THE AMERICAN PSYCHIATRIC PRESS

# **Textbook of Geriatric Neuropsychiatry**

SECOND EDITION

The cover depicts T1-weighted coronal magnetic resonance images of the human brain, at the level of the optic chiasm. Reading from left to right, the images depict increasingly severe levels of cortical atrophy and lateral ventricular enlargement, the hallmark changes of brain aging. Yet all three images are selected from a sample of elderly control volunteers living independently in the community, making the point that there is marked variability in the effects of aging on brain structure and behavior.

**Note:** The authors have worked to ensure that all information in this book concerning drug dosages, schedules, and routes of administration is accurate as of the time of publication and consistent with standards set by the U.S. Food and Drug Administration and the general medical community. As medical research and practice advance, however, therapeutic standards may change. For this reason and because human and mechanical errors sometimes occur, we recommend that readers follow the advice of a physician who is directly involved in their care or in the care of a member of their family.

Books published by the American Psychiatric Press, Inc., represent the views and opinions of the individual authors and do not necessarily represent the policies and opinions of the Press or the American Psychiatric Association.

# Foreword

**T**he publication of this second edition of *The American Psychiatric Press Textbook of Geriatric Neuropsychiatry* provides an opportunity to reflect on the many advances that have transformed the field since the first edition.

First, increasingly, the term *geriatric* is no longer associated with the feeble or impaired. With improvements in lifestyle and health care, the outer boundary of middle age has now been moved to age 64. Furthermore, the fastest growing sector of the American population is that of those over 80 years of age. Most of the elderly report living satisfying lives, engaged with family, hobbies, religion, and travel. Thus, the importance of geriatric neuropsychiatry must grow commensurate with these demographic changes and should focus increasingly on preventive strategies that maintain healthy brains in the elderly.

Second, the molecular mechanisms responsible for neuronal damage and degeneration that underlie many of the age-related disorders of the brain—stroke, Alzheimer’s disease, Parkinson’s disease, amyotrophic lateral sclerosis—have been worked out in considerable detail in recent years. For example, five risk genes for Alzheimer’s disease have been identified, thereby illuminating the final common pathway leading to senile plaques and selective neuronal vulnerability in this disorder. Through recombinant DNA technology, the human Alzheimer genes have

been inserted in the mouse genome, thereby creating mice who develop the neuropathology of Alzheimer’s disease. These advances provide molecular targets for the design of drugs that will not simply palliate the disease but will actually prevent it.

A common theme emerging from these studies is the role of reactive oxygen species in causing cumulative damage to neuronal membrane, proteins, and, most importantly, the DNA. The “new agers” obsession with antioxidants now has a scientific basis as aspirin and vitamin E appear to have protective effects in Alzheimer’s and Huntington’s disease. The cumulative damage to DNA by reactive oxygen species triggers a form of cell suicide known as apoptosis. In the periphery, apoptosis eliminates cells with DNA damage that are likely to become cancerous; however, in the nondividing neurons, it appears to account for neuronal elimination in neurodegenerative disorders. In the future, pharmacologic blockade of neuronal cell suicide may prevent or delay the onset of these neurodegenerative disorders, but the impact of these drugs on carcinogenesis will present a challenge.

Third, remarkable advances in imaging technology now permit noninvasive studies of human brain structure, chemistry, and function with increasingly higher resolution. With advances made in cognitive neuroscience, mental tasks are devised that challenge the systems affected by

disorders such as schizophrenia and obsessive-compulsive disorder much like the stress test is used in cardiology. These new, more refined “windows” into the brain are providing opportunities for better understanding the pathophysiology of age-related brain impairments and ways of testing new treatments and rehabilitation techniques.

Finally, the armamentarium of therapeutic agents to treat effectively neuropsychiatric disorders of late life has grown substantially and will continue to expand. The new drugs are generally much more specific in their actions and thus have fewer noxious side effects to which the elderly are particularly vulnerable. The molecular sites of action of

most are well characterized so that clinicians now have, for example, antidepressants that act at six different molecular targets alone or in combination.

It is the mind, the product of the brain, that defines our humanity, and it is the loss of mind that most terrifies the elderly. This textbook provides a remarkably comprehensive approach to the identification, diagnosis, and treatment of the broad range of neuropsychiatric conditions that affect the elderly. Given the pace of discovery and the rich knowledge displayed in this textbook, we and our patients can look forward with greater confidence to successful aging.

*Joseph T. Coyle, M.D.*

# Preface

Geriatric neuropsychiatry is an emerging clinical subspecialty that is devoted to the diagnosis and treatment of psychiatric or behavior disorders in aging patients with disturbances of brain structure or function. Such disturbances are particularly common in older individuals, and the continued expansion of the elderly segment of our population has recently resulted in considerable interest in the study of neuropsychiatric illness associated with brain aging.

The first edition of *The American Psychiatric Press Textbook of Geriatric Neuropsychiatry* was published in 1994. Its popularity exceeded even our mothers' expectations. Its publication also generated a number of cards, letters, emails, faxes, and phone calls from readers with appreciation for our efforts as well as suggestions for how future editions of the textbook could be improved. The 6-year interval since the first edition of the textbook has also witnessed a continued aging of the population (by almost exactly 6 years!), as well as the continued explosion in neuroscience research and in our understanding of human behavior.

The second edition of the *Textbook of Geriatric Neuropsychiatry* takes to heart the advice of our previous readers and advisors, embraces the “graying” of our population, and incorporates the very latest in neuroscience research in an updated text designed for clinicians interested in brain-behavior relations. This edition bridges the fields of

geriatric neurology and geriatric psychiatry, and emphasizes the relationships that exist between neuropsychiatric illness and aging of the nervous system. The book is intended for healthcare professionals—psychiatrists, neurologists, psychologists, geriatricians, and other clinicians—who desire to understand and manage disturbed behavior in the elderly through a comprehensive approach based upon a thorough knowledge of contemporary neuroscience. This textbook endeavors to establish a link between the neurobiology of idiopathic psychiatric illness and the neurobiology of neurologic disorders that cause disturbed behavior in the elderly and in so doing stimulate consideration of fundamental brain-behavior relationships.

A number of changes have been incorporated in the second edition of the *Textbook of Geriatric Neuropsychiatry*. The text has been expanded by 28%, from 32 to 41 chapters. In addition to the 9 new chapters, all previous chapters have been extensively revised and updated with the latest in published research.

The textbook is organized into five sections, each of which is edited by one or more of the book's editors or associate editors. The section editors have assembled an outstanding collection of world-renowned neuropsychiatrists and neuroscientists who in turn have produced chapters that impart clinically relevant information within the con-

text of the very latest in neuroscience research.

Section I, “Introduction to Geriatric Neuropsychiatry,” begins with an overview of the emerging clinical specialty of geriatric neuropsychiatry, followed by chapters on the demography of aging and the neurobiology of brain aging. The final chapter in this section provides an integrative model linking neurobiology with behavior and thus sets the stage for the subsequent sections in the book.

Section II, “Neuropsychiatric Assessment of the Elderly,” comprises three practical chapters on clinical and neuropsychological examination of the elderly, a chapter on memory changes in senescence, and four chapters on the role of advanced brain imaging technologies (updated chapters on magnetic resonance imaging [MRI], positron-emission tomography, and computerized topographic electroencephalography, as well as a new chapter on functional MRI and resonance spectroscopy) in the evaluation of the aging patient. This section accomplishes the essential and fundamental task of defining the acceptable limits of “normal” aging as assessed at the bedside and in the neuroscience laboratory.

Sections III and IV provide the clinical core of the book and focus on the neuropsychiatric aspects of psychiatric and neurologic disorders, respectively, in the elderly. Section III, “Neuropsychiatric Aspects of Psychiatric Disorders in the Elderly,” includes three new chapters that examine personality disorders in geriatric neuropsychiatry, neuropsychiatric aspects of aging in the mentally retarded population, and aggression in geriatric neuropsychiatry. Section IV, “Neuropsychiatric Aspects of Neurological Disease in the Elderly,” includes a new chapter on neurobehavioral syndromes. The comprehensive chapters in these sections highlight the influence of the aging nervous system on the pathophysiology, neuropsychiatric manifestations, clinical course, and prognosis of neurologic and psychiatric illness in the elderly.

Section V, “Principles of Neuropsychiatric Treatment of the Elderly,” emphasizes the special considerations that are essential for safe and effective treatment of neuropsychiatric disorders in the elderly. This section features up-to-date chapters on interactions between aging and neuropharmacotherapy, electroconvulsive therapy, psychosocial

and family therapies, and extended care. Four new chapters have been added on genetic interventions, behavioral and cognitive rehabilitation, ethical issues, and medico-legal and forensic issues. The discussions and recommendations for treatment are anchored as much as possible in a firm foundation of clinical science research. The new chapters in this section acknowledge the increasingly complex ethical, social, and forensic issues arising in the health care of the elderly.

## ■ Acknowledgments

We thank the associate editors, Mark R. Lovell, Ph.D., and Godfrey D. Pearlson, M.D., for the amazing effort they devoted to the textbook. They join us in thanking each of the chapter authors for their contributions—such quality work requires thought, time, and energy, all of which must be redirected from other pressing demands. Pam Harley, Martin Lynds, Anne Barnes, Claire Reinburg, and Carol Nadelson, M.D., of American Psychiatric Press, Inc., provided much guidance and were always available to assist with the many issues that invariably arise with a project of this scale. We are grateful that all of these collaborators—the associate editors, chapter authors, and APPI—shared our vision and made this textbook a priority.

We also acknowledge with special appreciation Tom Royer M.D. and the Henry Ford Medical Group, as well as the Board of Trustees of Henry Ford Behavioral Health, all of whom understand and value the importance of science in the enterprise of clinical medicine. Further, we acknowledge the federal (AG 16529) and state of California research support of Dr. Cummings, as well as the generous support of Mrs. Katherine Kagan and the Sidell-Kagan Foundation. We thank Kathy Bernardin and Janice May for their administrative assistance. Finally, this project was ultimately made possible by the understanding, patience, and support of our families.

**N**europsychiatry is the discipline devoted to understanding the neurobiological basis of human behavior. Neuropsychiatry has patient care, research, and educational dimensions emphasizing, respectively, the application, enhancement, and dissemination of neuropsychiatric information. The growth of neuropsychiatry has been stimulated by advances in neuroscience, neuroimaging, neuropsychopharmacology, geriatrics, and psychiatry. *Geriatric neuropsychiatry* represents the application of neuropsychiatry to older individ-

uals. Geriatric neuropsychiatry is an integrative activity bridging the fields of psychiatry, neurology, neuroscience, and geriatrics. The emergence of geriatric neuropsychiatry is a response to the increasing size of the elderly population and the high prevalence of brain diseases and behavioral disorders among them. The practice of geriatric neuropsychiatry reflects commitment to the principle that improved understanding of brain-behavior relationships can lead to a higher quality of life for older individuals through minimization of excess disability,

early recognition of diseases, and improved therapeutic interventions in behavioral disturbances.

The *Textbook of Geriatric Neuropsychiatry* is the first volume devoted exclusively to the discipline of geriatric neuropsychiatry. It is intended to serve as a guide to the practice and further development of this area of research and care. In this introductory chapter, we review the major issues in geriatric neuropsychiatry. Our purpose is to provide a neurobiological perspective on behavioral disturbances in elderly individuals, to create a context for the remaining chapters of this book, and to define and describe geriatric neuropsychiatry. In this chapter, we also review important aspects of training and research in geriatric neuropsychiatry.

## ■ Geriatric Neuropsychiatry as a Discipline

### Geriatric Neuropsychiatry

Most subspecialization or growth of an area of specific knowledge results from concentration on a small part of a parent discipline. With the explosion of information relevant to behavioral alterations in the elderly, however, the emergence of geriatric neuropsychiatry arises from a different imperative. Geriatric neuropsychiatry is an integrative specialty that draws from a diversity of fields (psychiatry, neuropsychiatry, neurology, neuroscience, neuroimaging, neuropsychopharmacology, neuropsychology, gerontology, molecular biology, genetics, epidemiology, and psychodynamics) with the intent of improving the care of elderly individuals with behavioral disorders and to stimulate research in this critical area (Figure 1–1).

The practice of geriatric neuropsychiatry depends on distinguishing normal age-related changes from those of disease and disordered brain function. Slowing of cognition, diminished access to specific bits of memory (e.g., names), and reduced cognitive flexibility may occur in the course of normal aging (Van Gorp and Mahler 1990) (see Chapters 7 and 8 in this volume). These changes must be differentiated from the effects of dementia, depression, and systemic illness. Geriatric neuropsychiatry provides expertise in this area.

### Neuropsychiatry and Geriatric Neuropsychiatry

Neuropsychiatry is an old discipline that has been resurrected to assume a prominent place in contemporary psychiatry. There is no consensus definition of *neuropsychiatry*.

Psychiatry	→ Geriatric psychiatry	Neuropsychiatry
Psychiatry	→ Neuropsychiatry	
Neurology	→ Geriatric neurology	
Neurology	→ Behavioral neurology	
Medicine	→ Geriatrics	
Psychology	→ Neuropsychology	
Psychology	→ Geriatric psychology	
Pharmacology	→ Neuropsychopharmacology	
Radiology	→ Neuroimaging	
Basic science	→ Neuroscience	
Sociology	→ Gerontology	

**FIGURE 1–1.** Geriatric neuropsychiatry is an integrative discipline importing information from a number of specialties relevant to behavioral alterations in elderly individuals.

Lishman (1992) suggested that it is that aspect of psychiatry that seeks to advance understanding of behavioral problems through increased knowledge of brain structure and function. Yudofsky and Hales (1989a, 1989b) defined *neuropsychiatry* as the discipline concerned with the assessment and treatment of patients with psychiatric illnesses or symptoms associated with brain abnormalities. Trimble (1993) emphasized that neuropsychiatry attempts to understand the effects of central nervous system structural or functional change on behavior, recognizing the essentially dynamic and individualistic nature of behavioral dispositions.

Neuropsychiatry is an umbrella discipline under which geriatric neuropsychiatry is subsumed. Geriatric neuropsychiatry, however, integrates information from geriatrics, gerontology, and aging research not specifically relevant to all areas of the broader discipline of neuropsychiatry.

### Geriatric Neuropsychiatry and Geriatric Psychiatry

Geriatric neuropsychiatry has a wide interface with geriatric psychiatry and can be regarded as an integration of geriatric psychiatry and neuropsychiatry. Both geriatric psychiatry and geriatric neuropsychiatry are concerned with care, education, and research related to behavioral changes in elderly individuals. The principal difference between the two is one of emphasis. Geriatric neuropsychiatry emphasizes its relationship to the neurosciences, the applica-

tion of pharmacological treatments, and the assessment and management of psychiatric aspects of neurological diseases in elderly patients. Geriatric neuropsychiatry is committed to the proposition that the cure of neuropsychiatric disorders of elderly patients, improved management of behavioral disturbances, and amelioration of adverse age-related changes in brain function are linked to advances in neuroscience, as well as to progress in psychology, sociology, and related disciplines. While accepting the incontestable importance of social, cultural, and psychological aspects of aging and diseases of the elderly population, geriatric neuropsychiatry emphasizes importing and developing neuroscience information with the goal of better understanding and treatment of disorders of the elderly.

### **Geriatric Neuropsychiatry and Behavioral Neurology**

No definitional boundaries exist between neuropsychiatry and behavioral neurology or between geriatric neuropsychiatry and behavioral neurology. Traditionally, behavioral neurology has been devoted to the study of “deficit disorders” such as aphasia, amnesia, agnosia, and apraxia, whereas neuropsychiatry has been concerned with the diagnosis and management of syndromes with “productive symptoms” such as hallucinations, delusions, and mood changes. In addition, behavioral neurologists usually have been trained in neurology, whereas neuropsychiatrists usually have had a background in psychiatry. Neither neurology nor psychiatry, however, completely prepares a clinician for the broad range of behavioral disorders associated with acquired and idiopathic brain dysfunction. Both disciplines produce behavioral neuroscientists who use similar concepts to relate abnormal behavior to brain dysfunction. Furthermore, individual patients often manifest both deficit and productive disorders, making it imperative that clinicians have knowledge of both neuropsychiatry and behavioral neurology. This knowledge is particularly important in geriatric neuropsychiatry where the prevalence of acquired brain disease as a cause of altered behavior is high.

A corollary of the absence of boundaries between behavioral neurology and neuropsychiatry is the transcendence of traditional restrictive definitions of individual diseases as “neurological” or “psychiatric.” Alzheimer’s disease and Parkinson’s disease are examples of disorders traditionally considered as “neurological,” whereas depression and obsessive-compulsive disorder have been thought of as “psychiatric.” Neither of these assumptions proves to be true from the perspective of geriatric

neuropsychiatry. Alzheimer’s disease and Parkinson’s disease both have major behavioral manifestations, whereas depression and obsessive-compulsive disorder are increasingly well understood as brain disorders. It is ever more evident that designating disorders as “neurological” or “psychiatric”—although convenient for some administrative purposes—is arbitrary and may be misleading. These designations are clinically unhelpful and may hinder the evolution of a behavioral neuroscience commensurate with optimum patient care.

### **Geriatric Neuropsychiatry: Clinical Training**

There is a marked lack of availability of individuals with expertise in geriatric neuropsychiatry and a dearth of training programs to provide experience in this area. This reflects the widespread lack of training in clinical care and research regarding both behavioral neuroscience and the care of elderly patients (Cummings et al. 1998). Few United States neurology residencies provide formal research training (Griggs et al. 1987), and only a small number of psychiatric faculty members have postgraduate research training (Burke et al. 1986). Geriatric psychiatry and geriatric medicine are decidedly understaffed (Rowe 1987; Small et al. 1988). Development of a cadre of individuals with expertise in the assessment and management of geriatric neuropsychiatric abnormalities is an essential response to the expanding elderly population. Currently available training programs are inadequate to meet the growing need.

### **Converging Information in Geriatric Neuropsychiatry**

The two principal dimensions in geriatric neuropsychiatry are the psychiatric manifestations of neurological disorders and the neurobiological basis of psychiatric illnesses. One exciting aspect of contemporary neuropsychiatry is the convergence of conclusions emanating from these two avenues of research (Table 1–1). For example, Robinson and Starkstein (1990) have demonstrated that depression is most common among stroke patients when the cerebrovascular lesion involves the anterior structures of the left hemisphere, whereas studies of idiopathic depression have found evidence of reduced frontal lobe volume (Coffey et al. 1993) and metabolism (Baxter et al. 1985, 1989). Thus, both avenues of investigation lead to similar anatomical implications. Neuropathological investiga-

**TABLE 1-1. Convergent results of investigations of the psychiatric complications of neurological disorders and the neurobiological basis of psychiatric illness**

Neuropsychiatric abnormality	Neurological disorder	Psychiatric illness
Depression	Poststroke depression after left frontal stroke	Reduced metabolism in the frontal lobes in idiopathic depression with PET; reduced frontal lobe volume in depression with MRI
Psychosis	Increased prevalence in temporal lobe disorders	Histological changes in the temporal lobes in schizophrenia
Obsessive-compulsive disorder (OCD)	Increased prevalence of OCD in diseases affecting frontal-subcortical circuits originating in orbitofrontal cortex	Increased glucose metabolism in orbitofrontal cortex in idiopathic OCD
Anxiety	Occurs with lesions of the temporal cortex	Increased blood flow in the temporal lobes during episodes of anxiety

*Note.* PET = positron-emission tomography; MRI = magnetic resonance imaging.

tions in schizophrenia have revealed abnormalities in the cellular architectonics in the temporal lobe (Altshuler et al. 1987), and studies of neurological disease with psychosis demonstrated that the temporal lobe is a common site of pathological changes (Cummings 1992b). Again, studies of psychiatric and neurological disorders with similar symptoms suggest shared pathophysiologies.

In studies of idiopathic obsessive-compulsive disorders, Baxter et al. (1987) found increased metabolism in the orbitofrontal cortex, and Cummings (1993) observed that obsessions and compulsions occur in neurological disease when there is involvement of structures participating in the frontal-subcortical circuit originating in orbitofrontal cortical regions. Preliminary studies with positron-emission tomography (PET) have suggested altered regional metabolic activity in anxiety disorders (Reiman et al. 1989; Wu et al. 1991), and anxiety symptoms have been associated with structural lesions of related cortical areas in neurological diseases (Drubach and Kelly 1989). The convergence of information from the neurological and psychiatric approaches to neuropsychiatry has many implications. When clinical neuropsychiatric symptoms are similar, even in seemingly different disorders, there may be involvement of the same underlying neuroanatomical structures and common pathobiological mechanisms. These observations also support the use of the same therapeutic agents in patients with diverse underlying diseases but similar neuropsychiatric symptoms.

These convergent data in neuropsychiatric research justify the working assumption of geriatric neuropsychiatry that the relationship between brain dysfunction and behavioral disturbances is rule governed, that the axioms relating structure and function are discoverable, and

that the rules will apply regardless of the etiology of the underlying disorder (Cummings 1999).

## ■ Aging, the Brain, and Geriatric Neuropsychiatry

The brain undergoes various neurochemical, structural, and neurophysiological alterations in the course of normal aging (Creasey and Rapoport 1985; see also Chapters 3, 9, and 10 in this volume). Grossly, there is a small decrease in brain weight in the course of normal aging with widening of cerebral cortical sulci and enlargement of the lateral ventricles.

Microscopically, neuronal loss occurs in specific cortical and subcortical structures (Brody 1982; Terry et al. 1987). In addition, lipofuscin, granulovacuolar changes, neuritic plaques, and neurofibrillary tangles also accumulate in the course of aging, and there is a progressive shrinkage of the dendritic domain of some cortical and subcortical neurons (Brody 1982).

Neurochemical changes also accompany aging. Decreased activity of catecholamine synthesizing enzymes and increased activity of monoamine oxidase (an enzyme involved in catecholamine catabolism) have been documented (Bowen and Davison 1982; Van Gorp and Mahler 1990). These biochemical changes may underlie the psychomotor retardation of elderly individuals, as well as the mild parkinsonian habitus associated with aging, and they may contribute to the occurrence of depression in elderly people (Veith and Raskind 1988). Neurochemical alterations may also have a role in the age-associated memory

impairment observed in elderly individuals (see Chapter 8 in this volume).

The underlying mechanisms of aging remain mysterious, but strides are being made in understanding some of the processes that contribute to age-related changes in function. Oxidative metabolism catalyzed by oxygen free radicals damages enzymes, and this in turn leads to a reduced synthetic ability and compromise of the aged organism's ability to respond to changing biological contingencies (Stadtman 1992). Trophic factors may be responsible for maintaining cellular connectivity, and changes in tropism with aging may contribute to some age-related brain alterations (Creasey and Rapoport 1985). Finally, some cells have genetically determined life-spans, whereas other cell populations manifest few, if any, changes in the course of aging (Finch 1990). Deciphering the molecular mechanisms responsible for programmed aging is critical to a comprehensive understanding of the neurobiology of aging.

The brain is continuously changing from its fetal developmental period through senescence. The changes associated with aging are not global, and they affect specific cellular populations, structures, and transmitters more than they do others. The temporal sequence of aging varies among different structures. The neurobiological changes of aging, as well as the differential involvement of functional systems, may influence the types of neuropsychiatric disorders to which elderly people are vulnerable.

## ■ Aging, Brain Diseases, and Geriatric Neuropsychiatry

The emergence and growth of geriatric neuropsychiatry are driven by four circumstances: 1) the growth of the size of the elderly population, 2) the increased prevalence of brain diseases among the elderly, 3) a high frequency of psychiatric disorders among elderly people, and 4) the recognition that behavioral disturbances often are manifestations of brain dysfunction.

### Demography of Aging

People over age 65 composed only 4% of the United States population in 1900; this population will increase to 13% by the year 2000 and to 22% by 2030 (Department of Health and Human Services 1990; see also Chapter 2 in this volume). The growth of the old-old population is proceeding at a disproportionately rapid pace. Those over age 80 numbered 6 million in 1985 and comprised 22% of the elderly population; by 2005, 31% of elderly Americans will be over

age 80 (Torrey et al. 1987). In 1980, there were approximately 15,000 centenarians in the United States; this number increased to 25,000 by 1986 and is projected to reach 100,000 by the year 2000 (Spencer et al. 1987).

Aging and the diseases of elderly people present a global challenge (Torrey et al. 1987). The world's elderly population is growing at a rate of 2.4% per year, faster than the rest of the population. In 1985, there were 290 million individuals over age 65 in the world; this number will rise to 410 million by the year 2000. Twenty-three countries had 2 million or more elderly individuals in 1985; 50 countries will have this number by 2025. The growth of the world's elderly population will occur disproportionately in the countries least able to provide services; by the year 2025, 69% of the world's elderly people will live in developing countries (Torrey et al. 1987).

### Neurological Diseases With Behavioral Manifestations Among the Elderly

The three neurological conditions most responsible for neuropsychiatric morbidity in elderly individuals are 1) Alzheimer's disease and other dementing disorders, 2) Parkinson's disease, and 3) stroke. The prevalence of dementia increases dramatically with age. A demographic study of dementia in Stockholm, Sweden (Fratiglioni et al. 1991), found that 5.7% of individuals 75–79 years old had mental status changes indicative of dementia, and 9.6% of those 80–84 years old had dementia; the proportion rose to 20.4% in those 85–89 years old and to 32% in those over age 90. Evans et al. (1989) found the rate of Alzheimer's disease among the elderly in a United States community to be 3% in those 65–74 years old, 18.7% in those 75–84 years old, and 47.2% in those over age 84. Parkinson's disease also exhibits an age-related prevalence. The reported frequency varies among studies, but a representative investigation (D'Alessandro et al. 1987) revealed a prevalence of 0.8% among people 55–59 years old, 3.8% in those 60–64, 5.7% in those 65–69, 12.4% in those 70–74, 19.5% in those 75–79, and 9.5% in those 80–84 years old. The prevalence of stroke and vascular dementia likewise increases with age. The prevalence of cerebrovascular disease rises from 2.3% in those 55–64 years old to 4.2% in those 65–74, 8.1% in those 75–84, and 10% in those over age 85 (National Center for Health Statistics 1986). The cumulative prevalence of neurological disease among the elderly and the chronic nature of many neurological illnesses make brain diseases a major source of morbidity and mortality among elderly individuals.

Neurological diseases of elderly people are often manifested by alterations in behavior. The dementia syn-

dromes are defined by loss of cognitive abilities, and many patients with dementia also exhibit delusions, depression, anxiety, agitation, and aggressiveness (Cummings and Benson 1992; Cummings et al. 1987; Mega et al. 1997; Merriam et al. 1988; Reisberg et al. 1987; Teri et al. 1988). Dementia occurs in 41% of patients with Parkinson's disease (Mayeux et al. 1992), and 40%–60% of patients with Parkinson's disease have depressive disorders, anxiety, and apathy (Cummings 1992a). With treatment, hallucinations and delusions may emerge. Eighty percent of strokes involve the cerebral hemispheres, where they produce neurobehavioral and neuropsychiatric syndromes such as aphasia, amnesia, visuospatial disturbances, depression, or psychosis (Beckson and Cummings 1991; Robinson and Benson 1981). One-fourth of all patients hospitalized with stroke meet criteria for vascular dementia (Hershey et al. 1987). Thus, behavioral disturbances are the principal clinical manifestations of many brain diseases of elderly people. Recognition and management of geriatric neuropsychiatric disorders is critical in an aging society.

### **Psychiatric Illness in the Elderly Population**

Psychiatric illness is present in 12.3% of the elderly population (Regier et al. 1988; see also Chapter 2 and Section III in this volume). Approximately 5.5% of elderly individuals have anxiety disorders (4.8% phobia, 0.1% panic), 4.9% have severe cognitive impairment, 2.5% have a mood disorder (0.7% major depressive episode; 1.8% dysthymia), 1% manifest alcohol abuse or dependence, 0.8% have obsessive-compulsive disorder, and 0.1% have schizophrenia or a schizophreniform disorder. These figures were derived from a household study (Regier et al. 1988) of individuals in five United States cities using the criteria of DSM-III (American Psychiatric Association 1980). In a similar community survey (Myers et al. 1984), the four most common psychiatric disorders in men over age 65 were severe cognitive impairment, phobia, alcohol abuse and dependence, and dysthymia; in women of the same age, the four most frequent diagnoses were phobia, severe cognitive impairment, dysthymia, and major depressive episode.

Thus, dementia, alcoholism, anxiety, and mood disorders are the most common psychiatric conditions among elderly people. Each of these diseases has an important neurobiological dimension. Dementia is an overt brain disorder produced by Alzheimer's disease, cerebrovascular disease, or other encephalopathic processes (Cummings and Benson 1992). In individuals with alcohol abuse, PET reveals diminished brain glucose metabolism (Volkow et al.

1992), and dysfunction of basal ganglia–limbic circuits is implicated in alcohol craving (Modell et al. 1990). Patients with anxiety disorders have an increased frequency of structural alterations of the right temporal lobe (Fontaine et al. 1990), exhibit regional alterations in metabolism (Reiman et al. 1989; Wu et al. 1991), and evidence functional disturbances involving a variety of neurotransmitter systems (Hoehn-Saric 1982).

Depression occupies a particularly important place in geriatric neuropsychiatry. This disorder is disabling and treatable and may occur for the first time in elderly individuals. If not detected and treated, depression may be fatal; men 65–74 years old have the highest suicide rate of any age group in the United States (Department of Health and Human Services 1990). Imaging studies suggest that depression is associated with alterations in brain structure and function, particularly in elderly people (see Chapter 13 in this volume). Reported structural abnormalities include cortical atrophy (especially of the frontal lobes), ventricular enlargement, and subcortical encephalomalacia (Coffey 1996; Coffey et al. 1993; Duffy and Coffey 1997). These findings may be related to the onset of mental disorders in late life (Coffey 1991), and they are associated with a poor long-term prognosis (Jacoby et al. 1981). Functional imaging studies reveal evidence of altered regional cerebral blood flow and metabolism in depressive disorders. The frontal lobes are most prominently affected (Baxter et al. 1985, 1989; Duffy and Coffey 1997; Sackeim et al. 1990; see also Chapter 13 in this volume). Although relatively few studies have examined elderly subjects, data suggest that functional brain imaging may be useful in distinguishing the neurodegenerative dementias from the dementia of depression. Together, these observations indicate that alterations of brain structure and function may interact with the aging process to facilitate the emergence of affective disorders in late life.

Late-onset psychoses may occur, although they are considerably rarer than late-occurring depression or anxiety (see Chapter 14 in this volume). Investigations of patients with late-onset delusional disorders reveal that about half have an identifiable underlying brain disease (Leuchter and Spar 1985; Miller et al. 1992). Thus, delusions may be the heralding feature of a neurological disease.

Together, these studies indicate that mental disorders are an important aspect of geriatric care, that there is an emerging understanding of the neurobiology of these psychiatric conditions, and that brain abnormalities are associated with many late-onset psychiatric disturbances. Geriatric neuropsychiatry addresses both the neurobiology of idiopathic psychiatric disorders and the psychiatric disturbances associated with neurological conditions.

## Cost of Brain Disorders

The annual cost of brain disease has been calculated, and the yearly expense is staggering (National Foundation for Brain Research 1992). The annual cost (direct and indirect total) in billions of dollars for psychiatric illnesses is \$136.1; for neurological disease, \$103.7; for alcohol abuse, \$90.1; and for drug abuse, \$71.2. Together, these diseases cost United States society \$401.1 billion annually. Fifteen percent of the average annual income of workers in the United States is devoted to brain diseases. Although the costs of diseases of the elderly were not separately calculated, dementia accounted for the largest share (45%) of the costs of all neurological illnesses, and it is obvious that a substantial share of the funds expended on brain disorders concerns diseases of elderly patients.

## ■ Aging, Medical Illness, Drugs, and Geriatric Neuropsychiatry

The rise of geriatric neuropsychiatry is fueled in part by the marked rise in medical illness in the elderly population and the increased frequency of associated behavioral disturbances. Medical disorders become increasingly common among elderly people, medications are more frequently administered, and there are changes in drug metabolism with aging (see Chapter 31 in this volume). These alterations create a neurophysiological setting that is conducive to brain dysfunction and behavioral abnormalities (Figure 1–2).

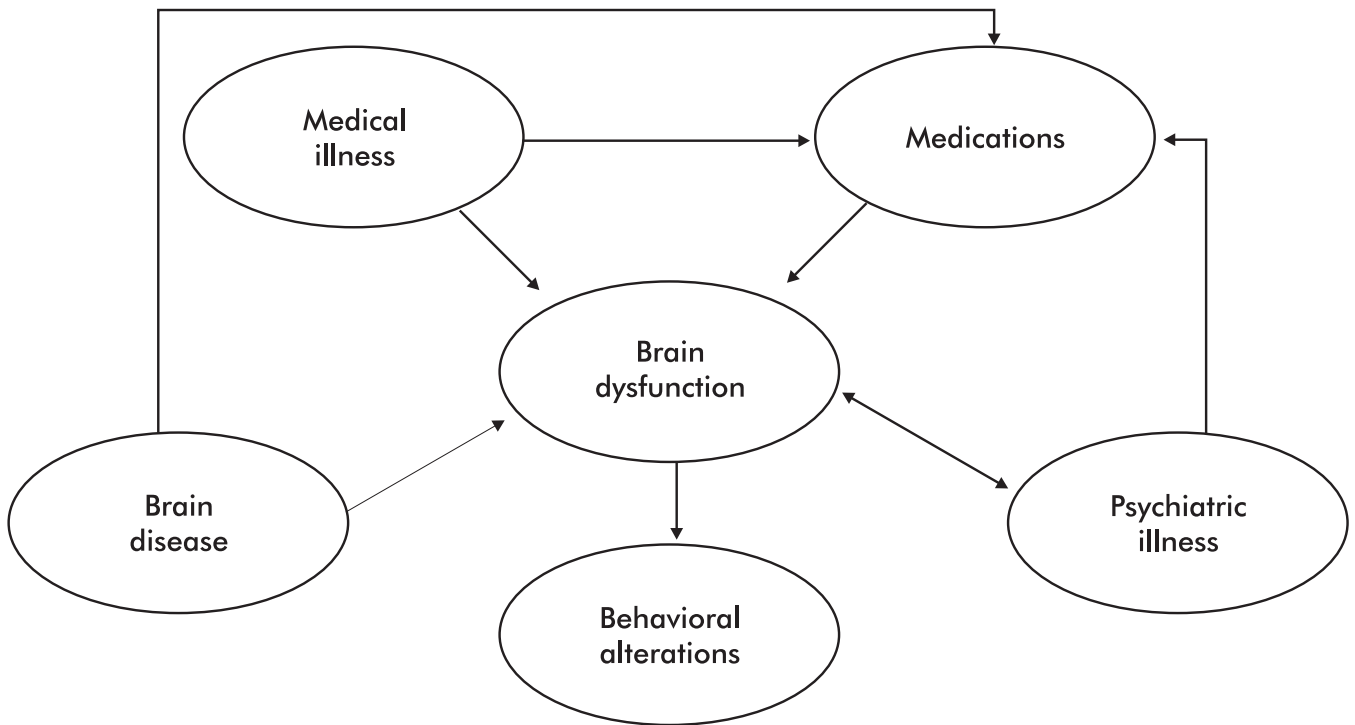

Medical illnesses are common in elderly people, and many of these affect brain function and produce behavioral alterations. Among the 10 most common nonneurological diseases of elderly people are hypertension, ischemic heart disease, diabetes, and arteriosclerosis (Cassel and Brody 1990). These may involve the brain through direct mechanisms such as stroke or through indirect mechanisms including hypoxia and renal failure. Epidemiological studies (Cohen-Cole 1989; Derogatis and Wise 1989) have revealed that approximately 20% of patients with medical illness have significant depressive symptoms and 5%–20% experience major depressive episodes; 10%–15% of patients with medical illness manifest anxiety disorders. The coexistence of medical and psychiatric illness increases the length of stay of hospitalized patients and is associated with a poorer postdischarge prognosis (Mayou et al. 1991; Saravay et al. 1991). Conversely, approximately 50% of elderly patients with psychiatric illness have significant medical illnesses. Nearly 60% of these conditions are undiagnosed before psychiatric admission, and in

10%–20% the behavioral changes are directly attributable to the physical pathology (Koranyi 1982).

