the result of bowel ischemia, infarction, or perforation, in addition to the occasional unrelated occurrence of intussusception or appendicitis. Symptoms of an acute abdomen include sudden onset of abdominal pain, vomiting, and diarrhea that may be bloody, although corticosteroids may obscure all signs and symptoms. The patient may go into shock rapidly. There is often localized abdominal tenderness, guarding, and rigidity with absent bowel sounds. Rectal examination should be performed to localize tenderness, palpate any masses, and obtain stool for occult blood testing. The patient should be well hydrated and shock promptly treated in an intensive care setting. A CBC count, serum electrolytes, and serum amylase determination should be obtained at once. A plain radiograph of the abdomen may show air–fluid levels or free air under the diaphragm. Abdominal ultrasound or CT may allow greater diagnostic precision. Paracentesis may help rule out infection or hemorrhage. Gram stain and culture of peritoneal fluid, in addition to blood culture, should be obtained immediately. Infection should be treated aggressively, and the ischemic or perforated area of intestine surgically repaired.

Pancreatitis must be considered in children with SLE and abdominal symptoms. SLE is the most common medical cause of *pancreatitis* in children, and corticosteroids are the medication most often associated with this complication. Whether pancreatitis is truly caused by steroids or merely tends to occur in sick patients receiving steroids for the underlying disease is not entirely clear; recent evidence supports the latter possibility. Accordingly, if the serum amylase is normal and pancreatitis is suspected, one should obtain an amylase clearance. An amylase/creatinine clearance ratio of greater than 5 suggests pancreatitis. In most cases it is prudent to assume that pancreatitis is secondary to active SLE and to increase immunosuppression in order to treat it. Recovery may be protracted, during which time the patient may have to be maintained on parenteral hyperalimentation.

GI hemorrhage may be secondary to NSAIDs (stomach), vasculitis of the GI tract (small intestines), or thrombocytopenia. Symptoms include abdominal pain, hematemesis, and melena if the bleeding is in the upper GI tract, and abdominal pain with hematochezia or occult blood in the stool if bleeding is from the lower GI tract. The patient may develop massive bleeding leading to shock. Immediate studies to be obtained in the ED include hematocrit, CBC count, serum electrolytes, and blood type and cross-match. Stool obtained by rectal examination should be tested for occult blood, even if the stool appears frankly bloody. If bleeding from a gastric ulcer is suspected, endoscopy can confirm the diagnosis. Therapy for a bleeding gastric ulcer includes volume replacement, hourly

antacid administration, and H_2-blockers (e.g., cimetidine 20 to 40 mg per kg per day, maximum 1,200 mg per day).

If active bleeding due to vasculitis is suspected, celiac axis angiography or endoscopy with deep intestinal biopsies is required for confirmation. GI vasculitis is rare in pediatric lupus, but when it develops, it most commonly occurs in the setting of chronically active disease. Children typically have an associated peripheral neuropathy, as well as chronic weight loss, anorexia, and inanition.

Cardiac Complications. Pericarditis and myocarditis are two of the important cardiac complications of SLE that may require emergency care. The features of lupus *pericarditis* are similar to those described in JRA and include chest pain, dyspnea, inability to lie flat, and pericardial friction rub. In the presence of cardiac tamponade, additional signs supervene (weak pulse, distended neck veins, distant heart sounds, and pulsus paradoxus of more than 20 mm Hg). Pericarditis without significant hemodynamic effects may be managed with NSAIDs or corticosteroids. Massive effusion leading to tamponade requires pericardiocentesis, in addition to treatment with corticosteroids, which may be injected directly into the pericardium at the time of pericardiocentesis.

Myocarditis is characterized by resting tachycardia out of proportion to fever, cardiomegaly without an effusion, CHF, ST-T wave changes on EKG, and arrhythmias. Infarction of papillary muscles or damage to aortic or mitral leaflets may lead to rapid development of valvular insufficiency. These patients should be on strict bed rest with monitoring. In addition to treatment of the basic disease, digoxin and diuretic therapy are often indicated.

Raynaud Phenomenon. Raynaud phenomenon (RP) is characterized by triphasic color changes of the extremities upon exposure to cold. These color changes proceed from cyanosis to blanching due to microcirculatory compromise, and resolve with erythema caused by reactive hyperemia. Severe episodes of RP may cause excruciating pain in the extremities, or even digital ulceration and autoamputation. Poor circulation impairs wound healing and clearing of infections, so patients with paronychia or digital cellulitis in the setting of acral ischemia may require admission for IV antibiotics.

Prophylactic techniques to improve digital circulation (avoidance of cold exposure, biofeedback) are the cornerstones of treatment of RP. Calcium-channel blockers (e.g., slow-release nifedipine, 30 to 180 mg daily) may decrease the frequency and severity of attacks, whereas oral (e.g., prazosin, sildenafil) and topical (e.g., nitroglycerine) vasodilators or medical or surgical sympathetic blockade may be necessary during severe episodes. Cases of impending gangrene may also be treated with prostacylin analogs such as Iloprost. These medications may cause dramatic vasodilation and result in pulmonary edema or cardiac arrythmias; therefore, they should only be used by experienced clinicians.

Hypertension. Hypertension may be a result of effects of SLE on systemic vasculature, a concomitant of renal involvement, or secondary to steroid therapy. Mild to moderate hypertension is usually controlled by combinations of diuretics, vasodilators, and α- or β-blockers, whereas angiotensin-converting enzyme (ACE) inhibitors are effective for renovascular hypertension. Hypertensive encephalopathy requires emergency therapy with nitroprusside, diazoxide, calcium-channel blockers, or other potent, rapidly acting agents.

Headaches. Up to 80% of patients with SLE develop headaches, many migrainous, and they may experience acute, incapacitating exacerbations. Meningitis (both septic and aseptic), hypertension, and pseudotumor cerebri must be ruled out in children with severe headaches. They should have appropriate investigations including an exhaustive neurologic evaluation and examination of the CSF once a space-occupying lesion has been excluded. If the headache is accompanied by blurring or loss of vision, an ophthalmologic consultation should be obtained to exclude other complications such as retinal vasculitis or retinal vascular occlusion. Gradual periodic release of CSF pressure is the immediate treatment of choice for pseudotumor cerebri. High-dose corticosteroid therapy should be added if the intracranial hypertension is believed to be because of SLE, whereas it should be tapered if the pseudotumor is secondary to steroid toxicity. If other causes are excluded, a child with a severe headache may be treated for a suspected acute migraine with analgesics, antiemetics, and ergot preparations or sumatriptan (Chapter 96).

JUVENILE DERMATOMYOSITIS

Background

Juvenile dermatomyositis (JDMS) is a rare rheumatic disorder characterized by inflammation of the skin and striated muscle. The annual incidence rate is roughly 3 cases per 1 million children in the United States. Girls are more often affected than boys (~2:1), as is typical of most autoimmune conditions. The mean age of onset is estimated at 6.9 years in the United States, with almost 20% of patients diagnosed at 4 years of age or younger. Prior to the availability of steroid therapy, as many as one-third of patients died of the disease, whereas another one-third developed permanent disabilities. More recently, the introduction of more effective therapies, particularly use of potent immunomodulators earlier in the disease course, has led to improved outcomes. The mortality rate may now be as low as 1.5% in the United States, and drug- and disease-related morbidity are also improving. Despite these advances, however, JDMS remains a serious disease that requires the care of physicians experienced with its management.

As with other idiopathic rheumatic diseases of childhood, diagnosis of JDMS depends on fulfillment of clinical criteria. Bohan and Peter's criteria for dermatomyositis (DM)/polymyositis (PM) in adults are typically used for diagnosing this condition, and they are given in Table 101.8. In fact, the condition in children differs significantly from that in adults: it includes a more prominent degree of vascular inflammation, less commonly involves detectable autoantibodies, and rarely accompanies malignancies. Further, in children, the appearance on MRI is essentially diagnostic because other causes of inflamed muscle and soft tissue are not seen in this age group (Fig. 101.8). New pediatric criteria are being developed, but until they are validated, Bohan and Peter's criteria remain the gold standard for classification of children with inflammatory myopathies.

TABLE 101.8

CRITERIA FOR DIAGNOSIS OF DERMATOMYOSITIS (DM)/POLYMYOSITIS (PM)*

1. Symmetric weakness of the proximal limb muscles and anterior neck flexors
2. Evidence of necrosis of type I and II fibers on muscle biopsy
3. Elevation of serum levels of skeletal muscle enzymes—creatine phosphokinase and aldolase
4. Short, small, polyphasic motor unit potentials with fibrillation; insertional irritability; and high-frequency repetitive discharges on electromyography
5. Skin rash—characteristic heliotrope rash, scaly erythematous rash over extensor aspects of the joints, and periungual erythema

Definite: 4 criteria (PM)
Probable: 3 criteria (PM)
Possible: 2 criteria (PM)

*N Eng J Med 1975;292:344–347

Pathophysiology

Microscopically, the skin in JDMS shows dermal atrophy, obliteration of appendages, and lymphocytic infiltration. The muscle typically demonstrates a mixture of degenerating and regenerating muscle fibers, variations in muscle fiber size, perivascular lymphocytic infiltration, and perifascicular atrophy of muscle fibers. Small arteries, venules, and capillaries of the skin, muscle, fat, and GI tract characteristically reveal angiopathy. Viral infections, particularly Coxsackie B, vasculitis caused by immune complex deposition, and cell-mediated cytotoxicity against muscle fibers, have been implicated in the pathogenesis of JDMS. Certain HLA haplotypes, especially HLA-B8/DR3, may predispose to the disease. Synthesizing these findings, JDMS is thought to represent an as-yet unexplained perpetuation of muscle inflammation in susceptible hosts following what is typically a self-limited illness in most children.

Clinical Manifestations

JDMS has a wide clinical spectrum, from a mild form involving mainly the skin to a severe vasculitic type with a rapidly fulminating course. JDMS may be conceptualized as passing through four overlapping phases that typically last for 2 to 5 years but may persist indefinitely: (i) a prodromal phase of nonspecific aches and pains, (ii) a phase of progressive muscle and skin inflammation characterized by weakness and rash, (iii) a phase of persistent active disease and cumulative tissue damage, and (iv) an indolent phase with development of contractures and calcinosis but minimal ongoing inflammation. The goal of therapy is to compress this natural history into a shorter time period that ends before irreversible sequelae occur.

FIGURE 101.8 Coronal fast multiplanar inversion recovery image of the thighs shows areas of increased signal intensity, especially in the adductor muscle groups, in a patient with dermatomyositis.

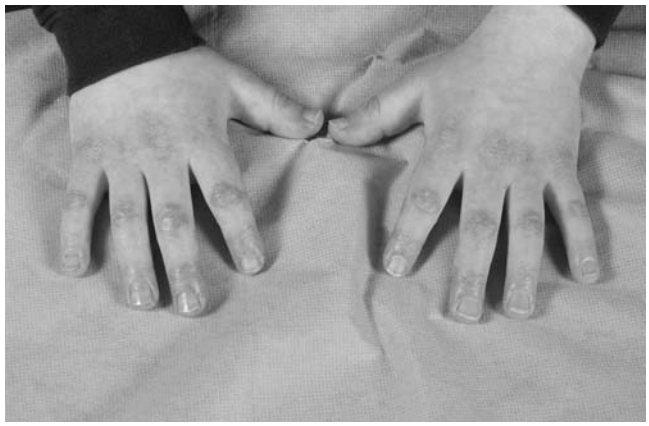

FIGURE 101.9 Gottron papules in juvenile dermatomyositis (JDMS). (Courtesy of Lisa Rider, MD.)

The onset of JDMS is often insidious, with aches and pains in the limbs, malaise, low-grade fever, and edema of the hands, feet, and eyelids. There may be a diffuse and nonspecific rash. This prodromal stage evolves into the acute phase, when the characteristic features of JDMS become evident. Classical skin manifestations include a violaceous heliotrope rash in the periorbital region and occasionally on the forehead; dusky red or atrophic lesions over the extensor aspects of the knees, elbows, and knuckles (Gottron papules); and periungual erythema (Fig. 101.9, see also color plate). Skin findings may precede or follow the onset of muscle weakness. Ulcerative skin lesions and anasarca are rare presenting manifestations of JDMS associated with a particularly severe disease course.

Muscular involvement in JDMS is characterized by pain, tenderness, and weakness of proximal muscles in a symmetric fashion. Strength of the anterior neck flexors and abdominal muscles is particularly affected, while facial muscles are spared. The disease may progress to involve the muscles of the palate and pharynx, resulting in regurgitation, nasal voice, and aspiration. Weakness of the respiratory muscles can lead to a poor cough, pneumonia, and respiratory failure. Risk of GI hemorrhage and perforation are increased at this stage and are associated with abdominal pain, hematemesis, and melena.

The clinical course of JDMS is variable. Traditionally, patterns such as "limited" or "monocyclic," with a single period of disease activity, were differentiated from a "chronic" or "polycyclic" pattern of exacerbations and remissions. It now appears that these distinctions are an artifact of inadequate therapy, however. With newer approaches to treatment, disease manifestations may be controlled within a few months in the vast majority of patients.

Children who continue to have florid or smoldering muscle inflammation for more than 6 to 12 months are at risk of developing late complications of JDMS. These include pronounced muscle wasting, contractures, lipodystrophy, and pigmentary changes of the skin. The rash over the extremities often becomes dry, scaly, and atrophic. Subcutaneous calcifications historically have occurred in up to 30% of children during this phase, although aggressive treatment of inflammation from the onset of JDMS dramatically lowers this figure. Calcifications are most typically discrete nodules around large joints, but at times they may take the form of a diffuse encasement of the soft tissues, known as calcinosis universalis. Occasionally, children pass through the early stages insidiously and come to the attention of physicians only when they develop contractures and calcinosis.

Although skin and striated muscle are the primary targets of the inflammatory process in JDMS, typically other organ systems are also involved. Up to one-third of children develop arthritis, which may be present at diagnosis or may develop months into the disease process. The arthritis of JDMS is generally nonerosive and often improves as the primary disease is treated, although some children require specific therapy for their arthropathy. Neurologic manifestations of JDMS are extremely rare, but peripheral polyneuropathy, seizures, psychosis, and one case of suspected brainstem vasculopathy have been reported.

Laboratory Studies

Weakness is a consistent manifestation of JDMS, but it is a late, variable, and subjective clinical sign. Objective evidence of muscle inflammation should also be sought by measuring serum levels of muscle enzymes that are released into the circulation when myocytes are injured. A wide variety of enzymes may be elevated in JDMS, including creatine kinase (CK), aldolase, lactate dehydrogenase (LDH), and transaminases (ALT and AST). These markers must be interpreted with caution, however, because none is specific for muscle. Elevated levels may be derived from damage to a variety of other tissues, including hepatocytes, brain cells, and the GI tract. Further, for unknown reasons many children do not reliably demonstrate elevated muscle enzymes despite significant myositis. This is particularly true during later stages of the disease, when subtle increases in LDH and aldolase may herald a disease flare-up, but CK levels often remain normal.

Because JDMS is a microangiopathic process, active disease is also characterized by elevated levels of von Willebrand factor antigen (vWF:Ag), which is released by damaged endothelial cells. In contrast, evidence of systemic inflammation may be absent, and acute-phase markers (including ESR and CRP) and CBC counts are typically normal. In particularly difficult cases, MRI of the thighs may be the most sensitive method of documenting muscle inflammation (Fig. 101.8). Evidence of cardiac involvement should also be sought, particularly with an EKG and an echocardiogram. Serologic markers of myocardial involvement are unreliable because both the CK-MB fraction and the troponin level are elevated in JDMS due to myoblast proliferation in skeletal muscles.

Management

General Management

The sine qua non of treating JDMS is aggressively controlling muscle inflammation. The more rapidly markers of myocyte damage such as CK and aldolase can be normalized, the less the chance that acute and chronic complications will occur. During the initial evaluation of JDMS, it is essential to monitor the function of the palatopharyngeal and respiratory muscles; palatal weakness increases the risk of aspiration. Eating only in the upright position, frequent suctioning, or placement

of a nasogastric tube may be necessary to avoid aspiration. Support of weak muscles, such as wearing a soft neck collar while riding in automobiles, helps minimize the risk of complications until children regain their strength.

Recognition of the importance of expeditious disease control is leading to modifications in the medical management of JDMS. Thus, virtually all children with clinical or biochemical evidence of muscle inflammation begin treatment with pulsed doses of IV methylprednisolone (30 mg per kg, maximum 1.5 g) infused over 1 to 2 hours. Oral prednisone is then started at a dose of 1 to 2 mg per kg per day. If muscle enzymes, weakness, or GI symptoms do not rapidly improve, steroid-sparing agents such as methotrexate (0.75 to 1.25 mg per kg per week), IV immune globulin (2 g per kg per month) or cyclosporine A (2 to 4 mg per kg per day) are introduced within 4 to 8 weeks. In more recalcitrant cases, it may be necessary to add imunosuppressive drugs such as cyclophosphamide (10 to 20 mg per m^2 every 2 to 4 weeks) or azathioprine (1 to 3 mg per kg per day). A potential role for biologic agents, including infliximab and rituximab, is currently the subject of multicenter studies. Parenteral administration of medications is generally preferable in order to bypass the GI tract, where absorption of orally administered medications may be impaired because of vasculitis. Plasmapheresis may be beneficial in particularly severe cases. Under all circumstances, the goal is to rapidly control disease activity while minimizing toxicity from medications. Fortunately, active disease generally does not recur if a complete remission can be induced and maintained for 1 to 2 years.

Management of Complications and Emergencies (Table 101.9)

The most serious emergencies in JDMS relate to the respiratory and GI tracts. In addition, complications may occur as a result of therapy with corticosteroids and immunosuppressive agents (e.g., infection and GI hemorrhage).

Respiratory Complications. Respiratory emergencies seen in childhood DM have diverse etiologies. Entities to be considered include (i) aspiration pneumonia secondary to weakness of velopalatine muscles; (ii) atelectasis and pneumonia secondary to difficulty in clearing secretions as respiratory muscles become involved; (iii) respiratory failure secondary to profound involvement of respiratory musculature, including the

TABLE 101.9

COMPLICATIONS OF JUVENILE DERMATOMYOSITIS

Clinical entity	Symptoms and signs	Investigations	Treatment
Respiratory failure	Air hunger, tachypnea, cyanosis, shallow respiration, alteration in mental status	Chest radiograph Arterial blood gas	Oxygen Mechanical ventilatory support Corticosteroids and immunosuppressives, plasmapheresis Antibiotics if evidence of aspiration pneumonia
Pneumothorax	Chest pain Breathlessness, tachypnea, cyanosis, diminished breath sounds, increased resonance to percussion	Chest radiograph	Chest tube
Velopalatine weakness	Pooling of secretions, drooling Nasal voice Aspiration pneumonia—recurrent	Careful barium cineradiographic study Chest radiograph	Corticosteroids Nasogastric feedings Tracheostomy
Gastrointestinal hemorrhage	Abdominal pain, nausea, vomiting Guarding, diminished bowel sounds (may be masked by corticosteroids) Hematemesis, melena, hematochezia	CBC; type and cross Abdominal radiograph: flat plate and upright Endoscopy Angiography Nuclear scan	NPO, NG tube Support of circulatory volume Antacids Corticosteroids Surgical consult Interventional radiology
Gastrointestinal perforation	May be silent (corticosteroids) or associated with abdominal pain, distension, vomiting	Abdominal radiographs: flat plate and upright	NPO, NG tube Surgical consult
Calcinosis	Swelling resembling cellulitis around large joints Fever	CBC Radiograph Aspiration	Antibiotics if superinfection suspected Pain control
Carditis	Dyspnea, tachycardia, arrhythmias	Chest radiograph EKG Echocardiogram	Digoxin, diuretics Antiarrhythmics Corticosteroids

CBC, complete blood count; NPO, nothing by mouth; NG, nasogastric; EKG, electrocardiogram.

diaphragm; (iv) progressive interstitial lung disease; and (v) opportunistic infection (tuberculosis, fungi, viruses, or *Pneumocystis*) in the immunosuppressed host.

The history should provide clues for differentiating between these possibilities. On physical examination, the child with a respiratory complication is often acutely ill with an elevated temperature. Because fever also may occur with active DM, it is necessary to differentiate pyrexia caused by infection from that caused by underlying disease. The patient with respiratory complications is often dyspneic and tachypneic, and has a weak cough with impaired production of sputum. Pooling of secretions in the mouth and a nasal voice should suggest the presence of palatal weakness. Each breath is shallow, with poor air entry on auscultation. The child cannot complete a sentence in one breath and often pauses between words. On auscultation, crackles may be heard. Cyanosis and alteration of consciousness imply impending respiratory failure.

Children with JDMS who develop respiratory problems are usually hospitalized for observation and diagnosis. Those at risk of developing respiratory failure should be cared for in an ICU. Preliminary investigations should include a CBC count, urinalysis, serum electrolytes, measurement of muscle enzymes (including CK, aldolase, AST, ALT, and LDH), and chest x-ray. Depending on the seriousness of the symptoms and the cooperativeness of the child, blood gas analysis, pulmonary function studies, and high-resolution chest CT may be obtained. These latter studies should be compared with baseline PFTs obtained previously on the same child because more than two-thirds of children with DM show restrictive disease and a diffusion abnormality.

If the etiology of the respiratory deterioration remains in doubt, more sensitive tests of disease activity, including vWF:Ag and MRI of the thigh muscles, may be necessary to determine whether more aggressive control of the underlying myositis is necessary. Corticosteroids are an essential component of the armamentarium for treating weakness of respiratory muscles and interstitial lung disease. If the weakness seems to be worsening, maximum efficacy may be obtained with pulsed-dose methylprednisolone. During this pulse therapy, blood pressure and cardiac rhythm should be monitored and the infusion stopped if there is sudden hyper- or hypotension or a rhythm disturbance. Plasmapheresis is reserved for children who deteriorate even after pulse steroid therapy. At best this provides temporary respite, so pheresis must be accompanied by institution of a long-term immunosuppressive regimen. Frequent suctioning, nasogastric feeding, and, occasionally, tracheostomy, may be necessary to avoid aspiration pneumonia. Conventional or high-frequency ventilation may be needed as supportive measures, and the use of extracorporeal membrane oxygenation (ECMO) has been reported in a particularly severe case of JDMS.

Aspiration pneumonia can be recognized on the basis of clinical and radiographic data. A chest x-ray with a severe interstitial or reticulonodular pattern may indicate progression of underlying lung disease or opportunistic infection. Lung biopsy may be helpful in such situations. If pulmonary problems are suspected to result from infection, treatment with IV antibiotics should be initiated after appropriate cultures are obtained. In addition, sufficient corticosteroids (three times physiologic need) are given to compensate for potential iatrogenic adrenal insufficiency if the child has recently received high doses of steroids.

Pneumothorax is another complication known to occur during the course of childhood DM. The usual symptoms are sudden onset of chest pain and tachypnea. Physical examination shows deviation of the trachea to the opposite side of the chest and increased resonance and diminished breath sounds on the affected side. A radiograph of the chest shows air in the pleural cavity. A chest tube should be placed and connected to underwater seal.

GI Complications. Vasculitic changes, characterized by intimal hyperplasia and arteriolar occlusion by fibrin thrombi, are characteristic of severe or poorly controlled JDMS. Arteries and veins of the skin, muscles, and GI tract may be involved. Resultant ulcerations and perforations may occur anywhere from the esophagus to the large intestine, and they may disrupt the integrity of the integument. Symptoms and signs of these complications depend on the site of the lesion. For example, bleeding from the esophagus is not common, but perforation may cause mediastinitis. In contrast, bleeding from ulceration of the stomach or duodenum typically leads to abdominal pain with vomiting and melena. If the bleeding is severe, hematemesis with a sudden drop in the hemoglobin will be the presenting manifestation. Laboratory studies to be obtained include a CBC count, electrolytes, and BUN. Endoscopy may prove useful in locating the site of bleeding. Treatment of upper intestinal hemorrhage includes support of circulatory volume and hematocrit, antacids, and H_2-blockers (e.g., cimetidine 20 to 40 mg per kg per day, maximum 1,200 mg).

Evidence of bleeding from the lower portion of the GI tract includes abdominal distension and pain, vomiting, and melena or bright red blood in the stool. The hematocrit may fall precipitously, and radiographs of the abdomen may show free air in the peritoneum. If there is active bleeding, a technetium scan to locate the area of hemorrhage is the initial step. This may be followed by an angiogram to localize the actual vessel that is bleeding. The details of the management of hemorrhage from the GI tract are discussed under SLE and in Chapters 29 and 89.

In a patient with JDMS, intestinal perforation may go unnoticed and present with pneumatosis intestinalis. This finding also may precede clinical perforation and pneumoperitoneum. Thus, any patient with JDMS and persistent abdominal pain should be examined radiographically for the presence of gas in the bowel wall. In the presence of acute perforation, usual physical findings are tenderness and guarding of the abdomen, and distant or absent bowel sounds. It should be stressed that corticosteroids may mask these physical findings. Supine and erect abdominal radiographs are indicated to demonstrate intramural gas or subdiaphragmatic air. Patients with this diagnosis require admission to the hospital and emergent surgical evaluation, although resolution with only supportive care may occur.

Calcinosis. During the period of formation of subcutaneous calcification, children with JDMS may develop high fever, chills, and one or more areas of swelling under the skin. The inflammation caused by the subcutaneous calcium deposit may be indistinguishable from that of cellulitis or abscess formation, with warmth, erythema, and tenderness. Eventually, the lesion may spontaneously extrude calcium, at which time the fever often subsides. Although this is the natural history of subcutaneous calcifications, it is often hard to exclude an infectious etiology for the swelling. If doubt exists, needle

aspiration of the site may be performed and the fluid examined for calcium crystals and organisms. In the face of uncertainty, it is best to treat for infection with antibiotics until culture reports are available. Incision and drainage or surgical debridement should be avoided, as the inflamed skin rarely heals satisfactorily. Complete control of the underlying disease offers the best hope for resolution of calcinosis, although this may be incomplete or require many years.

Cardiac Emergencies. Although EKG abnormalities may be seen in up to 50% of children with JDMS, development of myocarditis is uncommon. Tachycardia out of proportion to fever may be the earliest evidence of this complication. Involvement of the conduction system by edema and fibrosis leads to electrical abnormalities and arrhythmias. All patients with myocarditis should be admitted for an evaluation that includes an EKG, chest x-ray, and echocardiogram. Supportive management includes judicious and careful use of diuretics and cardiotonic drugs while aggressively treating the primary disease.

SCLERODERMA

Background

Scleroderma, or hardening of the skin, is most commonly a process restricted to the skin and subcutaneous tissues in children. The far more serious systemic form, systemic sclerosis (SS), is also far rarer, occurring in less than 1,000 children nationwide. Various conditions are included within the category of scleroderma, as listed in Table 101.10.

TABLE 101.10

CLASSIFICATION OF SCLERODERMA AND RELATED CONDITIONS

- Systemic Sclerosis
  - Scleroderma
  - CREST syndrome
  - Overlap connective tissue diseases
    - SLE
    - Mixed connective tissue disease (MCTD)
- Localized scleroderma
  - Morphea
  - Linear (include *"en coup de sabre"*)
  - Eospinophic fasciitis
- Toxin-mediated conditions
  - Eosinophilia-myalgia
  - Polyvinyl chloride
  - Toxic oil syndrome
  - Pentazocine
  - Bleomycin
  - Graft-versus-host disease
- Pseudoscleroderma
  - Edematous
    - Myxedema
    - Scleredema
  - Indurative
    - Porphyria cutanea tarda
    - Pheylketonuria
    - Acromegaly
- Atrophic
  - Progeria
  - Acrodermatitis chronica atrophicans

Pathophysiology

The most characteristic microscopic feature of affected areas of the skin is increased thickness and density of collagen in the dermis. In addition, flattening of rete pegs, mononuclear cell infiltrate around small blood vessels, obliteration of skin appendages, and hyalinization and fibrosis of arterioles are seen.

The etiology of this disease is unknown. Increased collagen production by fibroblasts, perhaps in response to disordered immune regulation and cytokine release, appears to be a final common pathway for a clinical entity with numerous genetic and environmental triggers. Similarities between this disorder and graft-versus-host disease after bone marrow transplantation, and to chronic LD (acrodermatitis chronica atrophicans), have stimulated many areas of research. Clear understanding of the underlying abnormalities in scleroderma, however, remains elusive.

Clinical Manifestations

Localized scleroderma is more common in children than in adults. The lesions may be one of three types. *Morphea* is a focal ivory-white patch with a violaceous or erythematous rim; it is often a single lesion on the trunk, although generalized morphea also occurs in children. *Linear scleroderma* causes scarring, fibrosis, and atrophy that crosses dermatomes. Involved skin develops a "hidebound" appearance due to tethering of the subcutaneous tissues to deeper structures. It may extend to involve an entire extremity (Fig. 101.10) and to affect underlying muscle and bone, leading to flexion contractures, leg-length discrepancies, and atrophy of an extremity. A variant affecting the forehead is called *scleroderma en coup de sabre;* this form may involve underlying skull and nervous tissue, as well as the skin. Although localized forms of scleroderma are generally not associated with internal organ involvement, one large pediatric cohort found nearly a quarter of patients to have at least one extracutaneous manifestation. In addition, though rare, progression to SS is reported. Therefore, complications related to SS should be considered if a child with localized scleroderma presents with acute clinical decompensation.

SS often presents with cutaneous changes such as RP (90% of patients), edema, induration, increased pigmentation, and tightening of the skin. Some of these children may also develop arthritis resembling JRA, muscle weakness resembling JDMS, and nodules along tendon sheaths. If these features are seen, one should consider the possibility of undifferentiated or overlap connective tissue disease, in which features of SLE, SS, JDMS, and JRA intermingle.

Serious illness and death can occur in SS. Severe, uncontrolled hypertension and rapidly progressive renal failure (scleroderma renal crisis) have been a major source of mortality, although introduction of ACE inhibitors has dramatically

FIGURE 101.10 Linear scleroderma involving left lower extremity in a 12-year-old girl.

improved short-term survival. Primary myocardial disease with conduction disturbances, pericarditis, and intractable CHF, as well as pulmonary hypertension secondary to fibrosis, remain significant sources of morbidity and mortality. Additional complications of SS include (i) digital gangrene and nonhealing ulcers most frequently involving the fingers, elbows, and malleoli secondary to vascular occlusion; (ii) disordered motility of the distal esophagus with dysphagia and reflux esophagitis (60% of affected children); (iii) malabsorption syndrome; (iv) thrombocytopenia with subsequent cerebral hemorrhage; (v) interstitial lung disease; and (vi) cranial nerve involvement with trigeminal sensory neuropathy, facial weakness, and tinnitus.

Management

General Management

Specific therapy for SS is nonexistent at present. Virtually every medication, from antihistamines to potent immunosuppressives, has been used in patients with this disease, though none shows clear benefit. During the inflammatory, prefibrotic stages of interstitial lung disease and pulmonary vascular involvement, corticosteroids (prednisone 2 mg per kg per day or the equivalent) are indicated. Cyclophosphamide appears to forestall pulmonary fibrosis if added early to the treatment regime. If the esophageal sphincter is involved, patients should be advised to sleep with the head comfortably elevated, and an antacid may be prescribed.

Minor episodes of Raynaud syndrome are managed with prophylactic measures such as the avoidance of cold exposure and the use of warm clothing. Biofeedback training and calcium-channel blockers such as nifedipine may be helpful in decreasing the frequency of attacks. Aggressive physical therapy is indicated to prevent contractures and to maintain normal function. Despite these measures, linear scleroderma with involvement of deep structures may lead to contractures of the extremities requiring surgery. Juvenile onset SS carries an approximate 5-year mortality rate of 10%.