The high prevalence of medical illness among elderly people results in an increase in the number of medications ingested (see Chapter 29 in this volume). Elderly people take more prescribed and over-the-counter medications than any other age group. They comprise 12% of the population and take 25%–30% of all prescribed drugs. The average older United States citizen receives 4.5 prescribed medications, and two-thirds also take at least one over-the-counter agent (Beers 1992; Lamy 1985). Forty percent of the elderly individuals who take medications receive prescriptions from more than one physician, and 12% take drugs prescribed for someone else (Lamy 1985). These practices are further complicated by intentional or accidental noncompliance with prescribing instructions. Up to 30% of elderly patients make serious errors in the way they take their medications, and up to 50% default on one or more prescribed agents (Lamy 1985).

Drug metabolism is altered in elderly patients, and the changes may have marked consequences for brain function and the treatment of behavioral abnormalities (see Chapter 34 in this volume). There is an increased sensitivity of receptors for most classes of drugs in the course of aging, making lower levels more effective and “standard” doses more likely to induce toxicity (Avorn and Gurwitz 1990). Changes also occur in drug distribution with aging. There is a relative increase in body fat and decrease in muscle; this produces a greater volume of distribution for fat-soluble drugs (e.g., benzodiazepines) and smaller volume of distribution for drugs absorbed primarily in lean body mass (e.g., lithium). There is reduced liver blood flow and impaired oxidative metabolism by hepatic enzymes in the course of normal aging, leading to reduced hepatic metabolism of many pharmacological agents. Renal function also declines with age; glomerular filtration rate is reduced by approximately one-third in elderly individuals (Avorn and Gurwitz 1990). These changes all tend to increase the risk of toxicity when medications are administered to elderly patients. Adverse drug reactions account for 12%–17% of all hospital admissions of elderly patients, and 21% of all elderly patients experience adverse side effects while in the hospital (Davison 1985; Lamy 1985).

The higher frequency of medical illness in the elderly population and concomitant need for more drug administration place elderly patients at a substantially increased risk of toxic-metabolic neuropsychiatric disturbances. Delirium, dementia, depression, mania, psychosis, and anxiety have all been observed in patients with brain dysfunction secondary to systemic illnesses and drug toxicity (Cummings 1985; Estroff and Gold 1986).

**FIGURE 1-2.** Interactions of medical illness, medications, brain disease, and psychiatric disorders to produce brain dysfunction and behavioral changes.

## ■ Neuroimaging

The emergence of new diagnostic technologies has accelerated the development of geriatric neuropsychiatry. Among these, neuroimaging has had the greatest impact. Neuroimaging plays an increasingly large role in the diagnosis, differential diagnosis, and treatment monitoring of behavioral disturbances in the elderly. Structural and functional imaging has provided new insights into brain function, the pathophysiology of brain disorders, and the neurobiology of normal aging.

Imaging brain structure, metabolism, and chemical composition are now possible (Mazziotta and Gilman 1992). In addition, specialized techniques allow visualization of arterial and venous blood flow. Images of brain structure are generated by computed tomography (CT) and magnetic resonance imaging (MRI) (see Chapter 4 in this volume). These techniques reveal the brain structure and the ventricular system. Tumors, large strokes, subdural hematomas, large demyelinating lesions, arteriovenous malformations, and hydrocephalus are demonstrated by both techniques. MRI is more sensitive to changes in white matter of the central nervous system and is superior to CT

in revealing evidence of ischemic and inflammatory disease.

MRI has been shown to have a potential role in predicting adverse responses to therapy. Patients with depression who have basal ganglia lesions and increased white matter abnormalities are more likely to exhibit prolonged interictal confusion during electroconvulsive therapy and a higher frequency of antidepressant-induced deliria than are elderly patients with depression who have normal MRI results (Coffey 1996; Figiel et al. 1990). Elderly patients with depression who have enlarged ventricles and cortical atrophy may have a poorer prognosis for recovery than elderly patients with depression but without these structural changes (Jacoby et al. 1981; Nasrallah et al. 1989).

Magnetic resonance spectroscopy is a specialized application of magnetic resonance technology that allows the determination of the concentration of specific chemicals in the brain, and new fast imaging techniques using magnetic resonance can be used to determine cerebral blood flow (see Chapter 11 in this volume). The rapid advances in MRI technology suggest that this tool will be of increasing importance in neuropsychiatry (Prichard and Cummings 1997).

Except for the marked caudate nucleus atrophy associ-

ated with Huntington's disease, degenerative brain diseases (e.g., Alzheimer's disease and Parkinson's disease) produce no pathognomonic changes that are detectable on conventional structural imaging. In these disorders, structural imaging techniques such as CT and MRI provide little specific diagnostic information. Moreover, idiopathic neuropsychiatric disorders such as depression, mania, psychosis, and anxiety are not associated with diagnostic structural brain alterations.

Functional brain imaging such as PET and single photon emission computed tomography (SPECT) provides a new approach to these neuropsychiatric disorders. PET may be used to study cerebral glucose metabolism (with radiolabeled glucose), cerebral blood flow (with radiolabeled oxygen), and neurotransmitter function (with radiolabeled receptor ligands and transmitters) (see Chapter 10 in this volume). SPECT is typically used to measure cerebral blood flow but may also be applied to assessment of neurotransmitters and receptors. Degenerative diseases and idiopathic neuropsychiatric illnesses may have distinctive alterations on metabolic imaging studies. For example, Alzheimer's disease typically causes reduced metabolism or perfusion in the temporoparieto-occipital junction region; frontal lobe degenerations cause decreased metabolism or perfusion of the frontal lobes; depression may be associated with diminished frontal lobe metabolism; and obsessive-compulsive disorder has been shown to be associated with increased metabolism of the orbitofrontal cortex (Holcomb et al. 1989).

These investigations demonstrate that reliable relationships exist between behavioral changes and brain metabolism or perfusion. Imaging research is beginning to provide important insights into the pathophysiology of neuropsychiatric disorders.

## ■ Advances in Treatment

The value of accurate diagnosis is enhanced when it proceeds in concert with advances in treatment. In this regard, the past decade has seen an unparalleled increase in the availability of medications to treat behavioral disturbances (see Section V in this volume). Antidepressant agents have proliferated and become highly differentiated, with relative selectivity for inhibition of reuptake of norepinephrine or serotonin. A variety of anxiolytics have been discovered, and the clinician can now choose an agent that best fits the patient's needs according to the rapidity of onset, duration of action, and side effects. Conventional neuroleptic agents are rapidly giving way to a new generation of novel antipsychotic drugs that produces fewer acute or chronic

extrapyramidal side effects (Baldessarini and Frankenburg 1991). With the evolution of these agents, patients should experience less risk of dystonia, parkinsonism, or tardive dyskinesia as their psychiatric disorders are controlled. The discovery that anticonvulsants such as carbamazepine and sodium valproate have antimanic benefits has improved the treatment of mania while emphasizing that common neurophysiological processes are shared by some neurological and psychiatric illnesses (Post et al. 1984).

Relevant advances also have been made in the pharmacological treatment of neurological disorders. Most remarkably, vitamin E has been shown to slow the progression of Alzheimer's disease (Sano et al. 1997). This represents a revolutionary treatment advance and the first success in intervening in a degenerative disease. The neuroprotective action of vitamin E implies that the behavioral aspects of Alzheimer's disease such as depression and dementia may also be delayed or ameliorated. In addition, modest symptomatic improvement is observed in patients with Alzheimer's disease treated with cholinesterase inhibitors (Farlow et al. 1992; Rogers et al. 1998), and intensive investigation at the molecular biological level has revealed a systematic cascade of events with individual steps that might be amenable to pharmacological manipulation. Ticlopidine (a potent platelet antiaggregate) has been shown to be more powerful than aspirin in preventing stroke and improving the prognosis for patients with cerebrovascular disease (Gent et al. 1989).

The rapid advances in neuropsychopharmacology provide the clinician with a varied and powerful armamentarium with which to meet the challenges of neuropsychiatric disease in the elderly patient. These developments also require that the clinician be familiar with the pharmacokinetics, side effects, and drug interactions of each of these new agents (see Chapter 34 in this volume). Geriatric neuropsychiatry is the clinical discipline committed to implementation of these advances for the benefit of elderly individuals with behavioral disorders.

## ■ Geriatric Neuropsychiatry and Ethical Issues

Ethical issues arise often in geriatric neuropsychiatry (see Chapter 40 in this volume). The main challenges concern the ability of individuals to take responsibility for their own actions and the responsibility of society to preserve the rights of elderly citizens. With regard to driving, for example, at what point are the wishes of the patient to maintain independence and mobility in conflict with the safety of

other drivers and pedestrians who might be endangered by the patient? At what point do patients relinquish their right to make decisions regarding disposition of property and money? When do they lose their right to decide when they can no longer live at home? When do they need a surrogate decision maker for questions of life support, treatment of infections, and postmortem autopsy? Who should make decisions for the patients when the patients themselves cannot? Should such decisions be based on family beliefs about what the patient would want, on advanced directives from the patient, or on an assessment of the apparent daily life satisfaction of the individual with dementia (Dresser 1992; Moody 1992; see also Chapter 32 in this volume)? Is euthanasia a viable societal response to severe dementia? These questions do not have categorical answers; they must be answered individually for each patient, taking into account the needs and abilities of the patient, the family context, and other patient-specific contingencies.

Geriatric neuropsychiatric illnesses strike at the self and alter the individual's personal identity; whereas a patient may *have* pneumonia, he or she *is* "demented." How does and how should this change in identity affect decision making for the patient? How can the dignity of the patient be preserved when institutional caregivers know the person only after the onset of disease and are unacquainted with the unique biography of the individual under their care? For the individual with dementia, how can extended care become an extended meaningful life?

The great majority of elderly people, and many of those in institutions, are competent, if physically infirm. How can we best preserve their autonomy, dignity, and quality of life? These ethical dilemmas must be given careful consideration as the elderly population grows, more and more elderly individuals require institutional care, and the resources available to care for them come steadily under more pressure.

## ■ An Agenda for Geriatric Neuropsychiatry

### Patient Care

The growth of geriatric neuropsychiatry can improve the quality of patient care. Appropriate treatment of neuropsychiatric illness depends on accurate diagnosis, and diagnosis in elderly patients depends on a comprehensive understanding of brain-behavior relationships. In addition, diagnosis increasingly demands familiarity with neuroimaging, electrophysiology, and a variety of laboratory tests, and geriatric neuropsychiatry incorporates data from

these techniques into diagnostic formulations. New medications have been developed and are able to effectively ameliorate many behavioral disturbances and improve the quality of life of elderly patients with brain disorders. Many of these agents have potentially serious side effects, and practitioners in this area must be familiar with the effects, as well as the adverse consequences, of these new agents.

### Education

The growth of the elderly population demands greater availability of practitioners of geriatric neuropsychiatry (Benjamin et al. 1995; Cummings and Hegarty 1994; Cummings et al. 1998). This field incorporates information from psychiatry, neurology, geriatrics, and neuroscience. Training opportunities must be developed and expanded.

### Research

Geriatric neuropsychiatry is a nascent field (Cummings et al. 1998). Its research agenda must include the application of advanced technologies to diagnosis in the elderly population: the usefulness of PET, SPECT, and magnetic resonance spectroscopy has yet to be defined in detail. Their sensitivity in early disease, specificity in differential diagnosis, and predictive ability for determining prognosis and treatment response have not been established. The correlations between behavior and metabolic and structural brain imaging findings, as well as between behavior and pathological alterations, must be described. Complex behavioral changes such as delusions and mood disorders are unlikely to correspond to single specific lesions, and the shared characteristics of lesions and conditions producing similar syndromes demand investigation. New treatments are continuously emerging and must be integrated into clinical practice to provide the most benefit for elderly patients. The effects, side effects, and drug interactions of these new agents must be discovered. Effective non-pharmacological interventions must also be identified and perfected. Molecular underpinnings of aging must be identified and explored. The appropriate ethical responses of society to severe illness in elderly individuals must be carefully considered. Finally, a means of bridging the gap between neuroscience and human experience must be found. Geriatric neuropsychiatry will succeed to the extent that advances in the neurosciences can be related to the suffering of elderly people and its relief. We hold the conviction that research advances will translate directly into improved care and a higher quality of life for elderly individuals.

# Epidemiology of Aging

Roberta Malmgren, Ph.D.

Aging populations present one of the world's major health care challenges. Industrialized countries currently face this challenge; but developing nations, with anticipated increases in the numbers and proportion of their elderly populations, will also soon need to deal with problems of growing geriatric populations (Holden 1996; Steel 1997). Concerns about the elderly population arise from two characteristics of that group: 1) the recent and continuing increases in the population age 65 and older ("65+") and 2) the increasing number and severity of health problems associated with aging. (Unless otherwise noted, "elderly" and "older people" refer to people 65 years old and older.)

Epidemiology characterizes groups rather than individuals. As cultural background and gender play an important role in an individual's health, so, too, do characteristics of an age group, such as the elderly, affect and reflect the well-being of its members. Although the subject of this book is neuropsychiatric disorders, it is important to understand how a range of other factors may affect the neuropsychiatric realm. Therefore, in this chapter my purpose is to define the population at risk, the elderly, and to describe some of the most salient epidemiological characteristics of this population, particularly its physical health. The focus is on the 65+ population in the United States. However, most of the concepts and problems apply to other industri-

alized countries now and presage issues that will affect developing nations in the near future. What, then, are some of the major epidemiological characteristics of the elderly?

## ■ Graying of the Population

One of the most remarkable and far-reaching demographic developments of the 20th century has been the "graying" of populations. This phrase often evokes the image of a horrendous set of problems produced by increasing numbers of elderly people. The specific problems—medical, social, financial, and psychological—are not all necessarily new. But what is unique are the great increases in the numbers and proportions of older people.

The graying of the population has three components (Table 2-1). First are the increases in the absolute numbers of people 65 and older. Between 1900 and 1995, the number of elderly people in the United States increased 10-fold, from 3 million to almost 34 million. Second are the increases in the proportion of the population that is elderly. In 1900, the elderly were only 4% of the total United States population; currently they are 13%. Third, the oldest old, those who are 85 or older ("85+"), are growing as a proportion of the 65+ group. In 1995, 3.6 million people in the United States were 85 or older, almost 30 times their num-

**TABLE 2-1. Population 65 and older (65+)—United States, 1900–2050**

Population	1900	1950	1995 <sup>a</sup>	2010 <sup>a</sup>	2030 <sup>a</sup>	2050 <sup>a</sup>
65+ population (in millions)	3.1	12.3	33.5	39.4	69.4	78.9
(As % of total population)	(4.1%)	(8.1%)	(12.8%)	(13.2%)	(20.0%)	(20.0%)
85+ population (in millions)	0.1	0.6	3.6	5.7	8.5	18.2
(As % of 65+ population)	(4.0%)	(4.7%)	(10.8%)	(14.4%)	(12.2%)	(23.1%)

<sup>a</sup>Middle series projections.

Source. Adapted from 1900–1990: Hobbs and Damon 1996; 1995–2050: Day 1996.

ber in 1900 and more than double their proportion in the total elderly population.

Table 2-1 shows that the graying of the United States population will continue well into the next century. In the year 2030, there will be close to 70 million elderly people, more than twice as many as there are now. As a proportion of the total population, today one of eight Americans is 65 or older; in 2030, one of five will be. In the next century, the 85+ group will be one of the fastest growing age groups, increasing from 3.6 million in 1995 to 18.2 million in 2050. Currently, 11% of the elderly population is 85+; but in 2050, 23% of the 65+ group will be 85 or older. The major reason for these rapid future increases in the 65+ population is past increases in birth rates: the baby boomers, a large cohort born between 1946 and 1964, will start to turn 65 in 2011, continuing to inflate the numbers of 65+ until 2030 (Day 1996).

### Changing Racial Composition

In the coming century, the racial composition of the elderly population will also change (Table 2-2). In 1995, 10% of the United States elderly population was non-white. In 2050, almost one-fifth will be non-white. By 2050, the black elderly population is projected to increase from 8% to 11% of the 65+ group, whereas Hispanic elderly people (who may be of any race) will have quadrupled as a percentage of the United States elderly population. By the middle of the next century, the number of Asian and Pacific Islander elderly will be almost 10 times their current number, an increase from 1.9% to 6.6% of the total 65+ group.

### Sex Ratio

Because of increased mortality rates among men, the ratio of men to women decreases strikingly from ages 65–69 (83 men to every 100 women) to ages 90+ (when the ratio is 31 to 100) (Figure 2-1). Many social and medical consequences of aging in developed countries are associated with

the sex ratio imbalance. With increasing age, women are more likely to be unmarried and living alone (Saluter 1996). Both of these characteristics are linked to poverty (Davis et al. 1997; Lewis 1997; Social Security Administration 1996) and other disadvantages, such as increased likelihood of admission to nursing homes (Davis et al. 1997; Hing and Bloom 1990).

### Marital Status<sup>1</sup>

Elderly men are more likely to be married, and elderly women are more likely to be widowed. According to the U.S. Bureau of the Census, in 1996 15% of all men 65+ were widowers, whereas 47% of all women 65+ were widows (Saluter and Lugaila 1998). As a corollary of this statistic, 73% of elderly men lived with spouses compared with 40% of elderly women.

### Living Arrangements

The percentage of elderly people living alone increases with age and is greater for women than for men. In 1996, 15% of men 65–74 years old lived alone, whereas 31% of women these ages did so; 21% of men 75+ lived alone compared with 53% of women 75+ (Saluter and Lugaila 1998).

### Income

The median income of the elderly population decreases with age, is lower for nonmarried people, and is lowest for nonmarried women (Social Security Administration 1998). In terms of median income and total assets, today's elderly people are financially better off than those in the past (Hobbs and Damon 1996; Social Security Administration 1996). Nonetheless, in 1996, 13% of the United States elderly people lived below the poverty level and another 37% would have been below that level had they not had Social Security benefits (Social Security Administration 1998). The risk of poverty is higher for unmarried people, for women, and for black and

<sup>1</sup> Statistics for marital status, living arrangements, and income are all based on surveys of noninstitutionalized elderly.

**TABLE 2-2.** Racial and ethnic changes in population of people 65 and older (65+)—United States, 1995–2050 (middle series projections)

	1995	2010	2030	2050
<b>All non-whites</b>				
Population (in millions)	3.5	5.0	10.6	14.4
As % of total 65+ population	(10.4%)	(12.7%)	(15.3%)	(18.3%)
<b>Blacks</b> (in millions)	2.7	3.4	6.9	8.6
As % of total 65+ population	(8.1%)	(8.7%)	(10.0%)	(10.9%)
<b>Asians/Pacific Islanders</b> (in millions)	0.6	1.3	3.3	5.2
As % of total 65+ population	(1.9%)	(3.4%)	(4.7%)	(6.6%)
<b>Native Americans<sup>a</sup></b> (in millions)	0.1	0.2	0.4	0.6
As % of total 65+ population	(0.4%)	(0.6%)	(0.6%)	(0.8%)
<b>Hispanics<sup>b</sup></b> (in millions)	1.5	2.8	7.8	13.8
As % of total 65+ population	(4.5%)	(7.2%)	(11.2%)	(17.5%)

<sup>a</sup>American Indian, Eskimo, Aleut.

<sup>b</sup>Hispanics may be of any race, including white, so sum of racial/ethnic subgroups exceeds “All non-whites.”

Hispanic elderly people (Hobbs and Damon 1996; Social Security Administration 1998).

## Worldwide Aging

The aging of populations is a worldwide phenomenon. In 1995, 371 million people, 6.5% of the world's population, were 65+ (Table 2-3). Their numbers will almost double in 2020, when 9% of the world's population will be 65+. In that year, two-thirds of the world's elderly people will live in developing countries. In the year 2050, one of four people in developed countries, and one of seven in developing countries, will be 65 or older.

## Life Expectancy

The single statistic that best summarizes a population's health is life expectancy—the average number of years of life remaining at a certain age. Although life expectancy from birth is the most commonly quoted, life tables generate life expectancy values for all ages of a population. Thus we can compare the longevity of elderly people in different groups or at different times using life expectancy at, for example, age 65 or age 85.

Older Americans have many years of life yet to live. In 1995, a 65-year-old person had a life expectancy of 17.4 years—more than 20% of his or her life still remained (Anderson et al. 1997). In the same year, a 75-year-old person had an expected 11 more years of life, and an 85-year-old could expect to live, on average, 6 more years. Life expectancy for elderly people has, in general, been improving since 1900. At the turn of the century, the life expectancy of a 65-year-old person was 11.9 years and that of an 85-year-old person was 4.0 years (Statistical Bulletin of the Metropolitan Insurance Co 1987). Thus in less than 100 years, life expectancy has increased by about 50% for older Americans.

As is true of virtually all health measures, life expectancy for elderly people varies by race and sex, with elderly women having a definite, but decreasing, survival advantage over men. Table 2-4 lists 1995 life expectancy for older subgroups: a 65-year-old man had a life expectancy of 15.6 years; a 65-year-old woman, 18.9 years. For ages 85+, male-female differences in life expectancy shrank to 1.1 years (5.2 for men versus 6.3 for women). For blacks and whites as well, the gap in life expectancy narrows with age:

**TABLE 2-3. World population of people 65 and older, by region: 1995–2050 (medium variant projections)**

Region	1995		2020		2050	
	Number (in millions)	% of total population	Number (in millions)	% of total population	Number (in millions)	% of total population

in 1995, the life expectancy of a 65-year-old white person was about 2 years greater than that of a black person the same age. However, at age 85, life expectancy of black people was much closer to that of whites: black men and women had life expectancies that were only 0.1 year less than those of their white counterparts. This closing of the gap of racial survival has been reported for many years and reflects a phenomenon known as the “black-white mortality crossover”: at very old ages mortality rates for whites exceed those of blacks (Nam 1995).

## ■ Mortality Rates

Life expectancy, though a succinct summary of a population's health, tells nothing of the specific components of survival: who dies, what people die from, and how these causes change over time. Mortality data, from which life expectancies are calculated, provide this information. In the United States, 5 of every 100 elderly people die each year (Table 2-5). Mortality rises dramatically with age: in 1995, the death rates were 2.6% for those 65–74 years old,

5.9% for those 75–84 years old, and 15.5% for those 85+. Men are at higher risk of dying than are women; and, up to very old ages, blacks have higher mortality rates than do whites (National Center for Health Statistics 1997a). However, with advancing age, differences in mortality rates lessen between the sexes and between the races; and, as noted previously, at very old ages, mortality rates for blacks of both sexes become lower than those of whites.

High mortality rates in the elderly result in a large turnover of this population in a short time and may result in considerable changes in the characteristics of the 65+ population in a short period. Myers (1990) estimated that 50% of those who were 65+ in 1970 had died by 1980. Thus the elderly population in one decade may be quite different from that in the next in terms of health, lifestyles, and attitudes.

The three leading causes of death in elderly people are heart disease, cancer, and stroke. In 1995, these accounted for two-thirds of all elderly deaths (Anderson et al. 1997). The major fatal cancers in elderly men are lung, prostate, and colon; in elderly women, the major sites are lung, breast, and colon (Yancik 1997). Chronic obstructive pulmonary disease is the fourth leading cause of death, and the combined category of pneumonia/influenza is the fifth. This last cause particularly affects the oldest old: in 1995, the pneumonia/influenza death rate among those 85+ was 18 times that of those 65–74 years old. In 1995, for the first time in the history of vital statistics reports in the United States, Alzheimer's disease (AD) appeared as one of the 10 leading causes of death in the elderly, ranking number eight in the 65+ population (Anderson et al. 1997) (see Chapter 24 in this volume).

In the United States, mortality has been declining for all three older age groups for many years (Figure 2-2). Between 1950 and 1995, mortality rates for people 65–84 years old decreased by more than one-third; for those 85+, the rates declined by approximately one-fourth (National Center for Health Statistics 1997a). Much of this remarkable decline in mortality is a result of improvements in car-

**TABLE 2-5.** Leading causes of death in the population 65 and older (65+)—United States, 1995

Cause	Death rates per 1,000 people			
	65+	65-74	75-84	85+

diovascular disease mortality (Bonita and Beaglehole 1996; Centers for Disease Control 1997; Feinleib 1995; Hunink et al. 1997). Between 1950 and 1995, the age-adjusted rates for heart disease for the total United States population dropped by more than 50%; those of stroke, by 70% (National Center for Health Statistics 1997a). These improvements occurred in the elderly population as well: in the past 45 years, death rates from both heart disease and stroke have decreased in all three of the elderly age groups. Unlike cardiovascular mortality, death rates for cancer have been increasing in the elderly (Ries et al. 1998). These long-term increases in cancer mortality have not been enough to offset the effects of improved cardiovascular disease mortality.

In developed countries, virtually all deaths are recorded, so that, of all health status measures, mortality data are the most complete. Cause-specific mortality, however, has a number of limitations, especially for older persons (Havlik and Rosenberg 1992). Diagnostic accuracy of cause of death partly reflects much lower autopsy rates in the elderly (Smith 1997), as well as attending physicians' perceptions of what is normal aging and what is disease. But even with thorough medical assessment of an elderly decedent, determining the underlying cause of death can be difficult because of the presence of multiple, chronic disorders.

AD exemplifies the limitations of mortality data. In a 1976 article on the senile type of AD, Katzman estimated that it was the fourth or fifth leading cause of death in the United States (Katzman 1976), although it was not listed among the 263 leading causes of death listed in United States vital statistics. (Until 1979, there was no specific cause-of-death code for AD.) Katzman's article greatly increased awareness of AD as a major health problem of the elderly population. Also, the International Classification of Diseases (ICD), used to code conditions on death certificates, now has a unique number for AD (U.S. Department of Health and Human Services 1980). Because there is now a specific ICD code for AD and because of increasing physician awareness of this illness, increasingly more deaths are appropriately attributed to this cause. However, even with both improved recognition of AD and assignment of an ICD code for it, current mortality rates still underestimate the public health importance of this disease (Hoyert 1996). Many cases are undiagnosed (Small et al. 1997) or, if diagnosed, AD may not be mentioned on the death certificate (Hoyert 1996).

## ■ Risk of Severe Medical Disease

The risk of developing a disease is not the same as the risk of dying from it. Even diseases that are the leading causes of death do not always result in death and so do not give a complete picture of the occurrence of those diseases in a population. The two epidemiological measures most often used to describe the occurrence of disease are incidence and prevalence. Incidence is the number of new cases of a disease or condition arising in a population within a certain period (usually a year). Prevalence is the number of existing cases in a population at a certain point in time (or in a short period). Though incidence is the only valid way to measure risk of developing disease, incidence studies are usually expensive and time-consuming to conduct. Because of this limitation, relatively few community-based incidence studies have been conducted on even the three leading causes of death: heart disease, cancer, and stroke. Fewer still have collected information on any but the youngest of the elderly. Where adequate data exist, they show that the prevalence and incidence of severe diseases increase greatly in elderly people.

### Heart Disease

Four-fifths of all heart disease deaths in the United States occur in people 65+ (Anderson et al. 1997). Yet there is remarkably little population-based research on the risk of this population developing heart disease. Rochester, Minnesota, has an excellent medical record linkage system that covers virtually all residents (Leibson et al. 1992). In Rochester, between 1979 and 1982, the average annual incidence of coronary heart disease for people 70+ was 1.7/100 for men and 1.4/100 for women (Elveback et al. 1986). The coronary heart disease rate in men 70+ was almost eight times greater than that observed in 30- to 49-year-old men; the rate in women 70+ was 24 times that of women who were 30–49. As has been shown in other studies, older men have a higher risk of heart disease than do women, but this gender difference narrows with age (Burke et al. 1989; Centers for Disease Control 1992b).

Unlike the clear decline in heart disease mortality over the past three decades, evidence for decreases in risk of developing heart disease (incidence) is very limited. Furthermore, published reports on whether or not there have been changes, and the direction of the changes, are mixed. In Rochester, between 1965–1969 and 1979–1982, the risk of myocardial infarction and sudden unexpected death declined for 50- to 69-year-old men but increased for women (Elveback et al. 1986). For those 70+, rates of these manifestations of heart disease declined only slightly over time

for men (9%) and not at all for women. Croft et al. (1997) calculated changes in age-adjusted hospitalization rates for heart failure in the 65+ population in the United States between 1986 and 1993: heart failure rates increased slightly in this period. The Minnesota Heart Survey found no significant changes in hospitalized myocardial infarction rates in Minneapolis-St. Paul between 1970 and 1985 (Burke et al. 1989). However, for the period 1985–1990, a slight decrease in hospitalization rates for acute myocardial infarction was found (McGovern et al. 1996). Sytkowski et al. (1996) looked at long-term changes in risk of cardiovascular disease in three cohorts of Framingham, Massachusetts, subjects (ages 50–59). The incidence of all cardiovascular diseases decreased by 21% in women and only 6% in men. Most of this decline occurred between 1950 and 1959, with little changes later. For women, the greatest declines occurred in the risk of having a stroke.

With so little change occurring in the risk of developing heart disease, what might be the reason for the large decline in heart disease mortality? A number of authors report improvements in survival of patients with heart disease (Feinleib 1995; Massie and Shah 1997; McGovern et al. 1996; Sytkowski et al. 1996). Thus, intervention efforts appear to be less effective in preventing the onset of heart disease than in reducing its severity (Hunink et al. 1997).

### Cancer

The Surveillance and Epidemiology End Results program, a major source of data on cancer incidence in the United States, estimates that 60% of all new cancers in the United States occur in the 65+ population (Yancik 1997) and that people 65+ have a risk of developing cancer that is more than 10 times that of those under 65 (Ries et al. 1998). The leading cancer incidence sites in older women are breast, lung, and colon. In men, they are prostate, lung, and colon (Rosenthal 1998). As is true for cancer mortality, the incidence rates of a number of neoplasms have increased in the 65+ population in the past two decades (Balducci and Lyman 1997). Some of these increased rates may be a result of improved detection methods, for example, prostate-specific antigen screening (Stephenson and Stanford 1997). For other neoplasms, such as lung cancer, these increases are a consequence of lifestyle differences, particularly tobacco use, in older birth cohorts (Levi et al. 1996; Travis et al. 1996). Recently, certain types of cancer appear to be declining in some elderly subgroups: Travis et al. (1996) report decreases in squamous cell carcinoma rates for both black and white men under 75 years of age, as well as declining small cell carcinoma rates for black men under 75.

## Stroke

More than heart disease or cancer, stroke is a disease of elderly people. Almost 90% of all stroke deaths occur in the elderly population (Anderson et al. 1997). Stroke is also one of the most disabling conditions to affect elderly people (Kalache and Aboderin 1995; Verbrugge et al. 1989), and its risk increases with age (Sudlow and Warlow 1997). Well-designed studies of stroke incidence indicate that 2%–4% of the 85+ age group have a first-ever stroke each year, and men have a somewhat greater risk of stroke than do women (Malmgren et al. 1987). Some of the best evidence for changes in stroke incidence with time comes from Rochester, Minnesota, where average annual stroke rates were calculated for 5-year periods starting in 1945 (Broderick et al. 1989). Between 1945–1949 and 1975–1979, total age-adjusted stroke rates dropped by 45% in this city (Figure 2–3). However, this decline was followed by a 17% increase in stroke incidence between 1975–1979 and 1980–1984 (Broderick et al. 1989). Over the 40-year period, changes occurred in all age groups, but were most pronounced in the 85+ age group. The most recent data from Rochester, for the years 1985–1989, show that the stroke risk in Rochester has changed little compared with that for the previous 5 years (Brown et al. 1996).

## Neuropsychiatric Disorders

### Dementia

Progressive loss of cognition and eventual total incapacitation make dementia one of the most dreaded consequences of aging. It is a major cause of functional disability

(Barberger-Gateau and Fabrigoule 1997) and the need for long-term care, including admission to nursing homes (Hing et al. 1989). Dementia is also an enormous burden to family caregivers (Office of Technology Assessment Task Force 1988; Schulz et al. 1995; Small et al. 1997).

If there is an “epidemic” among the elderly population, it is AD and related dementias (see Chapter 24 in this volume). An estimated 4 million people in the United States have AD, with a 6%–8% prevalence in the 65+ group and 30% in those 85+ (Small et al. 1997). Studies have been done in many parts of the world and have produced widely differing estimates of dementia prevalence (Corrada et al. 1995). However, for no other disorder of the elderly are methodological issues of conducting community-based studies so complex or variation in study design so great (Chandra et al. 1994; Jorm 1991; van Duijn 1996). These methodological variations, rather than true differences in frequency of dementia, are a major reason why estimates of prevalence rates of dementia are so disparate.