Management of Complications and Emergencies (Table 101.11)

Cardiac Complications. Signs and symptoms of myocardial fibrosis are essentially those of a cardiomyopathy with dyspnea, orthopnea, and fatigue. Angina pectoris and myocardial infarction also occur. Fibrosis of the conduction system may result in arrhythmias, presenting as palpitations, syncope, or sudden death. Pericarditis is usually silent and valvular involvement in scleroderma is rare. Even in the absence of symptoms or physical findings, cardiac involvement eventually develops in the majority of patients with SS, and sensitive imaging or functional studies reveal some cardiac involvement early in the course of disease in the majority of cases. Management of cardiac dysfunction is symptomatic, including inotropic support and afterload reduction. Extensive diuresis should be avoided because of potential adverse effects on renal cortical perfusion. No specific drugs are available to arrest the progress of cardiac involvement.

Pulmonary Complications. Pulmonary involvement in SS may have three manifestations: pleurisy, interstitial lung disease, or pulmonary artery fibrosis. Diffuse interstitial lung disease is often asymptomatic. A dry cough may be the first symptom. Early in the course of the disease, even before symptoms appear, pulmonary function tests in these patients show a restrictive pattern and diffusion abnormalities. Later, radiographs of the chest show increased reticulation, a so-called "honeycombed" appearance, mainly basilar and bilateral. Other diagnostic modalities, including high-resolution CT scanning, bronchoalveolar lavage, and lung biopsy, may identify earlier, prefibrotic states of disease more responsive to anti-inflammatory therapy. With progression of the disease, cough and dyspnea become prominent. On examination, crackles over both sides of the chest, particularly over the infrascapular area, may be the only finding. Development of right-sided heart

TABLE 101.11

COMPLICATIONS OF SYSTEMIC SCLEROSIS

Clinical entity	Symptoms and signs	Investigations	Treatments
Myocardial fibrosis	Exertional dyspnea, orthopnea, angina pectoris Distant heart sounds, gallop rhythm, arrhythmias	Chest radiograph EKG Echocardiogram Gated nuclear-ventricular scans	Digoxin Diuretics Antiarrhythmics
Pulmonary interstitial fibrosis	Cough, dyspnea Dry crackles Cor pulmonale	Chest radiograph, EKG Pulmonary function tests, including CO diffusion High-resolution CT, bronchoalveolar lavage Lung biopsy	Corticosteroids Oxygen, bronchodilators Treatment of right-sided heart failure
Pulmonary hypertension	Acute dyspnea Increased P_2 and widely split S_2	Chest radiograph EKG Echocardiogram Right-sided heart catheterization Lung biopsy	Corticosteroids Calcium channel blockers ACE inhibitors Direct PA installation of vasodilators
Scleroderma renal crisis	Severe headache, blurred vision, congestive heart failure, seizures Malignant hypertension, retinopathy	Electrolytes, BUN Creatinine Plasma renin activity	Captropril and other ACE inhibitors Minoxidil and other vasodilators, β-blockers Diuretics, dialysis; in refractory cases, nephrectomy
Impending gangrene	Pain, loss of sensation in distal digits Trophic changes	Cryoglobulins Doppler flow studies	Topical vasodilators Sympathetic ganglionic blockade (digital, regional), prostaglandin E_1 infusion
Esophagitis	Restrosternal pain, pyrosis, melena	CBC Barium swallow Esophageal pH probe and manometry	Antacids/cimetidine Surgical manipulation for chronic unremitting complaints

EKG, electrocardiogram; CO, carbon monoxide; CT, computed tomography; ACE, angiotensin-converting enzyme; PA, posteroanterior; BUN, blood urea nitrogen; CBC, complete blood count.

failure is heralded by increasing dyspnea, although edema of the lower extremities may not be appreciated because of hidebound skin. Patients with right-sided heart failure generally require admission and symptomatic management.

Patients with irreversible pulmonary fibrosis and chronic respiratory failure may also need admission. They have diminished respiratory reserve, so such patients must be treated promptly when they contract intercurrent respiratory infections. Supplemental oxygen, bronchodilators, and corticosteroids may be helpful. If residual inflammation is demonstrable after further investigations such as those noted previously, these patients should receive corticosteroids (prednisone 2 mg per kg per day) for 6 to 8 weeks, although the value of this therapy is doubtful in established fibrosis. In addition, treatment of right-sided overload is indicated.

Pulmonary hypertension is the most common cause of dyspnea in patients with SS. On auscultation, there is a wide or fixed splitting of the second heart sound and the pulmonic component is accentuated. The EKG shows right ventricular hypertrophy. Echocardiography and right heart catheterization may be necessary to differentiate cardiac from pulmonary etiologies of respiratory deterioration. Corticosteroids and cyclophosphamide (50 mg per day orally or 500 to 750 mg per m^2 by monthly IV infusion) are the treatment of choice in patients without established interstitial fibrosis, in addition to supportive measures. Endothelin-1 receptor antagonists such as bosentan, calcium-channel blockers, ACE inhibitors, and prostaglandin analogs (e.g., epoprostenol) may provide temporary improvement in individual cases.

Renal Complications. Sclerodermatous involvement of the vessels of the kidney is the most common cause of renal failure in adults with SS. Proteinuria, hypertension, rapid progression of skin thickening early in the illness, anemia, pericardial effusion, and CHF are all markers of the patient at risk for renal scleroderma. The development of a microangiopathic hemolytic anemia suggests imminent renal failure. These complications appear to be less common in children than in adults.

Renal failure may develop gradually or acutely in a patient with known renal disease, and use of corticosteroids may precipitate its appearance. The combination of rapidly progressing azotemia with malignant hypertension (scleroderma renal

crisis) requires hospitalization and urgent management. Characteristically, a patient displays a sudden rise in blood pressure to levels as high as 150 to 200 mm Hg diastolic, often with minimal or no symptoms (such as a headache). Evaluation reveals hypertensive retinopathy (flame hemorrhages, cotton wool exudates, and papilledema), elevated plasma renin activity, and rapid deterioration of renal function. Immediate investigation should include urinalysis, measurement of urine output and urinary electrolytes, serum electrolytes, BUN, creatinine, and plasma renin level.

A major advance in the pharmacologic management of scleroderma renal crisis has been the use of ACE inhibitors such as captopril. Patients who fail to respond to this drug may still respond to potent vasodilators such as minoxidil, along with β-blockers and diuretics; regimens involving multiple drugs may also be necessary (see Chapter 34). Renal dialysis and rarely bilateral nephrectomy may be indicated in hypertension unresponsive to pharmacologic therapy. Because most patients with severe scleroderma renal disease have a component of myocarditis and ventricular stiffness, maintenance of blood volume is essential to ensure adequate preload to support the circulation.

Peripheral Vascular Complications. RP can often be incapacitating, particularly in cold weather. Symptoms include severe pain in the extremities and loss of sensation in the tips of the digits. Treatment with calcium-channel antagonists such as slow-release nifedipine (30 to 180 mg daily) may decrease the frequency or severity of attacks. In urgent cases with impending gangrene, systemic or topical vasodilators (e.g., nitroglycerine paste or intraarterial reserpine) or sympathetic ganglion block may be tried, although these forms of therapy have not been validated in well-constructed studies. Excessive peripheral vasodilation may also precipitate cardiovascular collapse due to a "steal syndrome," so caution must be exercised to ensure cardiac filling pressures are maintained. Consequently, these procedures should be performed only with intensive monitoring. If gangrene has set in, it is best left alone if there is no infection. Spontaneous separation of the tips of the digits will occur and carries less risk and morbidity than surgical amputation.

GI Complications. Abnormal esophageal motility with reflux may result in esophagitis. The major symptom of this condition is retrosternal pain that is made worse by certain foods and recumbent positioning. The pain may be severe and incapacitating, and the risk of aspiration is increased. Although children with the complaint of retrosternal pain do not require admission to the hospital, they need an evaluation of their lower esophageal sphincter with esophageal manometry. Those with mild pain and objective manifestations of reflux (lower esophageal sphincter pressure of less than 10 mm Hg, evidence of esophagitis on endoscopy) are usually treated with simple measures, such as antacids 1 hour after meals and 1 hour before bedtime and elevation of the head during sleep. If symptoms are severe, H_2-blockers such as cimetidine (20 to 40 mg per kg per day, maximum daily dosage 1,200 mg) or protein pump inhibitors such as lansoprazole (15 to 30 mg once or twice daily) may be prescribed. Any patient with scleroderma who develops acute respiratory symptoms in association with reflux must be evaluated for possible aspiration pneumonia.

VASCULITIS

Although the pathologic process in vasculitis is limited to the blood vessels, the presence of vasculature in every organ of the body means that virtually any symptom could be a presentation of vasculitis. Vascular inflammation and damage can lead to anything from numbness to pain, thrombosis to bleeding, aneurysm formation to vascular obstruction. Pediatric vasculitides are very rare, however, so this section will be limited to a general overview of situations in which the diagnosis should be considered, followed by discussions of the two most prevalent chronic vasculitides found in children, polyarteritis nodosa (PAN), and KD.

Diagnosis

Early in the course of a vasculitis, findings are generally nonspecific, primarily reflecting systemic inflammation (fever, malaise, fatigue, failure to thrive, elevated acute-phase reactants). As vascular damage progresses, evidence of vascular compromise characteristic of the particular vessels involved becomes evident on physical examination. Although these findings are often consistent with vasculitis, they are seldom part of a routine screening evaluation, so a physician must consider the diagnosis of vasculitis before its manifestations are pathognomonic. Should the diagnosis be delayed beyond this stage, irreversible tissue damage may occur; it is important that therapy be initiated while the findings remain subtle.

Despite the extreme variability of the manifestations of vasculitis, certain specific symptoms are particularly suggestive of vascular inflammation. Involvement of large- or medium-sized muscular arteries, as may be seen in Takayasu arteritis (TA) or PAN, initially causes symptoms related to the severity of the inflammatory response. As vascular compromise progresses, symptoms of arterial insufficiency begin to dominate. Involvement of large vessels to the extremities, such as the subclavian or femoral arteries, typically leads to claudication, whereas involvement of visceral vessels causes hypertension (renal arteries), abdominal pain (mesenteric and celiac axes), chest pain (aortic or coronary artery involvement), or neurologic symptoms (focal neurologic deficits or neuropathic pain).

Inflammation of smaller arteries and arterioles leads to symptoms in richly vascularized organs. Skin involvement—livedo reticularis, purpuric (generally palpable) or nonblanching lesions, and palmar or plantar rashes—is most suggestive of vascular inflammation. Pulmonary, renal, and GI arterial beds are often involved as well. Consequently, hemoptysis, hematuria, hypertension, abdominal pain, or melena may signify vascular involvement. Capillary and venous inflammation typically involves the same organs, although the lower volume of blood flow through these vessels tends to make capillaritis and venulitis less of an acute emergency than arteritis.

Whenever vasculitis is considered as a diagnosis, a thorough history and careful general physical examination should be augmented by focus on clinical features of vascular disease. History should include recent illnesses, in particular infections, other exposures (including prescription and over-the-counter drugs), travel, and family history. All pulses must be palpated carefully, and bilateral Allen tests should be performed to

confirm patency of the radial and ulnar arteries and volar arch. The neck, abdomen, and proximal extremities should be auscultated for bruits, and blood pressures in all four extremities should be compared for asymmetry. The skin should be examined carefully for lesions that are nodular or do not blanch, and the two other windows on small vessel abnormalities—ocular fundi and nailbed capillaries—should be assessed as well.

Laboratory studies specific for the diagnosis of vasculitis are not yet available. When vasculitis is being considered, laboratory investigation should include a CBC count and acute-phase reactants (especially ESR and CRP) for evidence of systemic inflammation. Ongoing immune activation leads to hypergammaglobulinemia in many cases of systemic vasculitis. Certain small-vessel diseases (especially Wegener granulomatosis and Churg-Strauss syndrome) are characterized by antinuclear cytoplasm antibodies (ANCA). von Willebrand factor antigen is released by damaged vascular endothelium, so it is elevated in small-vessel vasculitides but also in other conditions that cause vessel damage, including stroke, trauma, and severe infections.

Imaging procedures should be used to confirm a clinical suspicion of vasculitis, not to hunt blindly for a diagnosis. When pulmonary involvement is suspected, pulmonary function tests and imaging of the lungs with radiographs or CT are often useful. Vascular imaging must be selected on a case-by-case basis, based on clinical and laboratory data. Doppler ultrasound studies and CT or MRI angiograms are adequate for resolving abnormalities in large- or medium-sized vessels, but conditions involving smaller vessels often can be visualized only by use of conventional angiography. Even in the hands of interventional radiologists experienced in pediatric procedures, these procedures are potentially morbid, so careful attention to history and physical examination should be relied upon to minimize the number of unnecessary studies.

The reference standard for diagnosing vasculitis remains histopathologic demonstration of vascular inflammation, although tissue specimens may not be available in many cases because of the inaccessibility of lesions or patchiness of the vascular involvement. When skin lesions are present, deciding to obtain a biopsy is relatively easy; when inaccessible structures such as the brain are involved, calculating the risks and benefits of a biopsy is significantly more complicated.

POLYARTERITIS NODOSA

Background

The annual incidence of PAN in adults is approximately 0.3 per 100,000; no comparable data are available for children. Prior to the introduction of corticosteroids for the treatment of PAN, mortality rates as high as 100% were reported; today, less than one in five cases is believed to have a fatal outcome.

Pathophysiology

PAN is characterized by focal, panmural, necrotizing inflammation of small- and medium-sized muscular arteries. As the name implies, vessels affected by PAN typically develop nodules in the walls of muscular arteries. Sites of bifurcation are particularly prone to involvement, presumably because of hemodynamic turbulence at these points. Biopsies reveal a cellular infiltrate initially predominated by polymorphonuclear leukocytes and fibrinoid necrosis. As lesions mature, mononuclear cells, thrombosis, and recanalization mark the healing process.

The etiology of PAN is unknown, although it is considered to be an archetype of immune complex–mediated vascular damage. Most children with PAN have serologic evidence of an antecedent streptococcal infection; up to one-third of adults have chronic hepatitis B or C, with viral proteins demonstrable in the circulating and fixed immune complexes. The incidence of hepatitis-associated PAN in children is significantly lower, particularly in Western countries.

Clinical Manifestations

Childhood PAN occurs in both cutaneous and generalized forms, and distinguishing between them may be difficult. Both types display systemic manifestations, including fever, malaise, and myalgias. However, generalized PAN is significantly more likely to also involve the renal, GI, and central nervous systems. Common to both are rashes, although these are more likely to be nodular or lacy (so-called livedo reticularis) in the cutaneous form, and urticarial, petechial, or ischemic in the systemic form. Renal involvement (including proteinuria, abnormal urinary sediment, and hypertension), abdominal pain (often a manifestation of gut vasculitis), arthritis, mononeuritis multiplex, and CNS involvement (seizures, hemiparesis) typify generalized PAN. Less commonly, children may have cardiac disease (pericarditis, cardiomegaly, EKG changes, myocardial infarction) or pulmonary involvement (diffuse infiltrates, pulmonary hemorrhage, or hemothorax). A rare subtype of PAN, Cogan syndrome, is characterized by interstitial keratitis and sensorineural hearing loss.

Laboratory Studies

Laboratory findings in polyarteritis are nonspecific. Most children have white blood cell counts higher than 15,000 per mm^3, hemoglobin less than 10 g per dL, broadly elevated acute-phase reactants, and hypergammaglobulinemia. Complement levels are usually normal or increased, and ANA and RF levels are elevated only slightly, if at all. Some children have evidence of ANCAs, although other autoantibodies are usually absent.

Diagnosis of PAN generally requires tissue confirmation. Acute necrotizing inflammation of small- and medium-sized arteries is demonstrable in renal, cutaneous, muscular, or GI tissues. At times, biopsy may not be practical, and angiographic visualization of aneurysms may provide an acceptable alternative. Other findings include visceral perfusion defects, especially in the kidneys, development of collateral arteries, and a "beaded" appearance of involved vessels as a result of alternating areas of constriction and dilatation. Performance and interpretation of these studies requires the expertise of a radiologist experienced in pediatric angiography.

Management

Prognosis in PAN is better in patients with less disease-related organ damage, so therapy should be initiated as early as possible. Absence of tissue confirmation need not delay therapy, but in most cases, empiric therapy for a presumed diagnosis of PAN should be avoided; most therapies for severe systemic vasculitis have unacceptably severe toxicities to use in unconfirmed cases. Thus, clinicians must balance a high level of suspicion and willingness to employ invasive diagnostic procedures when indicated, against a recognition that vasculitis in children is very rare.

The initial management of PAN should include corticosteroids (generally divided doses of prednisone, 2 mg per kg per day, to a maximum of 60 mg daily). Rash and constitutional symptoms improve first, followed by control of end-organ involvement. Pulse doses of methylprednisolone (30 mg per kg in 50 mL of 5% dextrose in water by IV infusion over 1 to 2 hours, maximum dose 1,500 mg) may offer an alternative for the treatment of acute exacerbations, provided that blood pressure and cardiac rhythm are closely monitored.

Cutaneous PAN may require lower doses of steroids to suppress disease activity, or alternative agents such as methotrexate, dapsone, or colchicine may adequately control the rash. Use of intravenous immunoglobin (IVIG) has also been reported in cutaneous PAN. In contrast, children with systemic PAN may not tolerate a reduction in their steroid dosage or may not respond adequately to steroids. In such cases, addition of immunosuppressive agents (e.g., oral or IV cyclophosphamide) or biologic response modifiers (e.g., infliximab 5–10 mg per kg monthly) may improve the outcome or allow tapering of steroids without a disease flare. Other pharmacologic agents, including NSAIDs for fever and arthritis, anticonvulsants, antihypertensives, and physical therapy, should be employed when appropriate.

Management of Complications and Emergencies (Table 101.12)

The most serious emergencies in childhood polyarteritis are (i) renal insufficiency; (ii) severe hypertension; (iii) cardiac complications such as CHF, myocardial infarction, and dysrhythmias; (iv) GI vasculitis resulting in bowel infarction, intestinal perforation, or cholecystitis; and (v) CNS manifestations, such as seizures and cranial nerve palsies.

Renal Emergencies. Although medical management of PAN has resulted in a significantly improved prognosis, azotemia and hypertension at the time of diagnosis continue to identify children with extremely aggressive disease. Arteritis of medium-sized vessels of the kidney may lead to renal infarction and ischemia or to glomerulonephritis manifested by hematuria, hypertension, and uremia. Sudden flank pain associated with gross hematuria, falling blood pressure, and an expanding abdominal mass suggest the possibility of aneurysmal dilatation and rupture, with renal artery hemorrhage.

Serial urinalyses, measurements of BUN and creatinine levels, and determination of creatinine clearance are essential components of the investigation of all patients with PAN. Management of renal failure includes correction of fluid and electrolyte abnormalities, as well as high doses of corticosteroids to control the underlying disease process (e.g., prednisone 2 mg per kg per day). Rupture of a renal artery aneurysm is initially managed with treatment of shock and replacement of volume, followed by surgical repair of the aneurysm once the patient is stabilized.

Hypertension. A mild to moderate elevation of blood pressure is noted in more than 90% of children with generalized PAN. Management follows the general rules for treating renovascular hypertension (Chapter 34). Severe hypertension associated with encephalopathy or CHF requires inpatient management.

Cardiac Emergencies. *Pericarditis* may be asymptomatic. Alternatively, chest pain (particularly in the recumbent position), shortness of breath, pericardial friction rub, and pulsus paradoxus may be present. EKG may reveal depression of the ST segment and T-wave inversion, and chest x-ray may demonstrate globular enlargement of the cardiac silhouette. Echocardiographic demonstration of pericardial fluid, however, is the most sensitive means of confirming the presence of pericarditis.

Chest pain with tachycardia, arrhythmia, and dyspnea may herald the occurrence of *myocardial infarction* in a patient with PAN involving the coronary arteries. Pericardial tamponade caused by a ruptured coronary aneurysm may present similarly. Occasionally, a patient with coronary artery disease may present with CHF. Characteristic EKG changes (deep Q waves) and areas of ischemia on myocardial nuclear scanning may be seen. Echocardiography is indicated to study the function of the myocardium and the status of the valves. Coronary arteriography is essential to establish the size, location, and extent of aneurysms and occlusions.

Patients with CHF, myocardial ischemia, and arrhythmias will require continuous monitoring and urgent management in an intensive care setting. Patients with pericarditis without effusion may be treated with bed rest, careful monitoring, and corticosteroids. Pericardiocentesis is indicated in the presence of tamponade or if infection is suspected. Patients with myocardial infarction need careful monitoring, pain relief (morphine), treatment of shock, antiarrhythmic agents, and treatment of CHF (Chapter 84). A radiograph of the chest, EKG, and echocardiogram should be obtained as soon as possible; thallium scan and coronary angiography may be indicated in certain patients.

Supportive medical management includes careful monitoring of cardiorespiratory status, judicious use of IV fluids, diuretics, and cardiotonics when needed. Treatment of the primary disease with steroids and immunosuppressive agents should be continued as described. If hypertension does not respond to diuretic therapy, other antihypertensive agents may have to be added. Serum electrolytes should be monitored because most patients will be taking high doses of steroids, diuretics, and antihypertensive agents, and electrolyte imbalances increase the risk of toxicity.

GI Complications. Abdominal pain is the most common manifestation of GI involvement in PAN. It may be diffuse and nonspecific or localized and severe. Hematemesis and melena suggest ulceration and hemorrhage. Patients with persistent

TABLE 101.12

COMPLICATIONS OF POLYARTERITIS NODOSA

Clinical entity	Symptoms and signs	Investigations	Treatment
Renal failure	Usually insidious; no symptoms until uremia sets in	Urinalysis (serial); BUN; creatinine; creatinine clearance; serum electrolytes	Fluid, electrolyte management Treatment of hypertension Peritoneal dialysis Hemodialysis
Renal infarction	Flank pain High blood pressure	Urinalysis; BUN; creatinine Renal arteriogram	Management of renal failure as given above, hemodialysis
Renal artery aneurysm with hemorrhage	Severe, sudden flank pain; gross hematuria; shock; palpable abdominal mass	Serial hematocrit Renal arteriogram	Management of shock Surgical consult
Hypertension	Asymptomatic or headache; retinal changes; encephalopathy	Serial measurement of BP; BUN; creatinine, creatinine clearance; IVP (or) renal arteriogram	Diuretics Antihypertensive agents
Pericarditis	Chest pain; pericardial rub; pulsus paradoxus (if tamponade)	EKG; radiograph chest; echocardiogram; removal of fluid for analysis	Rest, steroids, removal of fluid (if tamponade) *Caution:* if tamponade is sudden, it may be caused by ruptured aneurysm with blood in pericardium
Myocardial infarction	Sudden chest pain; shock; arrhythmia; dyspnea; congestive failure	EKG (continuous monitor); echocardiogram; thallium scan; coronary arteriography	Pain relief; oxygen Circulatory support Heparin, thrombolytic agents
Gastrointestinal hemorrhage	Abdominal pain; vomiting; melena, hematemesis, or hematochezia; shock; tenderness and guarding of abdomen; bowel sounds absent	Plain radiograph abdomen Peritoneal aspiration Endoscopy Celiac arteriogram	Treat shock; block bleeding vessel during angiography; surgical ligation
Gastrointestinal perforation	Sudden abdominal pain; shock; guarding, tenderness, and rigidity of abdomen; absent bowel sounds	Plain radiograph abdomen (upright)	Treat shock Surgical repair
Aneurysm with rupture (intraabdominal)	Abdominal pain (chronic) with acute exacerbation Palpable mass Sudden onset of shock	Ultrasound Celiac arteriogram	Treat shock Surgical repair
Central nervous system lesions	Convulsions; gradual onset of loss of consciousness; hemiparesis	Exclude hypertensive encephalopathy CT scan, MRI Carotid arteriography	Supportive care Control BP Anticonvulsants High-dose corticosteroids and/or immunosuppressives

BUN, blood urea nitrogen; BP, blood pressure; IVP, intravenous pyelogram; EKG, electrocardiogram; CT, computed tomography; MRI, magnetic resonance imaging.

abdominal pain, hematemesis, and melena require immediate admission.

Visceral perforation should be suspected in cases of active systemic disease and unrelenting abdominal pain. Tenderness on palpation of the abdomen, guarding of the abdominal wall, and absent bowel sounds are the usual physical findings, although they may be masked by steroid therapy. Arteritis involving specific organs may lead to cholecystitis, pancreatitis, appendicitis, or hepatitis. These complications are generally manifested by vomiting and localized abdominal pain and tenderness.

Mesenteric thrombosis with infarction of the bowel may present with sudden abdominal pain, vomiting, hematemesis or hematochezia, and shock. Exquisite tenderness of the abdomen and absent bowel sounds are the major findings. Hemorrhage from a ruptured aneurysm (mesenteric, hepatic, or renal) with hemoperitoneum is heralded by sudden onset of severe pain, vomiting, tachycardia, and shock. The abdomen is tender and tense, and bowel sounds are diminished or absent.

Initial management of each of these GI catastrophes includes volume replacement, gastric decompression, and stress doses of corticosteroids. All such patients will require measurement of

intake and output, as well as serial determination of hematocrit, BUN, and electrolytes. Abdominal x-rays (supine and upright), abdominal ultrasound, technetium scan, angiography of the celiac axis vessels, and peritoneal aspiration may be indicated in some cases. In selected instances, direct examination of the GI tract by endoscopy may yield valuable information concerning the nature, location, and extent of lesions. Surgical consultation should be obtained immediately, and in the presence of bleeding aneurysms or infarcted bowel, exploratory laparoscopy or laparotomy should be performed as soon as the patient can be stabilized.

CNS Complications. Clinical signs of CNS disease are less frequent than those of peripheral nervous system involvement. Seizures and hemiparesis are the most common manifestations of CNS involvement in PAN and require immediate hospitalization. A complete neurologic evaluation should be performed, including measurement of blood pressure, and fundoscopic examination for evidence of hypertension or intracranial bleeding. CT and/or carotid angiography may help localize the lesion.

Management of hypertensive encephalopathy and increased intracranial pressure are described elsewhere (see Chapters 34 and 96). Surgical correction of a ruptured aneurysm should be undertaken if the bleeding vessel can be localized and is accessible.

Miscellaneous Complications. As with all vasculitides, PAN may involve testicular vessels, leading to acute scrotal pain and purpura and accompanying dysuria. Once other causes of scrotal pain are excluded, including epididymitis and testicular torsion, treatment may proceed with steroids and immunosuppressive medications.

BEHÇET DISEASE

Behçet disease (BD) is a vasculitis that is rare in children, especially in nonendemic areas such as the United States. First described by the Turkish dermatologist Hulusi Behçet in 1937, the classical description of BD is a clinical triad consisting of recurrent buccal aphthous ulcers, recurrent genital ulcers, and uveitis with hypopion. In addition to these cardinal features of BD, there are a host of associated clinical manifestations, including arthritis, neurologic involvement, GI manifestations, vascular/thrombotic disease, and various dermatologic lesions including erythema nodosum and necrotic folliculitis. Thus, BD may resemble a large number of other conditions, and should be included in the differential diagnosis of various complaints evaluated in EDs.

Since Dr. Behçet's original description, there have been various revisions of the clinical criteria. The diagnostic criteria formulated by the International Study Group for Behçet Disease in 1990 have become fairly standard. This diagnostic schema requires recurrent oral ulceration observed by a physician at least three times in 12 months, plus two of the following four clinical manifestations: recurrent genital ulceration, ocular disease, skin lesions, and positive pathergy test. A pathergy test is considered positive if the patient develops an erythematous nodule or pustule greater than 2 mm in diameter 24 to 48 hours after the skin of the forearm is pricked with a sterile needle.

Because of the rarity of BD in children, most published clinical series are small. Overall, the clinical manifestations in children are similar to those in adult BD. Recurrent oral ulcerations are the most common presenting sign and ongoing manifestation of pediatric BD. Ulcerative mucocutaneous lesions are far from specific for BD; however, unlike those associated with inflammatory bowel disease, SLE, chronic oral aphthosis, and Sweet syndrome, oral lesions in BD tend to scar. In the United States, many children have so-called "incomplete Behçet disease," meeting only partial diagnostic criteria, but remaining at risk for complications of the disease.

Although oral and genital ulcers can certainly be painful for the patient and problematic from a management standpoint, there are other less common but more serious complications of BD that may lead to severe morbidity and even mortality. Ocular disease can be devastating, ultimately resulting in blindness. GI disease can result in perforation. Neurologic complications are varied, including headache, meningoencephalitis, pseudotumor cerebri, and quadriparesis. Psychiatric symptoms including depression, personality changes, and memory loss are also reported. Vascular/thrombotic complications are a particularly ominous development in BD patients; these can include dural sinus thrombosis and arterial lesions. In one multinational pediatric BD series, large vessel thrombosis was the leading cause of death, carrying a 30% mortality rate.

The general treatment of BD is similar to other forms of vasculitis discussed in this chapter, consisting of antiinflammatory/immunosuppressive agents. Topical corticosteroid preparations may be helpful for oral and genital lesions; steroid drops may be necessary for ocular disease. Colchicine can be an effective systemic agent for relatively mild mucocutaneous symptoms and can be helpful in preventing episodes of uveitis. Dapsone is also used for mucocutaneous disease. Thalidomide is particularly effective for oral and genital ulcers, although it must be used with extreme caution, given the potential for teratogenicity and neurologic disturbances. Cyclosporin A is often used for BD uveitis. Emerging data suggest that anti-TNF agents are often very effective for treating severe manifestations of BD.

Life-threatening cases of BD may require high-dose systemic corticosteroids and cyclophosphamide. Thrombotic disease requires formal anticoagulation, in addition to aggressive immunosuppressive therapies.

KAWASAKI DISEASE

Background

Mucocutaneous lymph node syndrome was first described by a Japanese pediatrician in 1967, and it is now known as KD in his honor. In fact, the condition certainly predates this description: A preserved heart from the 19th century shows pathologic changes characteristic of KD, and the entity of "infantile polyarteritis" probably represents the same syndrome. KD is an idiopathic vasculitis of small- and medium-sized vessels, which has surpassed acute rheumatic fever to become the leading cause of acquired heart disease in children in the developed world. Incidence estimates in the continental United States range from 9 to 19 per 100,000 children; the incidence in Asia may be up to

ten times as high. KD is 50% more common in boys than in girls, and it usually affects children younger than 5 years. However, pediatricians must remain vigilant in all age groups because the disease may be more difficult to diagnose, but more likely to cause chronic sequelae in infants and adolescents.

Characteristically, children with KD have fever, conjunctivitis, rash, mucosal inflammation, lymphadenopathy, and extremity changes. The major morbidity of KD, however, occurs in the heart. Coronary artery aneurysms or ectasia develop in approximately 15% to 25% of untreated children and may lead to myocardial infarction, sudden death, or chronic coronary artery insufficiency. IVIG decreases the incidence of coronary artery aneurysms by three- to fivefold if given within 10 days of disease onset. Management of children with suspected KD, therefore, requires accurate and expeditious diagnosis and close monitoring of the cardiovascular system.

Pathophysiology

In KD as in other vasculitides, blood vessel damage appears to result from an aberrant immune response leading to endothelial cell injury and vessel wall damage. A direct cell-mediated attack on endothelial cells, either because they are infected with an as-yet unidentified infectious agent, or simply as innocent bystanders, may underlie the vascular injury. Humoral factors, such as antiendothelial cell antibodies or circulating immune complexes, may also play a role. The reason that KD preferentially involves coronary arteries is unknown.

The pathologic changes of coronary arteries in KD have been classified by Fujiwara and Hamashima into four stages, depending on the duration of illness at the time of examination (Table 101.13). Initially, endothelial swelling is accompanied by a neutrophilic infiltrate. Lymphocytes and plasma cells replace polymorphonuclear cells by the subacute stage (beginning 2 weeks after onset), accompanied by destruction of the internal elastic lamina; coronary artery aneurysms characteristic of KD first become apparent at this time. Finally, during the convalescent state of KD, healing of the vascular lesions occurs with fibromuscular proliferation and scar formation, along with expansion of aneurysms due to hemodynamic forces.

Many lines of evidence point toward a role of infections in the causation of KD. The fact that the disease often occurs in epidemics, that boys are more susceptible than girls, and that household contacts of children with KD are at increased risk for developing the disease in Japan, all point to a transmissible agent. Nonetheless, although many putative etiologies have been proposed during the past four decades, suggestions that certain viruses (EBV, human coronavirus, parvovirus, HIV-2) or bacterial toxins (streptococcal erythrogenic toxin, staphylococcal toxic shock toxin) account for the majority of cases have not been substantiated. Many researchers now believe that KD represents a final common pathway of immune-mediated vascular inflammation in genetically susceptible children triggered by any one of a variety of common infections.

TABLE 101.13

PATHOLOGY OF KAWASAKI DISEASE[a]

Stage I—Disease duration <10 days
Acute perivasculitis of coronary arteries
Microvascular angiitis of coronary arteries and aorta
Pancarditis with pericardial, myocardial, endocardial inflammation
Inflammation of the atrioventricular conduction system

Stage II—Disease duration 12–28 days
Acute panvasculitis of coronary arteries
Coronary artery aneurysms present
Coronary obstruction and thrombosis
Myocardial and endocardial inflammation less intense

Stage III—Disease duration 28–45 days
Subacute inflammation in coronary arteries
Coronary artery aneurysms present
Myocardial, endocardial inflammation much decreased

Stage IV—Disease duration >50 days
Scar formation, calcification in coronary arteries
Stenosis and recanalization of coronary vessel lumen
Myocardial fibrosis without acute inflammation

IVIG, intravenous immunoglobin.
[a]Duration of each stage may be decreased by prompt treatment with IVIG.

Clinical Manifestations

KD is a clinical syndrome diagnosed on the basis of fever and four of five signs of mucocutaneous inflammation (Table 101.14). These criteria were established by Tomisaku Kawasaki in 1967, and they remain the sine qua non for diagnosing KD. Nonetheless, as with all clinical guidelines, these should be regarded as imperfect, with less than 100% sensitivity and specificity. Children who do not meet criteria may indeed have KD, whereas some children with other conditions may nonetheless manifest five or six criteria of KD. Acknowledgement of this fact was made explicit in 2004 when an expert panel published revised criteria for diagnosing and treating children suspected to have KD.

TABLE 101.14

DIAGNOSTIC CRITERIA FOR KAWASAKI DISEASE

Fever ≥5 days unresponsive to antibiotics
If the fever disappears because of intravenous gamma-globulin therapy before the fifth day of illness, a fever of <5 days' duration fulfills fever criterion for case definition.
At least four of the five following physical findings with no other more reasonable explanation for the observed clinical findings:
1. Bilateral conjunctival injection
2. Changes in the oropharyngeal mucous membranes (erythematous and/or fissured lips, strawberry tongue, injected pharynx)
3. Changes of peripheral extremities, including erythema and/or edema of the hands or feet (acute phase) or periungual desquamation (convalescent phase) (Fig. 101.12)
4. Polymorphous rash, primarily truncal; nonvesicular
5. Cervical lymphadenopathy ≥1.5-cm diameter

Fever is probably the most consistent manifestation of KD. It reflects the elevated levels of proinflammatory cytokines (e.g., TNF, IL-1), which are also believed to mediate the underlying vascular inflammation. A diagnosis of KD should be considered in all children with prolonged, unexplained fever, irritability, and laboratory signs of inflammation, especially in the presence of mucocutaneous inflammation. Conversely, the diagnosis must be suspect in the absence of fever.

The remaining cardinal manifestations of KD vary considerably in frequency. Up to one-half of children with KD do not have cervical lymphadenopathy, especially children younger than 2 years of age. When present, lymphadenopathy tends to involve the anterior cervical nodes overlying the sternocleidomastoid muscle. Diffuse lymphadenopathy, as well as other signs of reticuloendothelial involvement such as splenomegaly, should prompt a search for an alternative diagnosis.

Bilateral, nonexudative conjunctivitis is present in more than 90% of patients. A predominantly bulbar injection typically begins within days of the onset of fever, and eyes eventually develop a brilliant erythema, which spares the limbus. Children are also frequently photophobic, and five out of six patients have evidence of anterior uveitis during the first week of illness. Consequently, in ambiguous cases, slit-lamp examination may be helpful in confirming a diagnosis of KD.

Cracked, red lips and a strawberry tongue are characteristic of the mucositis typically seen during the first week of KD (Fig. 101.11). Discrete oral lesions, such as vesicles or ulcers, and tonsillar exudate, are suggestive of a viral or bacterial infection rather than KD. The cutaneous manifestations of KD are polymorphous. The rash typically begins as perineal erythema and desquamation, followed by macular, morbilliform, or targetoid lesions of the trunk and extremities. Vesicular or bullous lesions are rare. Changes in the extremities are generally the last clinical manifestation of KD to develop. Children demonstrate an indurated edema of the dorsum of their hands and feet, and a diffuse erythema of their palms and soles (Fig. 101.12). During the convalescent phase of KD, sheetlike desquamation that begins in the periungual region of the hands and feet is characteristic (Fig. 101.13, see also color plate). Linear nail creases known as Beau lines are also common late manifestations of KD.

As a systemic vasculitis, KD may cause a variety of other clinical manifestations. Pulmonary involvement may lead to symptoms such as cough and infiltrates, peribronchial cuffing, and pleural effusions on chest radiographs. GI signs may range from emesis and diarrhea to findings suggestive of an acute surgical abdomen. Neurologic involvement including seizures, facial nerve palsies, ataxia, hemiplegia, and severe encephalopathy is also reported. In general, as with other vasculitides, manifestations of KD may be protean, so clinicans should not exclude the possibility solely on the basis of atypical features.

FIGURE 101.12 Brawny edema of dorsum of hand and small joint polyarthritis in Kawasaki disease.

FIGURE 101.13 Periungual desquamation during the convalescent phase of Kawasaki disease.

TABLE 101.15

DIFFERENTIAL DIAGNOSIS OF KAWASAKI DISEASE

	Kawasaki disease	Toxic shock syndrome	Streptococcal scarlet fever	Stevens-Johnson syndrome	Systemic juvenile rheumatoid arthritis
Age	<5 yr	>10 yr	2–8 yr	All ages	2–5 yr
Fever	≤12 days	<10 days	Variable	Prolonged	Prolonged
Eyes	Nonexudative conjunctivitis, limbal sparing, anterior uveitis	Conjunctivitis	Normal	Exudative conjunctivitis, keratitis	Normal
Oral mucosa	Erythema, "strawberry tongue"	Erythema	Pharyngitis, "strawberry tongue," circumoral pallor	Erythema, ulcerations, pseudomembrane formation	Normal
Extremities	Erythema of palms and soles, indurative edema, periungual desquamation	Peripheral edema	Fine flaking desquamation	Normal	Arthritis
Rash	Polymorphous; targetoid or purpuric in 20%	Erythroderma	Erythroderma, Pastia's lines	Target lesions	Transient, salmon pink
Lymph nodes	Single anterior lymph node	Normal	Painful, diffuse cervical nodes	Normal	Diffuse
Other	Arthritis	Shock, coagulopathy, mental status changes	Positive throat culture	Arthralgia, associated herpes virus infection (30%–50%)	Pericarditis

KD is most commonly confused with exanthematous infections of childhood (Table 101.15). Measles, echovirus, and adenovirus may share many of the signs of mucocutaneous inflammation, but they typically have less evidence of systemic inflammation, and generally lack the extremity changes seen in KD. Toxin-mediated illnesses, especially β-hemolytic streptococcal infection and toxic shock syndrome, generally lack the ocular and articular involvement typical of KD. Finally, drug reactions such as Stevens-Johnson syndrome or serum sickness may mimic KD but with subtle differences in the ocular and mucosal manifestations.

The conventional diagnostic criteria are particularly useful in preventing overdiagnosis, but they may result in failure to recognize incomplete forms of the illness. It should be emphasized that children who do not fulfill formal diagnostic criteria are still at risk of cardiac complications. Depending on the series, between 10% and 60% of children who develop coronary aneurysms never meet clinical criteria for KD. The guidelines of the American Heart Association Council on Cardiovascular Disease in the Young provide a useful framework for managing children with suspected KD who do not meet criteria for the diagnosis (see Fig. 101.14 and also section on Incomplete KD below).

Clinical manifestations of KD tend to be most incomplete and atypical in the youngest patients, the subgroup at highest risk for development of coronary artery abnormalities. Infants younger than 6 months are at particularly high risk. Thus, KD should be considered in any infant with prolonged, unexplained fever. In contrast, alternative explanations for the child's symptoms must be carefully excluded before treating empirically with IVIG. Consideration should be given to referring children to a regional KD center for further evaluation when the diagnosis is unclear.

At the other end of the spectrum, older children and adolescents with KD appear to be at increased risk for developing coronary aneurysms; however, older age at presentation is also associated with delayed diagnosis, which is known to incur significant risk. Unlike infants, in whom the clinical findings of KD are often incomplete, older children appear to present with fairly typical manifestations. Diagnosis may be delayed because clinicians are less likely to consider the diagnosis in older patients because most cases involve young children. Further, children older than 8 years of age frequently exhibit GI and meningeal symptoms, potentially clouding the diagnostic picture. In any event, whether KD is indeed more aggressive in older children, or simply because diagnosis is more likely to be delayed, pediatricians must consider KD as a possible cause of prolonged fever in children of any age.

Laboratory Studies

No laboratory studies are included among the diagnostic criteria for KD, but certain findings may support the diagnosis. Most characteristic is systemic inflammation, with widespread

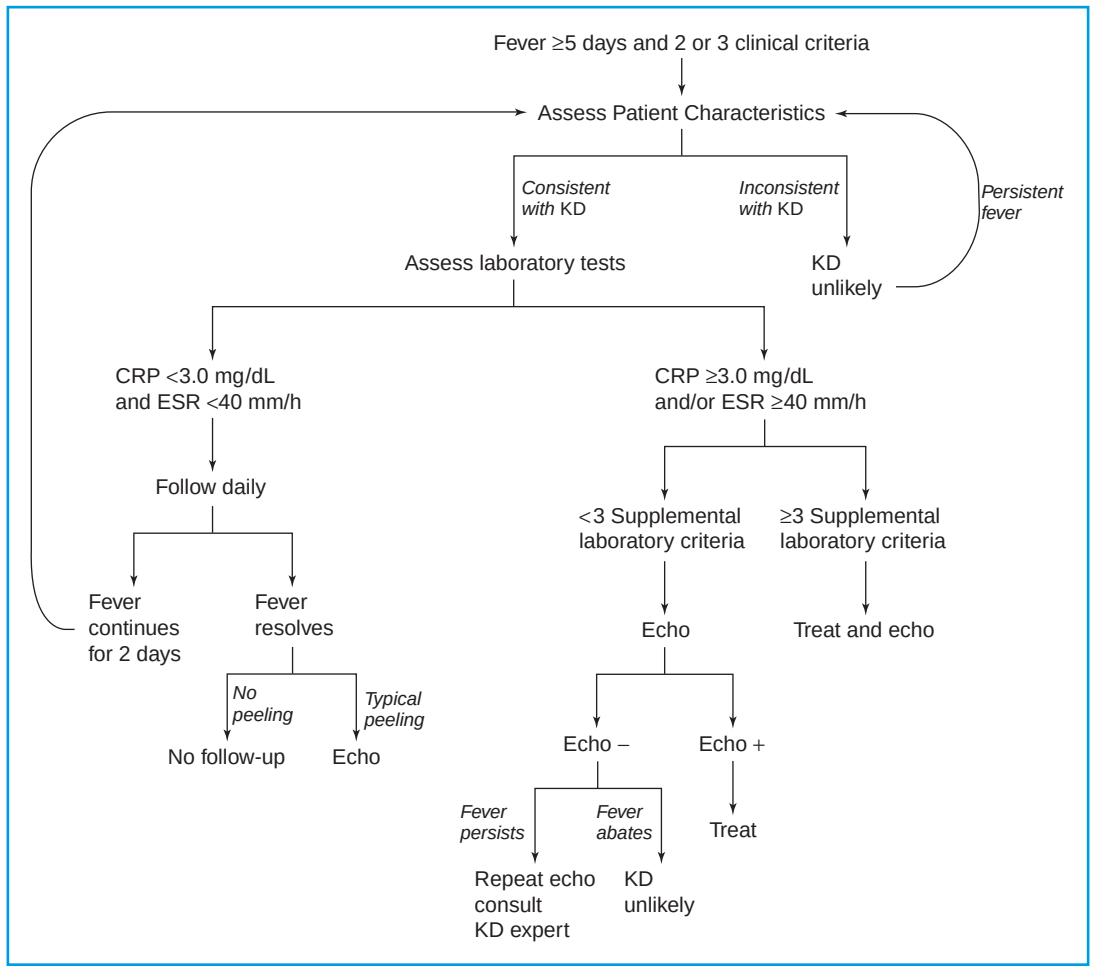

FIGURE 101.14 Evaluation of suspected incomplete Kawasaki Disease (KD). (From Newburger JW, Takahashi M, Gerber M, et al. diagnosis, treatment, and long-term management of Kawasaki disease: a statement for health professionals from the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease, Council on Cardiovascular Disease in the Young, American Heart Association. *Pediatrics* 2004;114:1708–1733.)

elevation of acute-phase reactants (including CRP and ESR), leukocytosis, and a left shift in the white blood cell count. By the second week of illness, platelet counts also rise, reaching 1,000,000 per mm^3 in the most severe cases.

Children with KD often present with a normocytic, normochromic anemia; hemoglobin concentrations more than two standard deviations below the mean for age are noted in approximately one-half of patients within the first 2 weeks of illness. Urinalysis commonly reveals white blood cells on microscopic examination; the cells are mononuclear, and so are not detected by dipstick tests for leukocyte esterase. They also originate in the urethra, so they will be missed on urinalyses obtained by bladder tap or catheterization. Measurement of liver enzymes often reveals elevated transaminase levels or mild hyperbilirubinemia due to intrahepatic congestion. In addition, a minority of children may develop obstructive jaundice from hydrops of the gallbladder. If sampled, other body fluids demonstrate inflammation as well: CSF typically displays a mononuclear pleocytosis (less than 100 cells per mm^3) with normal glucose and protein concentrations, whereas arthrocentesis of involved joints demonstrates 50,000 to 300,000 white blood cells per mm^3, primarily neutrophils.

Assessment of Incomplete KD

The limitations of the classical criteria for KD have long posed challenges for clinicians, particularly in those cases of "incomplete" or "atypical" KD. In 2004, the American Heart Association (AHA) put forth an algorithm suggesting an approach for evaluation of possible incomplete KD (Fig. 101.14). Unlike the classical criteria, this algorithm takes into account laboratory studies and findings on echocardiogram.

Prolonged fever is still the cardinal manifestation of KD under the AHA algorithm. Children with 5 or more days of fever and 2 or 3 clinical criteria in whom KD is being considered should be evaluated further for incomplete KD. This starts with a full assessment for possible characteristics suggesting KD, including those outlined in Table 101.16. Characteristics suggestive of an alternative diagnosis are considered as well,

TABLE 101.16

CLINICAL FINDINGS CONSISTENT WITH KAWASAKI DISEASE

Cardiovascular findings
Congestive heart failure, myocarditis, pericarditis, valvular regurgitation
Coronary artery abnormalities
Aneurysms of medium-size noncoronary arteries
Raynaud phenomenon
Peripheral gangrene
Musculoskeletal system
Arthritis, arthralgia
Gastrointestinal tract
Diarrhea, vomiting, abdominal pain
Hepatic dysfunction
Hydrops of gallbladder
Central nervous system
Extreme irritability
Lethargy
Aseptic meningitis
Sensorineural hearing loss
Genitourinary system
Urethritis/meatitis
Other findings
Erythema, induration at Bacille Calmette-Guerin (BCG) site
Anterior uveitis (mild)
Desquamating rash in groin

TABLE 101.17

ECHOCARDIOGRAPHIC CRITERIA SUGGESTIVE OF KAWASAKI DISEASE

Echocardiogram considered positive if any of the three criteria are met
I. z score of LAD or RCA of ≥2.5
II. Coronary arteries meet Japanese Ministry of Health criteria for aneurysms
III. If three or more suggestive features are present
Perivascular brightness
Lack of tapering
Decreased LV function
Mitral regurgitation
Pericardial effusion
z scores in LAD or RCA of 2–2.5

LAD, left anterior descending coronary artery; RCA, right coronary artery; LV, left ventricle.

including exudative conjunctivitis, exudative pharyngitis, discrete intraoral lesions, bullous or vesicular rash, and generalized adenopathy. If KD appears unlikely, watchful waiting is employed, but ongoing reassessment is recommended if fevers persist. If the clinical picture is consistent with KD, laboratory tests are evaluated. If inflammatory markers are relatively unimpressive (CRP less than 3 mg per dL, ESR less than 40 mm per hour), this is less suggestive of KD, though the child should be followed daily, and formally reassessed if fevers persist. Even in children with unimpressive inflammatory markers whose fever resolves, an echocardiogram should be considered if typical peeling of the skin develops.

In those children with a clinical picture consistent with KD and significantly elevated inflammatory markers (CRP greater than or equal to 3.0 mg per DL, ESR greater than or equal to 40 mm per hour), supplemental laboratory criteria are taken into consideration. Supplemental lab criteria include albumin less than or equal to 3.0 g per dL, anemia for age, elevated alanine aminotransferase, platelets greater than or equal to 450,000 per mm^3 after 7 days of illness, white blood cell count greater than or equal to 15,000 per mm^3, and urine greater than or equal to 10 white blood cells per high-power field. If the child has more than three supplemental lab criteria, treatment for KD is recommended, and can be started before an echocardiogram is performed. In children with less than three supplemental lab criteria, an echocardiogram is recommended, with treatment to follow if the echocardiogram is positive (Table 101.17); treatment is recommended even if the child is past day 10 of fever, if there are clinical and laboratory signs of continued inflammation. If the echocardiogram is negative and the fever subsides, KD is considered to have been unlikely. If the echocardiogram is negative and fever persists, a repeat echo and consultation with a KD expert are recommended.

It should be noted that special consideration is given to febrile infants less than or equal to 6 months of age. It is recommended that these young infants have laboratory studies if febrile for more than or up to 7 days, even if there are no other clinical manifestations of KD present. If systemic inflammation is found, it is recommended that those infants undergo echocardiogram and be treated if the echocardiogram is positive.

Management

Intravenous Immune Globulin

IVIG has revolutionized the care of children with KD; treatment within 10 days of onset significantly shortens disease duration and minimizes the incidence of complications. Overall, prompt diagnosis and appropriate therapy prevent aneurysm formation in approximately 95% of children and result in rapid symptomatic improvement in about 90%. Studies in Japan were the first to suggest relative protection from coronary artery aneurysms when IVIG is administered early in the course of KD. Since then, further trials in the United States and Japan have confirmed this finding and documented the safety of high-dose infusions of immunoglobulin. At present, a single large infusion of IVIG (2 g per kg) administered over 8 to 12 hours is the standard of care for KD. This is somewhat more effective and equally as safe as multiple smaller infusions, and it also significantly shortens the duration of hospitalization.

Therapy with IVIG also has other benefits. Treatment results in a reduced prevalence of giant aneurysms, the most serious form of coronary abnormality caused by the disease. It also accelerates normalization of abnormalities of left ventricular systolic function and contractility. Finally, high-dose IVIG reduces fever and laboratory indices of inflammation, suggesting a rapid, generalized antiinflammatory effect in addition to specific cardioprotective effects. Different preparations of IVIG purified in different manners are available, but data are insufficient to determine whether all are equally effective.

Despite its advantages, IVIG is an expensive and potentially toxic intervention. The greatest long-term concern is the possible transmission of blood-borne pathogens. Elaborate sterilization procedures, including lyophilization, pasteurization, and addition of solvent detergents, are generally effective in rendering the product free of infectious agents. Nonetheless, technical errors apparently led to more than 100 cases of hepatitis C in recipients of a single brand of IVIG in 1994, although none were children with KD. Overall, however, significant toxicity is rare, and benefits clearly outweigh risks in children with confirmed KD.

Aspirin

Aspirin was the first medication to be used for treatment of KD, both for its antiinflammatory and its antithrombotic effects. High-dose (greater than 80 mg per kg per day) and lower-dose regimens (30 mg per kg per day) are still used in conjunction with IVIG during the acute phase of the illness despite the fact that meta-analyses demonstrate no additive protection from coronary artery aneurysms from aspirin. Once fever resolves, patients are generally switched to antiplatelet doses of aspirin (3 to 5 mg per kg per day). Unless coronary artery abnormalities are detected by echocardiogram, aspirin is discontinued once laboratory studies return to normal, usually within 2 months of the onset of KD.

The risks of aspirin appear to be similar to those reported in other settings: transaminitis, chemical hepatitis, transient hearing loss and, rarely, Reye syndrome. These risks may even be increased in KD: Aspirin-binding studies have suggested that the hypoalbuminemia of children with KD predisposes them to toxic-free salicylate levels despite measured (bound) values within the therapeutic range. At least one case of Reye syndrome has been reported after 6 days of aspirin therapy for KD. Alternative antipyretic and antiinflammatory agents, such as ibuprofen, may be used for treatment of arthralgias, and aspirin should be rapidly discontinued whenever varicella or influenza are concerns.

Management of Complications and Emergencies

Cardiovascular. Cardiac abnormalities dominate the pathology of KD. Clinical examination is often remarkable for tachycardia and gallop rhythms that are more prominent than expected from the degree of fever and anemia. The EKG in acute KD may show mild abnormalities consistent with myocarditis, most commonly a prolonged PR interval and nonspecific ST- and T-wave changes. Echocardiographic evaluation of myocardial function early in the course of the disease frequently reveals reduced left ventricular function and contractility. Rarely, myocardial inflammation may progress to frank CHF. The severity of myocarditis does not correlate with the risk of coronary artery aneurysms or with other complications such as pericardial effusion, which may develop during the second week of illness. The effusion rarely progresses to tamponade and resolves spontaneously in most instances. Valvulitis presenting as either aortic or mitral regurgitation is seen in a percentage of children during the early phases of KD. Late-onset mitral regurgitation, from papillary muscle dysfunction or myocardial infarction, may also complicate the clinical course.

Most characteristic of KD is inflammation of the coronary arteries. This progresses to ectasia or aneurysm formation in 15% to 25% of untreated children. Male gender, age less than 1 year, prolonged fever, dramatic elevation of CRP and absolute band count, and pronounced depression of albumin level, identify children at greatest risk for developing coronary artery aneurysms. Dilatation of coronary arteries may be detected by echocardiography as early as 6 days after the onset of fever and usually peaks 3 or 4 weeks into the course of the illness. Cardiac catheterization need not be performed in patients with normal echocardiograms and EKGs throughout the disease course because the likelihood of finding unsuspected lesions is negligible.

Coronary aneurysms in early KD usually occur in the proximal segments of the major coronary vessels; abnormalities that occur distally are almost always associated with proximal coronary dilatation. Aneurysms may also occur in arteries outside the coronary system, most commonly the subclavian, brachial, axillary, iliac, or femoral vessels, and occasionally in the abdominal aorta and renal arteries. For this reason, abdominal aortography and subclavian arteriography are often performed in patients undergoing coronary angiograms for KD. For unknown reasons, visceral vessels are almost never involved.

Myocardial Disease. Myocardial infarction caused by thrombotic occlusion of an aneurysmal and/or stenotic coronary artery is the principal cause of death in KD. Rarely, dilated and weakened coronary arteries may rupture. Mortality due to KD has decreased from almost 2% to less than 0.1% as a result of improved treatment. Nonetheless, most deaths continue to occur during the first 6 months after disease onset, when myocardial and coronary artery inflammation are greatest. A Japanese registry of 195 children with myocardial infarction revealed that almost 40% infarcted within 3 months of disease onset, and 74% had their infarctions during the first year after KD. About two-thirds of myocardial infarctions were associated with symptoms (shock, crying, chest or abdominal pain, vomiting, dyspnea, or arrhythmia), but only three patients had a history of antecedent angina.

Treatment with thrombolytic agents in adults with myocardial infarction results in decreased mortality and improved function. In children with KD and coronary artery thrombosis, thrombolytic agents—mainly urokinase and streptokinase, either IV or intracoronary—have been used with variable success. Thrombolytic therapy for coronary artery thrombosis is most effective if begun within 3 to 4 hours of symptom onset. Immediately following clot lysis, systemic heparin is begun in combination with aspirin. Maintenance of reperfusion then requires chronic oral antithrombotic therapy (e.g., warfarin with dipyridamole), although the ideal regimen has not been established.

CHF may rarely complicate the acute phase of KD. When this is because of myocarditis, routine treatment with IVIG generally results in rapid clinical improvement. Although IVIG therapy involves infusing large volumes of isotonic solution—2 g per kg of 5% IVIG delivers 40 cm^3 per kg over 8 to 12 hours—improvements in myocardial contractility compensate for the volume load, and treatment rarely leads to circulatory deterioration. By the second week of illness, and especially in children with coronary artery dilatation, ischemia or infarction must be excluded as causes of new myocardial dysfunction. Characteristic electrocardiographic and echocardiographic changes allow this distinction to be made rapidly in most patients.

Vascular Obstruction. Children with severe KD, especially infants or those in whom treatment is delayed, may develop other complications related to arterial occlusion. Peripheral obstruction leading to ischemia and gangrene most typically occurs in children with other manifestations of critical disease such as giant coronary artery aneurysms or aneurysms in peripheral arteries. Various therapies may restore circulation, although control of vascular inflammation with sufficient IVIG and/or other medications (e.g., corticosteroids and anti-TNF agents) is an essential prerequisite to arterial reperfusion. Thereafter, treatments may include thrombolytic therapy if arterial thrombosis is present, or vasodilators if tissue viability is primarily threatened by vasospasm. Peripheral arterial obstruction may be corrected by thrombolysis with urokinase, streptokinase, or tissue-type plasminogen activator, after which perfusion is maintained with heparin followed by a chronic oral anticoagulant regimen.

Other Complications. *Arthritis* occurs in approximately one-third of children with KD. Because it is rare in many of the conditions that may mimic KD, the presence of synovitis adds supportive evidence for the diagnosis in ambiguous cases. The arthritis tends to involve the small joints of the extremities during the acute phase of illness and the large joints during the second and third weeks. The arthritis of KD is always nondeforming and self-limited, generally resolving within 30 days. Antiinflammatory medications such as ibuprofen are usually effective in relieving symptoms until spontaneous resolution occurs.

KD may *recur* in 1% to 2% of children within 12 months of diagnosis, and an additional 5% to 10% may respond poorly to IVIG treatment during the initial bout of illness. In fact, patients who fail to respond completely to IVIG pose the greatest therapeutic dilemma. Prolonged fever itself correlates with increased risk of developing coronary artery abnormalities, and fever lasting for more than 14 days identifies a group of children at risk for developing giant coronary artery aneurysms (internal diameter greater than 8 mm), the group that is most susceptible to infarction and sudden death.

In cases of persistent, recurrent, or recrudescent KD, most clinicians retreat with IVIG, 2 g per kg over 8 to 12 hours. The risk of additional IVIG seems to be minimal, and several studies show a dose response to IVIG in KD. It is, however, extremely important to confirm the diagnosis; it must be remembered that failure to respond to IVIG might indicate that the child has a different source of fever, such as a bacterial or viral infection, or a chronic inflammatory disease.

Approximately two-thirds of children with KD who fail to respond to an initial dose of IVIG improve with a second course. A small number seem to be resistant to IVIG, and approaches to these children vary. One regimen that appears to be safe and effective is the use of pulse doses of methylprednisolone, as employed in PAN and other vasculitides. A multicenter randomized double-blind placebo-controlled trial of pulse dose methylprednisolone in conjunction with IVIG and ASA as initial therapy did not find a significant difference in coronary outcome between the steroid and placebo groups. In those children who required retreatment with IVIG, however, there was improved coronary outcome in the steroid compared to the placebo group. This suggests perhaps that those children who are at risk for IVIG-resistant disease at baseline might benefit from initial use of corticosteroids.

LYME DISEASE

Background

Current knowledge of LD is the result of discoveries that have spanned most of the twentieth century. Afzelius (1921) in Sweden first described the chronic migrating erythematous skin rash of LD in 1909, in association with an ixodid tick bite. Twenty-one years later, Bannworth (1944) reported a tick-borne syndrome of lymphocytic meningitis, neuritis, radicular pain, and an expanding erythematous rash (erythema migrans). In 1975, an outbreak of arthritis in Lyme, Connecticut, allowed identification of the tick vector associated with late disease. Finally, in 1981, the spirochete that is transmitted by ticks and causes the illness, *Borrelia burgdorferi*, was characterized.

LD is now the most common tick-borne illness in the United States. The Centers for Disease Control and Prevention report a steady increase in the incidence of LD. There were 248,074 cases from the 50 states, the District of Columbia, and U.S. territories reported to the CDC between 1992 and 2006, representing a 101% increase over the course of those 15 years (9,908 cases in 1992 compared to 19,931 cases in 2006). The northeastern and north-central states remain the most endemic for LD, with 92.6% of all cases reported from 10 states (Connecticut, Delaware, Massachusetts, Maryland, Minnesota, New Jersey, New York, Pennsylvania, Rhode Island, and Wisconsin). The highest rate of LD was found in children aged 5 to 9 years (8.6 cases per 100,000), with a second peak at 55 to 59 years (7.8 cases per 100,000). While cases occurred year-round, the summer months of June, July, and August saw the highest reported incidence of LD.

Clinical Manifestations

Symptoms of *B. burgdorferi* infection may be classified into three stages, similar to the progression of syphilis. Stage 1 or early disease consists of a localized erythema migrans rash (Fig. 101.15). This begins as a small, red, indurated papule at the site of the tick bite, and then expands centrifugally for a period of days or weeks. Lesions ultimately may reach an average diameter of 15 cm and may be accompanied by mild flu-like symptoms, including fever, regional lymphadenopathy, and malaise.

Stage 2 of LD results from hematogenous dissemination of the spirochete. Integumental, musculoskeletal, and central nervous systems are most commonly affected. Approximately one-half of patients develop secondary annular skin lesions similar to erythema migrans but smaller and without central punctae. Debilitating fatigue may accompany myalgias and migratory arthralgias, followed in somewhat more than 50% of patients by a large-joint oligoarthritis. Severe headache and meningismus, cranial neuritis (especially seventh nerve palsy), and peripheral radiculoneuropathy may supervene. Finally, approximately 5% of patients demonstrate cardiac involvement, including conduction abnormalities or, more rarely, pancarditis. These symptoms generally resolve within weeks or months, but they may recur or persist.

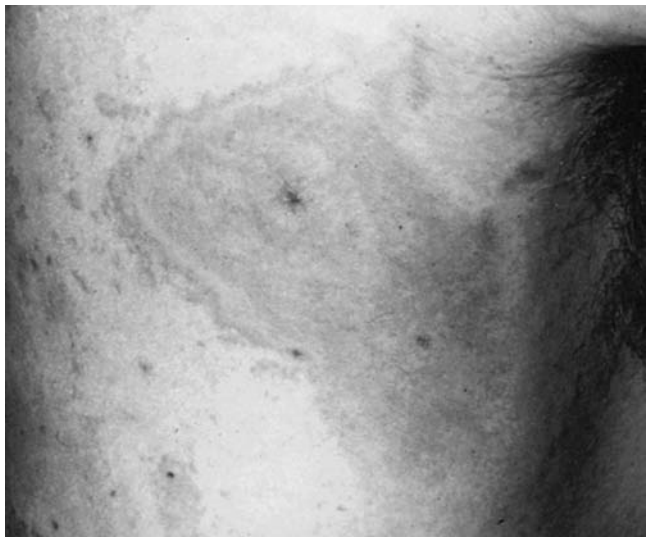

FIGURE 101.15 Primary erythema migrans lesion in Lyme disease. (Courtesy of James Leyden, MD.)

Stage 3 disease is characterized by persistent infection and symptoms of prolonged latency. A scleroderma-like skin rash, acrodermatitis chronica atrophicans, is seen most commonly in Europe. A potentially erosive chronic oligoarthritis may be seen months to years following the tick bite. Subtle neurologic findings, including peripheral neuropathies and organic brain syndromes, may become apparent long after other manifestations of spriochete infestation have resolved.