Another cause of differences in rates of overall prevalence of dementia is the type of dementia identified. The Office of Technology Assessment Task Force (1988) lists more than 80 conditions that cause or simulate dementia (see Chapters 23 and 24 in this volume). In many countries, AD is the most common cause and vascular dementia the second most common (Hebert and Brayne 1995; Small et al. 1997). The exact proportion of dementia attributable to each cause depends in part on the stroke risk in the population of interest: where stroke risk is higher, for example, among blacks (Broderick et al. 1998; Centers for Disease Control 1992a) or among Asian populations (Kalache and Aboderin 1995; Malmgren et al. 1987; van Duijn 1996), the proportion of dementia attributable to vascular causes will be higher. Similarly, secular declines in stroke risk should have an effect on the total risk of dementia, as well as on the type of dementia seen.

Few population-based studies of dementia incidence have been conducted (Keefover 1996; Kokmen et al. 1996). In Rochester, Minnesota, data were collected on all new cases occurring between 1970 and 1974 (Kokmen et al. 1988). The average annual incidence rates of all dementias there were 1.4/1,000 for those 60–69 years old, 6.4/1,000 for those 70–79 years old, and 20.5/1,000 for those 80+. AD was the diagnosis in 38% of new dementia cases in people who were 60–69, 71% of those 70–79, and 82% in those 80+. Some studies suggest a somewhat greater frequency of AD in women (Jorm 1990; Seshadri et al. 1997; Small et al. 1997); however, others find no significant differences by sex (Corrada et al. 1995; Hebert and Brayne 1995; van Duijn 1996).

Only a few studies have looked at secular changes in

**FIGURE 2-3.** Average annual stroke incidence in the elderly population—Rochester, Minnesota, 1945–1984. *Source.* Adapted from Broderick et al. 1989.

the incidence of dementia. In Lundby, Sweden, residents were followed from 1947 until 1972 (Rorsman et al. 1986). No change in the incidence of “age psychosis” was detected. Similarly, in Rochester, Minnesota, incidence rates for dementia were stable between 1960 and 1984, except for a slight increase in the very old (Kokmen et al. 1996).

## Other Mental Disorders

Except for dementia, the frequency of most mental disorders does not appear to increase in the elderly population. Though conducted 15 years ago, the Epidemiologic Catchment Area Program still provides one of the largest samples of population-based data on mental illness in elderly Americans (Eaton et al. 1989; Fichter et al. 1996). In the early 1980s, staff from this research program interviewed residents in five cities (Baltimore, Maryland; St. Louis, Missouri; Los Angeles, California; New Haven, Connecticut; and Durham, North Carolina), identifying major types of mental disorders by using a questionnaire based on DSM-III criteria (American Psychiatric Association 1980). The prevalence of all types of mental disorder in elderly people was 12.3%, lower than that for any other age group (Regier et al. 1988) (Table 2–6). By type of disorder, the prevalence was also lower in all categories except severe cognitive impairment: as measured by the Mini-Mental State Exam (Folstein et al. 1975), 5% of the elderly in this sample had severe cognitive impairment. For some of the disorders, differences by sex were found: the prevalence of alcohol abuse was six times greater in elderly men than in elderly women (see Chapter 16 in this volume), whereas the prevalence of affective disorders in women was more than double that in men (see Chapter 13 in this volume). Elderly men had a higher prevalence of severe cognitive impairment than did women at ages 65–74 and a similar rate at ages 75–84, but for those 85+, the prevalence in men was less than half that observed in women (8.2% compared with 19.5%).

The Epidemiologic Catchment Area Program re-

interviewed subjects 1 year after the baseline interview to determine the incidence (rate of new cases) in their population (Eaton et al. 1989). The authors found that the onset of major depressive disorder was rare in elderly subjects (except in St. Louis), as was the onset of panic disorders (see Chapters 13 and 15 in this volume). Not surprisingly, the risk of developing severe cognitive impairment increased with age: approximately 5 of every 100 subjects 65+ developed severe cognitive impairment each year. Unlike the prevalence data, the incidence of alcohol abuse increased after age 60: in men 75+ older, the rate was six times as high as that for men 65–74 (see Chapter 16 in this volume). For women, the incidence was twice as high in the 75+ group as in the 65–74 age group.

Reported prevalences of depression among the elderly vary widely (Roberts et al. 1997). Low estimates may be a result, in part, of methodological issues resulting in underascertainment (Garrard et al. 1998; Heithoff 1995; Pearson et al. 1997; Roberts et al. 1997; Slater and Katz 1995). Furthermore, depression is a significant cause of morbidity and mortality in older people (Zisook and Downs 1998). Suicide rates in older white males are currently the highest suicide rate of all age groups: in 1995, the rates for white men were 30/100,000 for those 65–74, 48/100,000 for those 75–84, and 68/100,000 for the 85+ group (National Center for Health Statistics 1997a) (see Chapter 13 in this volume). Since the early 1980s, the suicide rates for white males 85 and older have been rising (McIntosh 1995; National Center for Health Statistics 1997a). An urgent research question is whether or not the incidence and prevalence of depression are also increasing in this high-risk group (Roberts et al. 1997).

## Prevalence of Chronic Conditions

In addition to their high risk of fatal illnesses, many older adults suffer from less serious, but nevertheless affecting, chronic disorders. A major source of information about the

**TABLE 2–6. Epidemiologic Catchment Area Program 1-month prevalence of mental disorders in persons 65 and older (per 100 subjects)**

	Anxiety disorders <sup>a</sup>	Severe cognitive impairment	Affective disorders <sup>b</sup>	Alcohol abuse	Schizophrenia	Antisocial personality
Both sexes	5.5	4.9	2.5	0.9	0.1	0.0

prevalence of chronic conditions in the United States is the National Health Interview Survey, a continuing survey of the noninstitutionalized United States population (Havlik et al. 1987). Table 2–7 lists 10 of the most prevalent chronic conditions reported by the 65+ population. Almost 50% of older Americans living in the community report that they have arthritis, a third say that they are deaf or have other hearing impairments, and 8% are blind or visually impaired (not corrected by glasses). Surprisingly, the prevalence of many of these conditions does not increase with age. However, the National Health Interview Survey excludes nursing home residents. In very old subjects, some of the listed conditions are likely to result in institutionalization or death, removing subjects with these conditions from the community-dwelling population. Incontinence, too, is common among the 65+ population: Fultz and Herzog (1996) estimate that 30% of noninstitutionalized older people have urinary incontinence.

Many of the most prevalent conditions in the elderly population are not fatal but still have a major impact on the quality of life. Arthritis has been targeted as a major health problem in the elderly because of its high prevalence and impact (Boult et al. 1996; Callahan et al. 1996; Verbrugge and Patrick 1995). Both visual and hearing problems often lead to significant physical, social, and emotional problems (Crews 1994; Jerger et al. 1995; Maino 1996). Incontinence is associated with an increased risk of depression, social isolation, and institutionalization (Busby-Whitehead and Johnson 1998; Thom et al. 1997).

**TABLE 2-7. Percentage of self-reported conditions of noninstitutionalized elderly individuals—United States, 1990–1992**

## Comorbidity

Comorbidity, the coexistence of multiple conditions, is common in elderly individuals. The Supplement on Aging, a supplement to the 1984 National Health Interview Survey, focused on the elderly population (Fitti and Kovar 1987). Half of the Supplement's subjects 60+ reported two or more of nine medical conditions, the most frequent combination being arthritis and high blood pressure (Guralnik et al. 1989). Comorbidity complicates diagnosis and management of health problems in elderly patients and is associated with a number of health problems, including functional limitations (Guralnik 1996; Guralnik et al. 1996; Verbrugge et al. 1991) and mortality (Dunn et al. 1992).

Psychiatric disorders also often coexist with organic illnesses of the elderly (Zisook and Downs 1998). For example, depression is frequently reported in AD (Cummings and Mendez 1997) (see Chapter 24 in this volume), stroke (Finch et al. 1992) (see Chapter 27 in this volume), and Parkinson's disease (Tom and Cummings 1998) (see Chapter 26 in this volume). Methodological problems beset the accurate estimation of comorbidity and complicate the determination of whether depression accompanying organic illness is secondary or unrelated to the illness (Tandberg et al. 1997). Moreover, these disorders have clinical features that overlap with those of depression and make assessment difficult (Kramer and Reifler 1992; Tom and Cummings 1998; Zisook and Downs 1998). Whatever the precise risk of depression in AD, stroke, or Parkinson's disease, any such comorbidity in these devastating disorders will add to an already heavy burden of dysfunction. Because depression can often be alleviated in such patients, it is important that they be evaluated for depression (Cummings and Mendez 1997; Tom and Cummings 1998).

## Functional Limitations

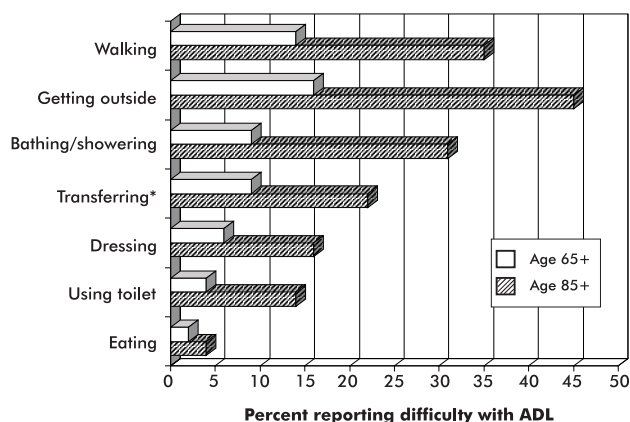

The well-being of the elderly population is measured primarily in terms of functional abilities. Kane (1990) wrote, "Function is the common language of gerontology" (p. 15). Impairment of physical and psychological function is associated with an enormous number of health problems, including greater risk of specific conditions and injuries, such as fractures, increased probability of institutionalization, and higher mortality (Guralnik et al. 1996, 1997).

If, however, function is the lingua franca of geriatric neuropsychiatric research and practice, it is a language with many dialects: functional ability has many compo-

nents, and for each there is a multitude of assessment instruments (Guralnik and LaCroix 1992; Guralnik et al. 1996), each with its own set of problems of application and interpretation (Rodgers and Miller 1997; Thomas et al. 1998; Wiener et al. 1990). In population-based surveys, the most common assessments are of activities of daily living (ADLs) and instrumental activities of daily living (IADLs). ADLs reflect basic personal care activities: eating, bathing, dressing, getting in and out of bed or a chair (“transferring”), using the toilet, and mobility. IADLs measure more complex functions of daily living such as preparing meals, using the telephone, managing money, and doing housework.

The Survey of Income and Program Participation, conducted by the U.S. Bureau of the Census, provides estimates of functional limitations for the noninstitutionalized United States population. Figure 2-4 shows the percentage of elderly people who reported difficulties with ADLs. Difficulty in walking was the most prevalent ADL limitation: 14% of the 65+ group and 35% of those 85+ had problems walking. However, only 2% of all elderly in the community and 4% of those 85+ had difficulties with eating activities. The most frequent IADL difficulty was with light housework (Figure 2-5).

Most studies indicate that the prevalence of functional limitations is greater in women than in men (Guralnik et al. 1996; Hobbs and Damon 1996; Manton 1997). This increased prevalence in women appears to be a result primarily of the longer survival of women with disabilities rather than true differences in risk (i.e., incidence) of developing functional limitations (Guralnik et al. 1997; Manton 1997).

## ■ Institutionalization

For the elderly population, ultimate dependency is symbolized by admission to nursing homes (see Chapter 37 in this volume). Murtaugh et al. (1997) estimate that 40% of all people reaching age 65 will enter a nursing home at some time in their lives. Nevertheless, at any one time, the proportion of the United States elderly population in nursing homes is not high. According to data from the 1995 National Nursing Home Survey, the percentage of elderly in nursing homes is 4.2% (National Center for Health Statistics 1997a); but the percentage increases from 1% for those 65–74 years old to 5% for those 75–84 years old and to 20% for those 85+. A greater proportion of women are in nursing homes, a difference that becomes especially pronounced at very old ages (Figure 2-6). This disparity by sex is the result of a number of factors including the higher prevalence of disability among women and the fact that, with their greater longevity, women are less likely to have spouses available as caretakers (Chenier 1997). Older whites are more likely to be institutionalized than elderly blacks (Wallace et al. 1998).

## ■ Conclusions

Aging is associated with increased vulnerability to a number of interacting and accumulating disadvantages: physical, functional, social, psychological, and economic. Assessment of all these dimensions is needed to give a complete picture of the health of the elderly individual (Fillenbaum 1990; Turpie et al. 1997). Beyond the specific

**FIGURE 2-6.** Percentage of elderly residents in nursing homes, by age and sex—United States, 1995.

Source. Adapted from National Center for Health Statistics 1997a.

impact that each dimension has on the well-being of elderly people, together they create a complex matrix of cause and effect (Fried and Wallace 1992). Furthermore, the health of an elderly person often greatly affects others. In 1991, 4.5 million elderly living in the community needed help with ADLs (Hobbs and Damon 1996). More than one-third of caregivers are themselves over 65 years old (Stone and Kemper 1989). Informal caregivers, often female relatives, are at increased risk for health problems, both physical and psychological (Chenier 1997; Schulz et al. 1995; Wijeratne 1997). In many instances, the caregiver is as appropriate an intervention target as the patient (Chenier 1997) (see Chapter 36 in this volume).

Characterizing and treating health problems of the elderly population is much more complex than doing so in younger groups. The traditional medical model of diseased versus not diseased is often too simplistic to address health issues in older populations, and health professionals need to expand and refocus expectations regarding health and prevention. As an example, elderly patients may have several impairments, with no obvious link to a specific disease. Halting or slowing progression of any one of these impairments may make a critical difference in their quality of life and ability to remain independent.

One of the most overlooked characteristics of the elderly population is its diversity in health. Age “65+” encompasses people whose ages range from 65 to greater than 100. Most research confirms that, with each successive 10 years of age, health worsens. Functional limitations, incidence and prevalence of specific conditions, and mortality all increase enormously. However, people who are extremely old (100+ years) appear to be healthier than those just younger than them (Perls 1995, 1997; Smith 1996,

1997). Also, for every morbidity statistic presented in this chapter, there is a complementary one of health. For example, 75% of the noninstitutionalized elderly population receive no help with ADLs and IADLs (Hing and Bloom 1990); and four-fifths of the 85+ population live in the community, not in nursing homes (National Center for Health Statistics 1997a).

The demographic heterogeneity of elderly Americans explains, in part, the diversity of health. Sex and race are associated with different health risks (Manton 1997). As has been described, women live longer than men, but risks for specific types of morbidity vary between the sexes. The elderly population is also racially diverse. Each of the minority elderly groups in the United States has a different health profile (Bernard et al. 1997; Clinics in Geriatric Medicine 1995; Markides et al. 1996; Mouton 1997; Tanjasiri et al. 1995). With future changes in the racial and ethnic characteristics of the 65+ population, the health needs of American elderly will change as well.

As the 65+ population in the United States is diverse, so are the elderly in other countries, both within those countries and compared with the data presented in this chapter. Although many of the general concepts outlined here will apply to the elderly in other nations, measures of specific morbidity, functional limitations, and institutionalization are not always comparable. Even when standardized methods are used to study the elderly populations of other countries, cultural, social, and economic differences may affect clinical presentation, as well as use of health services.

Much has been written about the compression of morbidity, that is, delaying or preventing the onset of illness and disability so that the amount of active, self-sufficient life in the elderly person increases as a proportion of total life expectancy (Campion 1998; Diehr et al. 1998; Fries 1980, 1996; Katz et al. 1983). There is a great deal of debate regarding whether many measures of health, such as functional ability, are being compressed (Crimmins et al. 1997; Kane et al. 1990). But there is no doubt that, according to mortality and some morbidity measures, the health of the elderly population is improving (Leibson et al. 1992; Manton et al. 1998), or is at least susceptible to improvement (Fried and Guralnik 1997; Fries 1997; Goldberg and Chavin 1997; Vita et al. 1998). Increasingly there are calls to study the vigorous, or successful, elderly (Rowe and Kahn 1997) and to enhance life, as well as to extend it (Lonergan 1991). More than for any other age group, the health of the elderly population is a continuum, and their heterogeneity strongly suggests that much ill-health in the elderly is preventable.

Besides health, other factors are changing that are

likely to have a positive effect on the well-being of older people. For example, in 1991, 8.5% of noninstitutionalized women 65+ had completed at least 4 years of college; this percentage is expected to increase to 22% in the year 2030 (Hobbs and Damon 1996). Because of such changes, women will be more able to make lives outside their immediate families. When they reach advanced ages, these women are likely to be more socially and financially independent than their past cohorts.

In spite of much debate about the health and welfare of our older population in the 21st century, much evidence suggests that this group will be healthier and financially more secure than the elderly of today (Vatter 1998). For geriatric health professionals, a commitment to understanding the unique characteristics of elderly people and the complexity of their health will help ensure that, in the coming century, these improvements will take place.

# Neurobiology of Aging

Richard E. Powers, M.D.

The human brain undergoes senescent changes governed by a complex mixture of biological, behavioral, and environmental factors. The boundary between normal aging and age-related disease can be difficult to mark. Most causes of age-related neurological degeneration involve a combination of senescent brain changes and physiological alterations outside the central nervous system (CNS).

The human brain reaches full maturity in the second or third decade of life, and senescent alterations usually become apparent after age 40 to the neuropathologist. Each human brain has a unique mixture of age-related alterations that vary in pathology, location, and intensity. The rate of progression ranges from linear to parabolic; however, the aging process is progressive in most instances.

Neuroscientists do not know whether human brain aging follows Gompertz Law, stating that mortality rates increase exponentially with age. Theories attributed to the gerontologist James Fries indicate that the body naturally wears out around age 85 (Comfort 1979). Newer theories suggest that death rates may level off for the oldest old (Barinaga 1992). Biodemographic longevity studies show deceleration of mortality rates after age 80 (Vaupel et al. 1998). The presence of dementia predicts poor 7-year survival after age 85 (Aevarsson et al. 1998).

Most mammalian species undergo neurological aging

identifiable with gross, microscopic, molecular biological, and chemical techniques. These alterations may be affected by genetic (Hayflick 1985) and environmental variables (Van Gool et al. 1987), as well as systemic disease outside the CNS. Human brain aging research is fraught with conceptual and technical problems. Methodological problems limit the precision of comparing brain alterations to behavioral changes in nonprimate species whose life cycle is sufficiently short to allow easy study of aging (Baxter and Gallagher 1996).

## Theories of Aging

Many theories attempt to explain the age-related degeneration that occurs across mammalian species. Aging theories can be divided into the organ-based, physiological, and genomic hypotheses (Hayflick 1985). Organ-based theories hypothesize that human aging results from incremental loss of organ function driven by the immune system or alterations in neuroendocrine function of the CNS. Physiological theories suggest that toxic levels of cellular waste products accumulate over time resulting from free radical damage, incapacitation of neuroprotective mechanisms, or cross-linkage of vital molecules, for example, collagen, deoxyribonucleic acid (DNA), and vital proteins.

The genomic theories hypothesize aging as the consequence of somatic mutations, multiple genetic errors, or programmed cell death. Life span studies suggest that heritability accounts for less than 35% of variance in human survival duration. Human twin studies show that nonshared environmental factors account for over 65% of variance in survivals (Finch and Tanzi 1997).

A conceptual disagreement exists between theories that human senescent brain alterations result from disuse versus overuse (i.e., the “use it or lose it” theory) and those that attribute aging to cumulative damage (i.e., the “wearing it out” theory) (Davies 1991; Greenamyre 1991; McEwen 1991; Scheff 1991; Swaab 1991). Most experimental aging data come from nonhuman models and provide the basis for this conceptual disagreement. Mammalian aging is most often described in the rodent, in which metabolic rates may influence the rate of aging (Hofman 1983, 1991). A 40% reduction of rodent calorie intake will extend life span by 40%–50%. Diminished feeding of rodents will slow aging and prolong reproductive life span (Swaab 1991). Such dietary restriction may lower oxidative stress by slowing metabolism. Consistent exercise will enhance brain vascularity (Black et al. 1987). The effect of environmental factors on human aging is unknown, although rodent studies demonstrate a positive relationship between environmental stimulation and brain size (Anthony and Zerweck 1979; Van Gool et al. 1987). The effect of chronic physical and emotional stress on aging is unclear, but elevated glucocorticoids are toxic to rodent hippocampal neurons (Sapolsky 1987a, 1987b).

## ■ Aging and Genomic Function

The role of genetics in aging is illustrated by life spans that vary from 1 day for mayflies to 150 years for some turtles. The human aging process is accelerated as a consequence of several common, complex genetic disorders, for example, Turner’s and Down’s syndromes, but accelerated aging is the primary manifestation in several disorders termed progeria, for example, Hutchinson-Gilford and Werner’s syndromes (Brown 1990). Progeria is a rare syndrome occurring in 1 per 8 million individuals, and affected patients survive about 12 years from birth. Most victims (80%) die from myocardial infarctions produced by disseminated atherosclerosis. These children retain normal intellect but manifest many age-related physical changes (e.g., cataracts, balding, osteoporosis, neoplasms). Werner’s syndrome may represent an autosomal recessive disorder, and recent genetic evidence in Hutchinson-Gilford syndrome implicates a mutated DNA

helicase as the gene responsible for defective DNA metabolism producing the accelerated aging (Yu et al. 1996). These rare disorders demonstrate the role of genetic dysfunction in systemic aging.

The role of genetic regulation on human brain aging is less clear, as is the effect of aging on genetic function. Most aging research is conducted in rodents because methodological obstacles limit the study of DNA and RNA obtained from human brain tissues. Messenger RNAs for many proteins are present in low abundance and are difficult to study in all species (Finch and Morgan 1990). Integrity of genomic function depends on accuracy of base-pair sequences, as well as on histone content, three-dimensional conformation, methylation states, and multiple other biochemical variables that affect the accuracy and speed of genetic transcription. Studies in rodents and primates suggest that aging may simultaneously alter DNA base-pair sequence, genetic repair mechanisms, mRNA metabolism, posttranslational modification, protein biochemistry, and axonal transport. Telomere loss may control senescence and might constitute a “mitotic clock” (Ehrenstein 1998; Fossel 1998). The telomere is synthesized by the ribonucleoprotein enzyme telomerase, and this segment of amino acid repeats is located at the ends of each chromosome. Every human chromosome must have telomeres of sufficient length to ensure replicative function. A threshold telomerase activity may be necessary to sustain sufficient telomere length to protect this replicative ability. Telomeric dysregulation may promote several age-related diseases such as cancer or macular degeneration (Bodnar 1998).

Other genetic theories suggest that aging results from multiple genomic errors accumulated over time. Experimental models involving irradiated animals or others exposed to mutagens fail to show accelerated aging (Hayflick 1985). Age-related reactivation of X-linked genes may increase the expression in females of steroid sulfatase and monoamine oxidase A (MOA-A) (Wareham et al. 1987). Age-related demethylation of 5-methyldeoxycytidine can also occur in aging. Aged rodent DNA shows age-dependent change of excision repair and reduction of single-strand break repair (Niedermuller et al. 1985). Nongenomic mitochondrial DNA lacks repair mechanisms. Specific biomarkers for oxidative damage are increased 10-fold in human mitochondrial DNA over nuclear DNA and 15-fold in neuronal DNA from individuals over age 70. Although mitochondrial DNA exhibits high rates of age-related defects, mitochondria DNA damage is not clearly linked to neuronal death (Tomei and Umansky 1998). The quantity of mutated mitochondrial DNA may be small in comparison to the size of available genetic material. Mitochondrial mutations may need to exceed 50%–80% of the mitochondrial genomic pool for

clinical expression (Johnson 1999). The significance of cumulative age-related oxidative damage to DNA is unclear (Johnson et al. 1999).

Brain RNA content changes with age. The RNA repertoire is not drastically altered with aging; however, selected RNAs are increased or decreased (Finch and Morgan 1990). For instance, the abundance of pro-opiomelanocortin mRNA decreases by 30% in aging rodents, whereas luteinizing hormone-releasing hormone production remains constant (Finch and Morgan 1990). Total RNA content and poly(A) RNA do not significantly change in aging rodent or primate brain, but selected human RNA, such as tachykinin message in hypothalamus, is increased (Rance and Young 1991). Reductions of nuclear or nucleolar size in neurons of elderly humans suggest diminished gene or RNA activity. Selected human neuronal populations have reductions in nuclear and nucleolar volumes that reflect perikaryal atrophy. Nucleolar shrinkage may result from decreased transcription of ribosomal RNA cistrons and diminished assembly of ribosomes. Neuron populations damaged by neurofibrillary tangles have reduced RNA metabolism as well (Doebler et al. 1987).

Studies in aging rodents show slowing of protein synthesis and axonal transport. Increased amounts of conformationally altered, inactive enzymes accumulate in aging rodents (Finch and Morgan 1990; Ingvar et al. 1985). Some proteins are produced simultaneously by astrocytes and neurons. The interpretation of neuronal protein content is complicated by age- and disease-related increases in the numbers of astrocytes (Frederickson 1992). For example, stability in the number of adrenergic receptors in aging rodents may reflect diminished numbers of neuronal receptors counterbalanced by increased numbers of astrocytes with this molecule. The increased number of astrocytes in aging human brain may obscure similar alterations (Finch and Morgan 1990).

Age-related changes in posttranslational modification of proteins can produce accumulations of advanced glycation end-products in pyramidal neurons. The production of these complex molecules is increased by oxidative stress and inhibited by free radical scavengers or thiol antioxidants (Münch et al. 1996, 1998). This family of glycosylated proteins may contribute to free radical damage, amyloid deposition, and neurofibrillary degeneration (Münch et al. 1997).

## ■ Apoptosis

Apoptosis, a word derived from Greek *apo* (away from) and *ptosis* (falling), refers to cell death mediated by intrinsic cellular physiology. Multiple stimuli trigger apoptosis such as

DNA damage, steroid hormones, deficiency of trophic factors, and expression of specific genetic regulators like the *Bak* gene (Johnson 1999; Obaini et al. 1999). Neuronal apoptosis occurs during normal brain development as well as in pathological states such as ischemia or  $\beta$ -amyloid peptide toxicity (Bredesen 1995). The biochemical mechanisms of neuronal apoptosis are unclear. Initiation factors produce cellular alterations such as nuclear chromatin condensation and DNA fragmentation. Multiple cellular events may induce this cascade including mitochondrial dysfunction (Tatton and Chalmer-Redmon 1998). Apoptotic neurons are difficult to identify, but research suggests that apoptosis may occur in Alzheimer's disease and Parkinson's disease (Bredesen 1995).

## ■ Aging and Oxidative Stress

Oxidative stress may contribute to aging and neurodegenerative diseases (Joseph et al. 1998; Mecocci et al. 1993). Oxidative damage is produced by extrametabolic insults, for example, pollution and radiation or intrinsic metabolic sources. Approximately 2%–3% of oxygen consumed by cells results in oxygen-free radicals. Electron transport systems within mitochondrial membrane produce oxygen-derived superoxide ( $O_2^-$ ) in response to free radicals as well as multiple other toxic products, for example, hydrogen peroxide ( $H_2O_2$ ) and hydroxyl radicals (OH). Nitric oxide is another free radical that may contribute to *N*-methyl-D-aspartate-mediated neurotoxicity from stroke.

Multiple antioxidant defenses remove excess superoxides and  $H_2O_2$  including superoxide dismutase catalase and multiple peroxidases. Glutathione, vitamin E, and ascorbic acid also function as antioxidants.

Healthy aging may require a proper balance of free radical production and detoxification. Oxidative stress may result from increased sensitivity to free radical damage, decreased antioxidant protection, altered calcium homeostasis, or impaired ability to repair damage. Human serum antioxidant levels remain constant over time. Serum antioxidant levels like those of ascorbic acid and  $\beta$ -carotene are positively related to cognitive function in subjects over age 65 (Perrig et al. 1997). Mitochondrial failure and free radical damage are hypothesized causes of both Parkinson's and Alzheimer's diseases as well as amyotrophic lateral sclerosis (Beal 1998; Mizuno et al. 1998), supporting the use of antioxidants to prevent neurological damage.

## ■ Normal Versus Abnormal Brain Aging

The neuropathological distinctions between "normal" aging and disease are frequently obscure and confused by

conflicting literature. For example, senile plaques, amyloid deposits, and cholinergic deficits were considered disease markers until studies demonstrated similar alterations in brains of some cognitively intact elderly humans (Ball et al. 1997; Berg et al. 1998; Braak and Braak 1997; Crystal et al. 1988; Jellinger 1997; Troncoso et al. 1996) (Table 3–1). Subtle anoxic neuronal injury can be extremely difficult to identify, and considerable ischemic damage may escape detection by standard histopathological methods (Garcia 1992). Clinicopathological correlations can be confused by the lack of diagnostic sophistication and understanding of neurodegenerative disorders by pathologists (Powers et al. 1989). Some neuropathologists propose a continuum from normal aging through pathological aging to disease states (Dickson 1997). These unresolved clinical and pathological distinctions between aging and disease will continue until more sophisticated markers of disease are available (Table 3–1).

Neurons, astrocytes, oligodendrocytes, microglia, and blood vessels are the major cellular constituents of human CNS (Figure 3–1). The neuropil is the woven fabric of the cortex that includes neuronal and astrocytic processes. A normal neuron has a large nucleus, prominent nucleolus, conspicuous dendrites, and straight, thin axons that are difficult to visualize in routine preparations (Figure 3–1). Neuronal atrophy is defined by a decrease in size of the cell body (perikaryon), nucleus, and nucleolus and retraction or loss of dendritic arborization. Neural vulnerability to age-related damage depends on connectivity and neuronal physiology. Senescent changes of glia and vascular tissue

may contribute to neural dysfunction or neurodegenerative disorders as well as to atrophy or death of neurons. Neurons do not replicate in the mature brain; however, plasticity allows them to reorganize synapses and dendritic arborizations. Age-related changes can influence the availability of a specific neurotransmitter by altering production, release, reuptake, and transport. The number and affinity of receptors can either increase or decrease for transmitters depleted by senescent changes. The molecular promoters of neuronal plasticity and reinnervation are altered in aging. Trophic factors, such as nerve growth factor, may play important roles in preventing or slowing the aging process. Each of these brain components changes with senescence; however, none will discriminate normal brain aging from disease. No scientific consensus exists for the definition, causes, or consequences of normal brain aging. Few studies examine these issues in the very old (i.e., those who are over age 85).

In this chapter, I describe important gross, microscopic, neurochemical, and molecular biological alterations of aging human brain. Aging human neurons may enter a complicated cascade of atrophy, hypertrophy, synaptic reorganization, or death. The presence of changes such as cortical atrophy, senile plaques, amyloid deposits, or cholinergic deficits does not always predict neuropsychiatric sequelae. The severity of histopathological alterations, lesion location, and other cumulative brain damage is also important.

**TABLE 3–1. Comparison of age- and disease-related alterations usually present in brains of elderly (65 years or older) people**

Pathology	Cortical alterations in elderly, cognitively intact subjects	Cortical alterations in subjects with Alzheimer's disease
Atrophy or ventriculomegaly	0–2+	0–3+
Senile plaques	0–2+	3+
Neurofibrillary tangles	0–1+	0–3+
Presence of amyloid	0–2+	0–3+
Dystrophic neurites	0–1+	1+–3+

Note. 0 = none; 1+ = mild; 2+ = moderate; 3+ = severe.

## ■ Neuronal Alterations in Aging: The Hippocampus as a Model

### Normal Intrinsic Hippocampal Connections

The hippocampus is frequently studied because most mammalian species have hippocampi with well-defined neuronal population, consistent morphology, and similar connectivity (Rosene and Van Hoesen 1986). The hippocampus is the center of a series of interconnected structures termed the limbic lobes (Figure 3–2).

The hippocampus is an allocortical structure (i.e., three-layered cortex) and adjacent parahippocampal cortex is neocortex (i.e., six-layered cortex). These structures are usually altered in human aging and damaged in neurodevelopmental as well as neurodegenerative diseases (Braak and Braak 1991; Powers 1999). Brain imaging studies in large numbers of nondemented aged subjects demonstrate hippocampal atrophy in 29% of normal elders with diminished volume correlated to increasing age

**FIGURE 3-1.** Normal neurons and reactive astrocytes. *Panel A:* A silver preparation of human cerebellum demonstrating Purkinje cell (*arrow*) with a prominent nucleus and nucleolus. Many straight, thin axons are seen. *Panel B:* An immunocytochemical stain of reactive astrocytes using antibodies to glial fibrillary acidic protein (GFAP). These astrocytes have many long, thin processes and variable amounts of cytoplasm (*arrow*).

(DeLeon et al. 1997) (Figure 3-3).

The hippocampus, entorhinal cortex, and associated parahippocampal cortices span 3.5 cm of the mesial temporal lobe (Figure 3-2). The hippocampal formation is important for short-term memory, and transmission through this allocortical structure proceeds in an orderly fashion (Figure 3-3, *panels A and B*). Afferent inputs originate from layer II of entorhinal cortex and synapse on dendrites of granule cells in the molecular layer of the dentate gyrus (Figures 3-3 and 3-4). Transmission proceeds to the CA4-CA3 region via mossy fibers and then to the CA1 subiculum via axons termed the Schaffer collaterals. Information is relayed out to the deeper layers of the entorhinal cortex, that is, layer IV, and to neocortical regions such as the temporal lobe (Figure 3-3, *panel C*). Important basal forebrain cholinergic inputs project to the dentate gyrus (Decker 1987) and synapse on the dendrites of granule cells in the molecular layer (Rosene and Van Hoesen 1986). Noradrenergic and serotonergic fibers project onto neu-

rons in the CA4 through CA1 (Powers et al. 1988; Rosene and Van Hoesen 1986). Adrenergic and serotonergic receptors are present in hippocampus, and rodent studies show that these catecholamines will facilitate or synchronize hippocampal transmission (Rosene and Von Hoesen 1986).

GABAergic<sup>1</sup> and peptidergic neurons are present in CA4 and provide inhibitory transmission. Proper hippocampal function depends on a balance of these excitatory, inhibitory, and neuromodulatory transmitters.