Particularly in the later states of the infection when the classic erythema migrans rash is not present, the diagnosis of LD requires the clinician to be familiar with its protean manifestations. This is particularly important for the pediatric ED physician because children and adolescents presenting to the ED are less likely to exhibit an erythema migrans rash than those evaluated in a primary care setting. Studies done in an LD-endemic area in Connecticut found that either single or multiple erythema migrans lesions were seen in 89% of LD patients presenting to pediatric practices, whereas only 24% of LD patients presenting to the Yale-New Haven Pediatric Emergency Department exhibited such a rash.

Laboratory Studies

B. burgdorferi is extremely difficult to grow in culture, and spirochetes generally cannot be identified in infected tissues. Diagnosis of LD is therefore made on the basis of characteristic clinical features accompanied by confirmatory serologic markers. Two caveats accompany serologic testing for LD. First, these tests are relatively difficult to perform, and standardization has been difficult to achieve. Many laboratories are plagued by both false-positive and false-negative results, so only experienced reference labs, preferably state or regional centers, should be employed. Second, serologic tests for LD are dependent on the patient's antibody response. Titers may not be measurable until the second month after a tick bite in up to 85% of cases, and they may be abrogated by early antibiotic therapy. Early LD is thus a clinical condition characterized by a typical EM rash, and serology should not be relied on to confirm the diagnosis.

Current recommendations for testing employ a two-step approach to optimize efficiency and accuracy. Patients are screened using an enzyme immunoassay or immunofluorescent assay. If these are negative, generally no further testing is indicated. Positive results by these methods, however, require confirmation because various viral illnesses and autoimmune conditions may cause false-positive results.

The second level of serologic evaluation involves Western or immune blotting. Any positive or equivocal antibody screening study should be confirmed by demonstrating the presence of at least 5 IgG bands directed against discrete *B. burgdorferi* proteins. This test is not foolproof, and false-positive studies may be seen in the setting of EBV and HIV infections, and in SLE. In addition, up to 10% of residents of endemic regions have positive Lyme titers without evidence of true infection. Consequently, only those with compatible clinical findings and positive serologies should be treated.

Other laboratory data are not specific for LD. Hemoglobin, white blood cell counts, and platelet counts are generally normal. ESR is elevated in approximately 50% of cases. ANA and RF are negative. Serum IgM is elevated in one-third of cases and correlates with the severity and chronicity of illness; IgM cryoglobulins are similarly associated. Immune complexes may be demonstrated in serum and synovial fluid.

In Lyme arthritis, synovial fluid analysis typically reveals elevated leukocyte counts ranging from 2,000 to 100,000 cells per mm^3. Polymorphonuclear leukocytes usually predominate, but LD is one of the few conditions in which a significant number of eosinophils may be identified in the synovial fluid. Total protein is elevated. Synovial biopsy reveals nonspecific synovial hypertrophy and mononuclear cell infiltration. In cases of neuroborreliosis, CSF analysis may reveal a mononuclear pleocytosis ranging from 25 to 500 cells per mm^3. At times, however, CSF may be entirely normal despite the presence of neurologic symptoms; even PCR testing might fail to reveal evidence of borrelial DNA. In such cases, MRI of the brain may be useful, although other causes of the symptoms must also be considered. Suspected involvement of the heart may be confirmed by electrocardiography, which reveals varying degrees of atrioventricular (AV) block and nonspecific ST-T-wave changes in children with Lyme carditis.

Management

General Management

The cornerstone of treatment of LD is antibiotics. Oral antibiotic therapy is beneficial in early stages of the infection, whereas IV medications have a lower failure rate in chronic LD. Late manifestations of LD may represent a host autoimmune response rather than direct effects of the spirochete, but antibiotics may nonetheless be beneficial.

Current treatment guidelines are shown in Table 101.18. Patients with erythema migrans should be treated with 14 to 21 days of doxycycline (100 mg bid). Pregnant women and children younger than the age of 8 years should receive amoxicillin (25 to 50 mg per kg per day, divided bid, maximum 2 g per day). For penicillin-allergic patients, cefuroxime axetil and azithromycin are alternative therapies, although the macrolides

TABLE 101.18

TREATMENT OF LYME DISEASE

Disease stage	Organ system	Treatment
Acute (stage 1)	General malaise, flulike symptoms Skin: erythema migrans	Oral regimens: doxycycline 100 mg bid for 14–21 days Children <8 yr old: amoxicillin 25–50 mg/kg/day divided tid (maximum 2 g/day) for 14–21 days
Chronic (stage 2)	Skin: multiple erythema migrans Neurologic: facial palsy Musculoskeletal: migratory arthralgias and arthritis	Oral regimen as for early disease, but for 21–28 days
Persistent (stage 3)	Skin: acrodermatitis chronica atrophicans Neurologic: meningitis, encephalitis Cardiac: heart block, myocarditis Musculoskeletal: chronic arthritis	Parenteral regimen: ceftriaxone 75–100 mg/kg IV or IM qd (maximum 2 g/day) for 14–28 days, or penicillin 300,000 U/kg/day IV divided q 4 h (maximum 20 million U/day) for 14–28 days

appear to be somewhat less effective. Therapy of early constitutional symptoms is supportive and includes bed rest, analgesics, and antipyretics. As with other spirochetal infections, a Jarisch-Herxheimer reaction may be seen after initial antibiotic therapy.

Management of Complications and Emergencies

Neurologic Complications. The presentation of neuroborreliosis is varied and may be categorized according to duration of infection. Early neurologic involvement, occurring during the first month after exposure, is seen in approximately 15% of untreated patients. Symptoms of aseptic meningitis and encephalitis are most notable, including severe headache, stiff neck, nausea and vomiting, photophobia, lethargy, and poor memory. Kernig and Brudzinski signs are generally negative. Cerebellar ataxia is also reported as a presenting manifestation of pediatric LD.

Facial nerve palsy is the most common cranial neuropathy of early neuroborreliosis. This is most often unilateral, but may be bilateral in up to one-third of cases. Facial nerve involvement due to *B. burgdorferi* must be distinguished from that of viral, autoimmune, and idiopathic Bell palsy, although in endemic regions up to 50% of cases of seventh nerve palsy are because of LD. A retrospective single-center study of patients with peripheral facial palsy presenting to the ED of a tertiary care pediatric center in Massachusetts identified (i) presentation during peak LD season (defined as June through October), (ii) no previous herpetic lesions, (iii) fever, and (iv) headache as independent predictors of LD in this endemic area. Lyme-induced facial nerve symptoms tend to resolve spontaneously, but oral antibiotics are recommended to prevent dissemination and late sequelae. If a lumbar puncture is performed, it will be abnormal in the majority of cases of LD, typically showing a lymphocytic pleocytosis with or without elevated protein. A CSF index, obtained by comparing the ratio of albumin to Lyme antibody levels centrally and peripherally, is currently the most sensitive marker of neuroborreliosis. Evidence of intrathecal production of antiborrelial antibodies may be found in 80% to 90% of patients with Lyme meningoencephalitis and is treated with parenteral ceftriaxone or penicillin for 14 to 21 days. In general, lumbar puncture is not recommended in cases of isolated facial palsy because it will not facilitate diagnosis, and long-term neuropsychologic outcomes of children with Lyme-induced facial nerve palsies are generally excellent with oral antibiotic therapy.

Some patients may develop late or chronic peripheral neuropathies months or years after infection. These manifest as symmetric or asymmetric paresthesias; radicular pain and muscle weakness are generally less intense than in early neuroborreliosis. Treatment with IV antibiotics, generally for 2 to 4 weeks, usually results in gradual improvement.

Most vexing of the late neurologic sequelae of LD is chronic Lyme encephalopathy. Symptoms are largely nonspecific, including debilitating fatigue, cognitive slowing, memory impairment, sleep disturbances, and depression. Distinction from idiopathic chronic fatigue syndrome or psychiatric conditions is extremely difficult. In cases attributable to LD on the basis of positive serologic markers of borrelial infection in addition to antibody, PCR, or MRI evidence of CNS involvement, symptoms often improve gradually with IV antibiotic therapy. In general, such cases are best cared for by physicians familiar with late LD, not in the ED.

Cardiac Complications. Lyme carditis may present weeks to months after the initial infection in 5% to 10% of untreated children. AV block is the most common manifestation; pericarditis, intraventricular conduction disturbances, and heart failure also may be seen. Patients may be asymptomatic with low-grade AV block, but 50% or more develop higher-grade conduction disturbances accompanied by dyspnea, chest pain, palpitations, dizziness, or syncope. In such cases, physical signs include those of CHF with gallop rhythm, bibasilar crackles, and hepatojugular reflux, or those of pericarditis with friction rub and pulsus paradoxus (greater than 10 mm Hg). The heart rate may be elevated in the face of myocarditis or congestive failure; bradycardia as low as 30 beats per minute can be seen in patients with conduction abnormalities. EKG reveals varying degrees of AV block and ST-T-wave changes. Chest radiographs may reveal cardiomegaly. Echocardiography is useful in documenting small pericardial effusions and ventricular dysfunction.

Treatment decisions are made on the basis of the severity of the carditis. Symptomatic patients or those with high-grade

conduction disturbances should be admitted to the hospital for close monitoring with telemetry. This course should also be considered for those with significant prolongation of the PR interval. Placement of a temporary pacemaker may be necessary in patients with complete heart block. There is no evidence that antibiotic therapy speeds recovery from Lyme carditis, but these agents are nonetheless employed to eradicate infection and prevent additional complications. Oral antibiotics are used in early or mild cases, while IV regimens are indicated for more severe or chronic disease. Antiinflammatory therapy with either aspirin (80 to 100 mg per kg per day) or occasionally prednisone (1 to 2 mg per kg per day) is recommended in cases of cardiomegaly, high-grade heart block, or markedly prolonged PR interval (more than 300 milliseconds) due to LD. The prognosis of all forms of cardiac involvement is excellent, with very few patients left with chronic sequelae.

Arthritis. Lyme arthritis occurs in more than 50% of untreated children, making it the most common late manifestation of borrelial infection. The classic presentation is a pattern of intermittent episodes of joint swelling beginning weeks to months after exposure. Approximately one-third of children develop an acute arthritis indistinguishable from bacterial infection, with joint pain, swelling, and erythema accompanied by fever. This presentation can be particularly vexing for the ED physician who must make a fairly immediate decision regarding the possibility of a septic joint. A small study focusing on the knee from a pediatric center in a Lyme endemic area suggests that MRI may be helpful in distinguishing between septic arthritis and LD; the presence of myositis and lymphadenopathy, and lack of subcutaneous edema, were statistically more common in LD than in septic arthritis.

Alternatively, synovitis might be migratory, simulating serum sickness or a postinfectious process, or chronic and persistent as in JRA. There is a propensity for large joint involvement, and often there is relatively little discomfort for the degree of swelling. The knee is affected in approximately 90% of cases, whereas more than two joints, or joints other than the knee, hip, ankle, or wrist, are involved in fewer than 2% of cases.

Lyme arthritis is clinically indistinguishable from JRA, septic arthritis, and postinfectious reactive synovitis, and it should be diagnosed only in the presence of convincing serologic evidence of borrelial infection. Current guidelines recommend initial treatment with oral antibiotics. Joint symptoms may only gradually improve over several weeks, but if joint pain and swelling persist for more than 2 months despite treatment, patients should be changed to IV therapy. Adjunct treatment with NSAIDs and physical therapy are important means of minimizing disability and accelerating recovery from Lyme arthritis. However, a small minority of patients develop a chronic inflammatory arthritis that must be treated in the same way as JRA.

CHAPTER 102 ■ TOXICOLOGIC EMERGENCIES

KEVIN C. OSTERHOUDT, MD, MS, MICHELE BURNS EWALD, MD, MICHAEL SHANNON, MD, MPH, AND FRED M. HENRETIG, MD

POISONED CHILD

Poisoning represents one of the most common medical emergencies encountered by young children and accounts for a significant fraction of emergency department (ED) visits in the adolescent population.

Estimates of poisoning episodes annually in the United States range in the millions. Poisonings may be unintentional or intentional. Unintentional or exploratory exposures to poisons make up 80% to 85% or more of all reports, whereas intentional poisonings comprise the other 10% to 15%. Persons in this latter group have much higher rates of treatment in the ED, hospitalization, and intensive care. Among children 5 years and younger, most poisoning exposures are related to exploratory behavior or result from willful child abuse. Although less common, the physician must also consider the possibility of environmental exposures, suicide attempts in children, and neonates exposed to toxicants in utero.

The exploratory ingestion of a drug or chemical by a toddler represents a complex interplay of host, agent, and environmental factors and may be considered a subset of the modern traumatic injury model. In this model, each factor contributes, more or less, in a given context to the probability of the injury occurring. Some children are more at risk because of peak age of 1 to 4 years, male gender, temperament that leans toward hyperactivity, and increased finger–mouth activity and/or pica. Some agents are more culpable because of ease of access, attractiveness/palatability, and toxic potential. Two classic examples are iron tablets, which may look like candy, are widely available, and are toxic in significant overdose; and mouthwash, which has a bright color, as well as a pleasant taste and smell, is often packaged in large volumes without child-safety caps, and may have surprisingly high ethanol content (15% to 25%). Typical environmental factors include an acute stressor, such as a recent move or new baby in the household, and chronic issues, such as parental illness/disability. The young child's exploratory encounter with a poison should not be viewed as an "accident," as the concordance of child, agent, and environmental factors may lead predictably to the statistical likelihood of toddler ingestion. Pediatricians have led the way in poisoning prevention strategies by modifying these risk factors with traditional anticipatory guidance and by spearheading the lobby for child-safety caps on particularly dangerous medications and household products. Although these efforts have resulted in a dramatic decrease in childhood poisoning morbidity and mortality since the 1970s, such poisonings continue to occur and demand the emergency physician's attention.

The scope of toxic substances involved in poisonings is broad, requiring a wide range of knowledge. Table 102.1 presents the categories of substances most commonly reported in human exposures in the United States for the year 2007. Table 102.2 presents the 10 most common toxic exposures involved in human deaths for the year 2007. The former listing much more closely approximates the profile of pediatric poisonings, whereas the latter is more typical of intentional adult exposures. The most important difference between the pediatric and the adult profile by type of agent is in the higher percentage of cases in which psychopharmacologic drugs (sedatives, tranquilizers, and antidepressants) cause poisoning in adults and the much higher frequency of exposures to household and personal care products and plants in children.

There are six basic modes of exposure to poisons: ingestion, ocular exposure, topical exposure, envenomation, inhalation, and transplacental exposure. Poisonings may be the result of acute or chronic exposures. Most poisonings treated in EDs are acute, and the patients are typified by the child who surreptitiously invades the medicine cabinet or the storage area for household cleaners or the adolescent or adult who takes a massive number of pills in a fit of despair. *Chronic poisoning* refers to toxicity produced over time in which a substance accumulates in the body, producing toxic results; it is best exemplified by environmental exposure to lead or other heavy metals. In the drug category, chronic toxicity can also exist. Acetaminophen hepatotoxicity that occurs in infants and small children or aspirin poisoning in older adults as a result of salicylate accumulation after administration of too much drug for too long is typical of chronic toxicity. Chronic toxicity is a special problem for the clinician because the source is not always apparent, the toxicity is not always clear, and the toxic process is not often obvious until serious clinical derangements occur.

GENERAL APPROACH TO THE POISONED CHILD

Following the analogy between unintentional poisoning and traumatic injury, a similar model may be used in formulating a management approach. The poisoned patient often represents an acute-onset emergency with a broad spectrum of multiorgan system pathophysiology that shares many features with the multiple trauma patient. In essence, poisoning might be viewed as a multiple chemical trauma. The concept of a brief window of opportunity to make critical diagnostic and management decisions is likewise analogous. One may conceptualize a management

TABLE 102.1

SUBSTANCES MOST OFTEN REPORTED IN HUMAN EXPOSURES

Substance	Percentage of total exposures
Analgesics	12.5
Cosmetics/personal care products	9.1
Cleaning substances	8.7
Sedatives/hypnotics/ antipsychotics	6.2
Foreign bodies/toys	5.1
Topical preparations	4.5
Cough and cold preparations	4.5
Antidepressants	4.0
Pesticides	3.9
Cardiovascular drugs	3.5

Adapted from Bronstein AC, Spyker DA, Cantilena LR, et al. 2007 Annual report of the American Association of Poison Control Centers' National Poison Data System. *Clin Toxicol* 2008;46:927–1057.

approach that attempts to prioritize critical assessment and, at times, simultaneous management interventions (Table 102.3). The initial phase (or primary survey) addresses the traditional airway, breathing, and circulation (ABCs) of airway securement and cardiorespiratory support, with a slight additional emphasis on emergent toxicologic considerations. The more specific evaluation and detoxification phase (or secondary survey) is aimed at simultaneously initiating generic treatment while assessing the actual extent of intoxication (in cases of known or presumed exposures) and/or identifying the actual toxicants involved (in unknown but highly suspected intoxications).

Initial Life Support Phase

The general approach to recognition and support of vital airway and cardiorespiratory functions (or ABCDs) is well known to most readers and is covered in detail in Chapter 1. In the context of the poisoned child, a few points deserve special emphasis. In addition to the usual signs of airway obstruction, the physician must pay special attention to evidence of disturbed airway protective reflexes. Many poisoned patients will vomit, and some may be administered charcoal, which poses an aspiration risk. Elective endotracheal intubation (see Chapter 5) may thus be indicated at a slightly lower threshold in this context than in another child with comparable central nervous system (CNS) depression.

TABLE 102.2

TOXIC EXPOSURES ASSOCIATED WITH THE MOST DEATHS

Nonprescription analgesics	Sedatives-hypnotics, antipsychotics
Antidepressants	Cardiovascular drugs
Stimulants and street drugs	Alcohols
Anticonvulsants	Gases and fumes
Muscle relaxants	Antihistamines

Adapted from Bronstein AC, Spyker DA, Cantilena LR, et al. 2007 Annual report of the American Association of Poison Control Centers' National Poison Data System. *Clin Toxicol* 2008;46:927–1057.

It is also particularly important to anticipate imminent respiratory failure in the deeply comatose poisoned child. Cyanosis and overt apnea are late findings with progressive drug-induced medullary depression. Thus, clinical or laboratory assessment of early ventilatory insufficiency is critical in such patients to avoid the chaos of a precipitous respiratory arrest. Likewise, it is far easier to establish intravenous (IV) access in a child with normal circulatory status than in a child in shock; early efforts to obtain a secure IV line in symptomatic overdose patients are thus well worth the time and effort.

After securing the airway, ensuring effective breathing, and supporting circulation, it is important to evaluate poisoned patients for neurological "disability," and the need for empiric "*d*rug" treatment, and emergent "*d*econtamination." Level of consciousness may be assessed rapidly with a semiquantitative scale such as the Glasgow Coma Scale or the AVPU (spontaneously *a*lert, response to *v*erbal stimulation or *p*ain, or *u*nresponsive) scale. Pupillary size and reactivity may be quickly noted. Rapid changes in mental status are common in serious intoxications and may herald precipitous cardiorespiratory failure.

Empiric "drug" treatment is warranted for most symptomatic poisoned children with altered mental status. All such patients may initially be given humidified *oxygen* and their blood oxyhemoglobin saturation monitored, if possible, by pulse oximetry. If available, rapid bedside blood glucose testing may be used; if low, or not readily available, a trial dosage of 0.25 to 1 g per kg glucose as 10% to 25% solution should be infused. It should be noted that drug- or toxicant-induced hypoglycemia does not present uniformly with coma or seizures. Almost any neuropsychiatric picture may predominate, including aphasia; slurred, dysarthric speech; and focal neurologic signs. Adrenergic signs, such as diaphoresis and tachycardia, are not uniformly present. Hypoglycemia is a complication seen in ingestions of ethanol, oral hypoglycemics, β-blockers, salicylates, and, of course, insulin injection. As basic as this intervention seems, in our experience, it is still one of the most often missed (or more accurately, *delayed*) critical treatments in the management of the poisoned patient.

Thiamine (100 mg IV), although routinely administered to adult overdose patients who receive hypertonic glucose to obviate precipitating Wernicke's encephalopathy, is not generally necessary in the pediatric population. Perhaps it should be considered in adolescent patients who may be thiamine deficient secondary to eating disorders, chronic disease (e.g., inflammatory bowel disease), or alcoholism. Last, empiric naloxone therapy is just as important in potentially poisoned toddlers with altered mental status as it is in adults. Although substance abuse is admittedly uncommon in the average 2-year-old child, it is amazing how many narcotics find their way into the curious child's mouth. Many households contain a variety of oral opioid analgesic agents, as well as cough medicines (codeine, dextromethorphan), antidiarrheal agents (paregoric, diphenoxylate), and partially naloxone-responsive antihypertensive agents such as clonidine. In addition, the possibility of

TABLE 102.3

GENERAL APPROACH TO THE KNOWN OR SUSPECTED INTOXICATION

Initial Life Support Phase
Airway: Maintain patency, assess protective reflexes
Breathing: Adequate tidal volume?
ABG or $ETCO_2$?
Circulation: Secure IV access, assess perfusion
Disability: Level of consciousness (AVPU or GCS)
Pupillary size, reactivity
Drugs: Dextrose (rapid bedside test)
Oxygen
Naloxone
(Other ALS medications)
Decontamination: Ocular—copious saline lavage
Skin—copious water, then soap and water
GI—consider options

Evaluation and Detoxification Phase
History—Brief, focused
Known toxicant: Estimate amount
Elapsed time
Early symptoms
Home treatment
Significant underlying conditions
Suspected but unknown toxicant—consider poisoning if:
Patient: Acute onset of illness
Pica-prone age
History of pica, ingestions
Current household "stress"
Multiorgan system dysfunction
Significantly altered mental status
Puzzling clinical picture
Family: Medications at home
Recent illness (under treatment)
Social: Grandparents visiting
Holiday parties, other events

Physical Examination
Vital signs
Level of consciousness, neuromuscular status
Eyes—pupils, extraocular movements, fundi
Mouth—corrosive lesions, odors
Cardiovascular—rate, rhythm, perfusion
Respiratory—rate, chest excursion, air entry
GI—motility, corrosive effects
Skin—color, bullae or burns, diaphoresis, piloerection
Odors
Laboratory (individualize)
CBC, cooximetry
ABG, serum osmolarity
EKG/cardiac monitor
Chest radiograph, abdominal radiograph
Electrolytes, BUN/creatinine, glucose, calcium, liver function panel
Urinalysis
Rapid overdose toxicologic screen
Quantitative toxicology tests (especially acetaminophen)
Assessment of Severity/Diagnosis
Clinical findings
Laboratory abnormalities (with consideration of anion, osmolar gaps)
Toxidromes (see Table 102.5)
Specific Detoxification
Reassess ABCDs
Institute appropriate GI decontamination (if not already under way)
Urgent antidotal therapy
Consider excretion enhancement
Continue supportive care

ABG, arterial blood gas; $ETCO_2$, end-tidal carbon dioxide; AVPU, *a*lert, *v*erbal, *p*ain, *u*nresponsive; GCS, Glasgow Coma Scale; ALS, advanced life support; GI, gastrointestinal; CBC, complete blood cell count; EKG, electrocardiogram; BUN, blood urea nitrogen.

exploratory ingestion of a "stash" of illicit opioids does exist. Thus, naloxone should be used as a therapeutic/diagnostic trial when there is a reasonable possibility that altered mental status is drug induced. Previous recommendations have based dosing on weight (e.g., 0.01 to 0.1 mg per kg); however, many authorities now prefer a unified pediatric dose of 0.4 to 2 mg for acute overdose patients of all ages (outside the neonatal period). Such an approach conceptualizes naloxone dosing as based on total narcotic load and number of opioid receptors that require competition for binding sites. In general, this latter approach is easier to remember and has not been associated with complication in the ED. Adolescent patients with a strong clinical picture for opioid intoxication (without habituation) may receive 2-mg bolus doses every 2 minutes, up to a total dose of 8 to 10 mg, before abandoning hope of benefit because several congeners of morphine (e.g., propoxyphene, illicit fentanyl derivatives, pentazocine) may require such large doses. If chronic abuse is suspected, lower initial doses (0.2 to 0.4 mg) are warranted. Administration of flumazenil to adolescents exhibiting depressed consciousness after an unknown drug overdose is not recommended by the authors (see "Central Nervous System Sedative-Hypnotics" section).

The rationale for decontamination of the poisoned child is discussed in the next section. This treatment phase may begin urgently, after or in concert with attention to the ABCDs. At times, a decision to perform gastric decontamination through the preferred technique can be made almost immediately upon presentation and, if so, should be instituted as soon as possible in light of the patient's clinical status and the number of hands available to assist in management. For example, a toddler with coma, shock, and massive hematochezia who is rushed into the ED by the rescue squad—and for whom there is witnessed or strong circumstantial evidence of massive iron overdose—requires a concerted team effort directed toward resuscitation, stabilization, and urgent gastric decontamination. However, an apparently asymptomatic adolescent who admits to ingesting 10 g of acetaminophen 1 hour before arrival at the ED may be more fully evaluated in a timely but orderly manner (as outlined in the next section) and within short order can be considered for less emergent gastric decontamination—in this case, possibly an oral dose of activated charcoal. Significant dermal or ocular exposures require immediate copious lavage, and precautions should be taken to protect the health-care providers tending to the patient from exposure.

At the completion of this initial life support phase, the poisoned patient should have been assessed for compromise of vital airway and cardiorespiratory function and for global neurologic status and should have had resuscitative measures instituted. Patients with significant altered mental status have been critically evaluated for respiratory status, have had IV access secured, and have had their therapeutic trials of oxygen, glucose, and naloxone. Other advanced life support interventions such as anticonvulsants or antiarrhythmics have been instituted as necessary. Consideration of decontamination options has begun.

Evaluation and Detoxification Phase

History

A brief and focused *historical evaluation* should be addressed as soon as the life support phase has been completed. The primary goal is to determine the potential severity of the exposure. This assessment requires poison and patient-related data alike.

For a known or highly suspected toxic exposure, an attempt is made to estimate the total amount ingested (number of pills missing, ounces left in the bottle, dosage of pills, concentration of alcohol, and so forth). The best estimate of time elapsed since ingestion is also sought. Parents should be questioned regarding early symptoms noted at home or en route to the ED and any treatments administered before arrival. Certain underlying medical conditions may be relevant [e.g., glucose-6-phosphate dehydrogenase (G6PD) deficiency for mothball ingestions]; thus, any significant medical history should be noted.

Often, children who are poisoned do not come to the ED with a clear history of exposure followed by onset of symptoms. Rather, they develop signs and symptoms that mimic other diseases and give no history of toxic exposure. Thus, the ED staff must always consider the possibility of ingestion when treating young children.

General historical features that suggest the possibility of poisoning include (i) acute onset; (ii) age range of 1 to 5 years or adolescence; (iii) history of pica or known exposure to a potential toxicant; (iv) substantial environmental stress, either acute (e.g., arrival of a new baby, serious illness in a parent) or chronic (e.g., marital conflict, parental disability); (v) multiple organ system involvement; (vi) significant alteration in level of consciousness; and (vii) a clinical picture that seems especially puzzling.

Certain family and social history variables are also important. Medications used by other household members, particularly new medications introduced into the home environment by virtue of recent illnesses or visits from grandparents and other relatives, are a common source of ingested drugs. Changes in routine and large family gatherings (e.g., holiday parties, moving to a new home) are particularly risky occasions for decreased parental supervision and new (or less carefully guarded) potentially toxic medications or household products.

Physical Examination

The focused physical examination should begin with a reassessment of vital functions and complete recording of vital signs, including core temperature. With secure airway and cardiorespiratory function confirmed, the examination should then focus on the central and autonomic nervous systems, eye findings, changes in the skin and/or oral and gastrointestinal (GI) mucous membranes, and odors (see Chapter 46) on the breath or clothing of the patient. These features represent those areas most likely affected in toxic syndromes and, when taken together, often form a constellation of signs and symptoms referred to as toxidromes (Tables 102.4 and 102.5). Such toxidromes may be so characteristic as to provide guidance for early therapeutic management before precise historical or laboratory confirmation of a specific exposure is available.

Laboratory Evaluation

Laboratory studies may be helpful in confirming diagnostic impressions or in demonstrating toxicant-induced metabolic aberrations. However, there is no "tox panel" that is uniformly helpful or necessary. Most poisonings can be managed appropriately without extensive laboratory studies, and in particular, the reflex ordering of rapid overdose toxicology "screens" has rarely been found to be helpful in acute patient management. They have important, nonemergent roles (e.g., in resolving medicolegal issues or considering drug-induced causes of behavioral changes in a psychiatric patient). In toddlers with a known or strongly suspected specific ingestion, rapid drug screens are rarely indicated. In the adolescent intentional overdose patient who is not critically ill or who does not have a particularly puzzling clinical picture, the drug screen again is rarely helpful, although the finding of an unexpected toxic level of acetaminophen (which may have been omitted in the history) may impact management, and some authors recommend that quantitative acetaminophen levels (in lieu of "tox screens") be sought in such patients.

The labor-intensive comprehensive urine drug screen may be useful for patients who are seriously ill with an occult ingestion or for the occasional intentional overdose adolescent patient whose clinical picture does not fit with the stated history. Often of greater help is the critical interpretation of routine measurements of serum chemistries and osmolality in patients with altered mental status. The presence of hypoglycemia or aberrations of serum electrolytes may provide crucial information about the poisoned patient. In certain circumstances, tests of liver or renal function, urinalysis, creatine phosphokinase levels, and other select tests may be useful. Metabolic acidosis with a high anion gap is found in many clinical syndromes and toxidromes, reflected by the often-cited mnemonic *MUDPILES*, for *m*ethanol and *m*etformin; *u*remia; *d*iabetic and other ketoacidoses; *p*araldehyde; *i*soniazid, *i*ron, and *i*nborn errors of metabolism; *l*actic acidosis (seen with hypoxia, shock, carbon monoxide, cyanide, and many drugs that cause compromised cardiorespiratory status or prolonged seizures); *e*thylene glycol; and *s*alicylates. Differences between calculated and measured serum osmolarity [calculated = 2 (serum Na mEq per L) + blood urea nitrogen (BUN) mg per dL ÷ 2.8 + glucose mg per dL ÷ 18; with normal osmolarity ~290 mOsm per kg] may suggest intoxication with ethanol, isopropanol, or more rarely in pediatric patients, methanol or ethylene glycol. Blood collection tubes containing ethylene diamine tetraacetic acid (EDTA) should not be used to send samples to the laboratory because the osmolal gap will be falsely elevated.

TABLE 102.4

CLINICAL MANIFESTATIONS OF POISONING

Vital Signs

Pulse

Bradycardia

Digoxin, opioids, organophosphates, plants (lily-of-the-valley, foxglove, oleander), clonidine, β-blockers, calcium channel blockers

Tachycardia

Alcohol, amphetamines and sympathomimetics, anticholinergic agents, tricyclic antidepressants, theophylline, salicylates, phencyclidine, cocaine

Respirations

Slow, depressed

Alcohol, barbiturates (late), narcotics, clonidine, sedative-hypnotics

Tachypnea

Amphetamines, barbiturates (early), methanol, salicylates, carbon monoxide

Blood Pressure

Hypotension

Cellular asphyxiants (methemoglobinemia, cyanide, carbon monoxide), antipsychotics, tricyclic antidepressants, barbiturates, iron, theophylline, clonidine, narcotics, β-blockers, calcium channel blockers

Hypertension

Amphetamines/sympathomimetics, phencyclidine, monoamine oxidase inhibitors (MAOIs), antihistamines, anticholinergic agents, clonidine

Temperature

Hypothermia

Ethanol, barbiturates, sedative-hypnotics, opioids, phenothiazines, antidepressants, clonidine, cabamazepine

Hyperpyrexia

Sympathomimetics, anticholinergics, salicylates, neuroleptics, inhalational anesthetics, succinylcholine, serotonin reuptake inhibitors, withdrawal from sedatives

Neuromuscular

Coma

Narcotic depressants, sedative-hypnotics, anticholinergics (antihistamines, antidepressants, phenothiazines, atropinics, OTC sleep preparations), alcohols, anticonvulsants, carbon monoxide, salicylates, organophosphate insecticides, clonidine, γ-hydroxybutyrate

Delirium/Psychosis

Alcohol, phenothiazines, drugs of abuse (phencyclidine, LSD, peyote, mescaline, marijuana, cocaine, heroin, methaqualone), sympathomimetics and anticholinergics (including prescription and OTC cold remedies), steroids, heavy metals, dextromethorphan

Convulsions

Alcohol, amphetamines, cocaine, phenothiazines, antidepressants, antihistamines, camphor, boric acid, lead, organophosphates, isoniazid, salicylates, plants (water hemlock), lindane, lidocaine, phencyclidine, carbamazepine

Ataxia

Alcohol, barbiturates, carbon monoxide, anticonvulsants, heavy metals, organic solvents, sedative-hypnotics, hydrocarbons

Paralysis

Botulism, heavy metals, plants (poison hemlock), ticks, paralytic shellfish poisoning

Eyes

Pupils

Miosis

Opioids, organophosphates, ethanol, barbiturates, phenothiazines, phencyclidine, clonidine

Mydriasis

Amphetamines, anticholinergic agents, barbiturates (if comatose), botulism, cocaine, methanol, glutethimide, LSD, marijuana, phencyclidine, antihistamines, antidepressants

Nystagmus

Phenytoin, sedative-hypnotics, carbamazepine, glutethimide, phencyclidine (both vertical and horizontal), barbiturates, ethanol, MAOIs, ketamine, phencyclidine, dextromethorphan

Skin

Jaundice

Carbon tetrachloride, acetaminophen, naphthalene, phenothiazines, plants (mushrooms, Fava beans), heavy metals (iron, phosphorus, arsenic)

Cyanosis (unresponsive to oxygen, as a result of methemoglobinemia)

Aniline dyes, nitrites, benzocaine, phenacetin, nitrobenzene, phenazopyridine, dapsone

Pinkness to Redness

Atropinics and antihistamines, alcohol, carbon monoxide, cyanide, boric acid

Odors

Acetone: acetone, isopropyl alcohol, phenol, salicylates

Alcohol: ethanol (alcoholic beverages)

Bitter almond: cyanide

Garlic: heavy metal (arsenic, phosphorus, thallium), organophosphates

Oil of wintergreen: methylsalicylates

Hydrocarbons: hydrocarbons (gasoline, turpentine)

OTC, over the counter; LSD, lysergamide.

Adapted from Mofenson HC, Greensher J. The unknown poison. *Pediatrics* 1974;54:336.

An immediate determination of quantitative levels is helpful in making management decisions for some drugs, and these are outlined in Table 102.6. Furthermore, many important causes of coma and altered vital signs are not detected on even the most sophisticated "comprehensive" toxicology panels (which are usually biased toward psychoactive medications and illicit drugs). An overview of such agents is presented in Table 102.7. An electrocardiogram (EKG) should be performed in all seriously ill patients in whom poisoning is being considered. Detectable conduction delays may provide diagnostic direction and impact management by predicting imminent life-threatening cardiac rhythm disturbances.

Assessment of Severity and Diagnosis

At this juncture, most intoxicated patients may be readily stratified by specific toxicant or category of drug(s) ingested

TABLE 102.5

TOXIDROMES

	Sympathomimetics (amphetamines, cocaine)	Anticholinergics (antihistamines, many others)	Organophosphates (insecticides, nerve gases)	Opioids/ clonidine	Barbiturates/ sedative-hypnotics	Salicylates	Theophyline
Mental status/CNS	Agitation, delirium, psychosis, convulsions	Delirium, psychosis, coma, convulsions	Confusion, fasciculations, coma	Euphoria, somnolence, coma	Somnolence, coma	Lethargy, convulsions	Agitation, tremor, convulsions
Heart rate	Increased	Increased	Decreased (or increased)	Decreased	—	—	Increased
Blood pressure	Increased	Increased	—	Decreased	Decreased	—	Decreased
Temperature	Increased	Increased	—	Decreased	Decreased	Increased	—
Respirations	—	—	Increased	Decreased	Decreased	Increased	Increased
Pupils	Large, reactive	Large, sluggish	Small	Pinpoint	—	—	—

CNS, central nervous system; —, minimal direct effect.
[a]SLUDGE is a mnemonic representing *s*alivation, *l*acrimation, *u*rination, *d*efecation, *g*astric cramping, and *e*mesis.

TABLE 102.6

FREQUENTLY USEFUL QUANTITATIVE TOXICOLOGY TESTS IN PEDIATRIC PATIENTS

Drug/toxin	Optimal time after ingestion (h)
Acetaminophen	4
Carbamazepine	2–4
Carboxyhemoglobin	Immediate
Digoxin	4–6
Ethanol	½–1
Ethylene glycol	½–1
Iron	4
Lithium	2–4[a]
Methanol	½–1
Methemoglobin	Immediate
Phenobarbital	1–2
Phenytoin	1–2
Salicylate	2–4[a]
Theophylline	1–2[a]
Valproate	2–4

[a]Repeat levels over 6 to 12 hours may be necessary with sustained-release preparations.

and some judgment made as to the potential or current severity of the exposure. For some children, clinical features of a complex illness of acute onset may suggest intoxication without a specific history of such ingestion. In a few cases, some laboratory confirmation of clinical suspicion will be available on an immediate basis. Using all the clinical clues available and with some familiarity of the "toxidrome" approach to differential diagnosis as detailed previously (Tables 102.4 and 102.5) and, at times, with help from the laboratory, the emergency physician must now establish a working diagnosis and proceed with consideration of options for specific detoxification.

TABLE 102.7

IMPORTANT DRUGS AND TOXICANTS NOT DETECTED BY MOST DRUG SCREENS

Coma causing	Hypotension causing
Bromide	β-Blockers[a]
Carbon monoxide	Calcium channel blockers[a]
Chloral hydrate	Clonidine[a]
Clonidine	Colchicine
Cyanide	Cyanide
γ-Hydroxybutyrate	Digitalis[a]
Organophosphates	Iron
Tetrahydrozoline (in over-the-counter eyedrops)	

[a]Hypotension is often seen with bradycardia.

Specific Detoxification

Again, the proviso that the patient be continually reassessed and managed for impaired vital function is addressed. All decisions about further decontamination and/or specific antidotal therapy involve a complex interplay between the toxicant(s) ingested and the patient's condition.

GI Decontamination. The effort to "get the poison out" has long been a mainstay of the traditional discussion of toxicologic management. However, gastric emptying measures have fallen out of favor over the past 15 years, and the routine use of activated charcoal as a poison adsorbent has been subjected to increased academic scrutiny. Unfortunately, young children have been underrepresented in clinical studies of GI decontamination. It is likely that as further research is conducted, particularly as directed toward the pediatric population, current dogma regarding optimal GI decontamination will evolve. For the sections that follow, several appropriate techniques for gastric decontamination are reviewed, all of which may be useful under certain circumstances. An approach to the overall decision process in a given patient is then offered.

Simple dilution. Dilution may be indicated only when the toxicant produces local irritation or corrosion. Water or milk is an acceptable diluent. Dilution for caustic agents is controversial; dilution may be used in the first few minutes after an exposure but only if there is no evidence of airway compromise or significant abdominal pain/vomiting. For drug ingestion, however, dilution alone should not be used because it may increase absorption by increasing dissolution rates of the tablets or capsules or it may promote more rapid transit into the lower GI tract.

Gastric emptying. The goal of gastric emptying is to rid the stomach of remaining poison to prevent further local effect or systemic absorption. The utility of gastric emptying diminishes with time and is most effective if done early after ingestion when unabsorbed drug is still present within the stomach (operationally, within the first 30 minutes to 1 hour). In certain circumstances, such as the delayed gastric emptying accompanying intoxication with anticholinergic drugs, benefit may be noted longer after ingestion. *Emesis* was once a favored means of gastric emptying, but the American Academy of Pediatrics has issued a policy statement recommending that syrup of ipecac no longer be used routinely for the poisoned patient in the home or health-care facility.

Studies addressing the efficacy of ipecac-induced emesis in reducing bioavailability of ingested drug have widely varying results with ranges from 0% to 70% decrease in absorption. Individuals with eating disorders and those with Munchausen syndrome by proxy can abuse syrup of ipecac. Furthermore, a more recent study of U.S. Poison Centers suggested no improvement in patient outcome or reduction in resource utilization when ipecac was used in the home. Finally, despite a long history of use, it has been difficult to prove improved clinical outcome in poisoned patients given ipecac compared with patients treated with activated charcoal alone, and ipecac has been found to delay the time to administration of activated charcoal and some specific antidotes.

An alternative to ipecac-induced emesis for emptying the stomach is *gastric lavage*. This procedure is usually reserved for

patients who have ingested a potentially life-threatening amount of poison, in cases where the procedure can be performed safely very early after ingestion and charcoal alone is not believed to be adequate. To carry out a satisfactory lavage, the patient should be on his or her left side, head slightly lower than feet, and the largest orogastric lavage tube that can reasonably be passed should be used (e.g., 24F orogastric tube for a toddler, 36F orogastric tube for an adolescent). A smaller caliber nasogastric (NG) tube is sufficient only for some liquid toxins. Gastric contents should be aspirated initially before any lavage fluid is introduced. Normal saline aliquots of 50 to 100 mL in young children and 150 to 200 mL in adolescents can be lavaged repeatedly until the return is clear. Like induced emesis, gastric lavage's efficacy in reducing drug absorption has been reviewed critically in more recent studies. Again, the efficacy has been highly variable and lavage has not been demonstrated to improve outcome in poisoned patients. Several important risks are associated with gastric lavage, including oxygen desaturation, aspiration, and mechanical trauma to the oropharynx and esophagus. Gastric lavage is rarely recommended anymore but might be considered for patients presenting very early after very dangerous ingestions (of toxicants such as colchicine or arsenic). Contraindications to the procedure include caustic or corrosive ingestions, impending loss of airway protection, and the presence of cardiac arrhythmia.

Activated charcoal. Activated charcoal minimizes absorption of drugs by adsorbing them onto its surface. Charcoal administration has become the decontamination strategy of choice to prevent pediatric poisoning after toxicant ingestion and is most effective when used in the first hour after ingestion. Therefore, if activated charcoal is considered as a treatment option, quick triage of an exposed patient may be necessary to allow charcoal administration in a timely fashion. A number of notable compounds, such as iron and lithium, do not adsorb well to activated charcoal (Table 102.8). The usual dose of activated charcoal is 1 g per kg; adolescents and adults should receive 50 to 100 g. Most activated charcoal is now available premixed with water to make a slurry that can be taken orally or administered by NG tube. Simply adding soda or another nonparticulate flavoring agent to the charcoal can improve palatability.

Activated charcoal was "rediscovered" by the toxicology community during the 1980s, with several studies finding its use to be superior to gastric emptying alone and, at least, equivalent to the combination of gastric emptying plus charcoal administration. The use of charcoal alone is less invasive and less likely to be associated with complications in the clinical setting than is gastric emptying. Aspiration of charcoal can be a serious concern among patients with poor airway protective reflexes, and vomiting remains the most common difficulty associated with its use. The use of an NG tube, which renders the esophagogastric sphincter patent, may also increase aspiration risk. Charcoal is contraindicated in patients with an unprotected airway or a disrupted GI tract (e.g., after severe caustic ingestion) or in patients in whom charcoal therapy may increase the risk and severity of aspiration (e.g., hydrocarbons). The use of multiple doses of activated charcoal to achieve enhanced drug elimination is addressed later in this chapter.

TABLE 102.8

SUBSTANCES POORLY (OR NOT) ADSORBED BY ACTIVATED CHARCOAL

Common electrolytes
Iron
Mineral acids or bases
Alcohols
Cyanide
Most solvents
Most water-insoluble compounds (e.g., hydrocarbons)

Catharsis. Two types of osmotic cathartics have most commonly been used to treat poisoned patients: the saccharide cathartics (e.g., sorbitol) and the saline cathartics (e.g., magnesium citrate, magnesium sulfate). *Whole bowel irrigation (WBI)* with a high-molecular-weight polyethylene glycol solution is discussed in the next section. Little evidence exists to suggest that standard cathartics accomplish their goal of reducing drug absorption by decreasing GI transit time. It is still unclear whether cathartics administered with activated charcoal reduce subsequent constipation, and some believe cathartics increase the incidence of vomiting. Repetitive doses of osmotic cathartics are associated with considerable diarrhea and cramping, and hypernatremic dehydration has been reported in young infants. A single dose of premixed charcoal/sorbitol is safe for most pediatric ingestions, but this preparation should be used with caution in young infants. Mineral oil or stimulant cathartics such as castor oil are discouraged because they may be aspirated, increase absorption of some poisons, or unnecessarily extend the cathartic effect.

Whole bowel irrigation. An additional technique of cathartic GI decontamination is that of intestinal irrigation with large volumes and flow rates of a polyethylene glycol-balanced electrolyte solution such as GoLYTELY® or Colyte®. Typically, these solutions are not significantly absorbed nor do they exert an osmotic effect, so the patient's net fluid/electrolyte status is unchanged. They have a long safety track record in patient populations such as infants and in those surgical patients requiring application of preoperative bowel preparation. WBI has been found to be particularly useful in pediatric iron overdoses, in which gastric lavage may be limited by tube size, the fact that metals do not bind to charcoal, and the possibility that the ingestion is not a recent one. It has been used for other metal ingestions (e.g., lead), overdoses of sustained-release medications (e.g., lithium, theophylline), ingested pharmaceutical patches, and ingestions of vials or packages of illicit drugs. It might also be useful in particularly massive and/or late-presenting overdoses for which the efficacy of gastric emptying and/or charcoal is expected to be suboptimal. The technique may be used by mouth in cooperative patients or by NG tube; the usual recommended dosing is 500 mL per hour in toddlers and 2 L per hour in adolescents and adults.

GI Decontamination Strategies

It should be apparent that no unique approach to GI decontamination of all poisoned patients is optimal in every case. Factors to be considered include the expected degree of toxicity from the drug, the physical nature of the drug, the current location of the drug within the body, and the presence of contraindications or alternatives. A risk–benefit decision must be made before the institution of any decontamination strategy.

Syrup of ipecac was used primarily as first aid treatment of potentially toxic ingestions in the home. However, the American Academy of Pediatrics no longer recommends routine use in the home, and induced emesis is not favored in the ED. The use of gastric lavage as a decontamination strategy has become more limited in recent years. If it still has a role, it is only in patients with recent ingestions of extremely toxic substances that put them at risk for a lethal course, especially when those substances do not bind well to charcoal. Likewise, patients with truly massive overdoses may benefit from gastric lavage because standard charcoal preparations may have diminished effectiveness when the charcoal-to-drug ratio is less than 10:1. The correct technique for gastric lavage requires that careful attention be given to prevent aspiration and anatomic trauma.

Overall, the mortality from acute poisoning is less than 1%. Suicidal overdoses in adolescents typically have more inherent lethality than unintentional overdoses in toddlers. If a GI decontamination strategy is to be used, the administration of activated charcoal or WBI are now the favored procedures. Some of the patients in question will have undergone endotracheal intubation during the initial life support phase of management, as detailed previously, or they may be strong candidates for such airway protection because of borderline mental status and in anticipation of their ensuing critical course. Others may be awake, alert, and cooperative, with normal airway protective reflexes, and thus be given activated charcoal without prior endotracheal intubation. The combative, agitated patient poses a dilemma and must be carefully managed on an individualized basis.

An attempt to summarize these considerations is diagrammed in Fig. 102.1; however, it should be reiterated that all decisions regarding gastric decontamination involve multiple patient and toxic agent-related factors and should not be made with a "cookbook" approach.

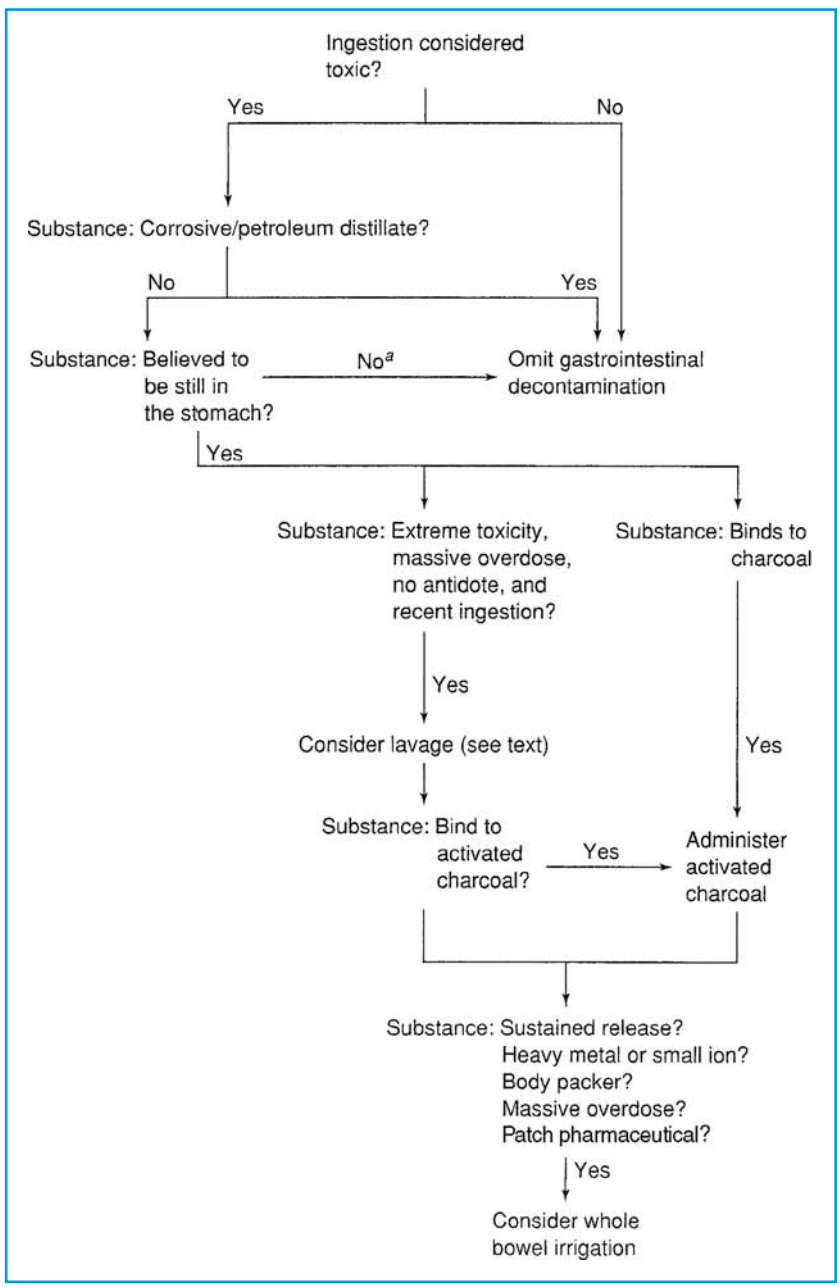

FIGURE 102.1 Approach to gastrointestinal decontamination. [a]For patients in whom the toxicant is no longer believed to be in the stomach, whole bowel irrigation might still be a valid consideration.

Antidotal Therapy. Beyond the setting of acetaminophen overdose, the overall number of toxic ingestions for which a specific antidote is necessary or available is small. When a specific antidote can be used, it is vital that it be administered as early as possible and in an appropriately monitored dose. Those antidotes that should be available for immediate administration include sodium bicarbonate (tricyclic antidepressants), sodium nitrite/sodium thiosulfate or hydroxocobalamin (cyanide), atropine and pralidoxime (cholinesterase inhibitors), ethanol or fomepizole (ethylene glycol and methanol), deferoxamine (iron), dextrose (ethanol, salicylates, oral hypoglycemics), methylene blue (methemoglobinemic agents), oxygen (carbon monoxide), flumazenil (benzodiazepines), pyridoxine (isoniazid and *Gyromitra* mushrooms), digoxin immune Fab (digoxin), and naloxone (opioids). Other antidotes usually do not require such urgent administration and may be given subsequent to initiation of other management modalities. Even when available, antidotes do not diminish the need for meticulous supportive care or other therapy. Indiscriminant use of antidotes without other forms of management should be discouraged. Table 102.9 summarizes a list of commonly used antidotes, suggested doses, and their indications for use. Because of its frequent use, naloxone is discussed further here.

Naloxone. Naloxone, a pure opioid antagonist, is one of the broadest-acting, safest, and most effective of any true antidotes now available. It is effective against all opioids. Naloxone is a synthetic congener of oxymorphone but is devoid of morphine agonist or depressant effects. It has no significant side effects in the treatment of acute overdose except narcotic withdrawal symptoms in the addicted patient. These symptoms include GI upset, tachycardia, hyperpnea, mydriasis, rhinorrhea, diaphoresis, sialorrhea, increased blood pressure, anxiety, restlessness, discomfort, and hyperalgesia. These symptoms are not usually life-threatening to teenagers and adults but can be fatal to an infant born to an addicted mother. Withdrawal symptoms secondary to naloxone, if observed during acute overdose treatment, would be expected to last no more than 30 minutes and should generally be treated with supportive care. The serum half-life of naloxone is 1 hour; its duration of action 1 to 4 hours. Initial reversal of narcosis may then revert to coma, requiring ongoing reassessment and readministration of naloxone. There are a few case reports of other adverse effects, including hypertension, pulmonary edema, ventricular irritability, and seizures after naloxone-induced reversal of narcosis in the perioperative setting, typically in patients with underlying cardiopulmonary disease and in the presence of additional medications or anesthetic agent use.

The mechanism of action of naloxone is by competitive displacement of narcotic analgesics at central opioid receptor sites. It can be used as a diagnostic test when faced with a questionable history. Current dosage recommendations reflect the proven safety of naloxone in large doses and the necessity of such doses to reverse effects of synthetic opioids such as propoxyphene and pentazocine. If severe respiratory depression is present, the initial dose should be 2 mg IV in any patient. Repeat doses may be given every 2 minutes until 10 mg has been administered for adolescent patients with suspected opioid overdose who fail to respond to the lower dosages. Of course, concomitant airway management is vital. In patients without respiratory depression, an initial dose of 0.4 to 1 mg can be used. In adolescents suspected of chronic opiate abuse, smaller initial doses (e.g., 0.2 to 0.4 mg) are warranted. Again, if there is no response but a strong clinical suspicion, 2-mg doses can be repeated up to a total of 10 mg before concluding that further dosing will be of no benefit. Naloxone can also be given intramuscularly (IM), sublingually, or by endotracheal tube if no IV access is available.

If a lightening response occurs, naloxone will have to be repeated at the effective total dose every 20 to 60 minutes. An alternative approach is to provide a continuous IV infusion; generally about two-thirds of the total reversal dose will need to be infused per hour initially, with subsequent adjustments as necessary.

Nalmefene and naltrexone are longer-acting opioid antagonists that may have use in some clinical situations in which a longer duration of action (4 to 6 hours for nalmefene, 24 hours for naltrexone) is deemed beneficial, such as in reversal of procedural/postoperative opioid depression or as aids in opioid detoxification programs. However, as antidotes for acute opioid overdose in the adolescent or pediatric population, their longer duration may be problematic in assessing the actual time course for resolution of clinical toxicity and/or in precipitating prolonged withdrawal symptoms in habituated patients. Nalmefene may be a useful substitute for prolonged naloxone infusions in cases for which such opioid antagonism is necessary, but little pediatric experience and few dosing guidelines for its use are currently available.

Enhancing Excretion

The procedures available for enhancing the elimination of an absorbed poison that have the greatest value are multiple-dose activated charcoal, diuresis/urinary alkalinization, dialysis, and hemoperfusion. Because some risk is involved, these measures are indicated only in those cases in which the patient's recovery would be otherwise unlikely or in which a specific significant benefit is expected.

Diuresis/Urinary Alkalinization

Diuresis has historically been advocated in cases of poisoning with agents that are excreted primarily by the renal route. Although it is important to maintain high glomerular filtration rates in the presence of rhabdomyolysis or when chelating with agents such as EDTA, forced diuresis has limited value in the treatment of acute poisoning. Similarly, diuretic use has fallen out of favor with the possible exception of mannitol therapy for ciguatera poisoning.

Ionized diuresis takes advantage of the principle that excretion is favored when a drug is in its ionized state. Urinary alkalinization promotes excretion of salicylate (a weak acid). It may also enhance clearance of phenobarbital, chlorpropamide, and chlorophenoxy herbicides, but in these poisonings, it cannot be considered a mainstay of therapy. Urine alkalinization can be initiated with sodium bicarbonate at a dose of 1 to 2 mEq per kg IV over a 1- to 2-hour period. Careful attention should be given to total fluid and sodium load administered, especially in patients at risk for congestive heart failure or pulmonary edema. Hypokalemia can interfere with the ability to alkalinize the urine and should be corrected.

TABLE 102.9

SUMMARY OF ANTIDOTES

Poison	Antidote
Acetaminophen	*N*-acetylcysteine; intravenous (IV)—150 mg/kg over 1 h, then 12.5 mg/kg/hr for 4 h, then 6.25 mg/kg/hr; enteral—140 mg/kg, then 70 mg/kg every 4 h.
Anticholinergics	Physostigmine (adult, 0.5 to 2 mg; child, 0.02 mg/kg) slow IV; may repeat in 15 min until desired effect is achieved; subsequent doses every 2–3 h PRN (*Caution: May cause seizures, asystole, cholinergic crisis; see text*)
Anticholinesterases	Atropine, 2–5 mg (adults); 0.05–0.1 mg/kg (children) intramuscular (IM) or IV, repeated every 10–15 min until atropinization is evident
Organophosphates	Pralidoxime chloride 1–2 g (adults); 25–50 mg/kg (children) IV; repeat dose in 1 h PRN, then every 6–8 h for 24–48 h (consider also constant infusion; see text)
Carbamates	Atropine, as above; pralidoxime for severe cases (see text)
Benzodiazepines	Flumazenil, 0.01 mg/kg IV (estimated pediatric dose; see text)
β-Adrenergic blockers	Glucagon, 0.1 mg/kg IV, followed by 0.05 mg/kg/h
Calcium channel blockers	Calcium chloride 10%, 10 mL (adult); 0.2 mL/kg (pediatric) IV Insulin (see text) Or Calcium gluconate 10%, 30 mL (adult); 0.6 mL/kg (pediatric) IV
Carbon monoxide	Oxygen 100% inhalation, consider hyperbaric for severe cases
Cyanide—cyanide antidote kit	*Adult:* Amyl nitrite inhalation (inhale for 15–30 s every 60 s) pending administration of 300 mg sodium nitrite (10 mL of a 3% solution) IV slowly (over 2–4 min); follow immediately with 12.5 g sodium thiosulfate (2.5–5 mL/min of 25% solution) IV *Children* (Na nitrite should not exceed recommended dose because dangerous methemoglobinemia may result):

Hemoglobin	Initial dose 3% Na nitrite	Initial dose 25% Na thiosulfate IV
8 g	0.22 mL (6.6 mg)/kg	1.10 mL/kg
10 g	0.27 mL (8.7 mg)/kg	1.35 mL/kg
12 g (normal)	0.33 mL (10 mg)/kg	1.65 mL/kg
14 g	0.39 mL (11.6 mg)/kg	1.95 mL/kg

Cyanide—hydroxocobalamin	*Adult:* 5g IV; *Child*: 70 mg/kg IV.
Digitalis	Fab antibodies (Digibind): dose based on amount ingested and/or digoxin level (see text, package insert)
Fluoride	Calcium gluconate 10%, 0.6 mL/kg IV slowly until symptoms abate, serum calcium normalizes; repeat PRN
Heavy metals (usual chelators)	*BAL* (British Anti-Lewisite; dimercaprol): 3–5 mg/kg/dose deep IM every 4 h for 2 days, every 4–6 h for an additional 2 days, then every 4–12 h for up to 7 additional days
Arsenic (BAL)	*EDTA* (ethylene diamine tetraacetic acid): 50–75 mg/kg/24 h deep IM or slow IV infusion given in 3–6 divided doses for up to 5 days; may be repeated for a second course after a minimum of 2 days; each course should not exceed a total of 500 mg/kg body weight (see text)
Lead (BAL, EDTA, penicillamine, DMSA)	(see text and Table 102.14)
Mercury (BAL, DMSA)	*Penicillamine:* 100 mg/kg/d (max 1 g) by mouth (PO) in divided doses for up to 5 days; for long-term therapy, do not exceed 40 mg/kg/d *DMSA (succimer):* 350 mg/m^2 (10 mg/kg) PO every 8 h for 5 days, followed by 350 mg/m^2 (10 mg/kg) PO every 12 h for 14 days
Iron	Deferoxamine: 5–15 mg/kg/h IV; use higher dosage for severe symptoms (see text) and decrease as patient recovers
Isoniazid (INH)	Pyridoxine 5%–10%, 1 g per gram of INH ingested (70 mg/kg up to 5 g if dose unknown) IV slowly over 30–60 min

(continued)

TABLE 102.9

SUMMARY OF ANTIDOTES (CONTINUED)

Poison	Antidote
Methanol/ ethylene glycol	Fomepizole: load 15 mg/kg; maintenance 10 mg/kg q12h 4 doses, then 15 mg/kg q12h (dose should be adjusted during dialysis; ethanol may be used if fomepizole unavailable) Ethanol loading dose: 0.75 g/kg infused over 1 h (fomepizole is preferred) Ethanol maintenance: 0.1–0.2 g/kg/h infusion; adjust as needed with target level 100 mg/dL Folate 1 mg/kg IV every 6 h (methanol) Thiamine 0.5 mg/kg and pyridoxine 2 mg/kg (ethylene glycol)
Methemoglobinemic agents	Methylene blue 1%, 1–2 mg/kg (0.1–0.2 mL/kg) IV slowly over 5–10 min if cyanosis is severe or methemoglobin level >40%
Opioids	Naloxone 0.4–2 mg IV, IM, sublingual or by ETT; may repeat up to total 8–10 mg in adolescent/adult (see text)
Phenothiazines (dystonic reaction)	Diphenhydramine, 1–2 mg/kg IM or IV; or Benztropine, 1–2 mg IM or IV (adolescents)
Sulfonylureas	Octreotide 1–2 μg/kg/dose subcutaneous (SC) or IV every 6–12 h
Tricyclic antidepressants	Sodium bicarbonate, 1–2 mEq/kg IV
Warfarin (and "superwarfarin" rat poisons)	Vitamin K_t 10 mg (adult); 1–5 mg (pediatric) IV, IM, SC, PO
Animals	Antivenin[a] For envenomation (see Chapter 91)
Snake, Crotalidae (all North American rattlers and moccasins)	Crotalidae polyvalent immune Fab (Savage)
Snake, coral	Antivenin (*Micrurus fulvius*), monovalent (Wyeth)
Spider, black widow	Antivenin *Latrodectus mactans* (Merck, Sharp & Dohme)

[a]See package insert for dosage and administration.

The rate of bicarbonate infusion can be adjusted to maintain a urinary pH of 7.5 to 8.5. Urinary acidification is never indicated because it may lead to serious side effects such as systemic acidosis and exacerbation of renal impairment in the context of myoglobinuria.

Dialysis

Dialysis is indicated for selected cases of severe poisoning or when renal failure is present. Indications for dialysis depend on patient- and drug-related criteria. Patient-related criteria include (i) anticipated prolonged coma with the high likelihood of attendant complications, (ii) development of renal failure or impairment of normal excretory pathways, and (iii) progressive clinical deterioration despite careful medical supervision. Drug-related criteria are (i) satisfactory membrane permeability, (ii) a correlation between plasma drug concentration and drug toxicity of the agent, (iii) plasma levels in the potentially fatal range or the presence of a significant quantity of an agent that is normally metabolized to a toxic substance, and (iv) significant enhancement of clearance. Those xenobiotics with low volumes of distribution (less than 1 L per kg), low molecular weight (less than 500 Da), and low protein binding are the most amenable to enhanced clearance with dialysis. Hemodialysis is the most effective means of dialysis. Because it requires highly technical skills, as well as a physician and a technician, it is not always available; however, it is an essential consultative service for units that manage severe poisoning cases. The emergency physician should be aware that most typical dialysis patients are hypervolemic but most toxicology dialysis patients (poisoning with salicylate, ethylene glycol, methanol, etc.) are hypovolemic; it is incumbent upon the ED care provider to try to achieve euvolemia prior to hemodialysis.