### Cellular Hippocampal Alterations With Normal Aging

A range of neuronal alterations occurs in hippocampus of aging human brains. An age-related decline in volume and numbers of hippocampal neurons (Simic et al. 1997), particularly in CA1 and subiculum is confirmed by stereo-

<sup>1</sup> GABA,  $\gamma$ -aminobutyric acid.

logical techniques that provide the most accurate assessments (West 1993). Older studies show that the number of granule cell neurons in the dentate gyrus is reduced by 15% when comparing young to old subjects (Dam 1979) (Table 3–2). These small neurons provide a useful model for age-related changes (Figure 3–4). The dendritic tree of granule cells increases in 50- to 70-year-old humans and declines in the very old (those over 90) or those with Alz-

**FIGURE 3–2.** The limbic lobe is a system of interconnected structures including temporal lobe (L1 and L2), cingulate gyrus (L3), and basal forebrain (L4). This mid-sagittal section of brain demonstrates corpus callosum and mesial temporal lobe structures visualized after removal of brainstem. Four major components of the limbic system include: 1) amygdala and associated uncinate cortices, 2) hippocampus and parahippocampal cortices, 3) cingulate gyrus, and 4) hypothalamus where the fornix enters the mammillary bodies. The hippocampus courses lateral to the mesial temporal cortex (L1 and L2), spanning approximately 3.5 cm of the temporal lobe and swings around the splenium of the corpus callosum. Entorhinal cortex spreads over the uncinate gyrus at the level of rostral hippocampus (L1) and tapers down to a narrow band of cells in mid-level hippocampus (L2).

heimer's disease (Flood and Coleman 1988). This proliferation may reflect attempts by intact granule cell neurons to compensate for the senescent loss of neighboring neurons (Flood et al. 1985). Loss of inputs from neurons in entorhinal cortex results in sprouting by axons from other afferent neurons to fill the vacant synapses. Collateral axons develop from cholinergic neurons, intrinsic hippocampal neurons, and neurons of other temporal lobe areas

**FIGURE 3–3.** Gross and microscopic appearance of hippocampus from elderly control subjects and an individual with Alzheimer's disease. A schematic drawing depicts hippocampal neuronal pathways. (See Figure 3–4 for the cytoarchitectonics discussed here.) Coronal hippocampal sections are dissected from the mid-segment of mesial temporal lobe, that is, L2 in Figure 3–2. *Panel A:* Comparison of temporal lobes and hippocampi (arrows) from an elderly control subject (upper) and a subject with Alzheimer's disease (lower). A normal hippocampus and inferior horn of lateral ventricle are seen in the control subject. The subject with Alzheimer's disease has atrophy of the hippocampus, widening of the collateral sulcus, and ventriculomegaly. *Panel B:* A low-magnification photomicrograph of a normal hippocampus stained with cresyl violet. Important anatomical regions include dentate gyrus (d), the cornu ammonis (Ammon's horn [CA<sub>4</sub> through CA<sub>1</sub>]), the subiculum (SUB), entorhinal cortex (ERC), parahippocampal cortex (P) aside the collateral sulcus (CS), and fimbria (f). This hippocampus is depicted in *panel C*. The granule cell layer is part of the dentate gyrus. Boundaries between the four fields CA<sub>4</sub> through CA<sub>1</sub> are determined by microscopic examination. *Panel C:* Schematic drawing of hippocampus depicting the complicated neuronal interactions in a typical 65-year-old human. Inputs from ERC neurons synapse on granule cell dendrites in the molecular layer (ML) of the dentate (intact afferents). Axons (mossy fibers) from the granule cells (GCL) synapse on CA<sub>4</sub>-CA<sub>3</sub> neurons that project to CA<sub>1</sub>-subiculum neurons via Schaffer collateral axons. Neurons in CA<sub>1</sub>-subiculum complete the loop with axons that synapse on neurons in ERC or temporal cortex. Each granule cell neuron is receiving many types of inputs from intact (IA) and damaged afferents (DA), from temporal cortices (e.g., from neurons in ERC), aminergic inputs from noradrenaline- or serotonin-producing neurons in brainstem (AI), cholinergic inputs from basal forebrain neurons, trophic factors (TF) such as nerve growth factor, and inhibitory inputs (II) such as  $\gamma$ -aminobutyric acid. Age-related decrease or loss of each type of input can affect granule cell firing and synaptic density. The vacant dendritic fields of some damaged granule cells may be partially occupied by dendritic sprouting (S) from adjacent healthy granule cells. Age-related loss of neurons in CA<sub>1</sub> region or subiculum (Sub) will eliminate targets for axons from CA<sub>3</sub> neurons. Loss of neurons in deep layers of ERC will disrupt outflow from CA<sub>1</sub>-subicular neurons. Hippocampal neurons and astrocytes (A) also respond to alterations of blood-brain barrier resulting from vascular damage (BV) such as arteriolosclerosis. F = fimbria.

**FIGURE 3-4.** Three types of cortex seen in human mesial temporal lobe. (See Figure 3-3 for the macroscopic appearance.) *Panel A:* Three-layered cortex from the CA<sub>3</sub> region of hippocampus. This allocortex has an outer layer consisting of the alveus (a) and stratum oriens (so), a middle layer comprised of pyramidal cells (sp), and an inner layer comprised of the stratum radiatum (sr) and stratum moleculare (sm). *Panel B:* The entorhinal cortex, a transition region from three-layered to six-layered cortex. Neurons in layer 2 (*star*) are damaged early in pathological aging and Alzheimer's disease. *Panel C:* Six-layered isocortex in the parahippocampal gyrus.

(Geddes and Cotman 1991). Dendritic extent in the neighboring CA3-CA2 region shows no change with aging (Figure 3-3, *panel C*), although neuronal loss may occur at up to 5.4% per decade from age 50 through 90 years (Ball 1977). Dendritic length of CA1 neurons also remains constant in normal aging but is significantly shortened in Alzheimer's disease (Hanks and Flood 1991). Loss of neurons may provoke gliosis (i.e., increased numbers of astrocytes with more conspicuous amounts of cytoplasm) (Figure 3-1, *panel B*). Hippocampal neurons are sensitive to a range of metabolic insults including hypoxia, hypoglycemia, and excitotoxic damage. For example, the hippocampus contains high densities of corticosteroid receptors. Elevation of adrenal steroids causes dendritic regression in rodents and may damage hippocampal circuits in humans (McEwen 1998). Steroid sensitivity may provide a link between stress and structural brain alterations.

The number of entorhinal cortex neurons remains stable with normal aging. Stereological counts show that a loss of 40%–60% of entorhinal neurons is required to produce mild cognitive impairment as opposed to 90% depletions for severe dementia (Gomez-Isla et al. 1996). (Figures 3-3, *panel A*, and 3-4). Selective injury to one group of neurons in the hippocampal circuit can disconnect the hippocampus and is a mechanism proposed in Alzheimer's disease (Hyman et al. 1984). Cholinergic, serotonergic, and noradrenergic inputs can be lost early as a result of damage to neurons in the basal forebrain (Decker 1987), raphe, or locus ceruleus (Tables 3-2 and 3-3). Intrinsic hippocampal neurons that employ excitatory amino acids can be damaged by neurofibrillary tangles, ischemic injury, or other processes. These processes, disturbing the inherent balance of excitatory and inhibitory transmission, also damage intrinsic inhibitory GABAergic and peptidergic neurons. While the process of neuronal injury and death proceeds, undamaged hippocampal neurons attempt reinnervation and reorganization (Figure 3-3, *panel C*).

Age-related alterations in hippocampus demonstrate the complicated cellular events associated with aging and the severity of cellular damage required to impair function. Hippocampal circuits are important because they are severely damaged in a range of neurodegenerative disorders (e.g., Alzheimer's and Pick's diseases) (Hyman et al. 1984). The resulting damage provides a model for aging of more complex circuits in neocortical regions.

## ■ Structural Brain Alterations in Aging

### Changes in Gross Anatomy

Normally, adult human brain volume varies by approximately 15% (Haug 1987) for given age groups. The average brain weight of a healthy man at age 65 is 1,360 g and at age 90 is 1,290 g (Dekaban and Sadowsky 1978). The male brain is typically 150 g heavier than the female brain. Gender differences in neuronal counts vary from 0% (Haug 1987; Haug and Eggers 1991) to 16% fewer neurons in female brains (Pakkenberg and Gundersen 1997). Rates of atrophy are similar among the sexes for some structures (Kemper 1984), but not all (Coffey et al. 1998; Cowell et al. 1994; Kaye et al. 1992; also see Chapter 9 in this volume). Brain volume for both sexes is reduced by 0.4% per year after age 60, as determined by radiographic measurements (Akiyama et al. 1997). Autopsy studies show a loss of 2–3 g per year after age 60 with an average lifetime loss of 7%–10% of brain weight (Table 3-2).

The dura mater contains the meningeal artery and

**TABLE 3-2.** Alterations in the number of neurons in selected brain regions of individuals over age 65

Location of neuronal count	Brain region	Change in neuronal count	Studies
Cortex	Middle frontal gyrus	0–10%	Terry et al. 1987
		28%–40% decrease in large neurons	Coleman and Flood 1987
	0–28% increase in small neurons

venous sinus systems that include arachnoid granulations. This fibrous covering can thicken and ossify with age. Cortical atrophy expands the arachnoid space, increases the length of bridging veins spanning from the cerebral hemisphere to the sagittal sinus, and may account for the higher rate of subdural hematomas in elderly people (Adams and Duchon 1992; see also Chapter 28 in this volume).

Cerebral cortical volume is reduced in aging based on premortem image analysis estimates (see Chapter 9 in this volume) and autopsy studies. Postmortem brain volume

peaks in the second or third decade and begins a gradual decline that is readily apparent after age 60 (Haug and Eggers 1991). The volume of the frontal lobes decreases approximately 10% with aging, and white matter is reduced 11% when brain volumes from younger subjects (20–40 years) are compared with those of elderly subjects (75–85 years) (Haug and Eggers 1991) (Figure 3-5).

“Atrophy” is defined as widening of sulci and narrowing of gyri (Figures 3-6, 3-7, and 3-8). Frontal (Figure 3-5), parasagittal, and temporal lobe atrophy are present in

**FIGURE 3-5.** Normal age-related atrophy. Coronal brain sections of frontal and temporal lobe contrast brain atrophy in an 85-year-old patient with nonspecific age-related atrophy (*bottom*) in a 15-year-old with a brain weight of 1325 g (*top*). Volume loss occurs in frontal, parasagittal, and temporal cortices.

both aging and Alzheimer's disease (Blessed et al. 1968; Kemper 1984; Tomlinson et al. 1970) (Figure 3–8). Severe cortical atrophy is rare in individuals whose cognition is intact (Table 3–1); however, mild to moderate ventriculomegaly is sometimes present (Blessed et al. 1968; Kemper 1984; Tomlinson et al. 1970) (Figure 3–5). The volumes of basal ganglia and thalamus are reduced by approximately 20% in aging (Haug et al. 1983; Murphy et al. 1992). The volume of the parieto-occipital region is found to be constant (Eggers et al. 1984) when comparing autopsy specimens from young individuals (20–40 years) to subjects over age 75.

### Cellular Changes in Aging

The cellular substrate of brain volume reduction is obscure. Atrophy may result from a net loss of neurons,

**FIGURE 3-6.** The coronal sections of normal (*panel A*) and atrophic (*panel B*) brain. *Panel A:* The brain from a 67-year-old control subject with minimal atrophy and normal ventricle size. The anterior commissure is highlighted by *arrowheads*, and the nucleus basalis of Meynert (nbM) is seen immediately beneath the anterior commissure (*arrow*). Normal-appearing amygdala (Amy) and superior temporal gyrus (Stg) are present. The third ventricle is normal in size, and hypothalamic nuclei are located immediately adjacent to the third ventricle. Histological examination of this brain showed occasional senile plaques. *Panel B:* A coronal brain section from a 70-year-old subject with Alzheimer's disease demonstrating atrophy, ventriculomegaly, and dilation of the lateral sulci. The inferior horns of the lateral ventricles (*arrows*) and lateral ventricles are dilated. The hippocampus, entorhinal cortex, and amygdala are reduced in volume. The third ventricle is moderately dilated. Histological examination of this brain showed high densities of senile plaques, neurofibrillary tangles, and neuronal loss (see Figure 3–10).

neuronal perikaryal volume, fibers, and synapses. The number of neurons in human brain ranges from 13.9 billion in both sexes (Haug and Eggers 1991) to 19 billion in females and 23 billion in males (Pakkenberg and

**FIGURE 3-7.** Disease-related brain atrophy: *Panel A:* Demonstrates the external features from elderly subjects not demented (*left*), moderately demented (*middle*), and severely demented (*right*). The brain volume is reduced, and gyral atrophy becomes more conspicuous. *Panel B:* Coronal sections through each brain demonstrate moderate atrophy seen in a patient with moderate dementia and severe atrophy present in a patient with end-stage Alzheimer's disease. Note the volume reduction of temporal lobes.

Gundersen 1997). Although early studies described generalized senescent neuronal loss (Brody 1955), reports show relatively stable numbers of cortical neurons in many brain regions as compared with those found in younger subjects (Haug and Eggers 1991). Stereological methods demonstrate a 10% reduction in neuronal numbers through age 90 (Morrison and Hof 1997). Hippocampal and subcortical neurons are depleted in subjects over age 65 (Coleman and Flood 1987; Katzman et al. 1988) (Tables 3-2 and 3-3). Some discrepancies may result from methodological problems, such as variations of sampling, and shrinkage artifact. Several authors (Haug 1987; Haug and Eggers 1991; Haug et al. 1984) have demonstrated stable numbers of cortical neurons with age-related reduction of neuronal perikaryal

diameter and diminished cortical thickness (Table 3-2). This neuronal atrophy begins around age 60 and may be layer specific. For example, neurons in layer 3 of gyrus rectus are shrunken, but those in layer 5 remain constant in subjects over age 65 (Haug et al. 1984). Neuronal atrophy is reported after age 40 in a few cortical regions, such as area 6 (Haug and Eggers 1991). Neuronal shrinkage may explain the net increase in the numbers of small neurons with aging (i.e., shrunken large neurons are counted with small neurons) (Finch 1993). Dendritic changes are common in aging neurons. Dendritic atrophy begins with loss of dendritic spines followed by alterations of horizontal branches and final loss of the dendritic shaft. Quantitative studies using Golgi stains of cortical areas 10 and 18 from aged human brains demonstrate an 11% reduction of dendritic length, but a 50% reduction in numbers of dendrite spines when compared with subjects under age 50 (Jacobs and Driscoll 1997).

Synaptic density declines with aging (Haug and Eggers 1991), and presynaptic terminals are reduced by 20% over age 60 (Masliah et al. 1993). Synaptic proteins associated with dendritic or axonal structural plasticity that control remodeling are reduced with aging (Hatanpaa et al. 1999). Brains showing Alzheimer's disease have substantial synaptic loss, and tangle-bearing neurons contribute to this reduction (Callahan and Coleman 1995; Dickson et al. 1995). Senescent reduction of synaptic numbers varies by brain region. Haug and Eggers (1991) cited stable numbers of synapses in area 6 but diminished (10%) numbers in area 11 (gyrus rectus) of subjects over 65. Synaptic damage may better predict functional loss than neuronal depletion predicts it. Rodents with hippocampal learning deficits and normal numbers of hippocampal neurons (Rapp and Gallagher 1996) demonstrate that clinical deficits may occur from synaptic loss rather than neuronal depletion. The age-related regression of synaptic density predicts synaptic numbers similar to those in demented patients at age 120 (Katzman 1997).

Reduction in the volume of neurons may be offset by a net increase in the number or volume of astrocytes. Studies in aged rodents and humans have demonstrated increased glial fibrillary acidic protein (Figure 3-1), an intermediate filament specific for astrocytes, and increased glial markers (e.g., glutamate synthetase) (Finch and Morgan 1990; Frederickson 1992). However, some authors have described a minimal increase in astrocytic numbers in aging (Haug and Eggers 1991; Haug et al. 1984). A distinct population of astrocytes in the hippocampus, striatum, and periventricular zones of normal age subjects accumulates cytoplasmic inclusions that may result from oxidative stress (Schipper 1996).

**FIGURE 3-8.** Comparison of the supratemporal plane (STP) of an 82-year-old control subject (*panel A*) with that of a patient with Alzheimer's disease (*panel B*). The temporal poles are oriented upward, and the superior surfaces of dissected temporal lobes are shown. The three main components of the supratemporal plane include the superior temporal gyrus (STG), the transverse temporal gyrus (TTG), and the planum temporale (PT); these appear normal in *panel A*. The supratemporal plane from the subject with Alzheimer's disease demonstrates severe atrophy of superior temporal gyrus (auditory association cortex); however, transverse temporal gyrus (primary receptive cortex) is less severely shrunken. Association cortex is preferentially damaged in Alzheimer's disease over primary sensory cortex.

Postmortem morphological studies of aged brains demonstrate variable neuronal loss, relative stability of dendritic length but significant reductions in numbers of dendritic spines and synapses. Neuronal plasticity continues into later life and the loss of spines and synapses may be altered by life-long cognitive stimulation.

### Alterations of White Matter With Aging

The integrity of myelin and oligodendrocytes is important to neural transmission, and alterations of white matter occur in aging. Brain imaging changes of white matter pathology are extensively reviewed elsewhere (see Chapter 9 in this volume), and white matter ischemia is described elsewhere in this chapter.

Standard autopsy techniques were used to show an 11% reduction in total white matter volume of elderly subjects (Haug and Eggers 1991). With stereological methods, a 15% age-related reduction in white matter and 17% reduction in total volume of myelinated fibers are estimated, although individual variation is so great that these alterations were not statistically significant (Tang et al. 1997). The estimated total length of myelinated fibers in white matter was 118,000 km in young versus 86,000 km in old subjects. The 27% loss of myelinated fibers may explain diminished white matter volume (Tang et al. 1997). Other postmortem studies demonstrate age-related loss of white matter volume up to 28% (Pakkenberg and Gundersen 1997), with estimates of white matter loss of 2 mL/year over age 60 (Double et al. 1996).

Studies in human occipital cortex from ages 30 through 90 reveal a linear, age-dependent myelin loss in the stripe of Gennari (Lintl and Braak 1983). The optic nerve loses more than 5,600 axons per year (Lintl and Braak 1983) from childhood through senescence. Morphological data on white matter are limited by methodological problems with measuring the volume of myelin or packing densities of axis cylinders in postmortem material.

The confusing clinical and radiographic terminology for white matter alterations includes subcortical hyperintensities, leukoaraiosis (Hachinski et al. 1987), subcortical encephalomalacia, Binswanger's disease, and subcortical arteriosclerotic leukoencephalopathy (Coffey and Figiel 1991; Giaquinto 1988). White matter lucencies are reported in 4%–35% of computed tomography evaluations of elderly individuals and up to 92% of magnetic resonance imaging examinations of elderly control subjects (Awad et al. 1986; Coffey et al. 1992). White matter alterations are also present in Alzheimer's disease (Bennett et al. 1992), depression (Coffey et al. 1993), hypertension, and cardiovascular disease (see Chapter 9 in this volume).

Neuropathological correlates to radiological white matter lesions range from normal myelin to Binswanger's disease (Coffey and Figiel 1991; Gupta et al. 1988; Kirkpatrick and Hayman 1987; Sze et al. 1986). Hypertensive vascular changes (i.e., arteriosclerosis) are frequently noted (Inzitari et al. 1987) in areas of abnormal white matter, as are dilated perivascular spaces and vascular ectasias (Awad et al. 1986; see also Chapter 9 in this volume) (Figure 3–17, *panel A*).

Although the number of brain astrocytes increases with age (Figure 3–1), alterations in the number of oligodendrocytes are not reported. Some oligodendrocytes in aging monkeys demonstrate bulbous inclusions and myelin degeneration (A. Peters 1996). Few studies have examined the composition of myelin and the biological activity of oligodendrocytes in aging human brain. No evidence exists indicating that aging oligodendrocytes develop degenerative changes (as found in neurons) or hypertrophy (as found in astrocytes). The composition of myelin and phospholipids remains relatively constant over time.

## Molecular Neuropathology of Aging

Aging neurons undergo a series of histological and molecular biological changes. Lipofuscin, a brown, wear-and-tear pigment, begins to accumulate within neuronal bodies (Figure 3–9, *panel A*). Neuromelanin, a brown pigment common to catecholamine-producing neurons, becomes visible in the brains of adolescent humans and progressively accumulates over years (Graham 1979) (Figure 3–9,

*panel B*). Neuronal inclusions, such as Hirano bodies, and granulovacuolar degeneration begin to appear in hippocampal pyramidal neurons (Figure 3–9, *panels C and D*). Lewy bodies are seen usually in catecholamine-producing neurons and occasionally in cortical neurons (Figure 3–9, *panel E*). Corpora amylacea, dense spherical inclusions, appear around the ventricles and in the neuropil, where they are numerous in aging and neurodegenerative disorders (Adams and Duchon 1992).

The neuronal cytoskeleton undergoes important, age-related alterations. The cytoskeleton is the delicate meshwork of microtubules, neurofilaments, and other proteins (e.g., microtubule-associated proteins). This matrix, barely visualized with the electron microscope, provides structure to neurons and organizes neuronal transport. The cytoskeleton is a dynamic system constantly cycling through production, transport, and degradation (Peng et al. 1986). Age-related alteration of axonal transport in human neurons is unknown, but slow transport is decreased by 30% in aging rodent brain (Finch and Morgan 1990). The production of antibodies to specific cytoskeletal antigenic sites (i.e., epitopes) allows the identification of molecular constituents within neurons. Immunocytochemical methods show abnormal collections of cytoskeletal constituents in neurons of human neocortex and allocortex in the fifth or sixth decade before developing neurofibrillary tangles (Figure 3–10, *panel A*). For example, phosphorylated neurofilament epitope is normally present in the axon, but not in the neuronal perikarya (Goldman and Yen 1986). Immunocytochemical methods demonstrate accumulation of phosphorylated neurofilament epitope in the body of aging neurons.

Microtubules serve as an intracellular ladder with microtubule-associated proteins as the rungs. Kinesins are specific motor proteins that pull materials, for example, vesicles, down the ladder through the axon (Mandelkow et al. 1995). Hyperphosphorylation of tau is integral to paired helical filaments (Morishima-Kawashima et al. 1995). Tau, a low-molecular-weight, microtubule-associated protein, is present in most forms of age- and disease-related microscopic pathology. Tau gene mutations are implicated in frontotemporal dementia (Tolnoy and Probst 1999).

Cytoskeleton is a major constituent of many age- and disease-related cellular histopathologies. Hirano bodies contain actin (Goldman 1983) (Figure 3–9, *panel C*), granulovacuolar degenerations contain tubulin (Maurer et al. 1990) (Figure 3–9, *panel D*), Lewy bodies contain filaments (Ince et al. 1998) (Figure 3–9, *panel E*), dystrophic neurites contain paired helical filament and tau, and neurofibrillary tangles contain multiple cytoskeletal constituents (Maurer et al. 1990) (Figure 3–10).

Selected groups of neurons are vulnerable to age-related damage, for example, nigrostriatal neurons in Parkinson's disease or corticocortical projections in Alzheimer's disease. Connectivity neurochemistry and cellular physiology can define these populations. Neurons that contain high levels of neurofilaments in the somatodendritic compartment demonstrate more intense damage whereas those with high levels of calcium-binding proteins are less vulnerable (B.M. Morrison et al. 1998). Connectivity and neuronal physiology combine to render specific neuronal populations vulnerable to age-related damage while adjacent neurons remain undamaged.

## ■ Vascular Alterations in Aging

Vascular pathology produces multiple neuropsychiatric disorders including depression and dementia (see Chapters 13 and 23 in this volume). Population studies indicate that up to one-third of subjects over age 65 have ischemic brain damage that is detectable with brain imaging (Bryan et al. 1997). Four major types of cerebrovascular pathology occur in aging: 1) atherosclerosis, 2) arteriosclerosis, 3) congophilic angiopathy, and 4) hypoperfusion (Table 3–4). Atherosclerosis is damage to the intima of large-caliber vessels, in contrast to arteriosclerosis, which is damage to the media of small-caliber vessels. Congophilic angiopathy is the deposition of amyloid around small vessels in the arachnoid, pia, or brain parenchyma. Hypoperfusion results from hypoxia or poor cardiac function. Cumulative brain damage may occur from a combination of each pathology whose risk varies according to age, gender, ethnicity, and systemic medical conditions.

Appropriate neuronal function depends on the provision of adequate nutrients, like, oxygen and glucose, via ce-

rebral blood flow. Vascular pathology, autoregulatory dysfunction, or cardiac disease can produce focal or diffuse abnormalities of cerebral perfusion. Imaging studies demonstrate a gradual reduction of cerebral blood flow with aging (Choi et al. 1998).

Autoregulation controls the response of cerebral blood vessels based on systemic blood pressure, oxygen tension, CO<sub>2</sub> tension, and cerebral metabolism. Cerebral autoregulation may be affected by age-related diseases such as atherosclerosis, hypertension, and diabetes (Choi et al. 1998).

The brain composes 2% of body weight but receives 17% of cardiac output and requires 20% of the body's oxygen to maintain normal function. The circle of Willis meets the brain's metabolic demand via an extensive anastomotic network that sustains adequate cerebral perfusion despite occlusion of major vessels, for example, the internal carotid artery (Figure 3–11). The tapering of blood vessel diameter in distal branches of major arteries dampens the effect of blood pressure on penetrating vessels. Vessels that branch directly from large-diameter arteries, for example, lenticulostriates of basal ganglia, frequently demonstrate hypertensive damage.

The large cerebral white matter structures such as the centrum semiovale are perfused by long, penetrating vessels that arise at right angles from arteries within the arachnoid space and radiate inward (Figure 3–12). Deep white matter is perfused by branches that originate from vessels located beneath the ventricular surface and radiate outward. The outer vessels are termed centripetal and the inner are termed ventriculofugal. White matter vessels do not arborize, but perpendicular side branches, termed distributing vessels, perfuse adjacent white matter (Pantoni and Garcia 1997). This overlapping system is vulnerable to changes in blood pressure. Subcortical U-fibers are

**FIGURE 3–9.** Eight hematoxylin and eosin preparations showing microscopic alterations frequently observed in the brains of elderly humans, including lipofuscin (*panel A*), ischemic neuronal injury (*panel B*), Hirano bodies (*panel C*), granulovacuolar degenerations (*panel D*), Lewy bodies (*panel E*), loss of neuromelanin-containing neurons (*panel F*), atherosclerosis (*panel G*), and arteriosclerosis (*panel H*). *Panel A:* Several neurons are shown. Two (*straight arrows*) contain abundant lipofuscin, a light-brown pigment. A normal neuron with abundant Nissl substance is present (*curved arrow*). *Panel B:* Photomicrograph of human hippocampus from a 68-year-old cognitively intact individual who had experienced brief cerebral hypoxia. Normal neurons surround a single shrunken pyramidal neuron in the center of the field with ischemic, eosinophilic degeneration (*arrow*). *Panel C:* Hirano bodies in hippocampal neurons from CA<sub>1</sub> region. A Hirano body, the cigar-shaped, eosinophilic rod immediately adjacent to the nucleus, is seen in the center of the field (*arrow*). *Panel D:* Granulovacuolar degenerations in the pyramidal neurons of CA<sub>3</sub> region. In the cytoplasm of the neuron in the center of the field, there are multiple, round, clear spaces with a central, slightly basophilic core (*arrow*). *Panel E:* Lewy bodies, circular eosinophilic masses with a thin, peripheral clear space (*arrow*) that displaces the neuromelanin, in the cytoplasm of substantia nigra neurons. Neurons that contain neuromelanin are also present. *Panel F:* Age-related damage of substantia nigra. Two normal-appearing pigmented neurons are shown (*arrows*); however, most neuromelanin is present in macrophages or in the neuropil (*arrowheads*). *Panel G:* Atherosclerotic damage in a branch of the posterior cerebral artery. The intima is detached and badly damaged with cholesterol deposition (CD), but the media is intact. *Panel H:* Arteriosclerosis in basal ganglia from a 74-year-old hypertensive individual. A small penetrating blood vessel in the center of the field contains pink, hyalinized material in the media and adventitia.

**FIGURE 3-10.** Photomicrographs showing the appearance of neurofibrillary tangles (*panel A*) and senile plaques (*panel B*) in a 100-year-old subject. *Panel A*: Four hippocampal pyramidal neurons with neurofibrillary tangles (i.e., flame-shaped masses of filamentous material [arrows]). Tangles were not present in neocortex. *Panel B*: A silver preparation of neocortex. A senile plaque (arrow) contains swollen neurites, an amyloid core, glia, and microglia. Insufficient numbers were present in neocortex to warrant diagnosis of Alzheimer's disease.

perfused by short branches of cortical vessels. The U-fibers are association bands immediately beneath the cortical ribbon, and this distinct perfusion reduces vulnerability to ischemia (Pantoni and Garcia 1997).

Arteries contain three layers: intima, media, and adventitia. The intima includes endothelial lining cells and a connective tissue stroma that prevent thrombosis and control movement of molecules, that is, a blood-brain barrier. Media contains smooth muscle that regulates diameter and accommodates to blood pressure. Adventitia contains a loose connective tissue stroma. Arterioles, capillaries, and veins lack the distinctive muscular media present in arteries.

**FIGURE 3-11.** The circle of Willis as dissected from the base of the brain. The internal carotid artery divides to form the anterior cerebral artery (ACA) and middle cerebral arteries (MCA). Anterior and posterior communicating arteries are not labeled. The vertebral arteries (VA) fuse to form the basilar artery (BA), which then divides to form the posterior cerebral arteries (PCA). This anastomotic network ensures adequate brain perfusion despite occlusion of single major vessels. See Figure 3-13A for in situ appearance.

Atherosclerosis results in damage to the intima of large- or medium-diameter vessels and contributes to most strokes in elderly individuals (Figure 3-13). Atherosclerotic changes are described in vessels of Egyptian mummies, and the frequency or severity of this vascular pathology varies by age, gender, and ethnic background. Atherosclerosis appears as discrete areas of white or yellow discoloration within thickened segments of blood vessel wall. The microscopic appearance includes loss or fibrosis of intima, lipid or cholesterol deposits beneath endothelial cells, narrowing of vessel lumen, and thrombosis on the plaques (Figure 3-9, *panel G*). Hemorrhage within a plaque can occlude the vessel lumen. Systemic atherosclerosis begins in the second decade of life (5%) and accelerates after the third decade. Only 4% of individuals over age 90 avoid atherosclerotic damage (Gorelich 1993). Fatty streaks occur within the aortic walls in the first decade of life followed by fatty streaks in coronary arteries or extracranial carotid vessels in the second. Fibrous plaques appear in vertebral arteries in subjects over age 30 (Moossy 1993) (Table 3-4).

Atherosclerosis has a complex pathogenesis including hyperlipidemia, homocystine deficiency, hypertension, elevated platelet numbers, and a myriad of other factors (Figure 3-13). Intimal damage from atherosclerosis can lead to thrombotic occlusion of vessels or embolization into distal arteries, with resulting cerebral infarction. Extracranial vascular pathology frequently produces cerebral damage. Embolization also results from either atrial fibrillation or

**FIGURE 3-12.** White matter vessels. The *thin dark lines* are long, penetrating vessels that pass through the cortical ribbon, traverse into the centrum semiovale, and perfuse a cylinder of white matter adjacent to the vessel (*arrow*). Deeper white matter is perfused by branches originating from beneath the lateral ventricle (*lower left*). White matter structures are sensitive to certain types of anoxic injury, and these vessels sustain hypertensive vascular damage.

myocardial infarction when a mural thrombus forms in either the atrium or the left ventricle (Ott et al. 1997) (Figure 3-14). Liquefactive necrosis and encephalomalacia, that is, discrete loss of brain parenchyma that is apparent to gross inspection, occur weeks or months following brain infarction (Figure 3-15). Abrupt revascularization may convert a pale or ischemic infarct into a red or hemorrhagic infarct (Figure 3-16, *panel A*). Smaller emboli lodge in arterioles where discrete segments of cortical ribbon are infarcted (Figure 3-16, *panel B*). Tiny emboli produce microinfarctions, which are difficult to visualize with imaging and require microscopic examination for identification. Radiographic white matter hyperintensities are also associated with atherosclerosis of internal carotid arteries (Bots et al. 1993).

Hypertension produces a variety of lesions via arteriosclerosis and damage to medium- and small-caliber arteries and arterioles (Table 3-4). Arteriosclerosis is damage to the muscular media of small penetrating arteries or arterioles that occurs commonly in small, nonarborizing branches from large-caliber arteries, for example, the lenticulostriate system (Figure 3-17). Vessels with arteriosclerosis have hyalinization or necrosis of the media that leads to thrombosis or leakage (Figure 3-9, *panel H*). Hypertensive brain lesions include loss of neuropil around small, penetrating arteries, arteriolar sclerosis, lacunar infarcts, and intracerebral hemorrhages. Lacunar infarcts are slitlike lesions measuring 1–10 mm in the cerebral hemisphere (Figure 3-17, *panel C*) and 1–5 mm in the brainstem (Figure 3-17, *panel D*). These punched-out lesions are common in deep nuclei, hemispheric white matter, brainstem, and cerebellar peduncles. Lacunar infarcts are present in up to 49% of autopsy brains, with lesions most commonly found in hemispheric white matter (Figure 3-17) and subcortical nuclei (Dozono et al. 1991). Lacunar infarcts are associated with older age, increased diastolic blood pressure, heavy smoking, internal carotid artery stenosis exceeding 50%, and diabetes mellitus (Longsteth et al. 1998). Hypertensive vascular pathology can also produce extensive damage via intracerebral hemorrhage (Figure 3-18) and associated complications such as bleeding into the ventricles or subarachnoid space. Cumulative hypertensive vascular damage may explain the association of hypertension with impaired psychomotor skills and cognitive loss (Skool et al. 1996; Starr and Whalley 1992).

Congophilic angiopathy is common in patients over age 90. Proteinaceous material is deposited in the media or adventitia of small arachnoidal or cortical arterioles (Table 3-4). Although amyloid angiopathy increases the risk for intracerebral hemorrhage, its effect on cerebral perfusion is unclear. Congophilic deposits probably alter blood-

**TABLE 3-4.** Common causes of vascular brain damage

Type	Anatomic distribution	Location of lesion	Etiology	Complications
Atherosclerosis	Large-caliber vessels	Intima	Hyperlipidemia Diabetes Hypertension	Stroke
Arteriosclerosis	Penetrating vessels	Media	Hypertension	Lacunae Hemorrhages
Congophilic angiopathy	Arachnoidal and parenchymal vessels	Adventitia	Amyloid production	Unclear
Hypoperfusion	Watershed zone	Cardiovascular dysfunction	Low blood pressure	Pale or red infarcts

**FIGURE 3-13.** Atherosclerosis of the circle of Willis. *Panel A:* Typical atherosclerosis in a basilar artery from a 68-year-old subject. Normal basilar artery has a translucent appearance, whereas this atherosclerotic artery has a thickened tortuous wall and an opaque white appearance. Thin posterior communicating arteries connect posterior cerebral to internal carotid arteries. *Panel B:* Cross-sections of normal and atherosclerotic arteries. The *top field* demonstrates normal, paper-thin muscular arteries, whereas the *lower field* contains serial sections through the thickened, narrowed atherosclerotic vessel.

**FIGURE 3-14.** Cerebrovascular damage from heart disease. Cardiac disease produces arrhythmias and emboli that damage brain. This patient had hypotensive and embolic infarcts caused by atherosclerotic cardiomyopathy (*top*) with a 15% ejection fraction and an apical thrombus in the left ventricle (*bottom*).

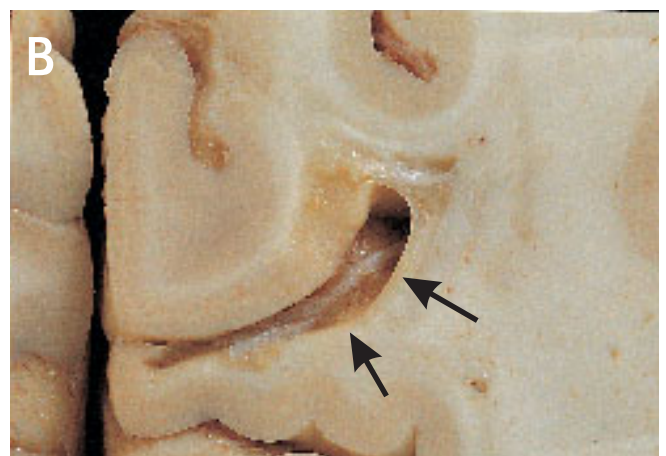

**FIGURE 3-15.** A stroke in the distribution of the middle cerebral artery (MCA). Encephalomalacia of the inferior parietal, anterior occipital, and superior temporal gyrus regions produces a cavity after a stroke.

brain barrier function in aging (Figure 3-19).

Low perfusion from systemic hypotension can damage brain parenchyma while providing few observable alterations (Table 3-4). Watershed or boundary zones are cortical regions that are located between distal vascular perfusion areas of the cerebral arteries. For example, cortex adjacent to the superior frontal sulcus is vulnerable to hypoperfusion during episodes of systemic hypotension because this region is perfused by distal branches of the anterior and middle cerebral arteries (Figures 3-16, *panel A*, and 3-20). Neuronal vulnerability to anoxia may increase with aging as the brain's capacity to meet energy demands decreases its ability to reinstate homeostasis and excitability (Roberts 1997). Specific regions such as hippocampus have selective vulnerability to anoxia and excitotoxic damage. Cognitive loss in subjects with poor cardiac pump function (i.e., cardiac arrhythmias), systemic hypotension (Sulkava and Erkinjuntti 1987), and cardiac left ventricular ejection fraction less than 30% (Zuccala et al. 1997) may result from low flow to vulnerable brain regions.

Age-related changes develop in all segments of the cerebrovascular system. Although atherosclerosis and arteriosclerosis are common in large- or medium-diameter vessels, changes also occur in the microvascular system. The density of hippocampal capillary clusters decrease, but the mean diameter of capillaries and arterioles increases in aging (Bell and Ball 1981). Cortical microvasculature studies show intertwining of small arterial branches (Akima 1986), convoluted vessels, and mild perivascular glial proliferation (Ravens 1978). Veins demonstrate fibrous thickening with aging that may slow venous return and increase

**FIGURE 3-16.** Reperfusion and embolic infarctions. *Panel A:* Coronal sections of frontal lobe from an individual who sustained hypotensive brain injury after a cardiac arrest (see Figure 3-14). Hemorrhage occurs in necrotic brain tissue located between the superior and middle frontal gyri, a common boundary zone location. Hemorrhagic or red infarcts are produced by reperfusion of infarcted brain parenchyma or lysis of thrombi within occluded blood vessels. *Panel B:* A small infarction in the occipital parietal cortex. A discrete strip of cortical ribbon in the center of the field is absent, but adjacent cortex is intact. This discrete loss of cortical ribbon results from embolic occlusion of small arteries (*arrows*).

edema in white matter. This periventricular venous collagenosis occurs in 65% of individuals over age 60 and may promote leukoaraiosis, that is, white matter thinning (Moody et al. 1995).

Aging brain is vulnerable to multiple types of vascular damage. Each brain manifests a mixture of embolic, atherosclerotic, hypertensive, or hypotensive damage. This range of pathology explains the difficulty in specifying types or locations of damage that cause vascular dementia.

**FIGURE 3-17.** Hypertensive brain damage. *Panel A:* Demonstrates loss of neuropil around penetrating vessels in basal ganglia (*arrow*). The intact vessel remains within the cavity. *Panel B:* Demonstrates periventricular leukomalacia. Computed tomography scan showed that this patient had extensive white matter thinning. The neuropil about the frontal horn of the lateral ventricle is thin and demonstrates a granular appearance (*arrows*). Extensive atherosclerosis is present in the anterior cerebral arteries bending around the genu of the corpus callosum. *Panel C:* A lacunar infarction present in the putamen. This slitlike lesion is well demarcated (*arrow*). Hemorrhage from such lesions causes intracerebral hematoma (see Figure 3-18). *Panel D:* Lacunar infarct in the pons. This slitlike lesion in the basis pontis can produce nonlateralizing neurological symptoms (*arrow*).

## ■ Age-Related Changes of the Blood-Brain Barrier

The blood-brain barrier has two major functions: transport of essential materials and protection of brain homeostasis. Although nutrients can reach the brain via spinal fluid, the volume of the blood-brain barrier is 5,000 times greater than the cerebrospinal fluid (CSF)–brain boundary (de la Torre 1997). The blood-brain barrier is located in the brain's microvasculature and consists of tight junctions and fenestration of brain capillary endothelium that use selective pinocytosis to control movement of molecules. Unlike capillaries of non-CNS organs, brain capillary pores do not allow free movement of substances. Carrier-mediated transports in the brain capillaries select specific substances

for entrance into the CNS. This barrier function is mediated by tight junctions between endothelial cells (Giaquinto 1988). The blood-brain barrier is the locus of three essential functions: 1) transport for critical nutrients, hormones, or drugs; 2) export of metabolic waste products; and 3) protection against influx of toxins and osmotically damaging agents (Mooradian 1988).

Histochemical studies of brains from human subjects over age 45 show alterations in the biochemical composition of arterioles, capillaries, and venules (Sobin et al. 1992). Aging of brain microvasculature, described elsewhere in this chapter, may result in minor leakage through the blood-brain barrier. Human serum proteins, such as IgG, IgA, IgM, and  $\alpha_2$ -macroglobulin, leak into cortical tissue of elderly subjects and are found in some neurons

**FIGURE 3-18.** Hypertensive vascular disease. Coronal sections from different brains that demonstrate acute and long-term consequences of hypertensive damage. *Panel A:* An acute hemorrhage into basal ganglia and thalamus producing cerebral edema and death. *Panel B:* An old healed intracerebral hemorrhage causes a lens-shaped lesion (ICH) in the putamen and internal capsule that produced a spastic hemiparesis. This lesion would also damage ascending catecholaminergic fibers.

(Mooradian 1988). Common systemic diseases in the elderly such as hypertension and diabetes mellitus damage the blood-brain barrier. Hypertension and mild ischemia increase transport of high-molecular-weight proteins through accelerated transendothelial transport and transcytosis. Leakage across blood-brain barriers increases proportionally to severity of ischemia—damage that loosens the tight junctions of endothelium.

### ■ Cerebrospinal Fluid and Aging

CSF is clear liquid produced by the choroid plexus within the ventricles and reabsorbed via the arachnoidal granulations located along the sagittal sinus. CSF, produced at 0.3–0.4 mL/min, contains electrolytes, protein, sugar, and

**FIGURE 3-19.** Perivascular amyloid visualized by Congo red and immunoperoxidase stains in the brain of a 91-year-old subject. *Panel A:* The faint-red discoloration of amyloid deposition within adventitia blood vessel stained by Congo red (arrow). Polarizing light confirmed the amyloid. *Panel B:* Immunoperoxidase stains of blood vessel, with anti-amyloid antibody demonstrating pale-brown amyloid deposits (arrow) around small cortical blood vessels.

a small number of cells. The rate of CSF production is reduced in aging, and CSF protein content is increased (May et al. 1990). The number or type of inflammatory cells in CSF is unchanged. The physiology of CSF reabsorption is poorly defined, and obstruction of return flow into the arachnoidal granulations may produce normal pressure hydrocephalus. Transmitter metabolic content of CSF changes in aging (Table 3-5).

### ■ Pathological Overlap of Aging and Neurodegenerative Diseases

The pathological hallmarks of Alzheimer's disease include senile plaques, neurofibrillary tangles, amyloid deposits,

**FIGURE 3-20.** Diffuse anoxic injury. A normal (nl) frontal lobe (*right*) is contrasted with a coronal section from an individual who suffered prolonged anoxia (*left*). The sulcal gyral pattern remains intact; however, the cortical ribbon is markedly reduced. Microscopic examination revealed severe neuronal loss and gliosis.

**TABLE 3-5.** Age-related alterations of transmitter metabolites reported in human cerebrospinal fluid

Transmitter system	Marker	Effect with age
Cholinergic	Acetylcholinesterase	Increase
Noradrenergic	MHPG	Increase
Serotonergic	5-HIAA	No change
Dopaminergic	Homovanillic acid	No change
Peptidergic	Somatostatin	No change
	$\beta$ -Endorphin	No change

*Note.* MHPG, 3-methoxy-4-hydroxyphenylglycol; 5-HIAA, 5-hydroxyindoleacetic acid.

*Sources.* Adapted from Giaquinto 1988; Gottfries 1990; Hartikainen et al. 1991.

and neuronal or synaptic loss (Markesbery 1997; McKhann et al. 1984). Senile plaques are abnormal collections of neurites, microglia, and astrocytes that disrupt the normal woven appearance of the neuropil (Figure 3-21). Senile plaques have a range of features and may contain amyloid deposits or cores (Figures 3-10 and 3-21). The appearance of senile plaques ranges from “immature” or diffuse (i.e., amorphous amyloid deposits) to “burned-out” with few remaining neurites (Probst et al. 1987) and amyloid cores. Neuritic plaques contain many dystrophic neurites and glia (Table 3-1). Diffuse plaques are common in normal elders, however the number of neuritic plaques correlates better with cognitive decline (Davies et al. 1999).

Neurofibrillary tangles are masses of abnormal straight and paired helical filaments (Figure 3-10). Neurofibrillary tangles are usually located within neuronal perikarya, although “ghost” tangles are seen in the neuropil. This neuronal pathology occurs first in the entorhinal cortex and later in the hippocampus and amygdala (see Figures 3-2, 3-3, and 3-5). Neurofibrillary tangles probably disrupt neuronal function (Figures 3-10 and 3-21). The nucleolus of tangle-bearing hippocampal neurons is smaller than the nucleolus of normal adjacent neurons, suggesting that neurofibrillary damage reduces metabolic capacity (Jellinger 1997) before neuronal death. Neurons that contain NFTs may survive for 20 years, but genetic function is altered in these damaged cells (Morsch et al. 1999). The density of tangles may correlate with severity of dementia in Alzheimer’s disease (Gomez-Isla et al. 1996).

Amyloid deposits include  $\beta$  pleated sheets of fibrillar material composed partially of  $\beta$  protein (A $\beta$ ), the cleavage product of  $\beta$ -amyloid precursor protein, a large transmembrane protein (Mattson and Rydel 1992). Amyloid deposition occurs in aging and Alzheimer’s disease (Braak and Braak 1991; Coria et al. 1992; Ikeda et al. 1989; Coria et al. 1992) and is present around blood vessels, in senile plaques, and in the neuropil (Figure 3-18). Autopsy evaluation of brains from cognitively intact elders demonstrates that 75% of specimens contain cerebral amyloid angiopathy (Davis et al. 1999). The role of amyloid in aging and disease is controversial and is the focus of considerable research.

Dystrophic neurites are swollen, tortuous neuronal processes that contain multiple cytoskeletal constituents including tau and paired helical filaments (Figure 3-21). Dystrophic neurites may be axons or dendrites, and these swollen, kinked processes may be degenerative or regenerative. Neurites contain many types of neurotransmitters (Powers et al. 1988; Struble et al. 1987) and are seen in aging, Alzheimer’s disease (Braak and Braak 1991; Braak et al. 1986), and other degenerative disorders including diffuse Lewy body disease.

National Institute of Neurological and Communicative Disorders and Stroke (NINCDS) criteria for Alzheimer’s disease are consensus values that are based on age-adjusted numbers of senile plaques per square millimeter in the neocortex (Markesbery 1997; McKhann et al. 1984). Senile plaque counts in the hippocampus are not used because the hippocampus is frequently damaged in normal aging. In fact, mesial temporal cortex is damaged in the early stages of Alzheimer’s disease (Braak and Braak 1991). The morphological features of aging and disease frequently overlap in this brain region.

Two important contradictions to the consensus crite-

**FIGURE 3-21.** Immature versus neuritic plaque shown in silver stains of a brain with Alzheimer's disease. *Panel A:* Demonstrates an immature senile plaque with diffuse silver-stained deposits within undisturbed neuropil. Discrete neurites are not present. *Panel B:* Depicts the appearance of a neuritic plaque with dystrophic neurites (*arrows*) and disruption of neuropil. Dystrophic neurites are also present outside the senile plaque. Neurofibrillary tangles are seen in the upper field (*arrow heads*).

ria for Alzheimer's disease include 1) a group of cognitively intact elderly individuals with large numbers of senile plaques in neocortex (Katzman et al. 1988) and 2) a small group of elderly subjects with dementia and morphologically normal brains (Heilig et al. 1985). Some cognitively intact elderly patients can have numerous senile plaques, occasional neurofibrillary tangles (Figure 3-9), and amyloid deposits (Crystal et al. 1988; Katzman et al. 1988; J. L. Price et al. 1991). Longitudinal autopsy studies (see Matsuyama and Nakamura 1978) demonstrated an age-dependent increase in the intensity of Alzheimer's disease pathology. In a retrospective study of neurologically intact patients ages 55-64, Ulrich (1982) demonstrated Alzheimer's disease-type pathology in 25% of brains. Katzman et al. (1988) first described a subpopulation (10%) of cognitively intact elderly individuals who met

NINCDS histopathological criteria for Alzheimer's disease as well as demonstrated cholinergic deficits, an observation reported by multiple other investigators. A longitudinal study of a community of elderly Catholic nuns has provided data on a group of women with limited environmental, intellectual, and neurotoxic variables, for example, diet, alcohol abuse, and daily routine (Berg et al. 1998; Markesbery 1997; Price 1991; Troncoso et al. 1996). Clinicopathological studies of prospectively studied elderly nuns demonstrate Alzheimer's disease pathology in cognitively intact nuns and a higher risk for cognitive loss in nuns with vascular damage. High premorbid intellectual function or professional achievement appears to lessen the risk of dementia, suggesting that cognitive or neuronal reserve, that is, synaptic density, plasticity, etc., may affect onset of dementia

(Snowden 1997; Snowden et al. 1996, 1997).

Neurofibrillary tangles may be a more reliable indicator of brain damage despite a subpopulation of subjects with Alzheimer's disease but without neurofibrillary degeneration (Berg et al. 1998; Terry et al. 1987). No single histopathological, neurochemical, or molecular biological marker always distinguishes normal aging from Alzheimer's disease (Table 3-1); however, some researchers contend that cognitively intact individuals with Alzheimer's disease histopathology would have developed clinical symptoms over time. Other scientists contend that some elderly individuals develop nonprogressive injury (i.e., senile plaques) in selected brain regions. This overlap of pathology between aging and Alzheimer's disease explains the difficulty in creating a premortem marker for Alzheimer's disease (Katzman 1997).

Lewy bodies, spherical neuronal inclusions with an eosinophilic core and clear halo, are comprised of neurofilaments (Goldman et al. 1983) (Figure 3-9). Lewy bodies are present in catecholamine-producing neurons in normal aging (Giaquinto 1988), as well as in diseases such as idiopathic parkinsonism and Lewy body dementia (Figure 3-22). These neuronal inclusions are present in 10 different degenerative diseases and 25% of patients with Alzheimer's disease (Ince et al. 1998). The Lewy body consists of cytoskeletal proteins cross-linked by advanced glycation (Münch et al. 1998) as well as ubiquitin, that is, cell stress-related proteins. Cortical Lewy bodies lack the distinctive halo of their brainstem counterparts and appear as eosinophilic neuronal inclusions best stained with antisera to ubiquitin (Figure 3-23). The frequency, distribution, and natural history of cortical Lewy bodies in normal aging are poorly defined.

The distinction between aging and disease may differ for the young-old, those 65-75, versus the old-old, those over age 90. Neuronal loss and Alzheimer's disease pathology are distinct for each group (Girnnakopoulos et al. 1996), although study populations over age 90 are usually small. Several conclusions are shared by multiple investigators who examined large numbers of aged brains: 1) the number of subjects without senile plaques, neurofibrillary tangles, or amyloid deposits decreases with age; 2) appearance of neurofibrillary tangles can precede amyloid deposition; 3) changes can occur in younger individuals, that is, those age 50-65; and 4) cortical neurofibrillary tangles are more specific for dementia. Prevalence studies based on neuropathological assessment of large numbers of brains predict that 100% of individuals will meet histopathological criteria for Alzheimer's disease at age 100 (Braak and Braak 1997; Davis et al. 1999; Duyckaerts and Haue 1997).

## Alterations of Transmitter Systems in Aging

The impact of aging on transmitter systems can be measured at the presynaptic or postsynaptic level. Presynaptic levels of chemical transmitters can be reduced by death or dysfunction of neurons that produce the transmitter, diminished release, and alterations of reuptake. Postsynaptic effects include alteration of postsynaptic receptor density, alterations of the receptor, and changes in signal transduction mechanisms that translate the receptor activation into cellular or membrane events. Signal transmission may be altered at several levels, confusing the interpretation of human data. Although many human brain transmitter markers are altered in aging, in this chapter I focus on systems of most importance to the geriatric neuropsychiatrist (Tables 3-2 and 3-3).

### Cholinergic Systems

Acetylcholine innervation is widely present throughout the mammalian CNS (see Chapter 4 in this volume). Most cortical cholinergic fibers originate from neurons in the nucleus basalis of Meynert, a band of large neurons in the basal forebrain that is most conspicuous beneath the anterior commissure (Hedreen et al. 1984; Mesulam and Geula 1988) (Figure 3-6). This band begins anteriorly in the medial septal region and is present posteriorly beneath the basal ganglia. This nucleus has an organized projection to cortex, with medial septal neurons projecting to hippocampus.

A plexus of cholinergic fibers is seen in cortex (Divac 1975; Mesulam et al. 1983), and immunocytochemical methodologies with antisera directed against nicotinic receptors demonstrate postsynaptic densities over neurons in layers 2, 3, and 5 (Schroder et al. 1991) of neocortex. Cholinergic fibers are altered in elderly humans and old primates (Decker 1987), and cholinergic deficits in rodents, primates, and humans are correlated to cognitive impairment (Olton et al. 1991).

No consistent loss of acetylcholine content is found in the brains of cognitively intact elderly humans (Table 3-3). Although acetylcholine transferase, the synthetic enzyme for acetylcholine, is reduced in Alzheimer's disease, the conflicting data in normal aging (Giaquinto 1988; Muller et al. 1991) demonstrate minimal reductions or no change. This minor senescent cholinergic loss may reflect complex alterations in the number and size of neurons in the nucleus basalis of Meynert with aging (Figure 3-6). The diameters of some human forebrain cholinergic neurons increase un-

til age 60. Nucleus basalis of Meynert neurons in elderly humans (over age 60) begin to atrophy, and neuronal loss varies according to region sampled (e.g., 0% in the anterior portion and 65% in posterior subdivisions) (de Lacalle et al. 1991; Finch 1993). A similar sequence of changes is seen in rodent and monkey. The large cholinergic neurons of the nucleus basalis of Meynert are frequently referred to as “magnocellular” and may contain occasional neurofibrillary tangles or Lewy bodies in older human subjects. Loss of these magnocellular neurons accounts for cholinergic deficits in Alzheimer’s disease (Whitehouse et al. 1981). Aging has a minimal effect on high-affinity choline uptake, the rate-limiting step in the production of acetylcholine. Levels of acetylcholinesterase are increased in CSF of elderly subjects (Hartikainen et al. 1991; Muller et al. 1991) (Table 3–5).

The density of cholinergic receptors changes with aging (Table 3–3). Release of acetylcholine may be reduced in aging brains because of diminished autoreceptor sensitivity. Alterations occur in both muscarinic and nicotinic receptor systems. Although five types of muscarinic receptors (m1–m5) are distinguished via genetic identification and four via pharmacological techniques (M1–M4), little is known about age-related alterations within either group or their encoding messages (Levey 1996). Aging brain has a 10%–30% reduction of muscarinic receptors in samples of cortex, hippocampus, and striatum and diminished nicotinic receptors in hippocampus. However, in thalamus, density of nicotinic receptors decreases, but density of muscarinic receptors increases (Giacobini 1990, 1991). Nicotinic receptor binding is mildly reduced in neocortex with aging, but significant reductions occur in entorhinal cortex and presubiculum over age 40 (Court et al. 1997). The nicotinic cholinergic receptor family is composed of  $\alpha$  and  $\beta$  subunits with seven  $\alpha$  and three  $\beta$  subunit genes. In normal elderly subjects, the  $\alpha_4$  nicotinic receptor subunit appears stable, but the  $\alpha_2$  subunit is diminished (Tohgi et al. 1998b). Nicotinic receptors are also reduced in Alzheimer’s disease (Nordberg and Winblad 1986).

It is unknown whether the structure of cholinergic receptors is altered in aging or Alzheimer’s disease. The ef-

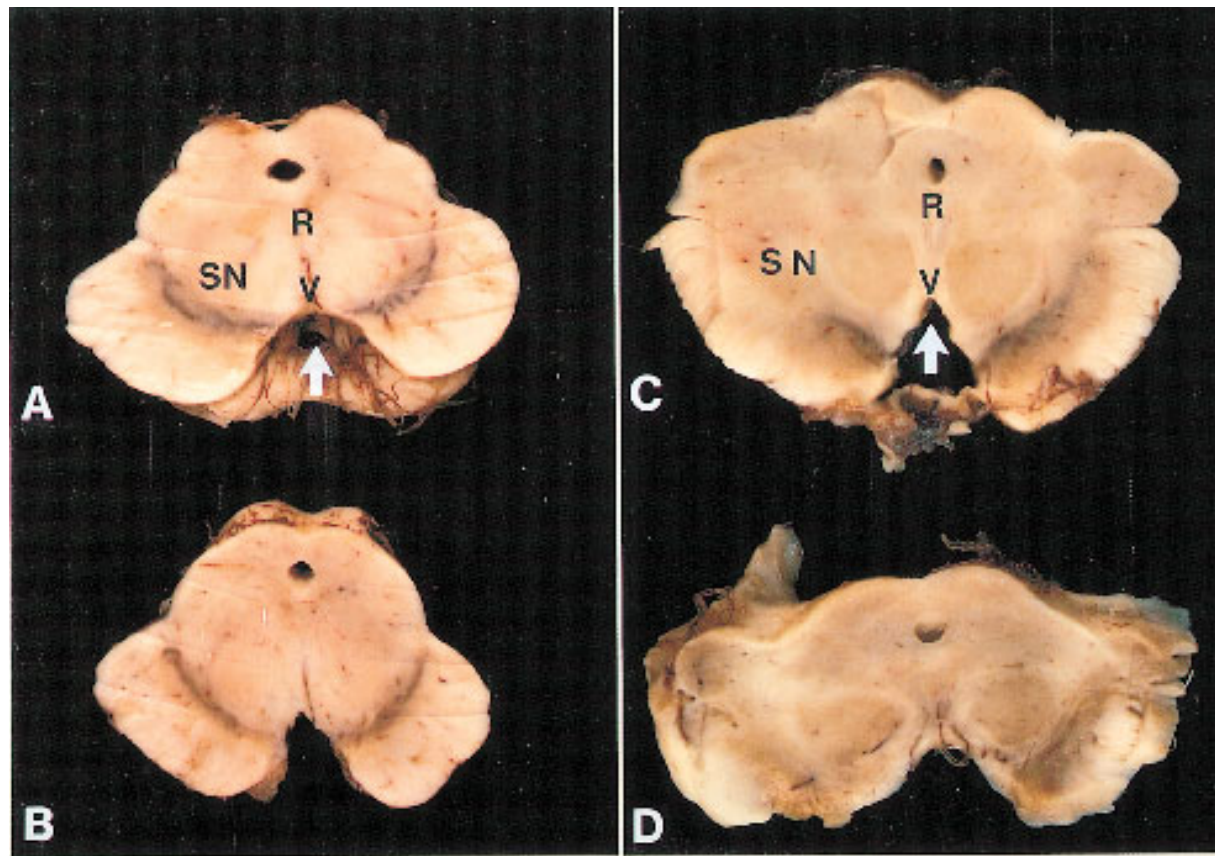

fect of human aging on the ratios of receptor subtypes and encoding messages is unknown. Studies in rodents demonstrate age-related decrease in receptor plasticity and diminished neural response to acetylcholine stimulation (Giacobini 1990; Muller et al. 1991).

Although our knowledge of senescent alterations of cholinergic systems is incomplete, a relationship exists between cholinergic deficits and cognitive impairment (Fields et al. 1986). Cholinergic systems are damaged in many neurodegenerative disorders including Alzheimer’s disease, progressive supranuclear palsy, parkinsonism with dementia, and other disorders.

### Noradrenergic Systems

Noradrenergic systems in human brain include an extensive network of fibers and receptors in neocortex, allocortex, selected diencephalic structures, and brainstem (Fallon and Loughlin 1987). In the human forebrain, noradrenaline is produced by the locus ceruleus, two bands of neurons located immediately beneath the fourth ventricle in the pons that range in number from 11,000 to 25,000 (Ohm et al. 1997) (Figure 3–22). A variable mixture of  $\alpha$ - and  $\beta$ -adrenergic receptors is present throughout the cerebral cortices (Mendelsohn and Paxinos 1991; Reznikoff et al. 1986). Conventional counting methodologies demonstrate a progressive loss of noradrenergic neurons throughout the aging human brainstem, commencing between ages 30 and 40 and progressing with a linear relationship to age (Mann et al. 1983, 1984) (Tables 3–2 and 3–3). In the locus ceruleus, 40% of pigmented neurons are lost by age 90, and similar losses are sustained by the A-2 cell groups in the medulla (i.e., the dorsal motor nucleus of the vagus). Stereological estimates suggest smaller age-related loss of pigmented neurons (Ohm et al. 1997) in the locus ceruleus. Occasional neurofibrillary tangles or Lewy bodies are present in these neurons after age 60. Noradrenergic neurites (i.e., abnormal, swollen processes that contain dopamine  $\beta$  hydroxylase) are present in the neuropil and within senile plaques of elderly subjects (Powers et al. 1988), as well as within the pineal gland

**FIGURE 3–22.** Comparison of midbrain and pons from elderly control subjects and individuals with depigmentation. Regions that produce dopamine and noradrenaline can be distinguished by the brown-black neuromelanin pigment. Serotonin-producing neurons are located in the midline of the brainstem (i.e., raphe [R]) but cannot be distinguished from adjacent structures with either gross or microscopic examination. The ventral tegmental area (V) is present in the midline between the substantia nigrae (SN) and above the interpeduncular fossa (*arrow*). *Panel A:* From an 85-year-old subject, a substantia nigra with some mild loss of pigment. *Panel B:* From a subject with Alzheimer’s disease, a substantia nigra with moderate depigmentation. *Panels C and D:* Specimens from a patient with idiopathic parkinsonism with more severe depigmentation on the left than on the right. *Panel E:* The appearance of locus ceruleus in an elderly control subject: a discrete area of brown-black pigment beneath the fourth ventricle (*arrow*). *Panel F:* Depigmentation in locus ceruleus of an aging subject with diffusion of neuromelanin into adjacent neuropil (*arrow*).

**FIGURE 3-23.** The appearance of cortical Lewy bodies. *Panel A:* Hematoxylin and eosin–stained preparation through parahippocampal cortex from a patient with diffuse Lewy body disease. The indistinct eosinophilic cytoplasmic inclusion in the neuron in the middle of the field is the Lewy body (arrow). *Panel B:* Antibodies to ubiquitin intensely stain two circular Lewy bodies, that is, brown sphere in neurons in center of field (arrows).

(Jengeleski et al. 1989). Enzymatic activities are reduced for tyrosine hydroxylase, the rate-limiting enzyme in the production of both dopamine and noradrenaline, as well as dopamine  $\beta$ -hydroxylase, the committed enzyme for the production of noradrenaline. Brain concentrations of methoxyhydroxylphenylglycol may remain constant in aging (Gottfries 1990), but CSF levels are increased (Table 3-5).

Age-related loss of  $\beta$ -adrenergic receptors is region dependent (Table 3-3). Receptor numbers remain constant in the frontal cortex (Kalaria et al. 1989); however, cingulate, precentral, temporal, and occipitotemporal regions demonstrate a linear age-dependent loss (Mendelsohn and Paxinos 1991).

Adrenergic receptors demonstrate a substantial decline in aging human brain (Pascual et al. 1992). Rodent studies also demonstrate age-related loss of adrenergic receptors in all regions except cortex, a phenomenon possibly a result of diminished receptor synthesis (Miller and Zahniser 1988; Scarpace and Abrass 1988). Pharmacological studies in rodent show a progressive age-dependent loss of postsynaptic response to noradrenaline and serotonin (Bickford-Wimer et al. 1988). This cumulative evidence suggests a gradual senescent loss of noradrenergic production and region-dependent loss of adrenergic receptors in human brain.

A relation may exist between the aging of the human catecholaminergic system and neuropsychiatric diseases such as depression (Mann 1991; Procter and Bowen 1987; Veith and Raskind 1988). Poststroke depression may be linked to catecholaminergic function (Robinson et al. 1984, 1987), and depression in Alzheimer's disease may correlate with loss of neurons in the locus ceruleus (Zubenko and Moosy 1988).

### Serotonergic Systems

Serotonin is produced by raphe nuclei, clusters of indistinct neurons in the midline of the midbrain and pons (Fallon and Loughlin 1987) (Figure 3-22). Methodological problems limit quantitation of nonpigmented serotonergic neurons in human brainstem. Extensive serotonergic innervation is found in human neocortex, allocortex, and some diencephalic structures. Serotonin content is reduced in selected neocortical and allocortical regions of aging human brain (Gottfries 1990; Morgan and Finch 1987). Concentrations of 5-hydroxyindoleacetic acid, the primary metabolite of serotonin, are not reduced in brain or CSF (Table 3-5). However, imipramine binding, a putative marker for serotonin reuptake, is reduced in aging. Activity of tryptophan hydroxylase, the synthetic enzyme for the production of serotonin, is reduced in the brains of aging rodents.

Multiple subtypes of serotonin (5-hydroxytryptamine [5-HT]) receptors are described using autoradiographic or in situ hybridization methodology (Bloom and Morales 1998; Burnet et al. 1995), and the densities of 5-HT<sub>1</sub> and 5-HT<sub>2</sub> are reduced in brains of elderly humans (Table 3-3). The density of 5-HT<sub>2</sub> is reduced 20%–50%, and 5-HT<sub>1</sub> declines up to 70% (Mendelsohn and Paxinos 1991). Studies of serotonin receptor subtypes are limited; however, the density of 5-HT<sub>1A</sub> receptors is diminished in aging (Dillon et al. 1991). Depletion of neurons in the raphe nuclei would explain the decreased serotonin content, but not the decreased serotonin receptor density. These limited

data on serotonergic systems in human aging suggest a gradual loss of serotonin production and receptor.

## Dopaminergic Systems

Dopaminergic systems are altered in aging and in many neurodegenerative disorders, including Alzheimer's disease, idiopathic parkinsonism, and progressive supranuclear palsy (Gibb et al. 1989; Morgan and Finch 1987; Morgan et al. 1987). The brainstem neurons of the mesocortical and nigrostriatal dopaminergic pathways are well defined in human brain (Figure 3–22). Although dopaminergic neurons are present in the human septal and hypothalamic regions (Gaspar et al. 1985), the tuberoinfundibular system is poorly defined in humans. A progressive loss of neurons in the substantia nigra occurs in aging and disease (Uchihara et al. 1992). The number of pigmented neurons in the substantia nigra may begin to drop between ages 40 and 50, and substantial loss (35%) is reported after age 65 (Mann et al. 1984; McGeer et al. 1977) (Table 3–2). Nucleolar volume of substantia nigra neurons is reduced after age 65, and neurofibrillary tangles or Lewy bodies begin to appear in small numbers (Mann et al. 1984) (Figures 3–9 and 3–22). Cytochrome *c* oxidase defects indicate an alteration of the respiratory chain function within nigral neurons (Itoh et al. 1996). Relatively few extrapyramidal symptoms are produced by senescent decline because 80% of nigral neurons must be lost to produce the symptoms of parkinsonism.

Age-related loss of neurons in the ventral tegmental area has not been determined (Hirai 1968; Jellinger 1987), but the ventral tegmental area is damaged by Alzheimer's disease (Torack and Morris 1988). Surviving catecholaminergic neurons progressively accumulate neuromelanin (Graham 1979), which displaces perikaryal RNA and reduces nucleolar volume (McGeer et al. 1977). Senescent alterations of dopamine-producing neurons in hypothalamus are unknown. Concentrations of dopamine are reduced in the striatum of individuals over age 65; however, homovanillic acid content, the primary dopamine metabolite, remains constant in tissue and CSF (Gottfries 1990; Hartikainen et al. 1991) (Table 3–5).

Immunocytochemical and receptor autoradiographic studies show an extensive plexus of dopaminergic fibers, terminals, and receptors in frontal, temporal, hippocampal, and parahippocampal cortices as well as basal ganglia (Joyce et al. 1997; Lewis and Akil 1997). Abnormalities of multiple forms of the dopamine receptor are described in schizophrenia (Gjedde et al. 1996; Joyce et al. 1997; Okubo 1997; Sanyal and van Tol 1997). In aging, the density of the D<sub>2</sub> receptor that binds haloperidol in caudate nucleus de-

clines about 1% per year after age 18 (Wong et al. 1997) and 0.6% per year over age 30 for <sup>11</sup>C-raclopride binding in putamen (Antonio et al. 1993). The dopamine transporter system also declines in basal ganglia during normal aging (Volkow et al. 1994). D<sub>1</sub> receptor binding declines 6.9% per decade in the caudate and 7.4% per decade in the putamen (Wong et al. 1998). Similar D<sub>1</sub> reductions are also described in the frontal and occipital cortex (Hubble 1998) (see Table 3–3).