Hemoperfusion

Hemoperfusion, the process of passing blood through an extracorporeal circuit and a cartridge containing an adsorbent after which the detoxified blood is returned to the patient, is also effective in drug removal. However, with newer "high flux" dialysis membranes, this technology is less commonly needed and less widely available. Indications for use are similar to those for hemodialysis. Table 102.10 summarizes the generally accepted common drugs and drug concentrations for which hemodialysis and hemoperfusion should be considered, in light of the previous discussion regarding clinical criteria.

Multiple-Dose Activated Charcoal (GI Dialysis)

Several studies have shown significant increase in clearance for a number of drugs when repeated doses of 0.5 to 1 g per kg of activated charcoal are given every 4 to 6 hours. By using a nearly continuous stream of fresh charcoal that descends through the intestinal tract, a constant concentration gradient

TABLE 102.10

A PARTIAL LISTING OF DRUGS AND THEIR PLASMA CONCENTRATIONS FOR WHICH HEMODIALYSIS OR HEMOPERFUSION SHOULD BE CONSIDERED

Hemodialysis	Hemoperfusion
Lithium (acute), 4.0 mEq/L	Phenobarbital, 100 mg/L
Lithium (chronic), 2.5 mEq/L	Theophylline, 60–100 mg/L
Ethylene glycol, 50 mg/dL	Paraquat, 0.1 mg/dL
Methanol, 50 mg/dL	
Salicylates, 60 (chronic) to 80 (acute) mg/dL	

Adapted from Winchester JF. Active methods for detoxification. In: Hadded LM, Shannon MW, Winchester JF, eds. *Clinical management of poisoning and drug overdose*, 3rd ed. Philadelphia: WB Saunders, 1998:175–187.

is maintained that favors the back diffusion of free drug from periluminal capillary blood into the intestinal lumen, where it may be bound immediately to the newer charcoal, so the free drug concentration in the intestinal lumen remains low. In addition, enterohepatic recirculation of some drugs may be interrupted as reabsorption from bile is prevented. To be safe and effective, this technique requires active peristalsis and an intact gag reflex or a protected airway. Common pediatric poisonings for which repetitive charcoal dosing may be considered include phenobarbital, carbamazepine, phenytoin, digoxin, salicylates, and theophylline. Cathartics, such as sorbitol, should be administered no more frequently than every third dose.

Supportive Care

The final step in optimizing treatment for the poisoned child is the direction of scrupulous attention to supportive care, including continued close monitoring of ABCDs, fluid and electrolyte status, urine output, and level of consciousness. The value of these efforts usually far outweighs that which may be ascribed to any specific toxicologic interventions in most cases. Severely symptomatic patients are most properly cared for in specialized facilities that have skilled pediatric critical care staff and access to toxicology consultation.

NONTOXIC INGESTION

Often, the emergency provider will be asked about a childhood ingestion of some common household products, many of which are nontoxic unless taken in huge amounts. The availability of a list of such nontoxic products often leads to immediate relief of parental anxiety and avoids the institution of unnecessary noxious interventions. Before using such a list, however, several precautions need to be kept in mind. The fact that an ingestion is nontoxic does not necessarily mean that it has no medical significance. Ingestions often occur in the context of a suboptimal environment. There may be poor supervision or unusual family stresses surrounding the incident, or the ingestion may not have been purely exploratory in nature. Several criteria have been suggested to qualify an ingestion as "nontoxic." These include the assurance that only one identifiable product is ingested in a well-approximated amount, that the product label includes no cautionary signal word, that the child is symptom free and younger than 5 years, and that an appropriate mechanism is available for telephone follow-up. When used with these criteria, Table 102.11 provides an updated list of nontoxic ingestions. In certain cases, consultation with a regional poison control center (in the United States, the phone number 1-800-222-1222 may be used nationwide) is often helpful.

PEDIATRIC OVERDOSES

The following section highlights selected agents that are ingested by children. They have been chosen for inclusion because of their common occurrence, because they represent the potential for serious or life-threatening toxicity, and because timely recognition and appropriate treatment may be lifesaving.

Acetaminophen

Background

Acetaminophen, *N*-acetyl-*p*-aminophenol (APAP), is the most popular pediatric analgesic-antipyretic and has now become one of the most common pharmaceutical preparations ingested by young children. It is also one of the 10 most common drugs used by adolescents and adults in intentional self-poisoning. Acetaminophen also occasionally turns up as an unreported coingestant in intentional overdoses. Fortunately, exploratory ingestion in young children has been associated with low morbidity, although occasional cases of hepatotoxicity occur, particularly in the context of inadvertent repetitive overdosing.

Pathophysiology

The major toxicity of APAP is severe hepatic damage. Acetaminophen is metabolized in three ways by the liver: (i) glucuronidation, (ii) sulfation, and (iii) metabolism through the cytochrome P-450 pathway to form a potentially toxic intermediate, which conjugates with glutathione. In a massive overdose, glutathione becomes depleted, thus allowing the undetoxified intermediate to bind to hepatocytes, leading to cellular necrosis. This damage is reflected by rising levels of liver enzymes, by hepatic dysfunction, and in severe poisonings, by hepatic failure and death. The use of *N*-acetylcysteine as an antidote relates in part to this molecule's ability to act as a glutathione precursor.

Clinical Findings

Initially, the signs and symptoms of APAP ingestion are vague and nonspecific but include nausea and vomiting, anorexia, pallor, and diaphoresis. These manifestations usually resolve within 12 to 24 hours, and the patient appears well for 1 to 4 days. During this latent period, levels of liver enzymes may rise, and jaundice with liver tenderness may ensue. Most patients have a gradual resolution of their hepatic dysfunction, although without antidotal treatment about 2% to 4% of intoxications that develop toxic plasma levels will go on to hepatic failure and death. Such patients with severe toxicity develop further clinical evidence of hepatic disease at 3 to 5 days after ingestion, and some develop renal damage. Anorexia, malaise, and abdominal pain may progress to signs of liver failure with hepatic coma.

TABLE 102.11

PRODUCTS THAT ARE NONTOXIC WHEN INGESTED IN SMALL AMOUNTS

Abrasives	Hand lotions and creams
Adhesives	Hydrogen peroxide (medicinal 3%)
Antacids	Incense
Antibiotics	Indelible markers
Baby product cosmetics	Ink (black, blue)
Ballpoint pen inks	Laxatives
Bath oil	Lipstick
Bathtub floating toys	Lubricating oils
Bleach (less than 5% sodium hypochlorite)	Magic Markers
Body conditioners	Matches
Bubble bath soaps	Mineral oil
Calamine lotion	Newspaper (black and white pages)
Candles (beeswax or paraffin)	Paint (indoor, latex)
Caps	Pencil (graphite)
Chalk	Perfumes
Cigarettes (less than 3 butts)	Petroleum jelly
Clay (modeling)	Phenolphthalein laxatives (Ex-Lax)
Colognes	Porous-tip marking pens
Contraceptive pills	Putty (less than 2 oz)
Corticosteroids	Rubber cement
Cosmetics	Shampoos (liquid)
Crayons (marked AP, CP)	Shaving creams and lotions
Dehumidifying packets (silica or charcoal)	Soap and soap products
Detergents (phosphate)	Suntan preparations
Deodorants	Sweetening agents (saccharin, cyclamates)
Deodorizers (spray and refrigerator)	Teething rings (water sterility)
Elmer's Glue	Thermometers (mercury)
Etch-A-Sketch	Thyroid tablets
Eye makeup	Toothpaste
Fabric softener	Vitamins (without iron)
Fertilizer (if no insecticides or herbicides added)	Warfarin (rat poison; excludes "superwarfarins")
Glues and pastes	Watercolors
Grease	Zinc oxide (Desitin)
Hair products (dyes, sprays, tonics; excludes "relaxers")	Zirconium oxide

Adapted from Mofenson HC, Greensher J. The unknown poison. *Pediatrics* 1974;54:336.

The potential severity of an acute intoxication may be predicted by the amount ingested, if accurately known, and the plasma level of APAP. APAP in single doses of less than 200 mg per kg in young children is likely to be harmless. Severe toxicity in adolescents or adults usually occurs with overdoses of at least 7.5 g. Initial GI symptoms, although vague, are generally more pronounced when the overdose is large. However, the only reliable indication of the potential severity of the hepatic damage is the plasma APAP level, taken at least 4 hours after ingestion. After a single acute overdose at a known time of ingestion, a nomogram (Fig. 102.2) is available for using the serum APAP level in the prediction of likely toxicity. We recommend use of the lower line of the nomogram, plotted 25% below the possible toxicity line, to err on the safe side in making therapeutic decisions. Importantly, the nomogram is not validated for chronic APAP toxicity.

Management

The basic toxicologic principles of preventing absorption apply to APAP overdoses, and it is important to note that both immediate- and extended-release preparations exist. Activated charcoal therapy may be used for adsorption of gastric APAP. Many APAP-poisoned patients will benefit from the use of the oral antidote *N*-acetylcysteine (NAC), and some have speculated that activated charcoal might decrease the bioavailability of the NAC. However, studies have demonstrated clinically insignificant decreases in NAC absorption, even when using large doses of charcoal. For most cases of acetaminophen overdose per se, and particularly for those typically seen early after ingestion, charcoal alone is probably effective and should not significantly alter the ability to use NAC several hours later. In cases that present after 4 hours have elapsed, gastric decontamination is usually not warranted.

NAC, given orally or IV, is most effective at ameliorating hepatotoxicity when instituted within 8 hours of ingestion. It also lessens the severity of hepatic damage if used in the setting of clinical presentation beyond 8 hours. The major adverse reaction associated with IV NAC is the occurrence of anaphylactoid reaction, which typically occurs during the relatively higher dose loading infusion. Clinicians administering IV NAC should be skilled at recognizing and treating anaphylactoid reactions

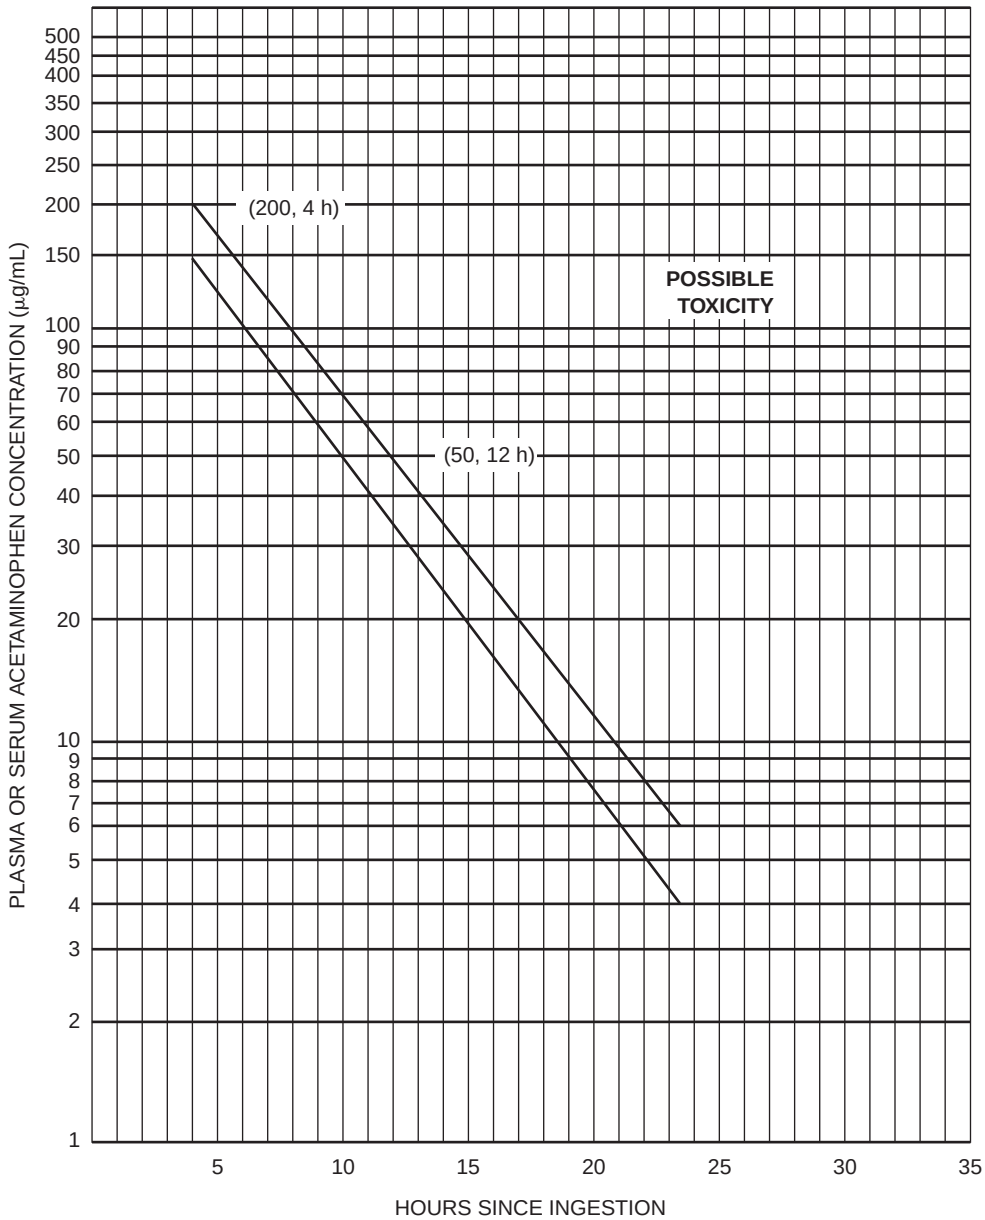

FIGURE 102.2 Nomogram for estimating severity of acute acetaminophen poisoning. (Modified from Rumack BH, Matthew H. *Pediatrics* 1975;55:871–876. Copyright 1975, American Academy of Pediatrics. Reprinted by permission.)

and should be particularly cautious when using this route in patients with a history of asthma. The inhalational form of NAC can be administered enterally and can be mixed with fruit juice or soda to disguise its foul smell, or it can be administered by NG tube. Only mild GI side effects result from its use, but persistent vomiting is an occasional obstacle to completing the course of therapy. This may be obviated by giving the dose slowly or by NG or duodenal tube infusion. Antiemetic therapy with metoclopramide or ondansetron may also be helpful.

The protocol for NAC therapy may be summarized as follows:

1. Consider GI decontamination options as already noted.
2. If patient presents less than 4 hours after a single acute ingestion, wait to draw 4-hour level and base therapeutic decision on nomogram (assumes rapid turnaround time so level will be available by 6 hours after ingestion); if necessary, initiate treatment as described next. For extended-release preparations, McNeil Consumer Products Co. (Fort Washington, Pennsylvania), a manufacturer of acetaminophen, suggests a second APAP level drawn 4 hours after the first; antidotal therapy is to be instituted if either level suggests possible toxicity.
3. If patient presents more than 6 to 8 hours after ingestion, initiate NAC therapy, obtain level and base subsequent course of therapy on nomogram.
4. If level plots out above the lower line on the nomogram, admit the patient to hospital and continue NAC until APAP is not detectable in the blood and liver function is either normal or clearly recovering. Monitor complete blood cell count (CBC) and renal and liver function tests.
5. Treatment for patients who present more than 24 hours after ingestion is controversial, as is treatment for patients with subacute, repetitive overdosing over several days. We consider children who receive more than 150 mg per kg per day for 1 to 2 days to be at risk; again, a combination

of a nondetectable APAP level and normal aminotransferases identifies a patient at low risk of hepatic injury from APAP.

Alcohols and Glycols

The alcohols and glycols are some of the most commonly found organic compounds in the environment. Ethanol is a commonly encountered solvent and is used as a topical antiseptic, chemical intermediate, beverage, and in some instances, a rubbing alcohol. It is also an ingredient in some mouthwashes and many perfumes, colognes, and toilet waters. Methanol, or methyl alcohol, functions as an antifreeze (in windshield washers/deicers and gasoline antifreeze) and as a solvent in many industrial and home products. Isopropyl alcohol serves as a rubefacient. Ethylene glycol is used primarily as a deicer or antifreeze. A related class of compounds, the glycol ethers, is widely used in rug shampoos and other cleaning compounds. The toxicity of these agents is believed to be comparable to (if not more severe than) ethylene glycol.

Ethanol

The most commonly ingested alcohol is ethanol. After ingesting ethanol, children may develop nausea, vomiting, stupor, and ataxia. Coma and death from apnea may occur if significant quantities are consumed. In adolescents, blood concentrations of less than 50 mg per dL rarely result in overt sensory or motor impairment. Values of 80 to 150 mg per dL are consistent with intoxication and cause mild neurologic findings. Lethal blood alcohol concentrations are generally higher than 500 mg per dL. Infants and toddlers who ingest ethanol have a clinical course that is significantly different from that in adolescents and adults; a triad of coma, hypothermia, and hypoglycemia appears once ethanol levels exceed 50 to 100 mg per dL. This triad may be accompanied by metabolic acidosis.

The amount of an ethanol-containing liquid that is of concern when ingested by a child depends on the alcohol concentration. However, a rough rule is that ingestion of 1 g per kg of ethanol is sufficient to raise blood alcohol to 100 mg per dL. Therefore, for a beverage such as beer (5% alcohol), approximately 10 to 15 mL per kg must be ingested before serious toxicity results. Similar estimates are 4 to 6 mL per kg for wine (14% alcohol) and 1 to 2 mL per kg for 80-proof liquor (40% alcohol).

The management of ethanol ingestion in children begins with prompt recognition and evaluation of blood glucose level. Airway or ventilatory compromise should be treated with endotracheal intubation. If seizures result from hypoglycemia, they should be promptly treated with 10% to 50% (0.25 to 1 g per kg) IV dextrose. Warming techniques should be instituted to increase core temperature. Because ethanol is rapidly absorbed from the gut and is not adsorbed by activated charcoal, there is rarely a role for GI decontamination.

Alcohol is metabolized by the hepatic enzyme alcohol dehydrogenase; its elimination rate is dose dependent. This means that the higher the blood alcohol concentrations, the longer the elimination process because the capacity of the body to produce alcohol dehydrogenase is limited. The rate of reduction in blood alcohol concentration varies from 10 to 25 mg per dL per hour. Although hemodialysis effectively enhances elimination (three- to fourfold), it is rarely necessary. The institution of hemodialysis may be useful in those patients who have impaired liver function or a blood alcohol concentration higher than 450 to 500 mg per dL.

Isopropyl Alcohol

Poisoning with isopropyl alcohol may be particularly insidious because oral ingestion is not the only route of exposure. Children may develop severe intoxication, including coma, after topical application of isopropyl alcohol for the relief of fever (although such exposure may represent inhalational exposure rather than direct, dermal absorption). Because isopropyl alcohol is usually available in a 70% concentration by volume, ingestion of 2 to 2.5 mL per kg of this solution may lead to symptoms. Ingestion of this compound causes many of the same features as ethanol ingestion, with the additional complication of severe gastritis. Unlike the other toxic alcohols, isopropyl alcohol does not lead to metabolic acidosis. This is because its metabolite, acetone, is not an acid. However, it is approximately twice as intoxicating as ethanol, leading to greater mental status impairment at comparable serum levels. The life-threatening toxicity of isopropyl alcohol is cardiac; at high serum concentrations, direct myocardial depression occurs, leading to hypotension and shock.

In any patient with coma and an unexplained osmolal gap (the difference between calculated and observed osmolarity), isopropyl alcohol should be strongly considered. The presence of ketonuria in conjunction with the absence of metabolic acidosis effectively makes the diagnosis of isopropyl intoxication.

Isopropyl alcohol is easily removed by hemodialysis. However, hemodialysis is rarely necessary because life-threatening toxicity does not occur until serum levels exceed 400 to 500 mg per dL. Therefore, the sole indication for hemodialysis is considered hemodynamic instability, regardless of serum concentration. Treatment is otherwise supportive.

Methanol

Although methanol is used primarily as a solvent for industrial purposes, it is found in other household products, including fuels for stoves, gel fuels for heating small dishes (e.g., Sterno), paint removers, and antifreezes.

Methanol is a model for the few drugs that, rather than being detoxified, become more toxic as they are metabolized. Thus, although methanol has little or no inherent toxicity, its metabolism by alcohol and aldehyde dehydrogenase to form formaldehyde and formic acid creates highly toxic compounds. Formic acid is a potent organic acid that results in severe metabolic acidosis and ocular toxicity. Fortunately, because methanol is metabolized slowly, toxicity appears after some delay, permitting time for intervention. Ingestions approaching 100 mg per kg should be considered dangerous.

The clinical effects of methanol ingestion usually occur after a latent period of 8 to 24 hours. This delay occurs as the result of the metabolic conversion of methanol to its toxic byproducts. In large ingestions, acute methanol poisoning may cause severe CNS depression, metabolic acidosis, and a number of reversible or irreversible optic changes. In the early stages of intoxication, funduscopic examination may be remarkable for hyperemia. However, if left untreated, methanol intoxication results in blindness, with the appearance of a pale, avascular retina. In subacute ingestions, the

nonspecific neurologic symptoms of methanol intoxication resemble those of ethanol with a "hangover," malaise, headache, and dizziness. During recovery from a mild ingestion, occasional paresthesias of the extremities may develop.

The most immediately significant clinical concern from methanol ingestion is severe metabolic acidosis. This acidosis is primarily the result of formic acid production. The metabolic acidosis may be intractable and results in multiorgan dysfunction, which includes cardiac arrhythmias, seizures, and pancreatitis. The ophthalmologic abnormalities that develop during methanol intoxication may be temporary or permanent. These include blurred or double vision, changes in color perception, and sharply reduced visual acuity. Permanent abnormalities may include diminished pupillary light reaction or frank blindness. The occurrence of permanent visual defects correlates directly with the degree of metabolic acidosis, the duration of the acidosis, and the quantity of methanol ingested.

Management. The treatment of methanol ingestion consists of supportive care, administration of specific therapies, and enhancement of elimination. Activated charcoal does not adsorb methanol effectively and is unnecessary.

Laboratory assessment includes serial blood gases, electrolytes, BUN, creatinine, glucose, serum osmolality, and methanol level analyses. Serum methanol concentration in milligrams per deciliter can be estimated by the formula (osmolar gap × 3).

There are three specific treatments for methanol intoxication: sodium bicarbonate, folic acid, and fomepizole (or ethanol). Sodium bicarbonate should be administered aggressively to correct metabolic acidosis. Folate is provided because of its role in formic acid disposition within the tetrahydrofolate cycle. Customary doses are 1 mg per kg IV every 6 hours.

Because serum methanol levels of 20 mg per dL or higher are associated with toxicity if untreated, higher levels require treatment to prevent its metabolism and/or interventions to enhance its elimination. Ethanol, which has a higher affinity for alcohol dehydrogenase than methanol, may be provided to "block" further production of toxic metabolites. Fomepizole, another alcohol dehydrogenase antagonist, is more expensive than ethanol, but the simplicity of fomepizole therapy has led to its rapid and widespread therapeutic acceptance.

An alcohol dehydrogenase inhibitor should be instituted if the calculated or measured methanol concentration is 20 mg per dL or higher. The loading dose of fomepizole is 15 mg per kg, which may be given IV or orally. The maintenance dose is 10 mg per kg every 12 hours for four doses, then 15 mg per kg every 12 hours thereafter. More frequent dosing is required during hemodialysis.

If fomepizole in unavailable, ethanol is administered with the goal of maintaining serum ethanol concentrations of at least 100 mg per dL. Ethanol may be given by continuous IV infusion (600 mg per kg bolus followed by 110 mg per kg per hour) or by oral administration. During dialysis, ethanol dosing may need to be doubled to maintain sufficient blood ethanol content to effectively block the metabolism of methanol. IV ethanol is preferred but has the problems of being often unavailable and hyperosmolar (precluding its administration in small veins) and of requiring large fluid volumes. When the oral route is used, it must be remembered that proof designation of a beverage is twice the alcohol concentration expressed as a percentage (e.g., 80 proof equals 40% alcohol). Children must be closely monitored for the complications of ethanol administration, including mental status depression, hypoglycemia, and hypothermia.

Hemodialysis should be strongly considered for children with a blood methanol concentration of 50 mg per dL or higher, after alcohol dehydrogenase inhibition has been achieved. When alcohol dehydrogenase is blocked, methanol has a very long time to elimination, primarily via exhalation.

Ethylene Glycol

The ingestion of ethylene glycol, although uncommon, causes significant morbidity and occasional mortality in adolescents and young adults. The toxicity of ethylene glycol, like that of methanol, is the result of drug toxification; ethylene glycol has virtually no toxicity in its parent state. However, metabolism by alcohol dehydrogenase produces several toxic intermediates, including glycolaldehyde, glycolic acid, and oxalate. These metabolites result in severe metabolic acidosis and deposition of calcium oxalate crystals in all vital organs. Therefore, ethylene glycol intoxication is associated with more systemic toxicity than that of methanol poisoning. Also, because ethylene glycol is metabolized more rapidly than methanol (elimination half-life approximately 3 hours), toxicity appears rapidly after ingestion.

The clinical syndrome of ethylene glycol intoxication appears in three different stages. The first stage consists predominantly of CNS manifestations and is accompanied by a profound metabolic acidosis. In this early stage, mild hypertension, tachycardia, and leukocytosis are often present. Nausea and vomiting commonly occur, and with larger doses, coma and convulsions may appear within a few hours. Another common finding is the presence of hypocalcemia. This is believed to result from the widespread formation of calcium oxalate. Hypocalcemia may be severe enough to cause tetany and cardiac conduction disturbances. Urinalysis usually reveals a low specific gravity, proteinuria, microscopic hematuria, and crystalluria. The second distinct state is ushered in by coma and cardiopulmonary failure; it is usually the result of acidosis and hypocalcemia. The third stage usually occurs after 24 to 72 hours. Here, renal failure emerges as the dominant problem. Usually, a picture of acute tubular necrosis develops with either polyuria or anuria. Urine sediment contains blood, protein, and casts. Patients often require dialysis for extended periods and may be left with permanent renal insufficiency.

Consideration of ethylene glycol poisoning should be based either on the history or, in the absence of diabetic ketoacidosis, the presence of any of the following criteria: (i) alcohol-like intoxication without the odor of alcohol, (ii) large anion-gap metabolic acidosis, (iii) an elevated osmolar gap in the absence of ethanol or methanol ingestion, or (iv) a urinalysis that demonstrates oxalate crystals. Another diagnostic tool is to perform a Wood's lamp examination of urine. If the ingested substance is radiator antifreeze, the fluorescein dye that it contains will be excreted in urine and may fluoresce under Wood's lamp. Serum chemistries or blood gas levels should be obtained frequently because of the rapid evolution of metabolic acidosis. The availability of ethylene glycol levels varies by institution.

Activated charcoal negligibly adsorbs ethylene glycol and is unnecessary. As with methanol intoxication, treatment of ethylene glycol poisoning falls into three areas: supportive care,

administration of pharmacologic agents, and enhancement of elimination. Supportive care includes close monitoring of vital signs and anticipation of life-threatening events, particularly cardiac arrhythmias secondary to hypocalcemia. An EKG should be obtained, and the patient should be placed on a cardiac monitor. Intubation and mechanical ventilation should be provided as needed for control of acid–base balance.

Pharmacologic therapy is subdivided into four areas: administration of sodium bicarbonate, calcium, pyridoxine with thiamine, and fomepizole or ethanol. Correction of acidosis should begin immediately with the administration of sodium bicarbonate and appropriate ventilation. Hypocalcemia may present as skeletal muscle disturbances (tetany) or cardiac dysfunction (prolonged Q-T interval). These may be alleviated by the prompt institution of calcium (e.g., 10% calcium gluconate, 0.3 to 0.6 mL per kg). Thiamine and pyridoxine are vitamins that act as cofactors in the nontoxic metabolic pathways of ethylene glycol and, theoretically, divert its metabolism toward formation of nontoxic metabolites. Therefore, thiamine (0.25 to 0.5 mg per kg) and pyridoxine (1 to 2 mg per kg) are recommended for the first 24 hours of treatment.

Fomepizole (or ethanol) administration is an option to inhibit ethylene glycol metabolism by alcohol dehydrogenase (previously discussed under "Methanol"). Inhibition should be initiated as soon as possible to interrupt further formation of organic acids. As with methanol, alcohol dehydrogenase inhibition is indicated for ethylene glycol concentrations of 20 mg per dL or higher. If a serum ethylene glycol cannot be obtained in a timely fashion, it can be estimated by the formula (osmolar gap $\times$ 6), assuming no other alcohols are contributing to the osmolar gap. Hemodialysis is indicated if there is renal failure or severe electrolyte disturbances, regardless of the serum ethylene glycol concentration. Hemodialyis may be considered for patients who are stable hemodynamically but who have very elevated blood ethylene glycol levels. The cost–benefit analysis of hemodialysis versus continued, prolonged fomepizole therapy is currently being investigated; however, recent case reports indicate that fomepizole alone can be effective for ethylene glycol ingestions when the acid–base status and renal function are normal at the time of presentation.

Antihistamines

Antihistamines are used to treat children with allergic diseases, as sedatives and antinauseants, and to prevent motion sickness. They are present in many cough syrups, available both over the counter (OTC) and by prescription. Antihistamines may also be found in combination with analgesics, sympathomimetic amines, and caffeine for the symptomatic relief of the common cold. They are combined with analgesics, such as salicylamide, and an anticholinergic drug, such as scopolamine, for use as a nonprescription sleep medication. Finally, they are included in some liquid cough and cold preparations that may also contain ethanol as the solvent.

Antihistamines may depress or stimulate the CNS. Used therapeutically, CNS depression is most commonly seen as drowsiness or dizziness. With increasing doses, stimulation results in insomnia, nervousness, and restlessness. In antihistamine overdose, the CNS stimulatory effects of the drug predominate. In children, CNS stimulation causes excitement, tremors, hyperactivity, hallucinations, and with higher dosages, tonic-clonic convulsions. Children are also more likely to have signs and symptoms of anticholinergic poisoning: flushed skin, fever, tachycardia, and fixed dilated pupils. The nonsedating antihistamines terfenadine and astemizole (both no longer available in the United States) have caused cardiac arrhythmia after overdose and as a result of drug–drug interactions. Cetirizine, loratadine, and fexofenadine have not produced this complication. Death from antihistamine ingestion in children is usually the result of uncontrolled seizures that progress to coma and cardiorespiratory arrest.

The treatment of antihistamine poisoning requires an accurate history of the time of ingestion and the type and quantity of drug consumed. Of particular importance is the type of drug ingested because numerous sustained-release antihistamine products are available on the market. Options for GI decontamination include the use of activated charcoal, and overdoses with the sustained-release preparations may benefit from WBI.

Patients with seizures (see Chapters 69 and 96) require anticonvulsant therapy immediately. Preferably, short-term control may be gained by using diazepam, in a dose of 0.1 to 0.2 mg per kg IV. Severely agitated patients with a clear anticholinergic toxidrome may have improved sensorium after administration of physostigmine. This is usually administered in an initial dose of 0.02 mg per kg (not to exceed 0.5 mg per dose) IV slowly over 3 minutes. The dose may be repeated every 10 to 15 minutes (adult maximum 2 mg) to establish the effective total dose. This minimal effective dose may be repeated in several hours, if necessary. It should be noted that when administered too rapidly or in too large of a dose, physostigmine might precipitate seizures or asystole. Physostigmine would be particularly dangerous to use in the context of any coingestants that might affect intracardiac conduction, such as tricyclic antidepressants. A 12-lead EKG should be examined for conduction delays before physostigmine is given. Cardiac rhythm should be monitored closely during antidote infusion, and atropine should be available to reverse severe cholinergic effects that may also occur with physostigmine use. The potential risks encountered with physostigmine may favor use of a benzodiazepine for treatment of anticholinergic delirium.

Meticulous attention to supportive care is critical. Some patients may develop extreme hyperthermia and thus require aggressive measures to reduce core body temperature, including ice water baths or misting and fans. There is little evidence for therapeutic efficacy of dialysis or hemoperfusion because of the high plasma protein binding and large volumes of distribution for most of these agents.

Aspirin

Background

Aspirin continues to be a common cause of poisoning in children and adolescents. Salicylism is the result of acute ingestion in about 60% of cases and chronic ingestion in the remaining 40%. Clinical features of acute versus chronic salicylate intoxication often require a different management approach, depending on the manner of intoxication.

Several factors work in concert to make chronic salicylate intoxication so common. The primary factor is aspirin's

elimination pattern. As serum salicylate concentrations increase, the ability of the liver to metabolize the drug diminishes until predictable, first-order elimination kinetics are replaced by unpredictable, dose-dependent, zero-order elimination. Thereafter, increments in dose are associated with disproportionate increases in serum salicylate concentration. Also, much of aspirin elimination is through urinary excretion of unchanged drug. Therefore, in the face of dehydration and decreased glomerular filtration, drug clearance is impaired even more. Finally, because aspirin is often prescribed for illnesses that may be associated with hepatic dysfunction, reduced biotransformation initiates the spiraling increase in serum concentration. Unfortunately, because chronic salicylism is associated with nonspecific symptoms (e.g., fever, vomiting, tachypnea), diagnosis may be delayed until more striking signs of intoxication appear.

Pathophysiology

The direct effects of aspirin on metabolism are multiple. Aspirin stimulates the medullary respiratory center, which leads to tachypnea and respiratory alkalosis—its hallmark. Metabolic disturbances are widespread and include CNS hypoglycemia, as well as abnormalities in lipid and amino acid metabolism. Inhibition of Krebs cycle enzymes and uncoupling of oxidative phosphorylation in conjunction with lipid disturbances create the combined lactic and ketoacidosis responsible for metabolic acidosis (which leads to the mixed respiratory alkalosis and metabolic acidosis found on the arterial blood gas). In addition to inhibiting platelet function, aspirin intoxication is associated with disturbances in vitamin K-dependent and vitamin K-independent clotting factors, resulting in a significant coagulopathy. Mild elevations in liver enzymes are also common. Other features of aspirin intoxication include leukocytosis and electrolyte disturbances, particularly hypokalemia. Physical manifestations include fever, tachypnea, nausea, vomiting, lethargy, slurred speech, and seizures. Children with chronic salicylism are more likely to present with severe metabolic acidosis and seizures than those with acute intoxication.

The combination of respiratory alkalosis with metabolic acidosis produces an arterial blood gas that is almost pathognomonic for salicylism. Serum pH typically ranges from 7.41 to 7.55, except in severe cases in which metabolic acidosis combined with respiratory acidosis from severe CNS depression leads to pH less than 7.35, and P_{CO_2} is generally less than 30 mm Hg. Serum bicarbonate is mildly depressed, often ranging from 15 to 20 mEq per L. However, although adults may continue to hyperventilate for extended periods when poisoned with salicylates, children with mild to moderate poisoning quickly lose this respiratory drive and are more likely to present with metabolic and respiratory acidosis.

As mentioned, glucose homeostasis is seriously altered in acute aspirin poisoning. Early in the course, hyperglycemia usually occurs because of glycogenolysis and decreased peripheral use. Later, hypoglycemia may supervene as glucose stores are depleted. High rates of oxidative metabolism in the CNS may lead to low CNS glucose concentration even in the presence of peripheral hyperglycemia.

Fluid and electrolyte disturbances are multifactorial, resulting in dehydration, hyponatremia or hypernatremia, and hypokalemia. Among contributing factors are increased insensible water losses through both skin and lungs, emesis, and increased renal water and potassium loss. The patient with severe salicylate poisoning may lose 4 to 6 L of water per square meter.

Clinical Findings

The initial clinical signs and symptoms, the estimate of dose ingested, and the measurement of salicylate levels all serve to gauge the severity of a given acute aspirin poisoning. However, in cases of chronic therapeutic salicylism, the clinical picture is the most useful guideline. Because of the nonspecific nature of symptoms with salicylism, the initial differential diagnosis is broad and may include diabetic ketoacidosis, iron intoxication, and ethylene glycol ingestion.

Signs and symptoms of salicylism depend on the method and severity of intoxication. Acute ingestion of amounts of 150 to 300 mg per kg are associated with mild symptoms, 300 to 500 mg per kg are associated with moderate toxicity, and more than 500 mg per kg are associated with death. With mild toxicity (serum concentrations 30 to 50 mg per dL), manifestations may be confined to GI upset, tinnitus, and mild tachypnea. With moderate salicylate poisoning (serum level 50 to 100 mg per dL), more visible signs of toxicity—fever, diaphoresis, and agitation—appear. After severe salicylate poisoning (serum concentrations higher than 100 mg per dL), signs and symptoms are primarily neurologic and consist of dysarthria, coma, and seizures. Pulmonary manifestations, particularly pulmonary edema, may appear in severe cases. In patients of chronic salicylism, these same conditions appear at significantly lower serum salicylate concentrations. Death from salicylism results from severe CNS toxicity with complete loss of function in cardiorespiratory centers, leading to respiratory and/or cardiac arrest. The severity of salicylate intoxication is best assessed by physical examination, electrolytes, and blood gas level analyses rather than through use of a nomogram.

Management

Assessment of the patient of salicylate intoxication begins with an accurate history that identifies the patient as having acute or chronic poisoning. Laboratory assessment is extensive and includes serum salicylate concentration, electrolytes and arterial blood gas levels, liver function tests, CBCs, prothrombin and partial thromboplastin times, urinalysis, and an EKG. In the case of intentional ingestions by adolescents, attention to a serum acetaminophen measurement is important (because many OTC analgesics contain aspirin and acetaminophen in combination).

Supportive care includes assessment of ventilatory function, cardiac monitoring, and vascular access. Because aspirin overdose is associated with delayed gastric emptying and drug coalescence to form bezoars, GI decontamination should receive careful consideration in those patients who present within 4 to 6 hours of ingestion. In patients who present more than 6 hours after ingestion or in those with chronic salicylism, activated charcoal might still be administered because it may enhance postabsorptive elimination of salicylates (through GI dialysis).

Health-care providers are cautioned to be wary of sedating or mechanically ventilating aspirin poisoned patients, as depressing the spontaneous ventilation rate may worsen aspirin-induced neurotoxicity. Specific therapeutic goals in salicylate intoxication include correction of fluid and electrolyte disturbances and the enhancement of salicylate excretion.

Fluid therapy should be aimed at restoring hydration and electrolyte balance, preventing distribution of salicylate to the brain, and promoting renal salicylate excretion. Aggressive restoration of intravascular volume is advisable; however, fluids should be given prudently to prevent precipitation of pulmonary edema, particularly in patients with severe intoxication. The blood pH should be kept alkaline, pH 7.45 to 7.5. For patients with symptomatic salicylate intoxication, urine alkalinization should be combined with fluid resuscitation. The administration of sodium bicarbonate, by increasing urinary pH, ionizes filtered aspirin, increasing tubular secretion and inhibiting its tubular reabsorption (ion trapping). The initial fluid is, therefore, designed to replace both sodium and bicarbonate losses as well as promote urine alkalinization. It should contain 5% dextrose with 100 to 150 mEq per L of sodium bicarbonate. Because hypokalemia impairs the ability of the kidney to create alkaline urine and is exacerbated by administration of sodium bicarbonate, potassium must be added to IV fluids. Forced diuresis does not appear to enhance salicylate excretion more than the clearance accomplished by alkalinization alone. Therefore, fluids are given as needed to restore normal hydration and to produce 1 to 2 mL per kg per hour of urine. Calcium homeostasis should also be monitored during therapy with exogenous bicarbonate. Both urine alkalinization and repetitive oral charcoal (up to every 4 hours) should be continued until salicylate concentration falls below 30 to 40 mg per dL and symptoms resolve.

Salicylate elimination can also be enhanced by hemodialysis or hemoperfusion. Although hemoperfusion results in superior clearance technique, hemodialysis is usually preferred because it permits correction of fluid and electrolyte imbalances. Hemodialysis should be reserved for seriously ill patients. Hemodialysis might be considered for patients with serum salicylate levels higher than 100 mg per dL after acute ingestion or 60 mg per dL or higher after chronic salicylism. Specific indications for hemodialysis include (i) severe acidosis or other electrolyte disturbance, (ii) renal failure, (iii) persistent neurologic dysfunction, (iv) pulmonary edema, and/or (v) progressive clinical deterioration despite standard treatment.

Cardiac Drugs

β-Adrenergic Blockers and Calcium Channel Blockers

The approaches to overdoses of these two categories of cardiovascular agents are discussed together because of similarities of clinical presentation and management approach. They both are commonly prescribed to adult patients with a variety of cardiovascular disorders, including angina and past myocardial infarction, hypertension, and arrhythmias. As such, experience with pediatric overdoses has been increasing in more recent years.

β-Blockers (BBs) vary considerably in terms of receptor specificity and pharmacokinetics, but most overdose experience is with propranolol. Similarly, the calcium channel blockers (CCBs) most commonly used in the United States (verapamil, diltiazem, nifedipine, amlodipine, etc) are chemically dissimilar and have varied degrees of effect on vasodilation, myocardial contractility, and sinoatrial (SA)-atrioventricular (AV) node function.

Both BBs and CCBs may present with fulminant cardiovascular and neurologic findings after a large overdose. Typical presentations of both agents include marked bradycardia and hypotension; particularly with the CCBs, common additional findings are those of abnormal AV node conduction, with AV block or accelerated junctional rhythm. The CNS may also be affected, with coma and/or convulsions that occur in either category of overdoses. Metabolic disturbances include hypoglycemia with BBs and hyperglycemia and metabolic acidosis with CCBs. Bronchospasm may further complicate BB toxicity in patients with underlying reactive airway disease.

Management begins with aggressive gastric decontamination for both types of agents. Activated charcoal/cathartic should be administered to patients presenting soon after ingestion. Sustained-release preparations may cause prolonged effects, and WBI may be considered in this context. Bradycardia and hypotension may improve with standard treatment such as atropine, fluid boluses, and pressors; however, many cases prove resistant to these measures.

Additional therapy includes calcium infusion for the CCBs, with the recommended adult initial dose being 10 mL of 10% calcium chloride or 30 mL of 10% calcium gluconate, which may be repeated two or three times as necessary (e.g., an initial pediatric dose of approximately 0.2 mL per kg calcium chloride or 0.6 mL per kg of calcium gluconate). Serum calcium should be monitored. Glucagon increases intracellular cyclic adenosine monophosphate (cAMP) by a mechanism independent of β receptors and has been used with success to improve heart rate and blood pressure in overdoses of BB agents. The usual adult dosing regimen is 3 to 5 mg by IV bolus, which may be repeated to a total dose of 10 mg, followed by infusion at 2 to 5 mg per hour. Such dosing translates to 50 to 150 μg per kg boluses and similar amounts per hour for pediatric patients.

For hemodynamically significant overdose of a CCB, hyperinsulinemia–euglycemia therapy is currently in favor; this therapy should be guided by a clinician or poison control center consultant familiar with its use. Severe cases may also benefit from pacemaker insertion and consideration of aortic balloon pump and/or cardiopulmonary bypass. (Lipid emulsion infusion has shown promise in animal studies of verapamil toxicity but is unproven in humans as of this writing.) It is unlikely that hemodialysis or hemoperfusion would benefit most of these cases.

Clonidine

Clonidine is an antihypertensive that appears to have growing popularity, part of which comes from its efficacy in illnesses other than hypertension, including nicotine withdrawal and attention deficit disorder. Also, the advent of clonidine in transdermal patches has become a convenient and somewhat unique vehicle for drug administration.

Clonidine exerts its antihypertensive effect through stimulation of CNS α_2-adrenergic receptors. These receptors are located on presynaptic neurons in cardiorespiratory centers of the midbrain. Their stimulation results in decreased secretion of catecholamines into the synaptic cleft, resulting in decreased pulse and blood pressure. In addition, clonidine appears to interact with or modulate CNS opiate receptors; this interaction has been used to explain clonidine's efficacy in opiate withdrawal and the picture of coma and miosis that accompanies

clonidine intoxication. An imidazoline compound, clonidine is related to other medications, including tetrahydrozoline and oxymetazoline—common vasoconstrictors found in nasal decongestants and ophthalmic agents.

Clonidine is an extremely potent drug with typical doses of 100 to 200 μg in adults. Therefore, ingestions of small amounts can potentially lead to significant toxicity in children. Initial toxic manifestations include altered mental status that may range from lethargy to coma. Patients may also develop significant hypothermia. In severe intoxications, coma, miosis, and respiratory depression may appear. The cardiovascular changes that accompany clonidine intoxications may range from profound hypotension and bradycardia to hypertension. Clonidine-induced hypertension occurs uncommonly and is believed to result from α-adrenergic effects at peripheral vascular receptors that override the central, antihypertensive effect. The clinical picture of clonidine intoxication typically lasts 8 to 24 hours.

Management. The treatment of clonidine intoxication requires immediate assessment of the ABCs. Because patients with severe intoxication often have coma and respiratory depression, emergency endotracheal intubation may be necessary. Also, because of blood pressure instability, vascular access should be achieved immediately for better hemodynamic control. Hypotension should be treated with fluids and vasopressors as needed. Hypertension is generally uncommon, is very transient, and would rarely require specific treatment.

Activated charcoal binds clonidine. In addition to supportive care measures, other pharmacologic interventions may be effective. Naloxone has been suggested as a specific antidotal agent after clonidine intoxication, based on case reports of improved mental status and cardiorespiratory function after its administration. However, in reported case series, there have not been consistent improvements after naloxone administration.

Because naloxone is a benign agent and may potentially improve mental status to the extent that intubation becomes unnecessary, a trial dose of 1 to 2 mg should be administered. Large amounts of naloxone (up to 8 mg) must be provided before it can be concluded that the intoxication is not responsive to this therapy. If effective, repeat doses or a continuous infusion of naloxone may be useful. Other pharmacologic agents that have been used include yohimbine, tolazoline, and phentolamine; but specific efficacy from these agents has not been demonstrated, and they are not considered important in the treatment of clonidine intoxication.

Digoxin

Digoxin is still widely used in young infants with congenital heart disease and elderly patients with congestive heart failure. This continued popularity, its narrow therapeutic index, and the appealing color of digoxin elixir make it a source of many childhood poisoning episodes annually. Also, related agents, particularly the foxglove and oleander plants, are occasionally ingested by children, leading to a clinical picture identical to that of digoxin.

Digoxin's primary pharmacologic action is to inhibit activity of sodium-potassium adenosine triphosphatase (ATPase), which is responsible for maintaining the electrical potential of excitable tissues through transmembrane concentration of electrolytes. Therefore, the effects of digoxin are largely related to disturbances in this action.

In all patients of digoxin poisoning, two distinct pictures of toxicity exist: acute and chronic. These pictures have several differences: The patient of acute digoxin ingestion is typically a toddler who ingests a relative's medication. The toddler is generally healthy with no underlying cardiac disease. The child with chronic digoxin poisoning, however, by definition has preexisting heart disease and is likely to be taking other medications known to modulate the effects of digoxin poisoning (e.g., diuretics). Therefore, it is the latter patient who is more likely to have severe toxic manifestations after digoxin intoxication.

Digoxin pharmacokinetics are complex. After ingestion, absorption is complete within 2 to 4 hours. However, after peak serum levels are achieved, the drug is rapidly redistributed, resulting in dramatic falls in serum concentration. This has particular importance with the patient of acute digoxin intoxication who may have an initial serum digoxin concentration (SDC) in the highly toxic range that falls to the therapeutic range within a matter of hours. After redistribution, digoxin elimination occurs primarily through renal excretion of unchanged drug. Therefore, any condition associated with decreased renal function may be associated with the insidious development of intoxication.

The therapeutic SDC is less than 2 ng per mL. A concentration in the slightly higher range often does not correlate with clinical manifestations and may be of limited value. However, when SDC exceeds 4 ng per mL, some evidence of intoxication usually appears. This toxicity is influenced by many host factors, including patient age; underlying illness; and disturbances in serum potassium, magnesium, and calcium.

With significant intoxication, the symptoms of digoxin poisoning include nausea, vomiting, and visual disturbances. With more severe intoxication, additional symptoms, including lethargy, disorientation, electrolyte disturbances, and cardiac disturbances, appear. The hallmark of severe acute digoxin toxicity is hyperkalemia, the result of profound inhibition of sodium-potassium ATPase activity. The typical pattern of cardiac toxicity with digoxin overdose initially is prolonged atrioventricular dissociation that appears as heart block that ranges from first to third degree. These conduction disturbances can lead to the development of ventricular or supraventricular escape rhythms. In patients with chronic digoxin intoxication, these symptoms may be more striking than in those with acute, single digoxin overdoses. In fact, children with acute digoxin intoxication rarely develop life-threatening illness if their peak SDC remains below 10 ng per mL.

Management. The management of the patient with digoxin intoxication begins with evaluation of the vital signs, particularly hemodynamic status. Patients should have an EKG performed, followed by continuous cardiac monitoring. If significant cardiac arrhythmias are already present, they are treated initially according to advanced cardiac life support protocols.

GI decontamination should include administration of activated charcoal. Clinical assessment typically includes an EKG, electrolytes (including magnesium and calcium) level, urinalysis, and SDC. Electrolyte disturbances should be treated aggressively because they will aggravate any digoxin-induced arrhythmias.

Digoxin-specific antibody fragments have become specific antidotal therapy for reversing the toxic manifestations. These

fragments are the result of sheep-derived immunoglobulin that is cleaved to extract only the Fab fragment. This low-molecular-weight antibody fragment is capable of avidly binding free digoxin so a gradient results that favors digoxin removal from receptor sites into interstitial water. The effect of this gradient is that sodium-potassium ATPase function is immediately restored. The digoxin–antibody complex is then rapidly excreted in the urine. Of note, after digoxin antibody fragments are administered, SDC increases astronomically, reflecting bound, inactive digoxin that has diffused into the vascular compartment.

These antibody fragments are indicated in the following circumstances after digoxin poisoning: (i) progressive signs and symptoms of intoxication, (ii) life-threatening cardiac arrhythmias, or (iii) severe hyperkalemia (defined as a serum potassium level of 5.5 mEq per L or higher). The dose of antibody fragments is calculated on the basis of ingested digoxin dose (in the case of acute intoxication) or on the basis of SDC (in the case of chronic intoxication). Each 40-mg vial of digoxin-Fab will bind 0.6 mg of digoxin. The total dose of Fab needed (in vials) may be estimated by dividing a known ingested dose by 0.6, or calculated for the steady-state context as body load of digoxin:

$$\text{No. of vials} = \frac{\text{SDC (ng/mL)} \times \text{wt (in kg)}}{100}$$

Complications from the administration of antibody fragments are low and consist of an allergic reaction (in approximately 0.6% of patients), precipitation of congestive heart failure (secondary to the abrupt loss of digoxin's inotropic action), and rebound hypokalemia. These complications should be anticipated and treated accordingly. Infusions should be given over 30 minutes, and some prefer to use a 0.22 μm in-line filter. If the patient is in cardiac arrest, the antibody fragments may be infused over 5 minutes.

Disc Batteries

The development and widespread use of disc batteries in home toys and appliances has led to a burgeoning increase in the rate of disc battery ingestions in young children. A somewhat unusual feature of these ingestions is the frequency among children 4 to 8 years of age who often ingest them inadvertently or out of curiosity. Children with hearing aids form another group at particular risk.

Disc batteries contain a number of potentially toxic substances, including mercury, lithium, and potassium hydroxide. However, their toxic potential is primarily confined to their corrosive action when they are in contact with a mucosal surface for an extended time. Thus, disc batteries that are placed in nasal or aural cavities should be removed immediately.

With the history of disc battery ingestion, all patients should receive an immediate chest radiograph. This is because disc batteries that are retained in the esophagus act as local corrosives, leading to esophageal injury or perforation. If the disc battery is found in the esophagus, it must be removed immediately. If the battery is beyond the esophagus, the patient may be discharged and followed as an outpatient.

The natural history of disc battery ingestion is that the object is usually expelled within 72 hours of ingestion without inducing symptoms. Therefore, the treatment of these ingestions involves no intervention. Rather, parents are asked to monitor stools for 3 days to document passage of the battery. In the event the battery is not passed within that time, an abdominal radiograph might be obtained to confirm that the battery has not been incarcerated in a bowel loop. If the battery is still in the gut, there is continued observation. Surgical removal of these objects is almost never necessary.

Foods/Fish

In addition to drugs and medications and household products and plants, toxic ingestions may occur through normal diet when the ingested product contains a toxin that is preformed by microorganisms. The largest class of such toxins is the enterotoxins produced by organisms that include *Shigella, Salmonella, Yersinia, Escherichia coli, Staphylococcus, Bacillus cereus, Clostridium, Vibrio,* and *Clostridium botulinum*. After this large group of toxins, the next most common cause of foodborne intoxications results from the ingestion of contaminated marine life.

The general approaches to the patient with diarrhea and infectious causes of the gastroenteritis syndrome are discussed in Chapters 18 and 89, respectively. The association of hemolytic-uremic syndrome with GI infection by *E. coli* O157:H7 is discussed in Chapters 89 and 100. Plant toxicity is discussed later in this chapter, under its own heading. Here, the common causes of acute bacterial toxin-induced food poisoning are outlined, followed by a discussion of marine-related illness.

When similar GI symptoms occur in a group of persons who share the same meal or the same food on separate occasions, the emergency physician may consider the possibility of foodborne disease. Detailed epidemiologic investigations are usually beyond the capacity of the ED setting, but the hospital infection control officer and/or local health department can often be helpful.

Staphylococcal food poisoning is probably the most common cause of such cases in the United States. The heat-stable toxins typically produce acute abdominal pain, nausea, vomiting, and diarrhea within 1 to 6 hours of eating the contaminated meal. The illness is usually self-limiting, although occasionally, patients develop severe symptoms and dehydration.

Other bacterial toxin-induced diarrheal food poisonings include those secondary to *Bacillus cereus, Clostridium perfringens*, and *Vibrio* species. The onset of clinical illness and usual food sources of these and staphylococcal disease are outlined in Table 102.12. All these illnesses are generally self-limiting, and treatment is supportive, with careful attention given to fluid and electrolyte status in unusually severe cases (e.g., the rare occurrence of cholera in the United States).

Infant botulism shares many pathophysiologic and clinical features with foodborne botulism (it is discussed in detail in Chapter 96). The etiology of the foodborne disease differs, of course, in that preformed toxin is ingested at the time of consuming contaminated food, typically improperly home-canned, low-acidity vegetables (e.g., potatoes, onions, beans) or poorly refrigerated pot pies or meats. The incubation period is usually 12 to 36 hours, with initial GI symptoms soon followed by weakness, malaise, and then cranial nerve symptoms, particularly diplopia, dysphagia, and dysarthria. The neurologic examination is notable for normal mental status

TABLE 102.12

COMMON CAUSES OF DIARRHEAL FOOD POISONING IN THE UNITED STATES

Organism	Onset (h)	Effect of heat	Typical sources
Staphylococcal	1–6	Stable	Meats, potato/egg salads, cream-filled desserts
Bacillus cereus			
Emetic type	1–6	Stable	Fried rice
Diarrheal type	12–16	Labile	Cooked meats
Clostridia	12–24	Spores, stable Toxin labile	Meats/poultry[a]
Cholera/other *Vibrio* spp.	12–24	Toxin labile	Raw shellfish

[a]In context of inadequate refrigeration.

and symmetric ocular findings, such as ptosis, lateral rectus weakness, and pupillary abnormalities.

Diagnosis should be suspected clinically and may be buttressed with positive serum or stool analyses for botulinum toxin and suggestive electromyelograph findings. The management of foodborne botulism shares with infant botulism the requirement for meticulous, intensive supportive care, with special attention to airway and ventilatory status. In addition, unlike the case in infant botulism, administration of bivalent antitoxin is recommended for all symptomatic patients. This antitoxin and details regarding its optimal use are available from the Centers for Disease Control and Prevention, which should be contacted through a state health department.

Scombroid Poisoning

Scombroid poisoning is an intoxication that occurs shortly after ingestion of spoiled fish from the Scombroidea family (e.g., tuna, bonita, skipjack), as well as ingestion of non-Scombroidea fish (e.g., bluefish, mahi mahi). The ingested toxin(s) has not been completely characterized, but large quantities of histamine-like compounds are invariably found in these fish when tissue histidine decomposes.

The clinical picture of scombroid poisoning consists of sudden-onset headache, facial flushing, a peppery taste in the mouth, dizziness, nausea, and vomiting. An urticarial eruption with pruritus may develop. In its extreme, patients may develop tachycardia, bronchospasm, respiratory distress, and hypotension.

In patients with severe symptoms, treatment is directed toward ensuring adequate ventilation and hemodynamic stability. Fluids and vasopressor support may be needed to treat hypotension. Pharmacologic treatment of scombroid poisoning includes administration of antihistamines, corticosteroids, and if necessary, adrenergic agents. Both diphenhydramine and cimetidine have been used successfully to treat the symptoms of scombroid poisoning. In the event of severe bronchospasm, other bronchodilators, including inhaled β_2 agonists may be necessary adjuncts.

Ciguatera

Ciguatera is an illness endemic to the South Pacific but is considerably less common in the continental United States, where it is largely confined to the lower Atlantic states. However, because it does occasionally appear in the United States or may occur in recent visitors from endemic areas, its clinical manifestations should be recognized.

Ciguatera results from ingestion of a toxin elaborated by the dinoflagellate, *Gambierdiscus toxicus*. This parasite is ingested by small fish, which begin to concentrate the toxin. As predators ingest those small fish, the toxin ascends the food chain until ingested by humans. The fish that most commonly harbor ciguatoxin include barracuda, grouper, red snapper, and parrot fish. The physiologic actions of ciguatoxin are primarily neurologic. The toxin decreases CNS concentrations of γ-aminobutyric acid (GABA) and dopamine. This action occurs in conjunction with sodium channels being "locked open," permitting unrestricted sodium ingress.

The clinical picture of ciguatera poisoning begins 4 to 36 hours after ingestion of contaminated fish. After a brief period of nausea and vomiting, patients develop paresthesias, particularly perioral, or weakness. A hallmark of ciguatera toxin is the reversal of hot–cold sensation. In severe cases, CNS dysfunction, including coma, may appear. Toxic manifestations may persist for days to months after significant exposure.

The diagnosis of ciguatera intoxication is clinical, based on the history of ingestion of a fish known to carry this toxin. Because symptoms appear many hours after ingestion of contaminated fish, there is no clear role for GI decontamination.

Management of ciguatera is supportive. Primary attention should be paid to CNS status and its effects on airway and ventilation. IV mannitol has shown great promise in reversing many of the neurologic manifestations, particularly coma. It is administered in a dose of 0.5 to 1 g per kg via an in-line filter.

Paralytic Shellfish Poisoning

The dinoflagellate *Gonyaulax* is responsible for elaborating the toxin (saxitoxin) that causes paralytic shellfish poisoning (PSP). The name "red tide" is based on the characteristic red pigment of the *Gonyaulax*. PSP appears in large bloom between the months of May and October and is found primarily along the eastern seaboard (although blooms have increased across the world in more recent years and may be found on either U.S. coast). The animals that ingest and concentrate this toxin are primarily bivalve shellfish, including

mussels, clams, oysters, and uncommonly, scallops. The toxin, saxitoxin, is capable of reversibly binding neuronal sodium channels, resulting in depolarization disturbances. The toxin is heat stable.

After ingestion of contaminated shellfish, patients quickly develop GI distress with nausea and vomiting. This is followed by generalized paresthesias, cranial nerve disturbances, and weakness. In severe intoxications, cardiorespiratory failure may ensue.

Treatment of PSP is supportive. Patients may require ventilatory support until the intoxication resolves over hours to days.

Household Cleaning Products and Caustics

Household Cleaning Products

Background. Until the early 1950s, cleaning products used for home laundering, household maintenance, and personal hygiene were usually some form of soap. However, soap has the disadvantage of forming an insoluble precipitate that clings to surfaces such as skin, bathtubs, clothes, and dishes. Most products today use synthetic detergents that do not form such precipitates. Soap is one type of surface-active agent (surfactant). A "detergent" is any cleansing product. However, in common use, the word *detergent* has come to mean a household cleaning product that is based on nonsoap surfactants, used mainly for laundering and dishwashing. Other cleaning products include disinfectant cleaners; cleaners for drains, ovens, and toilet bowls; bleaches; and ammonia. These agents are of concern because their accessibility to children makes them commonly involved in human ingestions. Furthermore, animal studies and clinical observations have shown some of these products to be injurious after topical applications.

Each year, about 8% of reported pediatric exploratory ingestions involve household cleaning substances. Most of these cases involve children younger than 5 years, of whom only 1% to 2% of those ingesting noncorrosive products are hospitalized. Most such exposures occur inside the home while the product is in use. In almost half of these cases, the product had been transferred out of its original container, often unfortunately, to an empty glass or soda bottle.

Caustics

Background and Pathophysiology. Many agents possess corrosive potential when they are placed in direct contact with biological tissues.

These agents, collectively referred to as *corrosives*, may be acidic, alkaline, or rarely, have neutral pH (e.g., silver nitrate, concentrated hydrogen peroxide). Essentially all corrosives found in the home are acids or alkalis. Strong alkalis and acids cause direct destruction of tissue but with differing histopathologic patterns. Acids produce coagulation necrosis that usually causes superficial damage, rather than deep, penetrating burns. Alkalis, in contrast, cause a deep and penetrating liquefaction necrosis, which often has severe consequences, such as esophageal perforation. Such deep burns are often associated with severe scarring and, ultimately, with stricture formation (Fig. 102.3). Acid corrosives include the mineral acids, such as hydrochloric, sulfuric, nitric, and hydrofluoric acids. Common household products that contain acid corrosives include toilet bowl and drain cleaners. However, many home incidents involve acids brought home (often in unmarked food containers) by parents from the workplace.

FIGURE 102.3 Barium swallow radiograph demonstrating esophageal stricture in a boy subsequent to ingestion of drain cleaner.

Alkali caustics are found in several household products. Sodium hydroxide (lye), which is available in crystalline and liquid forms, is used primarily as an oven cleaner or drain pipe cleaner. Other products may contain alkaline corrosives, including powdered laundry and dishwasher detergents.

Clinical Findings. Ingestions of acid and alkali corrosives cause immediate severe burning of exposed surfaces, usually with intense dysphagia. Associated glottic edema may cause airway obstruction and asphyxia. Severe acid ingestions most often cause gastric necrosis and may be complicated by gastric perforation and peritonitis. With alkalis, severe damage is more commonly found in the esophagus; deep-tissue injury may quickly lead to esophageal perforation, mediastinitis, and death. As already noted, alkalis also produce severe esophageal strictures in survivors.

Management. The initial step in the management of a caustic ingestion is to determine whether the agent is, in fact, corrosive and, if so, whether it is an alkaline or acid corrosive. Many products that are believed to have corrosive potential (e.g., household bleach) are simple irritants and do not require intervention. Identification of ingredients and their corrosive potential can be found through consultation with a regional poison control center.