Postmortem studies demonstrate diminished expression of mRNA for D<sub>2</sub> receptors in putamen with no alteration of D<sub>1</sub> mRNA levels (Tohgi et al. 1998a), alterations that can result from senescent loss of neurons in the basal ganglia. This decline of striatal dopaminergic activity is associated with loss of fine motor functions and impaired neuropsychological performance, for example, in the Wisconsin Card Sorting (Heaton 1985) or Stroop Color-Word test (Stroop 1935; Volkow et al. 1998).

## Alterations of Monoamine Oxidase and Aging

Monoamine oxidase (MAO) activity is significantly altered in the aging human brain. MAO-A, which facilitates the oxidative deamination of noradrenaline, serotonin, and partially dopamine, is not drastically altered in aging. MAO-B, which catalyzes the oxidative deamination of several amines and partially dopamine, increases with age (Fowler et al. 1997; Gottfries 1990). The importance of these age-related alterations is unclear, although increased quantities of this catabolic enzyme may result in depletion of dopamine and other catecholamines. MAO activity is also significantly altered in neurodegenerative disorders such as Alzheimer's disease (Morgan and Finch 1987; Perry et al. 1991; Procter and Bowen 1987).

## Alterations of Other Transmitter Systems

A wide array of neuropeptides function as neuromodulators and colocalize with other classical transmitters such as noradrenaline and serotonin. Corticotropin-releasing factor is diminished in aging; however, other more abundant peptides such as somatostatin and neuropeptide Y are not (Giaquinto 1988; Gottfries 1990). Age-related alterations of precursor proteins for substance P and enkephalin suggest a preferential loss of neurons in putamen that produce GABA and substance P (Tohgi et al. 1997). A variety of neuropeptides are present in dystrophic neurites and senile plaques of elderly subjects and include somatostatin, neuropeptide Y, and corticotropin-releasing factor (Struble et al. 1987). CSF contents (Table 3–5) of

somatostatin and endorphin are not changed in elderly humans (Hartikainen et al. 1991). Peptide receptors are not adequately characterized in human cortex to assess age-related alterations (Mendelsohn and Paxinos 1991). Studies in aging rodents show no loss of enkephalinergic receptors or diminished receptor affinity (Ueno et al. 1988). Excitatory amino acids are common transmitters in the human brain, and excitotoxic damage is implicated in stroke, anoxic brain damage, and a range of neurodegenerative disorders (Olney et al. 1997; Whetsell 1996). Regional tissue levels of glutamate and aspartate appear altered in aging (Banay-Schwartz 1992). Inhibitory transmitter systems are also altered in aging. GABAergic systems in human hippocampus and cortex are altered with decreased GABA content and diminished GAD activity.

### Signal Transduction and Aging

Signal transduction is transmitter dependent and mediated through a variety of cellular mechanisms. Senescent alterations of second-messenger systems are unclear. Phosphoinositide-derived second messengers and protein kinase-derived systems are altered in several neurodegenerative disorders such as Alzheimer's disease and Parkinson's disease. Although second-messenger systems appear stable in postmortem tissue, limited data are available for normal human aging (Pacheco and Jope 1996). Psychiatric disorders such as schizophrenia and depression, as well as subtle alterations of signal transduction systems, can occur in the brains of elderly subjects (Fowler et al. 1992).

### Trophic Factors and Aging

Trophic factors are substances produced by neurons or glia that maintain or promote the growth and integrity of cell populations. Receptors exist for trophic factors (Hefti and Mash 1989), and synthesis of these substances can be regulated by specific transmitter systems (Thoenen et al. 1991). The neurotrophins include nerve growth factor, brain-derived neurotrophic factor, neurotrophin-3, and neurotrophin-4 (Fuxe and Agnati 1992). Glial cell line-derived neurotrophic factor (GDNF) is produced from glial cells and affects neurons (Gash et al. 1998).

Nerve growth factor is best characterized by and is comprised of three subunits:  $\alpha$ ,  $\beta$ , and  $\gamma$ . Biological activity appears to be present in the  $\beta$  subunit. Nerve growth factor receptors are present in the human nucleus basalis of Meynert (Figure 3–6) and in sympathetic neurons (Hefti and Mash 1989; Hefti et al. 1989). This peptide promotes neurite extension and stimulates the activity of tyrosine hy-

droxylase and dopamine  $\beta$ -hydroxylase (Fuxe and Agnati 1992). Nerve growth factor is essential to the normal development and maintenance of cholinergic neurons. Administration of nerve growth factor to aging rodents will reverse the age-related dendritic spine loss of cortical pyramidal neurons (Mervis et al. 1991).

At the cellular level, nerve growth factor may increase the degradation of superoxide radicals and hydrogen peroxides. Human data suggest an age-related reduction in the synthesis of nerve growth factor (Hefti et al. 1989). Nerve growth factor protects damaged cholinergic forebrain neurons in monkeys, and a similar protective role is postulated for human neurons.

Other peptides such as insulin-like growth factor, platelet-derived growth factor, and fibroblast growth factor affect the production of neurites, development of glia, and regulation of nigrostriatal neurons in nonhuman models. GDNF is one of many new molecules that promote recovery of damaged neurons. GDNF has distinct neuronal receptors and activity on dopaminergic neurons. Infusion of GDNF into rhesus monkey increases dopaminergic neuronal size and neurite extent (Gash et al. 1998). Growth factors such as GDNF can arrest or reverse some of the atrophic changes in aging and are a focus of pharmacological research for neurodegenerative diseases like Alzheimer's or Parkinson's disease.

## ■ Neuroendocrinology of Aging

Senescent endocrinological changes of the pancreas, thyroid, and ovary produce significant direct or secondary brain alterations. Multiple other endocrine systems develop important age-related alterations mediated by changes in the hypothalamic-pituitary axis (Table 3–6). The human hypothalamus consists of multiple nuclei adjacent to the third ventricle (Figure 3–6). The hypothalamus receives noradrenergic, serotonergic, and cholinergic innervation (Mendelsohn and Paxinos 1991) affecting control of many pituitary-releasing factors. These small clusters of neurons control the pituitary gland via direct neuronal input or via factors released into the hypophysial portal system. The pituitary gland is a small collection of cells in the sella turcica and is divided into an anterior and posterior lobe. The anterior pituitary secretes multiple hormones, that is, growth hormone, thyroid-stimulating hormone, etc., while the posterior pituitary secretes oxytocin and vasopressin. Hypothalamic control of neuroendocrine functions is regulated by catecholaminergic inputs that influence the release of inhibiting factors.

Aging humans undergo a series of senescent sexual and

**TABLE 3-6. Endocrinology of aging**

System	Primary abnormality	Clinical consequence	Effective therapy
<b>Pituitary gland</b>			
Pituopause	↓ GH ↓ LH ↓ FSH	↑Frailty	Unclear
<b>Thyroid gland</b>			
Thyropause	↓ T <sub>3</sub> /T <sub>4</sub>	↑TSH Subclinical hypothyroidism	Yes
<b>Male gonad</b>			
Andropause	↓ Testosterone	Unclear	No
<b>Female gonad</b>			
Menopause	↓ Estrogen	Osteoporosis Atherosclerosis Alzheimer's disease	Yes
<b>Adrenal gland</b>			
Adrenopause	↓ DHEA ↓ DHEAS ↓↑ Cortisol	↑Frailty	Unclear
<b>Pancreas</b>			
Pancreopause	↓ Insulin	Diabetes mellitus	Yes

*Note.* This table demonstrates major endocrinological alterations associated with aging. Values represent consensus opinions from multiple sources. Therapy indicates treatments that are available, effective, and cost efficient. DHEA = dehydroepiandrosterone; DHEAS = dehydroepiandrosterone sulfate; FSH = follicle-stimulating hormone; GH = growth hormone; LH = luteinizing hormone; T<sub>3</sub>/T<sub>4</sub> = triiodothyronine/tetraiodothyronine; TSH = thyroid-stimulating hormone.

neuroendocrinological alterations (Rance et al. 1993). Circulating gonadotropins and hypothalamic nuclei manifest age-dependent, gender-specific alterations. Senescent hypothalamic neurons can atrophy, hypertrophy, or remain constant.

The sexually dimorphic nucleus and the preoptic area of the human hypothalamus contain neurons whose density and size are gender specific (Hofman and Swaab 1989). These neurons undergo a series of orderly, predictable changes with age. Sexually dimorphic structures have a sex-dependent pattern of growth and decay (Hofman and Swaab 1989). Males have a 43% reduction and females have a 62% reduction of the volume of the sexually dimorphic nucleus-preoptic area of young (20–30 years) versus old (70–90 years) control subjects. This contrasts with 6% reductions of net brain volume and 20%–25% reductions of basal forebrain structures (Hofman and Swaab 1989). Alterations of these nuclei may reflect the gender-dependent patterns of human sexual aging.

Menopause occurs in most women around age 50 and includes many physiological and psychological alterations. Menopause is caused by disruption of the gonadal-hypothalamic-pituitary cycle through loss of cyclical ovarian estrogen production (Lamberts et al. 1997; Rance 1992). The number of human ova peaks in utero at

mid-gestation (7 million) and is 1 million at birth. This number falls to 400,000 at menarche. This gradual ovarian attrition from ages 20 to 50 ends in ovarian follicles unresponsive to gonadotropins. Levels of serum follicle-stimulating hormone and luteinizing hormone rise as levels of serum estrogens fall (Evans and Williams 1992; Hazzard et al. 1990). Estrogen is important because this hormone probably retards atherosclerotic heart disease, osteoporosis, and Alzheimer's disease in women (Grady et al. 1992). The precise neural protective mechanisms of estrogen are unclear, although this hormone may interact with nerve growth factor and may be neuroprotective for hippocampal neurons. Estrogen replacement for postmenopausal women may slightly increase risk for breast or endometrial cancer. Each postmenopausal woman should be considered for estrogen replacement, weighing the modest risk of malignancy or hysterectomy against substantial risk of heart disease, osteoporosis, and dementia (Rowe and Kehn 1998).

The cyclical nature of the menstrual cycle may be partially driven by neurons in the anterior hypothalamus, which receive a variety of catecholaminergic inputs (Wise et al. 1987). Rodent studies have indicated that the release of luteinizing hormone is influenced by noradrenergic, serotonergic, dopaminergic, and peptidergic inputs. In

postmenopausal senescent women, some hypothalamic nuclei hypertrophy to include marked increase in the diameter of infundibular neurons expressing estrogen receptors (Rance et al. 1990) and increased tachykinin message in selected hypothalamic nuclei (Rance and Young 1991).

The senescent changes of gonadotropic nuclei that provoke the decline of sexual function in elderly men are undefined. The male sexually dimorphic nucleus also is reduced in size with aging. Testosterone levels fall after age 50, and more than 60% of older men have levels below younger men (Lamberts et al. 1997), thus producing “andropause” (Table 3–6). The number of testicular Leydig cells is reduced in older men. The physiological significance of low testosterone on sexual function, muscle bulk, and mood is unclear. The preventive use of exogenous testosterone by healthy older men is limited by concerns over the hormone’s hypertrophic effect on the prostate gland (Rowe and Kahn 1998).

The function of the hypothalamic-pituitary-adrenal axis has been extensively described in elderly patients, producing the concept of “adrenopause” (Lamberts et al. 1997) (Table 3–6). Basal levels of plasma cortisol may increase with age, but the reactivity of the axis as determined by suppression with oral dexamethasone is unchanged (Hazzard et al. 1990; Veith and Raskind 1988). The pattern of cortisol secretion varies significantly in elders, but the secretion of adrenocorticotrophic hormone remains relatively stable (Lupien et al. 1996).

A second, important adrenal hormone is dehydroepiandrosterone (DHEA) and its sulfate DHEAS. This steroid is 10 times more abundant than is cortisol, and the age-related decline of DHEA/DHEAS levels is associated with loss of physical and functional ability. These precursor steroids are transformed into active androgens or estrogens in peripheral target tissue. Plasma DHEA levels peak at age 20 and decline with age, resulting in levels at 70% normal around age 60 and 20% at age 85. In older men, lower DHEA levels are associated with higher mortality rates at 2 and 4 years following assessment (Berr et al. 1996). DHEA replacement may benefit elders, but the risk of long-term therapy is unclear. Thus, DHEA supplementation is not recommended for elderly subjects (Rowe and Kahn 1998).

Growth hormone is released from the pituitary gland in pulses that remain constant during aging; however, the pulse amplitude, and hormone secretion are diminished (Table 3–6). The fall in circulating growth hormone causes the liver and other organs to reduce production of insulin-like growth factor 1. Noradrenaline affects the release of growth hormone via control of growth hormone-releasing factor and somatostatin. Growth hormone secretion is

increased by adrenergic and dopaminergic receptor activation and inhibited by adrenergic stimulation. The peak of growth hormone secretion occurs in adolescence, followed by a progressive decline over years and a diminished number of growth hormone immunoreactive pituicytes in the glands of elderly subjects (Veith and Raskind 1988). Studies have shown that growth hormone injection in older humans produces a short-term increase of lean body mass (8.8%), skin thickness (7.1%), and bone density, while lowering adipose tissue mass (14.4%) (Rudman et al. 1990); however, these improvements may diminish after 12 months. Growth hormone replacement is expensive (Schoen 1991), and its potential side effects limit the usefulness of this therapeutic modality (Schoen 1991). Functional ability may not improve with growth hormone supplements, and replacement therapy is not recommended for elderly patients (Feller and Rudman 1997; Papadakis et al. 1996; Rowe and Kahn 1998).

Abnormalities of thyroid function are common in elderly patients (Table 3–6). Between 4% and 12% of subjects over age 60 may have chemical hypothyroidism. Individuals over age 60 have a sevenfold increase in the prevalence of hyperthyroidism (Evans and Williams 1992). Fifteen percent of patients over age 60 will have elevated blood levels of thyroid-stimulating hormone, and one-third will develop thyroid failure when followed for 4 years. Some elderly individuals have diminished pituitary responsiveness to thyrotropin-releasing hormone (Evans and Williams 1992), although blunting of thyroid-stimulating hormone response is present with depression (Veith and Raskind 1988).

Glucose intolerance occurs in approximately 40% of individuals over age 65, and almost half are undiagnosed. Diabetes is a significant risk factor for cerebrovascular disease. Diabetic complications such as renal disease, neuropathy, or blindness produce significant neuropsychiatric disability. Insulin production by beta cells of the pancreas falls with aging, and peripheral insulin resistance rises. Preventive measures such as weight control, dietary moderation, and exercise significantly improve glucose control in elders.

## ■ Age-Related Alterations of the Special Senses

Aging may affect all five of the special senses. Increased thresholds for touch-pressure, vibration, and cooling are present in aging. Patient deficits of olfaction, sight, and hearing are immensely important to neuropsychiatrists be-

cause they affect psychological testing and clinical management of patients.

### Taste

Taste is mediated by a chemosensory mechanism located in tongue, cheek margin, soft palate, and other oral structures. Impaired taste perception is common in older patients. More than 250 medications alter taste, and dentures that cover the soft plate diminish taste perception. Taste impairment is classified as ageusia (absence of taste) and hypogeusia (diminished taste sensitivity). Taste thresholds for both detection and recognition are elevated in aging. Detection thresholds in elders are 2.7 times higher for sweets and 11.6 times higher for salts, and such taste alteration may cause elderly people with diabetes to use more sugar and those with hypertension to use more salt (Schiffman 1997). The neuropsychiatric sequelae of diminished taste include weight loss, poor compliance with dietary restrictions, and loss in quality of life.

### Olfaction

Aging humans lose multiple olfactory abilities (Kesslak et al. 1988) including the ability to perceive odors, odor discrimination, odor recognition, and olfactory memory (Giaquinto 1988). Alteration of nasal mucosa, cribriform plate stenosis, airway pathology, and other factors contribute to olfactory loss (Doty 1991). Age-related olfactory histopathology, such as neurofibrillary tangles, begins to occur in individuals over age 50 (Doty 1991). Olfaction association areas such as amygdala and uncus cortices are frequently

damaged in aging (Braak and Braak 1991; Kemper 1984). Patients with Alzheimer’s disease demonstrate olfaction deficits and neuropathology in all components of the olfactory pathway (Hyman et al. 1991; Kesslak et al. 1988; Talamo et al. 1989). The loss of taste and smell can reduce the drive to eat, a problem corrected with simple dietary or behavioral intervention, for example, flavor and odor enhancement of foods (Schiffman 1997).

### Vision

Senescent visual loss results from environmental, genetic, metabolic, and vascular etiologies (Evans and Williams 1992; Hazzard et al. 1990). Visual impairment is common in elderly individuals, and frequent causes include opacification of the cornea (cataracts), increased intraocular pressure (glaucoma), retinal damage (diabetic retinopathy), deterioration of the macula (macular degeneration), or disturbance of ocular optics (presbyopia) (Table 3–7) (Abrams et al. 1995). Visual thresholds begin to decline between ages 30 and 40. Approximately 17% of all elders and 36% of individuals over age 80 have opacification of the lens (Giaquinto 1988). Low vision and blindness are common in those over age 85; however, one-half may never seek specialty care, and many can be assisted with simple interventions such as improved home lighting (Evans and Williams 1992). Diabetic retinopathy accounts for 10%–20% of blindness in subjects 65–74 years old and macular degeneration, for 50% of those over age 85 (Evans and Williams 1992; Hazzard et al. 1990) (Table 3–7).

The central visual fields, that is, area 17, include 140

**TABLE 3–7. Common causes and treatment of low vision in the elderly**

Type	Location of lesion	Etiology	Therapy	Clinical symptoms
Cataract	Lens	Age-related lens degeneration	Lens extraction	Like a blurry film over the eye
Glaucoma	Anterior chamber	Increased intraocular pressure ● Open angle 80% ● Angle-closure 10%	● Medication ● Surgery or medication	Progressive insidious loss of peripheral vision
Macular degeneration	Retinal area for central vision	Primary retinal degeneration ● Wet type 10% ● Dry type 90%	● Laser surgery ● None	Patient cannot focus clearly on an object as a result of loss of central vision
Diabetic retinopathy	Multiple foci on retina	Diabetic vascular disease and hemorrhage	● Laser therapy ● Prevention	Multifocal, variable loss of vision—described as looking through the top of a salt shaker

*Note.* This table describes common causes of visual loss encountered during the treatment of elderly patients.

million neurons in adult brain. A minimal number of neurons are lost with aging, and age-related reduction of visual cortical surface area may result from loss of neuropil, for example, in synapses (Leuba and Kraftsik 1994).

Primate studies show that visual information is processed along two pathways involving temporal and parietal cortices. A striate-inferior temporal circuit processes information about form and color distinction (J. H. Morrison et al. 1991). A striate-parietal pathway processes visuospatial and motor data. The effect of aging on these interconnected, high-level association cortices is not known; however, these brain regions are damaged in Alzheimer's disease (Hof and Morrison 1990) and other dementias.

Low vision can worsen neuropsychiatric symptoms and complicate management. Recognition of low vision, correction of refractive error, and maximal use of environmental light are important in management of the geriatric population (Table 3–7).

## Auditory Functions

Hearing impairment is a chronic condition that affects 30% of individuals over age 65. Auditory impairment worsens with age and affects 60% of individuals ages 71–80 (Davis et al. 1990). High-frequency hearing loss increases with aging and is usually caused by mechanical failure. Causes of hearing loss in elderly people include disorders of the outer, middle, and inner ear. Cerumen impaction is a common problem of the outer ear (Gulya 1992). Hearing loss from damage to the inner ear has four primary causes: 1) sensory presbycusis, 2) neural presbycusis, 3) strial presbycusis, and 4) cochlear conductive presbycusis. Precise epidemiological data are limited because correlative histopathological studies of the auditory apparatus are few, and many conditions have mixed pathology. Most age-related hearing loss is mechanical, and age-related histopathology (e.g., senile plaques or neurofibrillary tangles) is not reported in the peripheral auditory system. Conductive or sensorineural hearing loss can be improved with appropriate hearing amplification. The auditory cortex can be severely damaged in Alzheimer's disease (Esiri et al. 1986), in which a specific pattern of atrophy shows shrinkage of the association cortex (i.e., the superior temporal gyrus [Brodmann's areas 22 and 52]), with sparing of the primary auditory cortex (i.e., the transverse temporal gyrus [Brodmann's areas 41 and 42]) (Figure 3–8).

Subtle auditory impairment may be difficult to detect in the elderly patient who has developed accessory methods such as lip and face reading. Even mild (10 dB) hearing loss can significantly lower quality of life (Bess et al. 1989). Hearing loss can remain undetected by caregivers, and this

communication problem can be misinterpreted by caregivers as patient obstinacy. Unrecognized hearing loss can produce neuropsychiatric symptoms that are preventable or reversible such as confusion or irritability.

## ■ Aging of the Autonomic and Peripheral Nervous Systems

Autonomic regulation involves a balance between sympathetic and parasympathetic innervation. These two systems include neurons in hypothalamus, brainstem, spinal cord, and peripheral ganglia. Small-diameter myelinated and unmyelinated axons conduct impulses to target organs (McLeod and Tuck 1987). The number and density of peripheral or autonomic myelinated fibers are reduced in aging rodents and humans (Knox et al. 1989).

Aging of the human sympathetic nervous system results in a mixture of clinical alterations. Essential hypertension is an age-related disorder that has both central and peripheral causes (Evans and Williams 1992), and orthostatic hypotension is a common problem in the elderly. Postural hypotension occurs in 20% of selected geriatric patients and complicates the prescription of psychotropic medications (Mader 1989; see also Chapter 29 in this volume). Antihypertensive agents can cause depression in elderly patients. Individuals over age 65 are sensitive to the orthostatic effects of the tricyclic antidepressants. Although senescent changes occur in brainstem and spinal cord (Clark et al. 1984), the age-related alterations of central nuclei that control autonomic function are unknown. A progressive, age-related loss of sympathetic neurons occurs in the intermediolateral column of the spinal cord. These neurons span from T1 to L2 and are involved with vasomotor tone.

Sympathetic control of blood pressure is maintained through a complicated interaction of central, peripheral, and neuroendocrine interactions. The sympathetic nervous system is inhibited in the medullary brainstem and spinal cord through centrally located adrenergic mechanisms. Obesity is associated with increasing plasma norepinephrine levels, and older subjects have higher total body fat. Plasma norepinephrine is elevated in aging; however, the net effect of aging on the peripheral sympathetic tone is unknown (Rowe 1987). Senescent alterations are reported for sympathetic innervation to other organs.

Age-related pathologies (e.g., neurofibrillary tangles, senile plaques, and dystrophic neurites) occur rarely in the human spinal cord and peripheral nervous system, although neurofibrillary tangles are reported in the human

superior cervical ganglion (Kawasaki et al. 1987). Aging humans have reduced numbers of neurons in myenteric ganglia (Gomes et al. 1997). Lewy bodies are present in Auerbach's and Meissner's plexuses in elderly subjects, as well as in those with Parkinson's disease (Wakabayashi et al. 1988). Sympathetic innervation of human spleen is not described, but aging rodents have markedly diminished splenic noradrenergic innervation (Madden et al. 1998).

The aging of the human parasympathetic nervous system is poorly understood. A senescent loss of small-diameter peripheral nerve fibers may contribute to parasympathetic dysfunction. Sacral parasympathetic neurons are damaged in parkinsonism (Oyanagi et al. 1990). Many drugs with anticholinergic side effects alter parasympathetic tone (N. L. Peters 1989).

The spinal cord and peripheral nervous system demonstrate subtle age-related changes. The number of anterior horn cells declines with aging, possibly in response to changes in trophic factors such as neurotrophin 3, neurotrophin 4, and insulin-like growth factor 1. The number of swollen axons in spinal cord increases with aging, and amyotrophic lateral sclerosis is a disease of older individuals (Clark et al. 1984). Age-related loss of vibratory, tactile, and thermal response over lower extremities may reflect loss of myelinated axons in the peripheral nervous system (Flanigan et al. 1998).

## ■ Aging and the Immune System

The interaction of brain aging and the immune system can be viewed two ways: the effect of aging brain on immune function or the effect of an aging immune system on the brain. Components of the immune system, such as spleen, thymus, and lymph nodes, receive direct noradrenergic innervation and respond to substances (e.g., cortisol) produced by the neuroendocrine system. Selected products of the immune system are CNS-active and may complete the feedback loop to the CNS (Cotman et al. 1987; Madden et al. 1998).

The brain does not have a system of lymphatics or lymphoid tissue like other organs do (e.g., lung or gastrointestinal tract) (Adams and Duchon 1992). Microglia, the immune cells of the brain, are either hematogenous or CNS constituents. Subjects without neurological disease who are over age 60 have increased numbers of activated microglial cells that express the cytokine interleukin-1, and the number of enlarged or phagocytic microglial cells is increased, whereas quiescent cells are unchanged (Mrak et al. 1997; Thomas 1992).

Interleukin-1, a cytokine that mediates acute phase re-

action, innervates key endocrine and autonomic neurons in human hypothalamus that affect many components of the acute phase immune reaction (Breder et al. 1988). Interleukin-2 is centrally active and affects firing of locus ceruleus neurons (Nistic and De Sarro 1991). Interleukin-1 mRNA content is increased in aging brain.

Many systemic diseases of the elderly population, such as arthritis, are immune mediated. The intact blood-brain barrier provides some protection against autoimmunity; however, age- and disease-related changes increase its permeability for selected immunoglobulins. Brain-directed autoantibodies are absent in young subjects, but some older humans produce antibodies that recognize neurons and astrocytes (Gaskin et al. 1987), including cholinergic neurons (Lopez et al. 1991). Astrocytes and microglial cells participate in the immune response of the brain by presenting antigen to T cells (Cotman et al. 1987). Microglia are present in senile plaques (Figures 3-10 and 3-21) and associated with intracellular and extracellular neurofibrillary tangles (Cras et al. 1991). Anti-inflammatory drugs may slow the progression of Alzheimer's disease by altering the brain's immune response to degenerative changes.

## ■ Nutritional Deficiencies in Aging

A linear decline of food intake occurs from age 20 to 80. The increased obesity in aging may result from decreased physical activity or metabolic changes. The physiology of age-related anorexia is unclear, but increased circulating cholecystokinin in older subjects may diminish food intake and appetite (Morley 1997). Elderly individuals have significant risks for vitamin deficiencies that produce direct or indirect CNS complications.

Cobalamin or vitamin B<sub>12</sub> deficiency is common in the elderly, and subnormal serum cobalamin levels are present in approximately 5% of elderly individuals, although estimates range as high as 40% (Stabler et al. 1997). Vitamin B<sub>12</sub> deficiency is caused by poor nutrition or impaired gastric absorption (Carmel 1997), although this disorder rarely produces pernicious anemia. Low vitamin B<sub>12</sub> can lead to neurological disorders, and this deficiency can be avoided by supplementing the diet with 1 mg/day (Rowe and Kahn 1998).

Folic acid is available in green leafy vegetables, fruits, and liver, and its deficiency will elevate serum homocysteine. Accelerated atherosclerosis is common in young patients with homocystinuria, and high serum homocysteine is associated with increased risk for stroke, heart disease, and cognitive decline in elders. Low serum folate may worsen cognitive loss in patients with dementia

(Fioravanti et al. 1997). Folate and cobalamin are essential to DNA synthesis and repair. Folic acid deficiency can be avoided by daily supplementation of 400  $\mu$ g/day (Rowe and Kahn 1998).

Falls and fractures are serious patient complications to the geriatric neuropsychiatrist. Normal serum calcium levels in elders do not predict normal bone density. Older individuals at risk for osteoporosis should have a simple, cost-effective bone density screening using the dual energy X-ray absorption test. The daily calcium requirement for healthy elders is 1200 mg, but the average diet supplies 200–800 mg/day, requiring a supplement of 500 mg/day. Elders need 700 IU of vitamin D/day to sustain calcium absorption from the intestine (Rowe and Kahn 1998). Additional therapeutic interventions are used for patients with documented osteoporosis.

## ■ Neurobiology of Aging in Patients With Chronic Mental Illnesses

The neurobiology of aging in patients with chronic mental illnesses can differ from that of healthy individuals. Assessment of age-related alterations in patients with chronic mental illness is complicated by the effect of chronic neuroleptic usage, nutrition, environment, and health status. Current hypotheses suggest that schizophrenia results from neuronal migrational abnormalities, genetic factors, and environmental influences (Barta et al. 1990; Weinberger 1987). Subtle changes in temporal lobe, frontal cortex, and hippocampus are described in brain imaging and autopsy studies (Powers 1999). Other disorders such as mental retardation, autism, and dyslexia (Galaburda et al. 1985; Hier et al. 1978) can involve abnormalities of neuronal migration in brain regions such as hippocampus and planum temporale (Figure 3–8). The neurobiology of aging in migratorially disordered brain is unknown.

Patients with chronic mental illness have normal aging of organs in cardiovascular, pulmonary, and renal systems. Excessive rates of natural death can result from complications of physical disorders produced by psychosocial factors (Black et al. 1987), such as medical noncompliance, poverty, and unavailability of health care services. Medical illness in patients with serious mental illness is underdiagnosed by one-third of primary care doctors and one-half of psychiatrists (Jeste 1996).

Studies of brains from elderly patients with chronic schizophrenia have demonstrated conflicting data on the numbers of senile plaques, neurofibrillary tangles, and vascular alterations as compared with those of age-matched

control subjects (Arnold et al. 1998; Purohit et al. 1998). A meta-analysis of 10 postmortem studies showed that elderly patients with schizophrenia have age-related pathology similar to age-matched control subjects (Baldessarini et al. 1997). Postmortem studies of patients who receive long-term neuroleptic therapy demonstrate no specific pathology, and normal levels of iron are found in basal ganglia. The expression of the cytoskeletal epitopes, that is, microtubule-associated protein 2 and microtubule-associated protein 5, is altered in hippocampal subicular neurons (Arnold et al. 1991) of subjects with schizophrenia and of patients with serious mental illness. Such alterations of cytoskeleton may reflect abnormal development as opposed to abnormal aging.

## ■ Animal Models for the Neurobiology of Aging

Animal aging models include sheep, monkey, bear, dog, and others (Brizzee et al. 1978; Cork et al. 1988; Maurer et al. 1990). Brain weights of aging monkeys remain relatively constant over time (Herndon et al. 1998). Dystrophic neurites and senile plaques are described in all animal models, and substantial numbers of neurofibrillary tangles are described in the brains of aging bears and sheep (Cork et al. 1988). Other age-related changes such as granulo-vacuolar degeneration, Hirano bodies, and Lewy bodies are not described (Figures 3–9 and 3–23). Hypertensive rodents demonstrate some brain alterations (Wyss and Van Groen 1992; Wyss et al. 1992). Monkeys with surgically induced hypertension will manifest cognitive deficits and multiple cortical infarctions. Animal models for Parkinson's disease have significant limitations, and some degenerative diseases, such as frontotemporal dementia, diffuse Lewy body disease, etc., exist only in humans.

Aging primates demonstrate subtle cognitive decline similar to that of elderly humans (D. L. Price et al. 1991). Senescent cognitive deficits in aging rhesus monkeys correlate with alterations in prefrontal cortex and brainstem nuclei that project to neocortex, as well as damage to central myelin (A. Peters et al. 1996). Unlike aging humans, aged monkeys demonstrate neither cortical atrophy nor severe hippocampal damage (Herndon et al. 1998). Minimal synaptic loss is present in the dentate gyrus of monkey hippocampus (Tigges et al. 1996a, 1996b), and neurons in layer II of entorhinal cortex are spared in aging macaques (Gazzaley et al. 1997). Aging monkey brain can develop senile plaques, dystrophic neurites, and congophilic angiopathy closely resembling those of aging humans.

Apolipoprotein E is present in senile plaques of aging orangutans (Gearing et al. 1997). The A $\beta_{40}$  peptide length predominates in aging monkeys as opposed to the A $\beta_{42}$  length in humans with Alzheimer's disease. Very old dogs also develop amyloid deposits in the frontal cortex with early neuritic pathology (Satou et al. 1997). Neurofibrillary tangles are seen in aging bears, sheep, and very old primates with advanced disease (Cork et al. 1998; Nelson and Saper 1995). Individual bear and monkey neurons will atrophy, accumulate abnormal cytoskeletal proteins, and express amyloid precursor protein. Markers for cholinergic, noradrenergic, serotonergic, and peptidergic systems are decreased in brains of aging primates, suggesting that age-related pathology is not species specific but rather reflects the longevity of the animal (D. L. Price et al. 1991).

## ■ Healthy Aging

The aging process alters most organ systems in the human body; however, age-related loss of function is frequently overestimated in disease-free organ systems of elderly patients. Cardiovascular alterations, resulting from common diseases in the elderly such as hypertension and atherosclerosis, are immensely important to the geriatric neuropsychiatrist. Age-related loss of cardiovascular function is not dramatic in elders without heart disease (Evans and Williams 1992; Hazzard et al. 1990). Loss of exercise tolerance is partially explained by disuse (Evans and Williams 1992), rather than by atrophy. Age-related effects on systemic organ systems are displayed in Table 3–8, and alterations of pharmacodynamics are discussed elsewhere (see Chapter 34 in this volume). Epidemiological studies show that walking 30 minutes per day, avoiding depression, and maintaining a network of five friends will increase the likelihood of successful aging (Rowe and Kahn 1998; Seeman et al. 1995). Walking 30 minutes per day will decrease yearly hospitalizations for atherosclerotic heart disease by one-third, and elderly patients can regain some exercise capacity through supervised endurance training.

Although frequently overlooked, simple preventive measures remain effective in the elderly. Prevention of psychological and physical health problems can significantly retard the aging processes despite the role of genetics in longevity. Syndrome X refers to a collection of preventable, high-risk physical characteristics that include obesity, glucose intolerance, hypertension, and elevated serum lipids. Syndrome X is common in elders and predicts vascular disease. Pseudodiabetes of aging includes elevated glucose and elevated insulin levels. Weight reduction and exercise, especially for “potbellied” obesity, improve glucose

**TABLE 3–8. Age-related alterations of cardiovascular, renal, and pulmonary function in the absence of intrinsic diseases**

Function	Alteration
<b>Cardiac</b>	
Heart rate	No significant change
Ejection fraction	No significant change
Physical exercise capacity	Slight decrease
<b>Pulmonary</b>	
Total lung capacity (TLC)	No significant change
Forced vital capacity (FVC)	Decrease
Diffusion capacity (CDco)	Decrease
Physical work capacity (VO <sub>2 max</sub> )	Decrease
Partial pressure of arterial oxygen (PaO <sub>2</sub> )	Decrease
<b>Renal</b>	
Renal mass	Decrease
Renal blood flow	Decrease
Glomerular filtration rate (GFR)	Decrease

Source. Adapted from Evans and Williams 1992; Hazzard et al. 1990.

metabolism and lower morbidity from syndrome X. Injuries, osteoporosis, vitamin or nutritional deficiencies, and some sensory deficits are preventable conditions that increase morbidity and lower functional ability (Table 3–6).