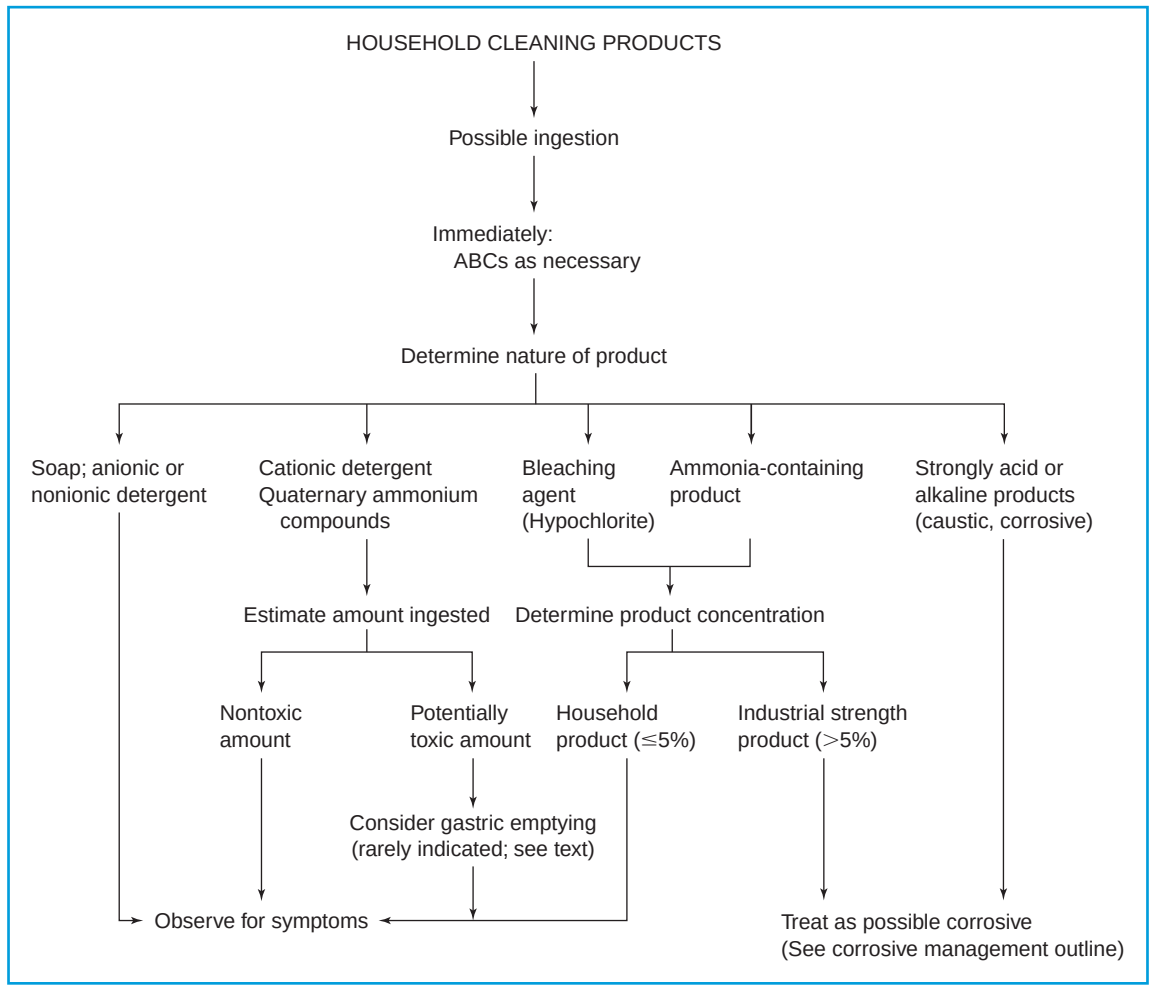

FIGURE 102.4 Algorithm for management of household cleaning product ingestion. ABC, airway, breathing, circulation. (Modified with permission from Temple AR, Lovejoy FH Jr. *Cleaning products and their accidental ingestion*. New York, NY: Soap and Detergent Association, 1980.)

The approach to management of cleaning products and caustic ingestions, as outlined in Figs. 102.4 and 102.5, begins with rapid clinical assessment of cardiorespiratory function, neurologic status, and evidence of GI hemorrhage. Life support measures may be needed emergently to secure the airway and to treat shock or metabolic acidosis. As noted previously, most patients with significant exposures develop symptoms early and may appear critically ill. However, even patients with minimal symptoms and the absence of oral lesions may have significant esophageal injury; thus, all patients with a convincing history of significant exposure to a caustic substance merit esophagoscopy to be evaluated fully for the presence of esophageal burns.

Simple dilution has been suggested as being safe and potentially diagnostic. However, there are several reasons why this should only be recommended as first aid in mildly symptomatic children. First, in the event esophageal injury or perforation has occurred, fluids may extravasate, inducing severe mediastinitis. Also, because esophagoscopy is the diagnostic procedure of choice in establishing the extent of injuries, an empty stomach is necessary for minimizing the risks of anesthesia. Finally, if administered fluids are alkaline or acidic, an exothermic reaction may occur that also can worsen esophageal injury. No GI decontamination is conducted after the ingestion of corrosive agents.

If the eyes are involved (something that should always be considered if a caustic has splashed on the face), copious irrigation should be provided and carried out for at least 15 minutes, with longer periods for crystalline caustics. The physician should perform pH testing of fluids in the ocular cul-de-sac after irrigation to confirm that corrosives have been neutralized; the normal pH of tears is 7. Alkali eye injuries require urgent ophthalmologic consultation. Skin contamination also deserves prolonged rinsing with water and removal of contaminated clothing. Irrigation should continue until the skin is free of alkali, as determined by disappearance of the soapy sensation.

The next phase of management calls for further evaluation. All exposed surfaces, especially the oropharynx, should be examined scrupulously. A CBC and chest radiograph should be obtained; the latter particularly if any respiratory signs or symptoms are noted. Immediate referral should also occur.

Analgesic therapy may be necessary for severe pain. An IV line should be established if not previously done for basic life support. Conflicting data regarding the role of corticosteroids in the treatment of corrosive esophageal injury exist.

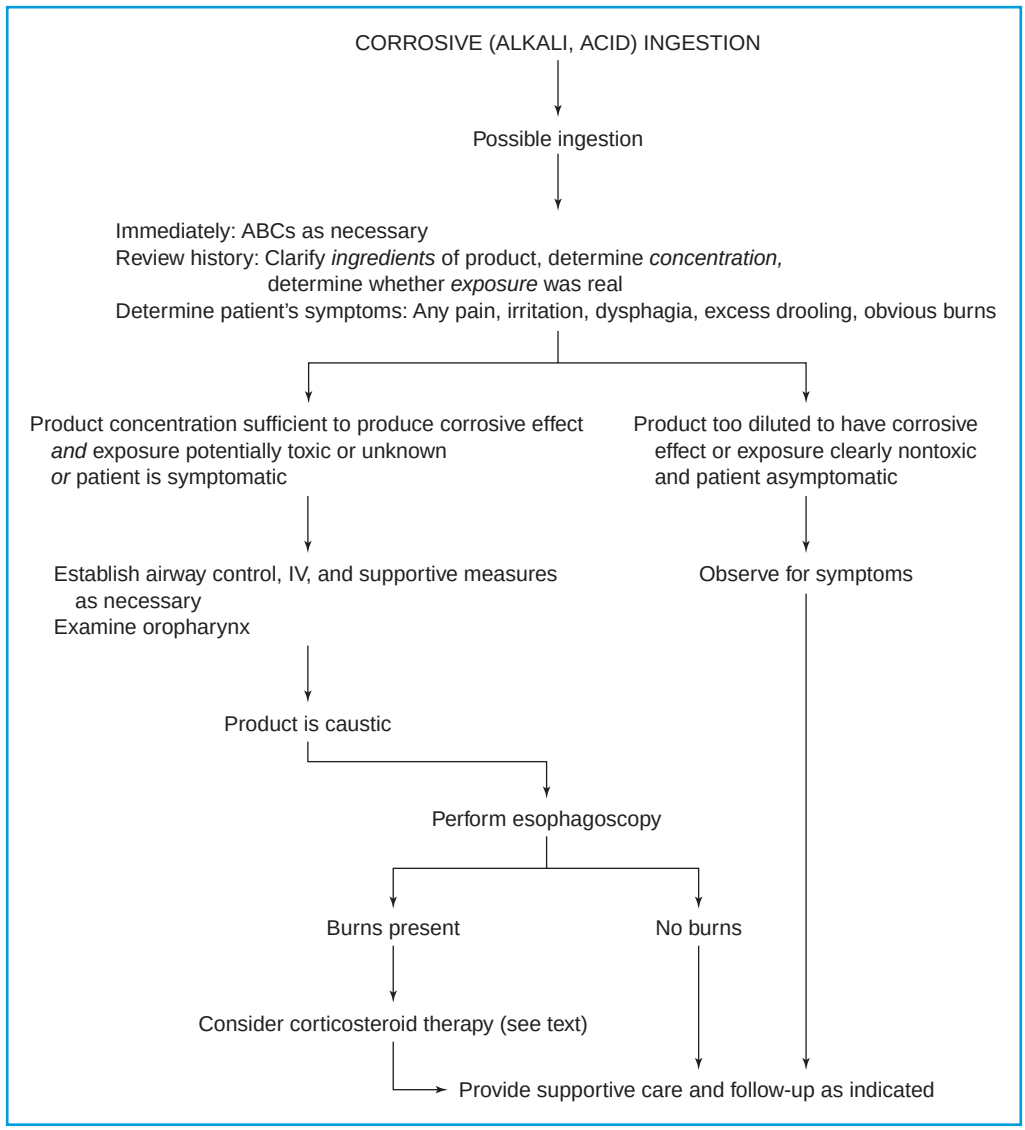

FIGURE 102.5 Algorithm for management of corrosive ingestion. ABC, airway, breathing, circulation; IV, intravenous. (Modified with permission from Temple AR, Lovejoy FH Jr. *Cleaning products and their accidental ingestion*. New York, NY: Soap and Detergent Association, 1980.)

First-degree burns typically heal without long-term sequelae. Circumferential second-degree burns may be less likely to stricture after steroid administration; therefore, corticosteroids with empiric antibiotics may be considered in this scenario. Third-degree burns are likely to scar despite treatment, and administration of steroids in this situation may provide more risk than benefit. The consulting otolaryngologist or surgeon may elect to administer steroids in select patients on the basis of endoscopic findings. All patients are admitted for supportive care and monitoring for acute complications such as mediastinitis, pneumonitis, and peritonitis.

The long-term management of survivors with severe caustic esophageal burns and stricture formation is complex, involving many surgical, medical, and psychologic stresses to the patient. Years of repeated bougienage may be necessary, and some patients will require esophagectomy with colonic interposition in an effort to replace the destroyed esophagus. The patient may be incapable of tolerating solid foods for prolonged periods.

Hydrocarbons

Hydrocarbons are carbon compounds that become liquid at room temperature. The term *hydrocarbons* is somewhat confusing and is often used interchangeably with the term *petroleum distillates*. However, whereas all petroleum distillates are hydrocarbons, not all hydrocarbons are petroleum distillates (e.g., pine oil). Hydrocarbons can be found in solvents, fuels, household cleaners, and polishes.

Hydrocarbons are typically divided into three categories: the aliphatic hydrocarbons, the aromatics, and the "toxic" hydrocarbons. The aliphatic hydrocarbons are petroleum distillates and are found in such household products as furniture

polish, lamp oils, and lighter fluids. The aromatic hydrocarbons are cyclic structures and include toluene, xylene, and benzene. These agents are found in solvents, glues, nail polish, paints, and paint removers. The "toxic" hydrocarbons consist of a broad class of substances that possesses no specific profile of toxicity. These agents include halogenated hydrocarbons and hydrocarbons that serve as vehicles for toxic substances such as pesticides.

The major toxicity of hydrocarbons varies from class to class. However, the feature that these agents have in common is a low viscosity and surface tension that permits them to spread freely over large surface areas, such as the lungs, when ingested. This property (plus their solvent actions) leads to a necrotizing, potentially fatal chemical pneumonitis (Fig. 102.6) when these compounds are aspirated. The high volatility of these substances is responsible for alterations in mental status, including narcosis, inebriation, and frank coma. In addition to these toxicities, the solvents possess additional toxicities (see "Inhalants" section), including the risk of bone marrow injury (in the case of benzene). Finally, with the toxic hydrocarbons, additional toxicities may occur as a result of actions such as cardiotoxicity or as a result of the pharmacologic properties of the other agents contained within these compounds. The major toxicity of hydrocarbons is classified in Table 102.13.

The amount of a hydrocarbon that has been ingested by a pediatric patient is often difficult to quantify. However, any degree of aspiration results in signs, including coughing, gagging, or tachypnea. Less than 1 mL of some compounds, when aspirated directly into the trachea, may produce severe pneumonitis and eventual death. When ingested, these compounds are poorly absorbed from the GI tract.

The major aspiration hazard associated with hydrocarbons can be quantified by their viscosity. Products with a viscosity of 150 to 250 Saybolt seconds units (SSU), such as oils, pose a small risk of chemical pneumonitis; those with a viscosity less than 60 SSU, such as furniture oils or polishes, have a high aspiration hazard.

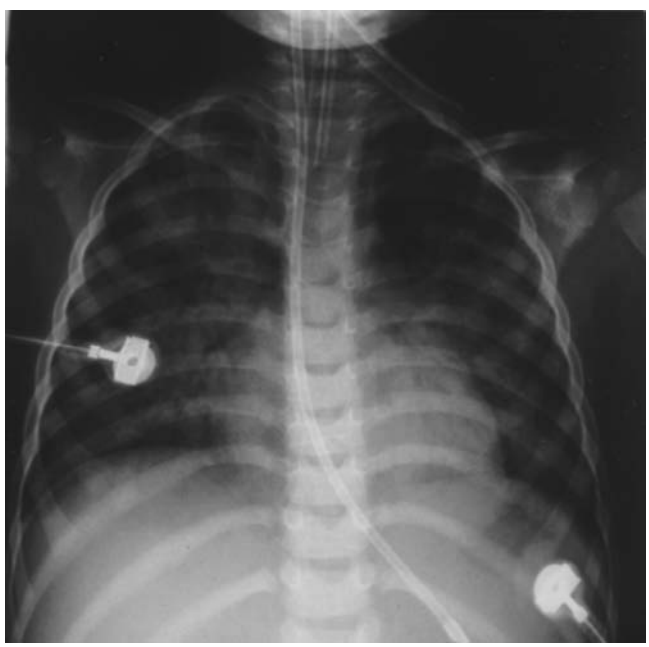

FIGURE 102.6 Chest radiographic findings in a young girl subsequent to lamp oil ingestion.

TABLE 102.13

CLASSIFICATION OF HYDROCARBONS

Nontoxic (Unless Complicated by Gross Aspiration)
Asphalt, tars
Mineral oil
Liquid petrolatum
Motor oil, axle grease
Baby oils, suntan oils

Systemic Toxicity
Halogenated (carbon tetrachloride, trichloroethane)
Aromatic (benzene, toluene, xylene)
Additives (camphor, organophosphates, heavy metals)

***Aspiration Hazard* (Without Significant Systemic Toxicity Unless Ingested in Massive Quantity)**
Lamp oil/torch oil
Turpentine
Gasoline
Kerosene
Mineral seal oil (furniture polish)
Charcoal lighter fluid
Cigarette lighter fluid
Mineral spirits

Clinical manifestations of hydrocarbon ingestion depend largely on the specific profile of toxicity of the ingested substances. These agents cause significant GI irritation that may be associated with nausea and bloody emesis. CNS effects may range from inebriation to coma. Hemolysis with hemoglobinuria has been reported after significant ingestions. Finally, hydrocarbon ingestion may be associated with the development of fever and leukocytosis in up to 15% of patients in the absence of clinically evident pneumonitis.

Because most hydrocarbons cause clinical toxicity only when aspirated, the mainstay of treatment is to leave ingested compounds in the gut (when possible) and to prevent emesis or reflux. Gastric emptying is generally reserved only for those compounds with the potential for systemic toxic effects (Table 102.13). These compounds include the halogenated hydrocarbons (e.g., trichloroethane, carbon tetrachloride) and aromatic hydrocarbons (e.g., toluene, xylene, benzene). In addition, some petroleum distillates contain dangerous additives, such as heavy metals or insecticides.

Patients who have aspirated may exhibit immediate choking, coughing, and gagging as the product is swallowed and then vomited after ingestion. Aspiration of the product may also occur at the time of the initial swallowing. ED management of these patients is outlined in Fig. 102.7. If the patient has any cough or respiratory symptoms upon arrival to the ED, a chest radiograph should be obtained immediately. Because there is a gradual evolution of abnormal radiographs, an initially negative chest radiograph should be repeated at 4 to 6 hours after ingestion. All patients with abnormal chest radiographs or persistent respiratory symptoms after 4 to 6 hours of ED observation warrant futher medical observation. Patients who are asymptomatic after this period of observation may be discharged. Because pneumonitis occasionally appears

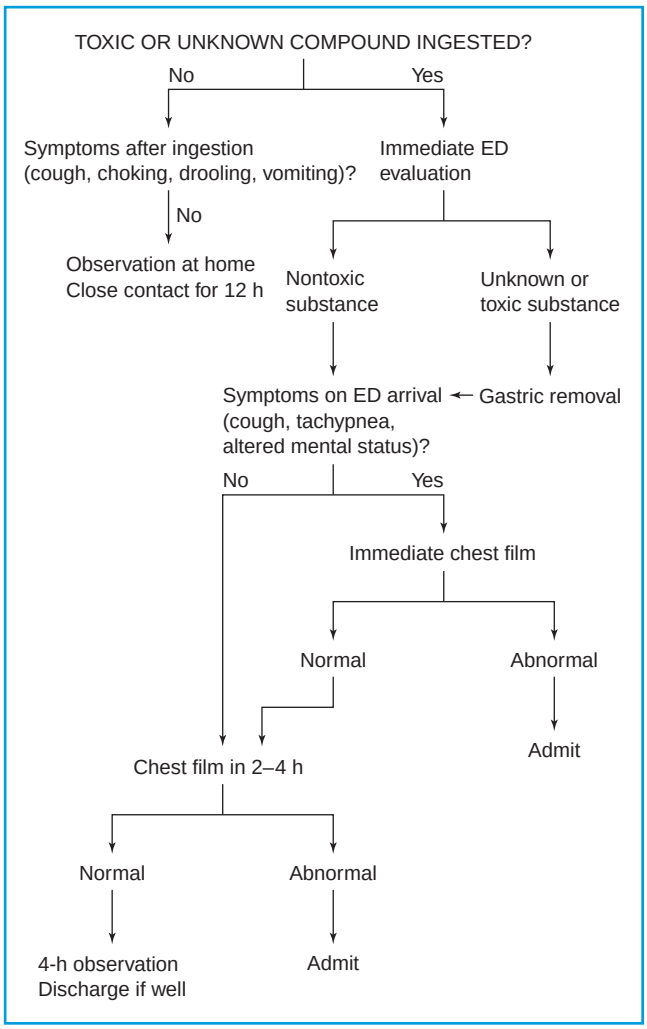

FIGURE 102.7 Management of petroleum distillate ingestion. ED, emergency department.

12 to 24 hours after exposure, detailed instructions should be provided for warning signs of respiratory dysfunction.

Treatment of hydrocarbon pneumonitis consists of airway control if there is mental status depression and mechanical ventilation if ventilation is impaired. Adult respiratory distress syndrome may ensue, and heroic measures such as extracorporeal membrane oxygenation have been successfully employed. Antibiotics should not be used prophylactically but should be reserved for specific infections if they develop. The use of corticosteroids in the treatment of aspiration from hydrocarbons has been associated with increased morbidity and is not recommended. In the event of hypotension or bronchospasm, epinephrine is contraindicated because hydrocarbons are known to cause ventricular irritability and predispose to fibrillation, an effect that is exacerbated by catecholamines.

Iron

Background

In the 1990s, iron poisoning was one of the most common, potentially fatal intoxications in children. Most serious childhood poisonings result from ingestion of prenatal vitamins or ferrous sulfate tablets (which unfortunately often look much like candy) that were intended for adults. A common scenario is that the patient is a toddler whose mother has just had a new baby; the increased demands on the mother's attention and almost universal prescription of iron to postpartum women combine to set the stage for this ingestion. In addition, numerous exposures result from ingestion of iron-fortified children's vitamins, but these tend to be far less toxic.

Sufficient data to define a safe lower limit for toxic iron ingestions are not available. As little as 20 mg per kg of elemental iron has caused toxicity, whereas ingestions of more than 50 mg per kg often produce toxic effects. Of course, it is often impossible to know the exact number of tablets ingested. As few as ten 300-mg $FeSO_4$ tablets have been fatal to a young child. Furthermore, the elemental iron content of whole bottles of chewable vitamins is usually about 1,200 mg. Industry standards typically lead to the use of child resistant caps for vitamin bottles that contain more than 250 mg of elemental iron. Unit dose (blister) packaging has been advised for pills with high iron content. These measures have led to a dramatic reduction in deaths due to exploratory iron poisoning.

Pathophysiology

Iron toxicity results from direct caustic effect on the GI mucosa and the presence of free iron in the circulation. Pathologic changes include hemorrhagic necrosis of stomach and intestinal mucosa and lesions in the liver that range from cloudy swelling to areas of complete necrosis. Occasionally, pulmonary congestion and hemorrhage are noted. Excess free iron is believed to act as a mitochondrial poison, particularly in the liver, with resulting changes in cellular energy metabolism and the production of metabolic acidosis.

Clinical Manifestations

The clinical effects of iron poisoning are classically divided into four phases. Phase I represents the effects of direct mucosal injury and usually lasts 6 hours. Vomiting, diarrhea, and GI blood loss are the prominent early signs; when severe, the patient may lapse into early coma and shock caused by volume loss and metabolic acidosis.

Phase II, which lasts from 6 to 24 hours after ingestion, is marked by diminution of the GI symptoms. With appropriate therapy to replace fluid and/or blood losses, the child may seem relatively well and often goes on to full recovery without any subsequent symptoms. However, this remission may be transient and may be followed by phase III, characterized by metabolic acidosis, coma, seizures, and intractable shock. This phase is believed to represent hepatocellular injury with consequent disturbed energy metabolism; elevated levels of lactic and citric acids are noted in experimental iron poisoning before cardiac or respiratory failure occurs. Jaundice and elevated transaminases are noted in this phase. A phase IV has been described in survivors of severe iron poisoning, marked by pyloric stenosis that results from scarring and consequent obstruction.

Laboratory abnormalities often associated with severe iron intoxication include metabolic acidosis, leukocytosis, hyperglycemia, hyperbilirubinemia and increased liver enzymes, and a prolonged prothrombin time. If fluid loss is significant, there will be hemoconcentration and elevated BUN. Abdominal films may show radiopaque material in the stomach, but the absence of this finding does not indicate a trivial ingestion.

Management

All children alleged to have ingested iron are potentially at significant risk for life-threatening illness. However, severe iron poisoning is uncommon compared with the number of children who develop only mild symptoms or remain entirely asymptomatic. Thus, the emergency physician needs an approach that encompasses the response to the severely poisoned child and to most who will remain well.

As noted earlier, the amount of iron ingested is often hard to quantify, and minimal "safe" amounts are not well established. Serum iron levels have been shown to correlate with the likelihood of developing symptoms (usually a reflection of the serum iron that exceeds the iron-binding capacity and results in free-circulating iron). Usually, when drawn 3 to 5 hours after ingestion, iron levels lower than 350 μg per dL predict an asymptomatic course. Patients with levels in the 350 to 500 μg per dL range often show mild phase I symptoms but rarely develop serious complications. Levels higher than 500 μg per dL suggest significant risk for phase III manifestations. However, the serum iron determination is not always available on a stat basis.

Although serum iron levels are useful, toxicity from iron overdose remains a clinical diagnosis. Ill patients require vigorous hydration and support. Children who are completely asymptomatic 6 hours after ingestion are unlikely to develop systemic illness. Among laboratory studies, the presence of metabolic acidosis or acidemia probably best correlates with toxicity. Radiopaque material on abdominal radiograph also suggests potential for significant absorption of iron (Fig. 102.8). Measurement of the total iron-binding capacity is no longer believed to be useful in acute management. With these observations in mind, it is possible to construct a protocol for the triage and initial management of the patient who has ingested a possibly toxic amount of iron (Fig. 102.9).

Categorization

Patients who arrive with severe early symptoms, including vomiting, diarrhea, GI bleeding, depressed sensorium, or circulatory compromise merit urgent, intensive treatment in the ED. The first priority is to obtain venous access. Simultaneously, blood is drawn for CBC, blood glucose, electrolytes, BUN, liver function tests, serum iron, and type and cross-match analyses. GI decontamination is begun as detailed in the following section. Blood pressure should be supported with normal saline. Specific chelation therapy with IV deferoxamine is begun immediately in all severely poisoned patients. An abdominal radiograph should be obtained as soon as possible after GI decontamination to determine its efficacy and to investigate for the presence of iron pill concretions.

Patients with only mild vomiting and diarrhea in the early postingestion period still need urgent treatment but usually do well. Again, GI decontamination strategies should be promptly addressed. Blood studies, as previously noted, are drawn, and parenteral deferoxamine therapy is begun.

If serum iron levels are available, blood should be sent for this study, an abdominal radiograph should be obtained, and the patient should be observed for 6 hours. An iron level of less than 350 μg per dL taken 3 to 5 hours after ingestion in an asymptomatic patient with a normal radiograph suggests that the patient is at minimal risk and may be discharged. Iron levels higher than 500 μg per dL, the development of any symptoms, or a positive radiograph should lead to admission and management as previously described for the mild to moderately ill patient.

When serum iron levels are not available on an emergency basis, clinical decisions must be made based on symptoms, electrolytes, and abdominal radiography. Patients are observed for 6 hours in the ED. Those who have normal screening tests and remain asymptomatic may be discharged. Patients with abnormal screening laboratory tests should have an iron level sent for later reference. Acidotic or symptomatic patients should be admitted and treated with deferoxamine. Patients asymptomatic after 6 hours may be discharged.

Treatment

The treatment for acute iron poisoning includes efforts to decrease absorption and hasten excretion, as well as appropriate supportive care.

Most children with toxic iron exposures will exhibit spontaneous vomiting. Administration of ipecac may interfere with the clinical interpretation of early signs of iron toxicity, as detailed previously. Activated charcoal is not effective in binding iron salts. For serious poisonings, gastric lavage with normal saline can be considered in patients who present early, in the hope of minimizing any direct mucosal injury caused by residual particulate matter and possibly contributing to the dissolution of pill concretions.

The mainstay of GI decontamination currently for iron-poisoned patients is the early and aggressive use of WBI. This approach is believed to be effective in decreasing iron absorption and in breaking up pill concretions that might be a risk for direct mucosal injury. As noted previously, an abdominal radiograph should be obtained early in the evaluation of symptomatic patients. If this study demonstrates significant radiopaque material and the patient's condition allows it, WBI should be instituted for at least 4 to 6 hours. A few hours of WBI (until rectal effluent is clear) may be indicated in symptomatic cases even without definite radiographic findings to hasten elimination of residual iron pill particles or "sludge," as long as there is no evidence of peritonitis or perforation. In patients with considerable initial radiographic findings, particularly pill concretions, a follow-up radiograph should be obtained to assess the adequacy of bowel cleansing. Further options of gastroscopy or even gastrotomy are reserved as last resorts to effect iron pill removal. Large clumps of coalesced iron tablets in the stomach or duodenum have led to severe hemorrhagic infarction of these viscera with subsequent perforation, peritonitis, and death. As previously noted, even in such patients who survive the acute phase, there is considerable risk of subsequent pyloric or bowel stenosis with obstruction, usually 4 to 6 weeks after ingestion. In this regard, we also urge early pediatric surgical consultation for patients in the first few days after ingestion who show any evidence of peritoneal irritation.

Chelation therapy with parenteral deferoxamine enhances the excretion of iron as the feroxamine complex, which turns urine an orange or *vin rose* tint. The most efficacious route is a continuous IV infusion, and the maximum recommended dose is 15 mg per kg per hour (maximum daily dose 360 mg per kg, up to 6 g total). A higher infusion rate has been associated with hypotension but may be necessary (in conjunction with blood pressure support) for severe ingestions. Chelation is continued until the serum iron level returns to normal, metabolic acidosis has resolved, the patient is clinically improved, and the urine color returns to normal. The dose of deferoxamine may be titrated down in concert with the patient's clinical response and fall in iron levels.

Once the patient has been stabilized initially, further problems may include hypotension, profound metabolic acidosis, hypoglycemia or hyperglycemia, anemia and colloid loss caused by GI hemorrhage (after equilibration), renal shutdown resulting from shock, and hepatic failure with an associated bleeding diathesis. The maintenance of an adequate urine output is critical to prevent renal failure and to foster excretion of the feroxamine complex. If renal failure supervenes, chelation may be continued with concurrent dialysis because the complex is dialyzable.

Isoniazid

Isoniazid (INH) is an important treatment for tuberculosis. Even when taken appropriately, INH has many actions that can lead to clinical toxicity. These include hepatic dysfunction and interactions with foods such as those containing tyramine. However, its greatest toxicity appears after acute single ingestions of more than 20 mg per kg in children or more than 1.5 g in an adult.

INH's mechanism of toxicity involves its potent effect at reversing the biological activity of vitamin B_6 (pyridoxine). This action, as well as other effects on the synthesis of catecholamines and the neurotransmitter GABA, provides an explanation for the epileptogenic toxicity of the drug. INH also prevents hepatic conversion of lactate to pyruvate.

In overdose, the hallmark of INH poisoning is the triad of seizures, metabolic acidosis, and coma. Seizures induced by INH are typically generalized and appear to have a rhythmic recurrence. They are generally difficult to treat; patients usually remain comatose between seizures. The metabolic acidosis of INH can be severe; pH values of as low as 6.4 have been reported. This places INH on the list of substances associated with the development of high anion gap metabolic acidosis (see MUDPILES mnemonic). Of all these drugs, only INH possesses seizures as a prominent characteristic. Interestingly, in animal models of INH poisoning, metabolic acidosis does not occur if seizures are prevented through paralysis. Finally, the coma of INH intoxication can be severe and prolonged.

Because of the striking clinical picture of INH poisoning, diagnosis is often easily made on the basis of demographic characteristics and clinical manifestations. INH is not usually detected on routine toxicology laboratory screens, and serum concentrations are of little value in acute management. Laboratory tests that are important in initial assessment include arterial blood gas levels, electrolytes level, liver function tests, creatine kinase level, and urinalysis.

Management

Management of INH intoxication begins with advanced life support. Because of seizures and coma, airway protection and ventilation are typically necessary. Cardiac monitoring should be initiated to monitor for the development of cardiac arrhythmias (resulting from severe metabolic acidosis).

Although of unproven benefit, orogastric lavage might be considered within 30 minutes of ingestion. Activated charcoal may also be considered if it can be given safely. Theoretically,

giving multiple doses of activated charcoal to enhance postabsorptive elimination of INH may be advantageous.

Pharmacologic treatment for INH intoxication includes sodium bicarbonate, anticonvulsants, and pyridoxine. Sodium bicarbonate is provided as needed to restore serum pH to normal. In treating seizures, effective anticonvulsants include the benzodiazepines or phenobarbital (both of which are GABA agonists). Either diazepam (0.1 to 0.3 mg per kg) or lorazepam (0.1 mg per kg) should be administered IV to terminate seizures.

Administration of pyridoxine has been shown to provide specific antidotal therapy for INH poisoning. After administration of vitamin B_6, seizures and metabolic acidosis promptly resolve. Pyridoxine is given as an IV dose that equals the estimated dose of INH in milligrams. In cases in which the ingested amount is unknown, a single dose of 5 g (70 mg per kg in children) of pyridoxine is administered. Rarely, repeat administration is necessary.

Although INH clearance can be enhanced by hemodialysis or hemoperfusion, these techniques are rarely necessary if pyridoxine, activated charcoal, and aggressive supportive care are provided.

Lead

Background

Although lead poisoning is usually the result of chronic ingestion by pica-prone children or of occupational exposure in adults, patients with lead poisoning may come to the ED with varied complaints of recent onset that often mimic diverse acute illnesses. Fortunately, severe lead encephalopathy is now rare, attributable in large part to widespread screening programs and early treatment of asymptomatic or mildly ill children. However, the risk of lead intoxication still exists, and emergency physicians and pediatricians in every community must maintain an index of suspicion.

Sources of Lead