## ■ Conclusions

The secret of successful aging is unknown. The distinction between “normal” senescent phenomena and age-related disease remains unclear. Human neuronal aging includes a complex mixture of atrophy, hypertrophy, synaptic reorganization, and cell death. Genetic, environmental, systemic, and immunological factors may influence human brain aging. Smoking, exercise, and body mass in mid to late life predict survival and disability. Elders with good health habits survive longer and compress end-of-life disability into fewer years (Vita et al. 1998). Simple, cost-effective preventive measures for physical and psychological health can slow the aging process and sustain function in elders (Strawbridge et al. 1996).

# Neurobiological Basis of Behavior

Jeffrey L. Cummings, M.D.

C. Edward Coffey, M.D.

All behavior and experience are mediated by the brain. No behavior, thought, or emotion lacks a corresponding cerebral event, and abnormalities of human behavior are frequently a reflection of abnormal brain structure and are accompanied by aberrant brain function. This premise does not deny the influence of learning, life events, education, or the socio-cultural dimension of human existence; these factors create the context of human behavior and exert powerful biological, developmental, and situational influences. In all cases, however, psychological and sociocultural effects are mediated through brain function. Thus, a comprehensive approach to human behavior demands an understanding of the neurological basis of human cognition, emotion, and psychopathology.

A life-span perspective adds another dimension to understanding behavior: brain function alters dramatically from uterine life through infancy, childhood, adolescence, adulthood, and old age. Physiological functions vary more

widely in elderly people than in young people, tolerance of injury and potential for recovery are diminished in elderly patients, and the types of behaviors associated with brain dysfunction often differ depending on the age of the patient.

In this chapter, we provide a review of the neuroanatomical and neurochemical basis of human behavior. First, we present a synoptic model of behavioral neuroanatomy as a framework for the remaining discussion. The model divides the nervous system into three behaviorally relevant zones: an inner zone surrounding the ventricular system, a middle zone encompassing the basal ganglia and limbic system, and an outer zone comprised primarily of the neocortex. We present the anatomy of each zone and describe the behavioral consequences of injury to each. Next, we describe two distributed systems; these cross the three zones to allow information to enter the brain (thalamocortical system) and allow impulses mediating action to exit the brain (frontal-subcortical circuits). We also present neuro-

psychiatric syndromes associated with abnormalities of these systems. Finally, we integrate the biochemical basis of behavior with this anatomical approach.

## ■ A Model of Behavioral Neuroanatomy

Paul Yakovlev developed a comprehensive model of the nervous system in terms relevant to behavior (Yakovlev 1948, 1968; Yakovlev and Lecours 1967). He adopted an evolutionary perspective and noted that the brain consists of three general regions: a median zone surrounding the ventricular system, containing the hypothalamus and related structures; a paramedian-limbic zone consisting primarily of limbic system structures, basal ganglia, and parts of the thalamus; and a supralimbic zone containing the neocortex.

In this chapter, we present the Yakovlev approach—updated with information from more recent anatomical studies (Benarroch 1997; Mesulam 1985)—as a foundation for understanding brain-behavior relationships (Figure 4–1). The *median zone* is immediately adjacent to the central canal, is poorly myelinated, and has neurons with short axons that synapse on nearby cells, as well as on cells with longer axons that project to more distant nuclei. The median zone contains the hypothalamus, medial thalamus, and periventricular gray matter of the brainstem as well as functionally related areas of the amygdala and insular cortex. The system mediates energy metabolism, homeostasis, peristalsis, respiration, and circulation. The median zone contains the reticular activating system and the nonspecific thalamocortical projections that maintain consciousness and arousal in the awake state and participate in sleep mechanisms. No lateral specialization is evident in the median zone. This system is fully functional at birth and is responsible for the early survival of the infant.

The *paramedian-limbic zone* has neurons that are more well myelinated than the median zone, and neurons here are grouped in nuclear structures that are connected in series. Many of the thalamic nuclei, the basal ganglia, cingulate gyrus, insula, orbitofrontal region, hippocampus, and parahippocampal gyri are included in this zone. The paramedian-limbic zone includes the structures composing the limbic system (Papez 1937). Structures of this zone mediate the experiential aspects of emotional states. They also mediate posture and the outward expression of emotion in vocalization, gestures, and facial affective display. There is little lateral specialization of the paramedian structures. Phylogenetically, this level of brain development is present in reptiles (MacLean 1990). The paramedian-limbic zone is partially functional at birth, and

**FIGURE 4–1.** Updated version of Yakovlev’s model of the nervous system demonstrating the median zone (*yellow*), paramedian-limbic zone (*green*), and supralimbic zone (*red*) Source. Modified with permission from Yakovlev PI, Lecours A-R: “The Myelogenetic Cycles of Regional Maturation of the Brain,” in *Regional Development of the Brain in Early Life*. Edited by Minkowski A. Oxford, England, Blackwell Scientific, 1967, pp. 3–65.

its emerging integrity becomes evident in smiling and crawling. Disorders of motivation, mood, and emotion are associated with paramedian-limbic dysfunction, and this zone is the anatomic site of structures involved in many neuropsychiatric disorders. Parkinson’s disease with its depression, apathy, akinesia, masked face, hypophonic voice, and marked postural changes is an example of a common disease of elderly people affecting the paramedian-limbic zone.

The *supralimbic zone* is outermost in the brain and includes the neocortex and the lateral thalamic nuclei. The neurons of this zone have long, well-myelinated axons that project via white matter tracts to more distant targets. The supralimbic neocortex contains the neurons mediating higher cortical (association) functions, as well as the pyramidal neurons projecting to limbs, lips, and tongue. It mediates highly skilled, fine motor movements evident in human speech and hand control. Ontogenetically, this zone first finds expression in the pincer grasp and articulate speech. Phylogenetically, the supralimbic zone first appears in mammals and is most well developed in humans (MacLean 1990). The supralimbic zone is expressed in human cultural achievements including art, manufacture, speech, and writing. The supralimbic zone exhibits lateral specialization with marked differences between the functions of the neocortex within the two hemispheres.

The supralimbic zone is vulnerable to some of the most common neurological disorders associated with aging, including stroke and Alzheimer's disease. For example, the expansion of the neocortex has been at the expense of a secure vasculature. The enlarged association areas have created border zone areas between the territories of the major intracranial blood vessels that are at risk of stroke because of limited interconnections and poor collateral flow; reduced cerebral perfusion with carotid artery disease or cardiopulmonary arrest regularly results in border zone infarctions at the margins between these vascular territories. In addition, penetrating branches form arterial end zones that have no collateral supply as they project through the white matter to the borders of the ventricles. This vascular anatomy creates an area of vulnerability to ischemia at the margins of the lateral ventricles. Periventricular brain injury has been associated with depression (Coffey et al. 1988), vascular dementia, and Binswanger's disease. Along with the hippocampus, the supralimbic zone is the major site of pathological changes in Alzheimer's disease. Focal lesions of the neocortex result in restricted neurobehavioral deficits such as aphasia, apraxia, and agnosia.

This model of behavioral neuroanatomy provides an ontogenetic life-span perspective showing the emerging function of these structures in early life and their disease-related vulnerability in later life. The model reflects an evolutionary perspective of the brain emphasizing its development through time and its increasing complexity in response to evolutionary pressures. From a clinical point of view, most neuropsychological deficit syndromes such as disorders of language and praxis are associated with dysfunction of the supralimbic neocortex, whereas disorders of mood, psychosis, and personality alterations are more likely to occur with abnormalities in the paramedian limbic system. The median zone is responsible for more basic life-sustaining functions, and disturbances there are reflected in disorders of consciousness and abnormalities of metabolism, respiration, and circulation. Thus the patterns of neuropsychiatric disturbance occurring with brain disorders are highly organized events that reflect the history, structure, and function of the nervous system.

## ■ Neocortex (Supralimbic Zone)

### Histological Organization of the Cortex and Behavior

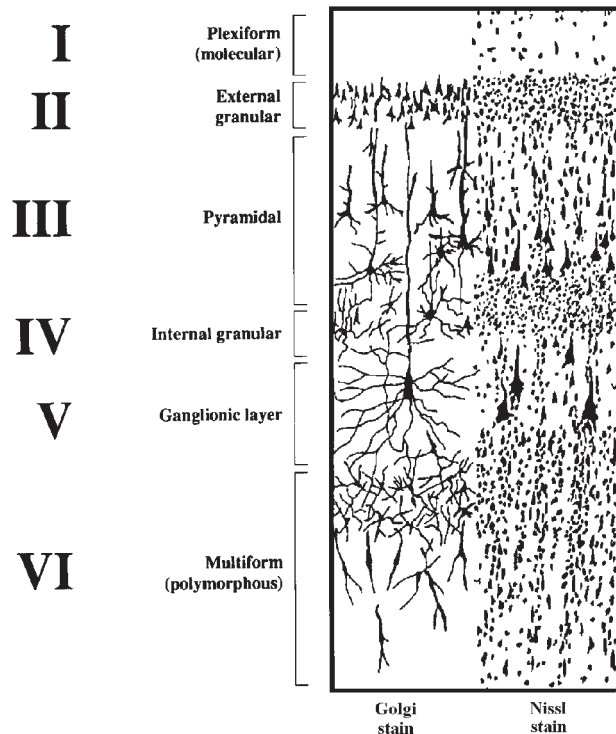

Brodmann originally described 46 cortical areas with distinctive histological characteristics, and Brodmann's maps have remained the classic guide to the histological organi-

zation of the cerebral mantle. Within Brodmann's areas, three types of cortex relevant to understanding behavior have been identified: a three-layered allocortex, a six-layered neocortex, and an intermediate paralimbic cortex. The limbic system cortex such as the hippocampus has a three-layered allocortical structure, whereas the sensory, motor, and association cortices of the hemispheres have a six-layered organization (Kelly 1991). In the neocortex, layer I is outermost and consists primarily of axons connecting local cortical areas; layers II and III have a predominance of small pyramidal cells and serve to connect one region of cortex with another; layer IV has mostly nonpyramidal cells, receives most of the cortical input from the thalamus, and is greatly expanded in primary sensory cortex; layer V is most prominent in motor cortex and has large pyramidal cells that have long axons descending to subcortical structures, brainstem, and spinal cord; and layer VI is adjacent to the hemispheric white matter and contains pyramidal cells, many of which project to thalamus (Kelly 1991) (Figure 4-2). Layers II and IV have the greatest cell density and the smallest cells; conversely, layers III and V have the lowest density and the largest cells. Cell size correlates with the extent of dendritic ramification, implying that cells of the layers III and V projecting to other cortical regions have the largest dendritic domains (Schade and Groeningen 1961).

### Functional Organization of the Neocortex

The *neocortex* is highly differentiated into primary motor and sensory areas and unimodal and heteromodal association regions (Mesulam 1985) (Table 4-1). Figure 4-3 shows the anatomical distribution of the different cortical types in the cerebral hemispheres. Association cortex occupies 84% of the human neocortex, whereas primary motor and sensory areas account for only 16%; this indicates the marked importance of association cortex in human brain function (Rapoport 1990). The neocortex is organized in a mosaic of cortical columns, and local circuit neurons (confined to the cortex) compose approximately 25% of the cellular population (Rapoport 1990). Cortical regions receive and send information via white matter tracts.

Primary motor cortex occupies the motor strip in the posterior frontal lobe and serves as the origin of the pyramidal motor system (Figure 4-1). Lesions of the motor cortex produce contralateral weakness, particularly of the leg flexors and arm extensors, hyperreflexia, and an extensor plantar response. *Primary somatosensory cortex* is located in the postcentral gyrus in the anterior parietal lobe, *primary auditory cortex* occupies Heschl's gyrus in the superior tem-

**FIGURE 4-2.** Histological structure of six-layered neocortex.

poral lobe anterior to Wernicke's area, and *primary visual cortex* is situated in the calcarine region of the occipital lobe (Figure 4-4). Lesions of these regions typically result in contralateral hemisensory deficits (the auditory system is an exception).

Unimodal association areas mediate the second level of information processing in the cerebral cortex after the primary sensory cortex. Unimodal somatosensory cortex is located in the superior parietal lobule, unimodal auditory cortex is situated in Wernicke's region in the left hemisphere and the equivalent area of the posterior superior temporal cortex of the right hemisphere, and unimodal visual cortex occupies peristriate, midtemporal, and inferotemporal cortical regions (Figure 4-5). Lesions of these regions produce deficits confined to a single sensory modality; the syndromes associated with dysfunction of these regions reflect the higher level of information processing. Wernicke's area lesions produce fluent aphasia; lesions of right-sided auditory unimodal cortex produce sensory aprosodia (i.e., the inability to comprehend speech inflection and melody); and lesions of the unimodal visual association cortex produce visual agnosias (e.g., visual object agnosia, prosopagnosia, and environmental agnosia) (Kirshner 1986).

The highest level of information processing in the cerebral hemispheres occurs in the *heteromodal association cortices*. It is also primarily in these regions that sensory information from primary sensory and unimodal association cortex is integrated with limbic and paralimbic input

**TABLE 4-1.** Structure and function of different types of cerebral cortex

Cortex	Layer number	Brain regions	Relevant behaviors
<b>Neocortex</b>			
Primary cortex			
Koniocortex	6	Primary sensory cortex (parietal)	Vision, hearing, somatic sensation
Macropyramidal	6	Primary motor cortex (motor cortex)	Movement
Unimodal association cortex	6	Secondary association (parietal, temporal, occipital cortex)	Modality-specific processing of vision, hearing, and somatic sensation
Heteromodal association cortex	6	Multimodal association (inferior parietal lobule, prefrontal cortex)	Higher-order association
<b>Allocortex</b>			
Archicortex	3	Hippocampus	Memory
Paleocortex	3	Piriform cortex	Olfaction
<b>Paralimbic (mesocortex)</b>	4, 5	Orbitofrontal cortex, insula, temporal pole, parahippocampal gyrus, cingulate gyrus	Emotional behavior

**FIGURE 4-3.** Distribution of different histological types of cortex in the human cerebrum. The hippocampal allocortex is shown in *white*, paralimbic cortex in *green*, unimodal association cortex in *yellow*, multimodal association cortex in *red*, and primary motor and sensory cortex in *blue*.

(Mesulam 1985). Two heteromodal association regions are recognized in the human brain: the inferior parietal lobule and the prefrontal cortex (Figure 4-6). Dysfunction of these areas produces complex behavioral deficits that transcend single modalities. Lesions of the left inferior parietal lobule produce the angular gyrus syndrome with alexia, agraphia, acalculia, right-left disorientation, finger agnosia, anomia, and constructional disturbances (Benson et al. 1982). Right-sided inferior parietal lesions produce visuospatial deficits affecting constructions, spatial attention, and body-environment orientation. Prefrontal cortical dysfunction produces deficits in motor programming, memory retrieval, abstraction, and judgment (Stuss and Benson 1986). Posterior heteromodal association cortex dysfunction observed with inferior parietal lobe lesions reflects abnormalities of the highest level of processing of incoming sensory information; anterior heteromodal associ-

ation cortex dysfunction in conjunction with prefrontal disturbances produces deficits in active organizational or executive behaviors.

Thus a behavioral neuroanatomy can be discerned in the organization of the cerebral cortex. Information processing proceeds through progressively more complicated levels of analysis and integration and is then translated into action through a series of executive processes (using anterior heteromodal cortex and supplementary and primary motor cortex). Each cortical region carries on specific types of information processing activities, and regional injury or dysfunction produces a signature syndrome. From a clinical perspective, neurobehavioral and neuropsychological abnormalities such as aphasia, aprosodia, and agnosia are products of dysfunction of neocortical association cortex or connecting pathways. Although each region has unique functions, each also contributes to more complex integrative processes required for human experience and behavior.

### White Matter Connections

White matter of the brain consists of myelinated axons of neurons and contains three types of fibers: 1) projection fibers that connect the cortex with the basal ganglia,

**FIGURE 4-4.** Primary motor (*red*) and sensory (*blue*) cortex. *Source.* Image courtesy of M. Mega and the UCLA Laboratory of Neuroimaging.

**FIGURE 4-5.** Unimodal association cortex (yellow).

Source. Image courtesy of M. Mega and the UCLA Laboratory of Neuroimaging.

thalamus, brainstem, and spinal cord; 2) association fibers that interconnect cortical regions of the same hemisphere; and 3) commissural fibers that connect the two hemispheres with each other (Carpenter and Sutin 1983). The principal *projection tracts* include the efferent corticostriatal projections; corticothalamic connections; corticobulbar, corticopontine, and corticospinal fibers; and the afferent thalamocortical radiations. There are also short and long *association fibers*. The short association or “U” fibers connect adjacent sulci; the long association fibers form large tracts connecting more distant regions within each hemisphere (Figure 4-7). The main long association tracts are the uncinate gyrus connecting the orbitofrontal region with the anterior temporal cortex, the arcuate fasciculus projecting between the temporal lobe and the superior and middle frontal gyri, the superior longitudinal fasciculus reaching between parieto-occipital and frontal cortices, the inferior longitudinal fasciculus connecting the parieto-occipital region with the temporal lobe, and the cingulum containing fibers connecting frontal and parietal regions with the hippocampus. The *commissural fibers* are situated in the massive corpus callosum interconnecting all lobes of one hemisphere with areas of the contralateral

hemisphere and in the more diminutive anterior commissure interconnecting the olfactory regions and the middle and inferior temporal gyri of the hemispheres (Figure 4-8).

Intact cerebral function depends on the integrity of the axons of the white matter, as well as on the activity of the neurons of the gray matter. White matter diseases with diffuse or multifocal demyelination produce memory abnormalities, dementia, depression, mania, delusions, and personality alterations. Focal lesions of white matter tracts produce a number of *disconnection syndromes* that arise when critical neuronal areas are uncoupled by an intervening lesion (Geschwind 1965; Kirshner 1986). Table 4-2 summarizes the principal disconnection syndromes.

Disruption of *commissural fibers* by stroke, surgery, or trauma disconnects the left and right hemispheres, and several commissural or callosal syndromes are recognized clinically. With an anterior callosal lesion, the right hemisphere controlling the left hand becomes disconnected from the left hemisphere; thus the left hand no longer has access to the verbal and motor skills of the left hemisphere, and callosal apraxia, left-hand tactile anomia, and left-hand agraphia result. When the splenium of the corpus callosum is damaged in association with injury to the left occipital

cortex (usually from a left posterior cerebral artery occlusion), the visual information available to the right hemisphere cannot be transferred to the left for semantic decoding, and alexia without agraphia ensues.

Disconnection syndromes also occur with lesions of association fiber tracts. Interruption of the arcuate fasciculus is responsible for conduction aphasia and parietal apraxia. Lesions of the right inferior longitudinal fasciculus produce prosopagnosia and environmental agnosia, whereas bilateral inferior longitudinal fasciculus damage causes visual object agnosia. Hemisensory deficits and homonymous hemianopsia result from lesions affecting the thalamocortical projections, and hemimotor syndromes occur with lesions of the descending corticospinal projections. The locked-in syndrome occurs with bilateral lesions of descending corticobulbar and corticospinal projection tracts at the pontine level.

The complex histological organization of the cerebral cortex, with its different cytoarchitectonic areas subsuming different processing tasks (as described above), is reflected in the complex connectivity of the cerebral white matter. White matter tracts connect specialized cortical regions, and neuropsychological syndromes may reflect focal cortical injury or disconnection of the cortical regions through injury to the white matter connections. Disconnection syndromes occur with lesions of commissural, long association, or projection fibers. Discrete neurobehavioral syndromes have been identified and occur primarily when lesions of callosal or association fibers disconnect unimodal association areas (e.g., interruption of visual processing in the agnosias or motor activities in the apraxias).

### **Hemispheric Specialization, Laterality, and Dominance**

**Anatomic asymmetries.** The two cerebral hemispheres, although grossly symmetrical, differ in some aspects of development, structure, and biochemical composition. Differences between the right and left hemispheres have been shown in both the upper surface of the temporal lobes and the inferolateral surface of the frontal lobe. The temporal lobe area corresponding to Wernicke's area (in 65% of cases) and the frontal region corresponding to Broca's area are both larger than the corresponding right-brain regions (in 83% of cases) (Falzi et al. 1982; Galaburda et al. 1978). The superior temporal surface is longer and the total area is approximately one-third larger in the left hemisphere. The sylvian fissure is longer and more horizontal on the left, whereas it is curved upward on the right (Galaburda et al. 1978). Cytoarchitectonic differences correspond to these morphological asymmetries: there is a larger region corresponding to Wernicke's area on the left compared to that on the right.

**TABLE 4–2. Fiber tracts and related disconnection syndromes of the cerebral hemispheres**

Fiber type	Tract	Symptoms
Commissural	Corpus callosum	Left-hand tactile anomia, left-hand agraphia, left-hand apraxia, inability to match hand postures or tactile stimuli of the two hands, reduced constructional skills in the right hand
	Splenium	Alexia without agraphia (this syndrome occurs when there is a left occipital injury and right homonymous hemianopsia in addition to the splenial lesion)
Association	Arcuate fasciculus	Conduction aphasia
	Arcuate fasciculus	Parietal apraxia
	Inferior longitudinal fasciculus (right)	Prosopagnosia, environmental agnosia
	Inferior longitudinal fasciculus (bilateral)	Visual object agnosia
Projection	Corticospinal tract	Locked-in syndrome

Other gross asymmetries of the human brain include a wider and longer left occipital lobe, wider right frontal lobe, larger left occipital horn of the lateral ventricular system, and a tendency for the left descending pyramidal tract to decussate before the right in the medulla (Galaburda et al. 1978). Asymmetries of neurotransmitter concentrations also have been identified. Cortical choline acetyltransferase activity is greater in the left than in the right temporal lobe (Amaducci et al. 1981).

Cerebral asymmetries do not occur in the brains of nonprimates but are present in gorillas, chimpanzees, and orangutans, as well as in humans (LeMay 1976). Studies of endocasts of fossil skulls reveal that brain asymmetries similar to those of modern humans were evident in the brains of Neanderthal people 40,000 years ago and may have been present as early as 400,000 years ago in Peking man (Galaburda et al. 1978).

Investigations of asymmetries between the two hemispheres have identified differences at the gross morphological level, in the cytoarchitectonic structure of the hemispheres, in the shape of the brain, in the shape of specific aspects of the ventricular system, and in the concentrations of neurotransmitters. The magnitude of these differences is relatively small and does not correspond to the marked differences in hemispheric function. The means by which the dramatic differences in function of the two hemispheres are achieved remain enigmatic. The advantage of hemispheric specialization and lateralized development of functional capacities is that the capacity of the human brain is nearly doubled (Levy 1977). The principal disadvantage is that reduced redundancy exaggerates the effects of lateralized cerebral injury; in humans, a unilateral lesion often has devastating behavioral consequences because of the limited compensatory capability of the contralateral hemisphere.

**Asymmetric cognitive function of the hemispheres.** Hemispheric specialization refers to the differential functions of the two hemispheres. Nearly all human behavior has contributions from both hemispheres, and complex behavior requires the integrated action of both halves of the brain. Almost no skills are completely unique to one hemisphere. Nevertheless, the two hemispheres differ substantially in their potential for many skills and are differentially engaged in most tasks. Numerous attempts have been made to identify antinomies of function that characterize the right and left hemispheres (i.e., verbal versus nonverbal, propositional versus appositional, and holistic versus analytic); none of these have been entirely successful, and it is unlikely that the brain is organized along such polar dimensions. A more accurate approach is to acknowledge that the two hemispheres perform different but not necessarily correlated or complementary roles. Table 4–3 lists capacities mediated to a significantly different extent by the two hemispheres.

Language is the best known example of a lateralized function. The right hemisphere mediates the prosodic aspects of verbal expression; the left brain mediates propositional speech. The left hemisphere is specialized for symbol usage including words (spoken, written, heard, and read), mathematical symbols, symbolic gesture, and verbal memory. The left brain is language dominant in nearly all right-handed individuals and in most left-handed people. The lateralization of language functions is not complete, and rudimentary language skills are present in the right brain.

Praxis refers to the ability to execute learned movements on command. This ability is mediated by the left hemisphere, and most instances of apraxia occur in pa-

**TABLE 4-3. Abilities mediated primarily by the right or left hemisphere and corresponding clinical deficits resulting from lateralized lesions**

Hemispheric function	Correlated clinical deficit
<b>Left hemisphere</b>	
Language	Aphasia
Execution	Nonfluent aphasia
Comprehension	Comprehension defect
Reading	Alexia
Writing	Agraphia
Verbal memory	Verbal amnesia
Verbal fluency (word list generation)	Reduced verbal fluency
Mathematical abilities	Anarithmetia
Praxis	Apraxia
Musical rhythm (execution)	Impaired rhythm in singing
Contralateral spatial attention	Right-sided neglect
Contralateral motor function	Right hemiparesis
Contralateral sensory function	Right hemisensory loss
Contralateral visual field perception	Right homonymous hemianopia
<b>Right hemisphere</b>	
Speech prosody	Aprosodia
Executive	Executive aprosodia
Receptive	Receptive aprosodia
Nonverbal memory	Nonverbal amnesia
Design fluency (novel figure generation)	Reduced design fluency
Elementary visuospatial skills	
Depth perception	Reduced depth perception
Angle discrimination	Reduced angle discrimination
Complex visuospatial skills	
Familiar face recognition	Prosopagnosia
Familiar place recognition	Environmental agnosia
Unfamiliar face discrimination	Impaired facial discrimination
Visuomotor abilities	
Constructional ability	Constructional disturbance
Dressing (body-garment orientation)	Dressing disturbance
Musical melody (perception and execution)	Amusia
Contralateral spatial attention	Left-sided neglect
Contralateral motor function	Left hemiparesis
Contralateral sensory function	Left hemisensory loss
Contralateral visual field perception	Left homonymous hemianopia
Miscellaneous	
Familiar voice recognition	Phonagnosia

tients with left-sided brain injury.

The right hemisphere is dominant for *visuospatial functions*, but the left hemisphere has considerable visuospatial ability and left-hemisphere injuries frequently produce at least minor visuospatial deficits. The most marked and enduring visuospatial abnormalities occur with lesions of the posterior right hemisphere. Elementary visuoperceptual skills (e.g., judging line orientation and depth perception), complex visual discrimination and recognition abilities (e.g., discriminating between two unfamiliar faces or recognizing familiar faces), and visuomotor skills (e.g., drawing, copying, and dressing) are mediated primarily by the right hemisphere (Kimura and Durnford 1974).

Components of *music* appear to be differentially processed in the hemispheres. At least in nonprofessionals, the left hemisphere appears to be involved primarily in the mediation of rhythm, whereas the right brain mediates the perception and execution of melody (Gordon 1983).

Cortically mediated processes are well lateralized, and neurobehavioral phenomena such as aphasia, alexia, agraphia, amusia, abnormalities of visual discrimination and recognition, and altered affective expression occur with local damage to the left or right hemisphere. The cortex is comprised of regionally specialized modules that can be rendered dysfunctional by local cortical injury or by disconnection from other regions by white matter lesions.

## ■ Limbic System (Paramedian Zone)

Limbic system structures comprise a critical neuroanatomic substrate for the mediation of mood, emotion, and motivation. Limbic dysfunction contributes to a variety of neuropsychiatric syndromes including psychosis, depression, mania, personality alterations, and obsessive-compulsive disorder.

“Limbic” means “border” or “hem” and was first used in an anatomical context by Broca, the French anatomist, to describe the structures that lie beneath the neocortex and that surround the brainstem (Isaacson 1974). In 1937, Papez authored the landmark article, titled “A Proposed Mechanism of Emotion,” in which he hypothesized that these structures surrounding the upper brainstem formed a functional system mediating human emotion. Since then, research and clinical observations have largely confirmed the idea that limbic structures are involved in the mediation of behaviors and experiences that share the common feature of having an emotional component.

As currently conceived, the limbic system includes the hippocampus, olfactory cortex, caudal orbitofrontal cortex, insula, temporal pole, parahippocampal gyrus,

cingulate cortex, amygdala, septal nuclei, hypothalamus, and selected thalamic nuclei (Carpenter 1991; Mesulam 1985) (Figure 4–9). The limbic system is poised between the hypothalamus with its neuroendocrine control systems of the internal milieu and the neocortex mediating action on the external environment.

The principal known function of the hippocampus is the mediation of new learning and recent memory. Localized injury to hippocampus produces an amnesic disorder with deficient storage of new information. This syndrome has been described with hippocampal damage secondary to stroke, anoxia, trauma, early Alzheimer's disease, and herpes encephalitis.

Paralimbic cortex includes the orbitofrontal area, insula, temporal pole, parahippocampal gyrus, and cingulate gyrus. Paralimbic cortex is represented in brain regions critical to emotional control, social judgment, civility, and motivated behavior. Lesions of the orbitofrontal cortex produce marked personality changes with disinhibition, impulsiveness, loss of tact, and coarsened behavior. Cingulate dysfunction results in marked apathy with disinterest and loss of motivation (Cummings 1993).

**FIGURE 4–9.** Paralimbic cortex.

*Source.* Image courtesy of M. Mega and the UCLA Laboratory of Neuroimaging.

Portions of the basal ganglia are included in the limbic system. The head of the caudate nucleus consists of ventromedial and dorsolateral portions. The ventromedial section has major limbic system connections and receives projections from the hippocampus, amygdala, cingulate cortex, and the orbitofrontal cortex. The dorsolateral portion, in contrast, receives projections from the lateral prefrontal cortex and has little limbic input (Nauta 1986). The globus pallidus is divided similarly into dorsal-nonlimbic portions and ventral-limbic portions. As predicted by these anatomic observations, basal ganglia diseases are commonly accompanied by emotional dysfunction and psychopathology.

Various clinical neuropsychiatric disorders are associated with limbic system dysfunction (Cummings 1985; Doane 1986) (Table 4–4). The limbic system serves no single unifying function, and the only common feature shared by limbic system disorders is that they have an emotional dimension. Limbic system lesions produce emotional disturbances and rarely cause intellectual deficits. (An exception is the amnesia produced by hippocampal system lesions.)

Psychosis, mood disorders, obsessive-compulsive behavior, personality alterations, and disturbances of sexual behavior have all been linked to limbic system dysfunction. *Psychosis* occurs with lesions of the temporal lobes and subcortical limbic system structures. The schizophrenia-like disorder of epilepsy occurs almost exclusively in patients with seizure foci in the temporolimbic cortex (Perez et al. 1985). Stroke, tumors, herpes encephalitis, and Alzheimer's disease are other disorders that affect the temporal cortex and produce psychotic features in the elderly. At the subcortical limbic level, Huntington's disease, idiopathic basal ganglia calcification, and lacunar state are examples of conditions with pathology of the limbic system and increased frequencies of psychosis.

*Mood disorders* also have been related to limbic system dysfunction (Duffy and Coffey 1997). Depression occurs with basal ganglia dysfunction in stroke, movement disorders, and idiopathic depressive disorders (Baxter et al. 1985; Cummings 1992; Starkstein et al. 1987, 1988a). Manic behavior has been associated with disorders affecting the caudate nuclei, thalamus, and basotemporal areas (Bogousslavsky et al. 1988; Cummings and Mendez 1984; Folstein 1989; Starkstein et al. 1988b).

Investigation of idiopathic *obsessive-compulsive behavior* has revealed increased metabolism in the orbitofrontal cortex (Baxter et al. 1987). Focal lesions and neurological disorders producing obsessive-compulsive behavior frequently involve the caudate nucleus or globus pallidus (Cummings and Cunningham 1992).

**TABLE 4-4. Neuropsychiatric disorders with evidence of limbic system dysfunction**

Neuropsychiatric disorder	Anatomical structure implicated	Diseases affecting structure
Amnesia	Hippocampus, hypothalamus	Stroke, anoxia, trauma, tumors, herpes encephalitis
Psychosis	Temporal cortex	Epilepsy, stroke, tumors, herpes encephalitis, Alzheimer's disease
	Striatum	Huntington's disease, idiopathic basal ganglia calcification, lacunar state, schizophrenia
Depression	Striatum	Stroke, Huntington's disease, Parkinson's disease, idiopathic basal ganglia calcification, idiopathic depression
Mania	Striatum	Huntington's disease, idiopathic basal ganglia calcification
	Thalamus	Stroke
	Temporal cortex	Stroke, trauma
OCD	Orbitofrontal cortex	Idiopathic OCD
	Striatum	Huntington's disease, Sydenham's chorea, PEPD, manganese intoxication, carbon monoxide intoxication
Personality alterations	Orbitofrontal cortex	Trauma, tumors, degenerative disorders
	Temporal cortex	Epilepsy
	Amygdala	Herpes encephalitis, trauma
	Striatum	Huntington's disease
Anxiety	Temporal cortex	Idiopathic anxiety
	Striatum	Parkinson's disease
Hyposexuality	Temporal cortex	Epilepsy (interictal)
	Hypothalamus	Trauma (surgical)
Hypersexuality	Orbitofrontal cortex	Tumors, trauma
	Temporal cortex	Epilepsy (ictal)
	Amygdala	Herpes encephalitis, trauma
	Septal nuclei	Trauma
Paraphilias	Hypothalamus	Tumors, trauma, encephalitis
Addictions	Septal nuclei, hypothalamus	Idiopathic addictive behavior

*Note.* OCD = obsessive-compulsive disorder; PEPD = postencephalitic Parkinson's disease.

A variety of *personality alterations* have been correlated with limbic system lesions. Orbitofrontal or orbitofrontal-subcortical circuit lesions produce disinhibited, impulsive, and tactless behavior; temporolimbic epilepsy has been associated with a rigid, viscous demeanor with hypergraphia, circumstantiality, hyposexuality, and hyperreligiosity (Brandt et al. 1985); and bilateral amygdala lesions produce behavioral placidity as part of the Klüver-Bucy syndrome (Lilly et al. 1983).

Idiopathic *anxiety* is associated with increased temporal and decreased basal ganglia glucose metabolism (Wu et al. 1991). Anxiety has been associated with temporal lobe and basal ganglia disorders including Parkinson's disease and Alzheimer's disease (Reisberg et al. 1989; Stein et al. 1990).

*Apathy* is recognized increasingly as a common behavioral change in patients with brain disorders. Reduced motivation, interest, engagement, affection, and activity contribute a syndrome of diminished involvement (Marin 1990). The syndrome varies in severity from mild loss of interest and reduced involvement in previous affairs to an akinetic mute state with markedly reduced movement, speech, and intellectual content. The syndrome most commonly results from lesions of the anterior cingulate cortex or related structures of the cingulate-subcortical circuit including nucleus accumbens, globus pallidus, and thalamus (Cummings 1993).

*Disorders of sexual function* also may reflect limbic system disturbances. Diminished libido has been associated with hypothalamic injury and with the interictal state of

patients with temporal lobe seizure foci. Hypersexuality has been observed in patients with orbitofrontal injury or trauma to the septal region and as an ictal manifestation in the course of temporal lobe seizures (Gorman and Cummings 1992). Paraphiliac behavior including pedophilia, transvestism, sadomasochistic behavior, and exhibitionism has been observed in patients with temporal lobe injury and epilepsy, basal ganglia disorders, and brain tumors involving limbic structures (Cummings 1985; Miller et al. 1986). Opiate and cocaine *addictions* appear to be mediated in part by receptors located in limbic brain regions (Gawin 1991).

Thus neocortical disorders and white matter lesions tend to produce deficit disorders of language, praxis, and gnosis. Limbic system disorders have little associated intellectual impairment and produce diverse “productive” disorders of emotional function with the new appearance of positive neuropsychiatric symptoms.

### **Limbic System Asymmetries and Lateralized Neuropsychiatric Syndromes**

**Anatomic and biochemical asymmetries of the limbic system.** Asymmetries of subcortical structures are less marked than are asymmetries of cortical regions, but the left globus pallidus, right medial geniculate nucleus of the thalamus, and left lateral posterior nucleus of the thalamus have been found to be larger than the corresponding nuclei of the contralateral hemisphere (Eidelberg and Galaburda 1982; Kooistra and Heilman 1988). Asymmetries of neurotransmitter concentrations in limbic system structures have been identified. The content of dopamine and choline acetyltransferase (a marker of cholinergic function) is increased in the left globus pallidus compared with their content in the right (Glick et al. 1982); norepinephrine concentrations are greater in the left pulvinar and in the right somatosensory nuclei of the thalamus (Oke et al. 1978); and choline acetyltransferase activity is greater in the left than in the right temporal lobe (Amaducci et al. 1981). Transmitter asymmetries may underlie the differential occurrence of mood disorders and anxiety with lesions of the left and right hemispheres.

**Lateralized neuropsychiatric syndromes.** Some aspects of emotional function are lateralized, with greater representation in one hemisphere than in the other (Coffey 1987). Emotional functions include the perception of emotional stimuli in the environment (e.g., apprehending facial expression, comprehending voice inflection, and inter-

preting postural adjustments), the expression of emotion (e.g., facial affective display and inflection of voice), and the subjective experience of emotion. Emotional perception and expression appear to be mediated primarily by the right hemisphere. For example, the right hemisphere is superior to the left in discriminating among unfamiliar faces, recognizing familiar faces, and interpreting facial emotional expression (Borod et al. 1986). The right brain also is better able to recognize familiar voices than is the left (Van Lancker et al. 1989) and to comprehend the emotional inflection of spoken language (Tucker et al. 1977). Emotion is more intensely expressed on the left side of the face, suggesting that the right brain has more efficient access to cerebral mechanisms required for affective expression (Moscovitch and Olds 1982). Finally, the right hemisphere also shows evidence of electroencephalographic activation when processing emotional stimuli (Davidson 1992), and emotional information may serve to activate the right hemisphere (Bryden and Ley 1984).

Experiential aspects of emotion are more difficult to study, and the underlying neurobiology is less securely established. Information has been derived from depth electrode investigations, from emotional changes reported in association with epileptic seizures, from temporary hemispheric inactivation with intracarotid amobarbital injections (Wada test), and from lesion studies. Stimulating depth electrodes located in and around the amygdala produces the sense of déjà vu, anxiety, visceral sensations, hallucinations (Halgren et al. 1978), and occasionally intense fear or anger (Girgis 1981), irrespective of which hemisphere is stimulated. Fear is the most common affect experienced in the course of spontaneous epileptic seizures. Some studies have found a predominance of right-sided foci (Hermann et al. 1992), but fear is also observed in patients with left-sided lesions, suggesting that this experience is not consistently lateralized (Strauss et al. 1982). Depression is the second most common ictal affect and occurs with both left- and right-sided foci (Williams 1956). A small number of patients have positive emotional experiences as ictal manifestations, and laughter as an ictal behavior may be more common with left- than with right-sided seizure foci (Sackeim et al. 1982), although a consensus is lacking regarding interpretation of this observation (Coffey 1987). Taken together, these data suggest that many experiential aspects of emotion are mediated by nonlateralized limbic system structures.

An important source of information regarding the laterality of emotional processing is the Wada test. In this technique, amobarbital is injected into the carotid artery of patients with epilepsy before temporal lobectomy to establish which side of the brain is dominant for language func-

tion. The carotid is the principal arterial supply for the ipsilateral hemisphere, and transient hemispheric inactivation follows the injection. Approximately 50% of patients undergoing this procedure evidence a marked change in emotion soon after the amobarbital perfusion. When the left hemisphere is inactivated, a depressive or catastrophic reaction occurs; when the right hemisphere is involved, patients manifest euphoria or an indifference reaction (Loring et al. 1992).

Studies of emotional changes in patients with unilateral lesions lead to conclusions similar to those suggested by the Wada test. Patients with left-hemisphere lesions have more catastrophic reactions and are more anxious and depressed; patients with right-hemisphere lesions evidence more indifference and tend to joke about, minimize, or deny their disability (Gainotti 1972). Investigation of stroke patients have found a higher prevalence of severe depression among those with left frontal lobe lesions, whereas patients with right-brain lesions exhibited more undue cheerfulness or, occasionally, frank mania (Robinson and Starkstein 1990; see also Chapter 23 in this volume). Van Lancker (1991) observed that many functions of the right hemisphere subserved determination of the personal relevance of environmental stimuli, and Weintraub and Mesulam (1983) reported that children who sustained right-brain injury characteristically had interpersonal difficulties, shyness, and impaired prosody and gesture. An impaired ability to comprehend personally relevant information or to execute interpersonal cues appropriately may lead to difficulties in establishing interpersonal relationships and to subsequent social isolation. In elderly individuals, right-hemisphere dysfunction may contribute to the disengagement and interpersonal abnormalities evident in many patients with right-brain strokes and dementia syndromes.

Another avenue for investigating the hemisphericity of emotion is to search for evidence of lateral brain dysfunction in idiopathic psychiatric disorders. A number of neuropsychological studies have suggested preferential right-hemisphere dysfunction during depressed mood states that normalizes during euthymia, and a few patients have been reported to exhibit frank neurological deficits referable to the right hemisphere that were present only during the depressed period (for a review, see Coffey 1987). Electrophysiological studies have demonstrated electroencephalographic changes referable to the right hemisphere during episodes of depression (Davidson 1992), but studies of regional cerebral blood flow and metabolism have produced conflicting findings, with dysfunction in either or both hemispheres accompanying depression (Baxter et al. 1985; Delvenne et al. 1990; Dolan et al. 1992; Drevets et al. 1992; George et al. 1996; Sackeim et al. 1990).

In other psychiatric disorders, several lines of evidence point toward dysfunction of left temporal lobe structures in schizophrenia, but this hypothesis is controversial (Gruzelier 1983; Sedvall 1992; Suddath et al. 1989). Even more tentative are data suggesting greater left-hemisphere dysfunction in violent individuals and more right-brain involvement in patients with conversion hysteria and alexithymia (Flor-Henry 1983; Nachson 1983; Stern 1983; TenHouten et al. 1986). Most idiopathic disorders have not been found to be strongly linked to a single hemisphere. Table 4-5 summarizes the neuropsychiatric syndromes associated with lateralized brain dysfunction.

## ■ Reticular Formation (Median Zone)

The median zone contains the reticular formation including the ascending reticular activating system, the vaso-

**TABLE 4-5. Neuropsychiatric disorders associated with lateralized brain dysfunction**

pressor and respiratory mechanisms, and the central components of the sympathetic and parasympathetic nervous systems (Carpenter 1991). The reticular formation is a dense network of neurons with short and long axons that form nuclei in the periventricular gray areas surrounding the cerebral aqueduct in the midbrain, is adjacent to the floor of the fourth ventricle in the pons, and extends into the medulla. The ascending reticular activating system projects to the intralaminar nuclei of the thalamus, and these in turn project to the cerebral cortex. The intralaminar nuclei project primarily to layer I of the cortex, the layer comprised of parallel fibers whose stimulation results in local cortical activation (Figure 4–10).

The thalamic reticular nucleus is a unique structure that forms a thin shell around the anterior aspects of the thalamus and governs cortical arousal. It receives projections from the cerebral cortex, dorsal intralaminar nucleus, and dorsal specific sensory nuclei. It has no projections to the cerebral cortex but projects back to the dorsal thalamic nuclei. It is positioned to serve as a gate, modifying and censoring information projected from thalamus to cortex, and its principal effect is to inhibit cortical activity (Carpenter and Sutin 1983; Plum and Posner 1980).

Increased input from the brainstem reticular activating system reduces the tonic inhibition of the reticular nucleus and activates the cortex by disinhibiting the cortical projections of other thalamic nuclei (Plum and Posner 1980). The ascending reticular activating system is respon-

sible for the maintenance of consciousness, and disturbances of the system result in impaired arousal varying from drowsiness to obtundation, stupor, and coma.

Nuclei of the reticular formation also are involved in control of heart rate, blood pressure, and respiratory rhythms (Carpenter 1991). Dysfunction of these nuclei results in alterations in blood pressure, cardiac arrhythmias, and respiratory irregularities. The hypothalamus is contained in the median zone, and abnormalities of basic life functions (e.g., appetite, libido, and sleep) may occur in individuals who sustain hypothalamic injury. The hypothalamus influences endocrine function via its connections with the pituitary gland, and endocrine abnormalities are produced by hypothalamic lesions.

## ■ Connections Between the Cerebral Cortex and Subcortical Structures

Information enters the nervous system one principal way, and there is one principal exit pathway by which humans act on their environment. The entry pathway is via thalamocortical afferents that receive sensory information from peripheral sensory receptors and convey the data to the cortex. The principal exit pathway is via the descending corticospinal tracts, particularly the pyramidal system. Thus the flow of information is from the thalamus to the primary sensory cortex, unimodal association cortex, and then heteromodal association cortex. From there, the long association fibers connect the posterior heteromodal cortex to the anterior (frontal lobe) heteromodal cortex that in turn connects to the subcortical nuclei. After processing through frontal-subcortical circuits, executive commands flow to the primary motor cortex and then to bulbar and spinal effector mechanisms. The thalamocortical afferents and frontal-subcortical efferents are distributed systems that include portions of both the paramedian (limbic) and supralimbic (neocortical) zones. Activation of brain structures is not limited to the sequence described above; there is simultaneous activation of many brain regions, as well as feedback mechanisms from ongoing activity.

### Thalamic-Cortical Relationships

The thalamus plays several crucial roles in human brain function. Specific thalamic nuclei receive input from a relatively restricted number of sources and project to layers III and IV of the cortex.

The specific nuclei include sensory nuclei that process all incoming sensory information except olfaction (ventral posterior, medial geniculate, and lateral geniculate); nuclei

**FIGURE 4–10.** Cortical projections from the thalamus. *Source.* Image courtesy of M. Mega and the UCLA Laboratory of Neuroimaging.

that participate in the motor pathways (ventral anterior and ventral lateral); association nuclei that have major connections with frontal (dorsomedial nuclei) or temporoparietal (lateral nuclei) association cortex; and nuclei that are included in the limbic circuits (anterior and medial nuclei) (Carpenter and Sutin 1983; Nauta and Feirtag 1986). Table 4–6 presents a functional classification of thalamic nuclei with their principal afferents and efferents.

A number of distinctive behavioral disorders have been associated with dysfunction of the associative and sensory thalamic nuclei. Disorders of the associative dorsal medial nuclei produce amnesia and a “frontal lobe”-type syndrome (Cummings 1993; Stuss et al. 1988). Apathy also is common after dorsal medial nuclear injury. Lesions of the specific thalamic sensory nuclei cause deficits in primary sensation. Ventral posterior nuclear lesions disrupt all sensory abilities of the contralateral limbs, trunk, and face. In some cases, spontaneous disabling pain of the affected side occurs (Dejerine-Roussy syndrome) (Adams and Victor 1981). Lesions of the lateral geniculate bodies

produce a contralateral visual field defect. Mania has been observed in several patients with right-sided thalamic lesions involving the paramedian thalamic nuclei (Bogousslavsky et al. 1988; Cummings and Mendez 1984; Starkstein et al. 1988b).

### Frontal-Subcortical Circuits

The frontal lobe is the origin of executive processes that guide action. The output from the frontal lobe is through subcortical circuits that eventually reach motor pathways. Five circuits connecting the frontal lobes and subcortical structures are currently recognized: a motor circuit originating in the supplementary motor area, an oculomotor circuit with origins in the frontal eye fields, and three circuits originating in prefrontal cortex (dorsolateral prefrontal cortex, lateral orbital cortex, and anterior cingulate cortex) (Alexander and Crutcher 1990; Alexander et al. 1986, 1990). The prototypic structure of all circuits is an origin in the frontal lobes, projection to striatal

**TABLE 4–6. Function and anatomic relationships of the thalamic nuclei**

Nuclei	Input	Output	Function
<b>Limbic nuclei</b>			
Anterior	Mammillary body	Cingulate	Emotional function
<b>Motor nuclei</b>

Reticular	Thalamic nucleus and cortex	Dorsal thalamic nuclei	Samples, gates, and focuses thalamocortical output

structures (caudate, putamen, or nucleus accumbens), connections from striatum to globus pallidus and substantia nigra, projections from these two structures to specific thalamic nuclei, and a final link back to the frontal lobe (Figure 4–11).

The *motor circuit* originates from neurons in the supplementary motor area, premotor cortex, motor cortex, and somatosensory cortex (Alexander and Crutcher 1990; Alexander et al. 1986). Throughout the circuit, the discrete somatotopic organization of movement-related neurons is maintained. Distinct types of motor disturbances are associated with lesions at different sites in the motor circuit. Motor initiation abnormalities (akinesia) are associated with supplementary motor area lesions; parkinsonism and dystonia are observed with putaminal dysfunction; and choreiform movements occur with caudate and subthalamic nucleus damage.

The *oculomotor circuit* originates in the frontal eye fields, as well as in the prefrontal and posterior parietal cortex. Acute lesions of the cortical eye fields produce ipsilateral eye deviation, whereas more chronic lesions produce ipsilateral gaze imperistence. Lesions in other areas of the circuit produce supranuclear gaze palsies such as those seen in Parkinson's disease, progressive supranuclear

palsy, and Huntington's disease.

Three distinct frontal lobe neurobehavioral syndromes are recognized, and each corresponds to a region of origin of one of the three prefrontal-subcortical circuits. Dysfunction of any of the member structures of the circuits results in similar circuit-specific behavioral complexes, and these frontal-subcortical circuits compose major anatomic axes governing behavior (Cummings 1993). The *dorsolateral prefrontal circuit* originates in the convexity of the frontal lobe and projects primarily to the dorsolateral head of the caudate nucleus (Alexander and Crutcher 1990; Alexander et al. 1986) (Figure 4–12). This caudate region connects to globus pallidus and substantia nigra, and pallidal and nigral neurons of the circuit project to the medial dorsal thalamic nuclei that in turn project back to the dorsolateral prefrontal region. The dorsolateral prefrontal syndrome is characterized primarily by executive function deficits. Abnormalities include developing poor strategies for solving visuospatial problems or learning new information and reduced ability to shift sets. Such behavioral changes are observed in patients with dorsolateral

**FIGURE 4–11.** Organization of the prefrontal-subcortical circuits. The prefrontal cortical regions (dorsolateral prefrontal, orbitofrontal, and anterior cingulate) project to specific striatal regions that in turn project to globus pallidus and substantia nigra. These structures project to thalamic nuclei that connect to frontal lobe, completing the circuit.

prefrontal lesions, as well as in those with caudate, globus pallidus, and thalamic dysfunction.

The *orbitofrontal circuit* contains primarily limbic system structures. It begins in the inferolateral prefrontal cortex and projects to the ventromedial caudate nucleus (Alexander and Crutcher 1990; Alexander et al. 1986) (Figure 4–12). This caudate region projects to the pallidum and substantia nigra. Pallidum and nigra connect to medial portions of the ventral anterior and medial dorsal thalamic nuclei that project back to the orbitofrontal cortex. Disorders involving cortical or subcortical structures of the orbitofrontal circuit feature marked changes in personality, including a tendency to be more outspoken, more irritable, and more tactless and to worry less and have an elevated mood.

The *anterior cingulate circuit* begins in the cortex of the anterior cingulate gyrus (Brodmann area 24) and projects to the ventral striatum (also known as the *limbic striatum*), which includes the nucleus accumbens and the ventromedial portions of the caudate and putamen (Alexander and Crutcher 1990; Alexander et al. 1986) (Figure

4–12). The most dramatic cases of anterior cingulate injury exhibit akinetic mutism. The patients are profoundly apathetic: they typically have their eyes open, do not speak spontaneously, answer questions in monosyllables if at all, and are profoundly indifferent. Apathy also has been associated with lesions of nucleus accumbens, globus pallidus, and thalamus, the principal subcortical members of the anterior cingulate circuit. Table 4–7 summarizes the behaviorally relevant frontal-subcortical circuits including the anatomical structures involved, the behavioral disturbances observed with circuit dysfunction, and the common diseases affecting each circuit.

Frontal-subcortical circuits are involved in several neuropsychiatric disorders. In addition to personality alterations (e.g., apathy and disinhibition), mood changes and obsessive-compulsive behaviors are associated with focal brain lesions affecting these circuits. Depression occurs with lesions of the dorsolateral prefrontal cortex and the head of the caudate nucleus, particularly when the left hemisphere is affected (Robinson et al. 1984; Starkstein et al. 1987, 1988a; see also Chapters 13 and 27 in this volume).

Note. UD = undetermined.

Positron-emission tomography in patients with idiopathic unipolar depression reveals diminished glucose metabolism in the prefrontal cortex and the caudate nuclei, suggesting that dysfunction of frontal-subcortical circuits may be a shared substrate for both idiopathic and acquired mood disorders (Baxter et al. 1985). Lesions producing secondary mania also involve nuclei and connections of frontal-subcortical circuits. Mania has been observed with lesions of the medial orbitofrontal cortex, diseases of the caudate nuclei such as Huntington's disease, and injury to the right thalamus (Bogousslavsky et al. 1988; Cummings and Mendez 1984; Folstein 1989; Starkstein et al. 1988b).

Both acquired and idiopathic obsessive-compulsive disorders have been related to dysfunction of frontal-subcortical circuits. Obsessive-compulsive behavior has been observed in patients with caudate dysfunction in Huntington's disease and after Sydenham's chorea (Cummings and Cunningham 1992; Swedo et al. 1989), as well as with globus pallidus lesions in postencephalitic Parkinson's disease, progressive supranuclear palsy, manganese-induced parkinsonism, and after anoxic injury (Laplane et al. 1989; Mena et al. 1967; Schilder 1938). Idiopathic obsessive-compulsive disorder has been associated with increased glucose metabolism in the left orbitofrontal frontal gyrus and caudate nuclei (Baxter et al. 1987) and with increased blood flow in the medial frontal area (Machlin et al. 1991).

Frontal-subcortical circuits are affected in patients who have diseases of the basal ganglia. The high frequency of neuropsychological alterations, the increased prevalence of personality and mood disturbances, the occurrence of obsessive-compulsive disorder, and the similarity between behaviors of patients with basal ganglia diseases and patients with frontal lobe injury are attributable to dysfunction of multiple frontal-subcortical circuits in basal ganglia disorders.

## ■ Neurochemistry and Behavior

The anatomical organization of the brain is complemented by an equally complex neurochemical organization. Many behavioral disorders reflect biochemical dysfunction, and the most effective interventions available are neurochemical in nature. Neurobehavioral deficits stemming from focal cortical lesions (e.g., aphasia and apraxia) have limited available remediable neurochemical treatments; neuropsychiatric disorders associated with limbic system dysfunction are frequently modifiable through neurochemical interventions.

There are two types of cerebral transmitters: 1) projec-

tion or extrinsic transmitters that originate in subcortical and brainstem nuclei and project to brain targets and 2) local or intrinsic transmitters that originate in neurons of the brain and project locally to adjacent or nearby cells. Projection transmitters or their synthetic enzymes must be transported within neurons for long distances from subcortical nuclei to distant regions and are vulnerable to disruption by stroke, tumors, and other processes. Transmitters are highly conserved from an evolutionary point of view, and many function locally in some neuronal systems and function as projection transmitters in others. The classic neurotransmitters have served neuronal communication for 600 million years of evolution (Rapoport 1990). Table 4-8 summarizes the origins and destinations of the extrinsic transmitters. The effects of neurotransmitters are mediated by receptors to which the transmitter binds after it has been released into the synaptic cleft. Receptors may be located on the presynaptic or postsynaptic terminal. Presynaptic receptors (autoreceptors) regulate neurotransmitter synthesis or release. Postsynaptic receptors mediate the effects of the neurotransmitter on the postsynaptic cell. Heteroreceptors (receptors for neurotransmitters other than those produced by the neuron) also regulate synaptic activity. Binding of a neurotransmitter to a receptor results either in opening of an ion channel (ionotropic receptors) or initiation of second messenger cascades via guanosine triphosphate-binding (G) proteins (metabotropic receptors). The neurotransmitter is removed from the synapse (either before or after binding to a receptor) either by enzymatic degradation or by active reuptake into the presynaptic terminal by a high-affinity transporter protein. Behavioral effects can rarely be assigned to alterations in a single transmitter, but some aberrant behaviors are associated with changes that affect predominantly one type of transmitter. Table 4-9 presents the principal transmitter-behavior relationships currently identified.

There are two main *cholinergic projections* from subcortical sites to the brain. The first originates in the reticular formation and projects via the dorsal tegmental pathway to the thalamus. This pathway is the essential component of the ascending reticular activating system (Nieuwenhuys 1985). The second cholinergic projection begins in the cells of the nucleus basalis in the basal forebrain and projects to the hippocampus, hypothalamus, amygdala, and diffusely to the neocortex (Figure 4-13). The afferents to nucleus basalis are primarily from cortical and subcortical limbic system structures establishing the nucleus basalis as a relay between the limbic system afferents and efferents to the neocortex (Mesulam and Mufson 1984).

**TABLE 4–8. Origins and destinations of the major extrinsic transmitter projections**

Neurotransmitter	Origin	Destination
<b>Acetylcholine</b>		
Reticular system	Reticular formation	Thalamus
Basal forebrain system	Nucleus basalis and nucleus of diagonal band of Broca	Neocortex, hippocampus, hypothalamus, and amygdala
<b>Dopamine</b>		
Nigrostriatal system	Substantia nigra	Putamen and caudate nucleus
Mesolimbic system	Ventral tegmental area	Nucleus accumbens, septal nucleus, and amygdala
Mesocortical system	Ventral tegmental area	Medial temporal and frontal lobes and anterior cingulate cortex
<b>Noradrenaline</b>		
Dorsal pathway	Locus ceruleus	Thalamus, amygdala, basal forebrain, hippocampus, and neocortex
Ventral pathway	Locus ceruleus	Hypothalamus and midbrain reticular formation
<b>Serotonin</b>	Raphe nuclei	Entire nervous system
<b>Histamine</b>	Posterior hypothalamus	Entire nervous system
<b>GABA</b>	Zona incerta	Neocortex, basal ganglia, and brainstem
	Caudate and putamen	Globus pallidus and substantia nigra
	Globus pallidus and substantia nigra	Thalamus
<b>Glutamate</b>	Neocortex	Caudate, putamen, thalamus, and nucleus accumbens
	Subthalamic nucleus	Globus pallidus
	Thalamus	Neocortex
	Hippocampus, subiculum	Septal region
	Entorhinal cortex	Hippocampus

Note. GABA =  $\gamma$ -aminobutyric acid.

Cholinergic function is mediated by either nicotinic (ionotropic) or muscarinic (metabotropic) receptors. Both receptor types are present in the brain, but the latter appear to be of special interest to neuropsychiatry. The muscarinic receptors are classified pharmacologically as  $M_1$  (located postsynaptic) or  $M_2$  (located presynaptic) and have different distributions throughout the brain. Cholinergic systems mediate a wide range of behaviors. Disruption of central cholinergic function (e.g., through the administration of cholinergic receptor-blocking agents such as scopolamine) produces amnesia (Bartus et al. 1982), and intoxication with anticholinergic compounds produces delirium and delusions. Alzheimer's disease is one major disorder associated with cholinergic deficiency. This disease produces atrophy of the nucleus basalis with consequent reduction in the synthesis of choline acetyltransferase, the enzyme that synthesizes acetylcholine; loss of synthetic activity leads to interruption of cortical cholinergic function (Katzman and Thal 1989). Increasing evidence indicates that some of the neuropsychiatric disturbances of Alzheimer's dis-

ease—hallucinations, apathy, disinhibition, purposeless behavior—are produced by the cholinergic deficit (Cummings and Kaufer 1996). Cholinergic hyperactivity has been posited to play a role in the genesis of depression (Dilsaver and Coffman 1989), and in some species cholinergic stimulation of limbic system structures produces aggression (Valzelli 1981).

There are three main *dopaminergic projections* from the brainstem to the cerebral hemispheres: 1) a nigrostriatal projection arising from the compact portion of the substantia nigra and projecting to the putamen and caudate, 2) a mesolimbic projection originating in the ventral tegmental area and projecting to limbic system structures, and 3) a mesocortical system beginning in the ventral tegmental area and projecting to frontal and temporal areas (Nieuwenhuys 1985) (Figure 4–14). Targets of the mesolimbic dopaminergic projection include the nucleus accumbens, septal nucleus, and amygdala. The mesocortical projections terminate primarily in the medial frontal lobe, medial temporal lobe, and the anterior cingulate

**TABLE 4–9. Behavioral alterations associated with transmitter disturbances**

Neurotransmitter	Reduced function	Increased function
Acetylcholine	Memory impairment, delirium, and delusions	Depression, aggression
Dopamine		
Motor function	Parkinsonism	Chorea, tics
Behavior	Dementia and depression	Psychosis, anxiety, confusion, elation, obsessive-compulsive behavior, and paraphilias
Noradrenaline	Depression, dementia, and reduced attention	Anxiety

**FIGURE 4–13.** Cholinergic projections from the nucleus basalis.

region. Less robust projections are distributed to the neocortex.

Dopaminergic function is mediated by metabotropic receptors that can be classified pharmacologically as  $D_1$  (stimulate cAMP) or  $D_2$  (inhibit cAMP). These receptors have different distributions throughout the brain. The  $D_2$  receptors are blocked by the neuroleptics, and it is possible that subtypes of the  $D_2$  receptor differentially mediate the motor and mental effects of dopaminergic drugs.

Dopamine plays a key role in motor functions and behavior. Dopamine deficiency or blockade leads to parkinsonism; dopamine excess produces chorea, dyskinesia, or tics. Behaviorally, dopamine deficiency causes at least mild cognitive impairment and may contribute to the depression that commonly accompanies Parkinson's disease and other parkinsonian syndromes. Dopamine excess leads to psychosis, elation or hypomania, and confusion. Dopamine hyperactivity may contribute to the pathophysiology

of schizophrenia, obsessive-compulsive behavior, anxiety, and some paraphiliac behaviors (Cummings 1985, 1991).

The locus coeruleus and adjacent nuclei comprise the origin of the *noradrenergic projection system*. A dorsal noradrenergic bundle courses in the dorsal brainstem to the septum, thalamus, amygdala, basal forebrain, hippocampus, and neocortex (Nieuwenhuys 1985) (Figure 4–15). A ventral noradrenergic bundle projects to the hypothalamus and midbrain reticular formation. Adrenergic function is mediated by metabotropic receptors that can be classified pharmacologically as  $\alpha$  (inhibit cAMP) or  $\beta$  (stimulate cAMP) receptors.  $\alpha$ -Adrenergic receptors can be further subtyped as  $\alpha_1$  or  $\alpha_2$ ; the former are located postsynaptically and the latter presynaptically and postsynaptically. These receptors have different distributions throughout the brain. Effective treatment for depression is associated with decreased numbers (downregulation) of

$\beta$ -adrenergic receptors. Noradrenergic hypofunction has been linked to depression, dementia, and diminished alertness and concentration (Agid et al. 1987). Increased noradrenergic activity has been linked to anxiety (Lechin et al. 1989).

Serotonergic neurons are located almost exclusively in the median and paramedian raphe nuclei of the medulla, pons, and midbrain (Figure 4-16). The projection system of these serotonergic neurons is a complex, highly branched, fiber system that embraces virtually the entire central nervous system (Nieuwenhuys 1985). Serotonergic function is mediated by multiple metabotropic receptors ( $5\text{-HT}_1$ ,  $5\text{-HT}_2$ ,  $5\text{-HT}_4$ ) and to a lesser extent by ionotropic receptors ( $5\text{-HT}_3$ ). These receptors have different distributions throughout the brain. Serotonin deficiency has been hypothesized to play a major role in suicide, depression, and aggression (Agid et al. 1987), and serotonin hyperactivity can play a role in obsessive-compulsive behavior and anxiety (Lechin et al. 1989; Zohar et al. 1987).

$\gamma$ -Aminobutyric acid (GABA) is an inhibitory neurotransmitter present in both projection systems and local neuronal circuits. The principal GABA projection system begins in the zona incerta and projects bilaterally to the entire neocortex, basal ganglia, and brainstem (Lin et al. 1990). In subcortical regions, one projection system originates in the caudate and putamen and projects to the globus pallidus and substantia nigra, and another begins in the globus pallidus and substantia nigra with projections to the

thalamus (Alexander and Crutcher 1990; Nieuwenhuys 1985). Local circuit neurons using GABA are found in the raphe nuclei, reticular nucleus of the thalamus, and basal ganglia. Local circuit neurons of the cerebral cortex also use GABA as their principal neurotransmitter (Rapoport 1990). GABA function is mediated by ionotropic ( $\text{GABA}_A$ ) and metabotropic ( $\text{GABA}_B$ ) receptors, the former being of special interest to neuropsychiatry because they contain the binding sites for alcohol, anticonvulsants, and benzodiazepines. These receptors have different distributions throughout the brain. GABA concentrations are decreased in the basal ganglia of patients with Huntington's disease, and the GABA deficiency may contribute to the dementia, mood disorder, obsessive-compulsive disorder, and psychosis occurring with increased frequency in this condition (Morris 1991).

Glutamate is an excitatory neurotransmitter that is used in the massive projection from the neocortex to the ipsilateral caudate, putamen, and nucleus accumbens. Glutamate is the principal neurotransmitter of projections from cortex to thalamus, from thalamus to cortex, and from one region of cortex to another. Glutamatergic neurons also project from subthalamic nucleus to globus pallidus. Glutamate functions in several hippocampus-related projections, including the perforant pathway projecting from entorhinal cortex to hippocampus and the pathways originating in hippocampus and adjacent subiculum and projecting to the septal region (Alexander and Crutcher 1990; Nieuwenhuys 1985). Glutamatergic function is mediated by ionotropic and metabotropic receptors, with subtypes

**FIGURE 4-16.** Serotonergic projections (blue).

of the former (e.g., *N*-methyl-D-aspartate receptor) having been implicated in learning, excitotoxicity, and the psychotomimetic effects of phencyclidine. These receptors have different distributions throughout the brain. Glutamate release is inhibited by several drugs recently introduced into clinical practice. These include lamotrigine (anticonvulsant) and riluzole (amyotrophic lateral sclerosis). The behavioral consequences of alterations in glutamate function are unknown.

Several other transmitters occur in behaviorally relevant areas, but their role in human behavior remains to be determined. *Histaminergic* neurons are situated in the posterior hypothalamus and project diffusely to most brain structures including the neocortex, amygdala, septum, caudate, and putamen (Nieuwenhuys 1985). *Glycine* is an inhibitory transmitter that may function in local circuit neurons in the substantia nigra, caudate, and putamen. *Substance P* is present in the projection from caudate and putamen to the substantia nigra, and *enkephalin*-containing neurons project from caudate and putamen to the globus pallidus (Alexander and Crutcher 1990; Nieuwenhuys 1985). *Vasoactive intestinal peptide* neurons are intrinsic to the cortex and participate in local neuronal circuits (Nieuwenhuys 1985).

## ■ Summary

The brain consists of a median zone mediating arousal and basic life-sustaining functions, such as respiration, digestion, circulation, and neuroendocrine function; a paramedian-limbic zone mediating extrapyramidal function and many aspects of emotional experience; and a

supralimbic-neocortical zone mediating instrumental cognitive functions such as language and praxis (Table 4–10). Injury of the supralimbic-neocortical zone is associated with neurobehavioral deficit syndromes such as aphasia and apraxia; dysfunction of the paramedian-limbic zone correlates with neuropsychiatric disorders including mood disorders, psychoses, anxiety, and obsessive-compulsive disorder. Within each zone, behavioral deficits can be related to dysfunction of specific neurotransmitters. This approach provides a comprehensive framework for understanding brain-behavior relationships.

# Neuropsychiatric Assessment

John J. Campbell III, M.D.

Neuropsychiatry is an ambiguous construct. Its precise definition remains elusive (Cummings and Hegarty 1994; Lishman 1992; Trimble 1993). In practice, however, a neuropsychiatric approach permits a broad conceptualization of a particular clinical problem that transcends a basic neurological or psychiatric paradigm. This is of particular relevance for the geriatric patient, in whom the interplay between biology and psychology is complex and pervasive. A thorough neuropsychiatric examination can reconcile this dichotomy and form the basis for a comprehensive treatment plan. Several outstanding reviews have detailed the areas relevant to a proper assessment (Cummings 1985a; Mueller and Fogel 1997; Ovsiew 1997; Strub and Black 1993; Weintraub and Mesulam 1985).

Mueller and Fogel (1997) have elaborated on the neuropsychiatric gestalt. The approach represents a fundamental departure from traditional psychiatry and neurology in several ways. Collateral confirmation of historical details is emphasized. Neuropsychiatric syndromes often affect recall and insight, thus requiring supplementary history from those who know the patient. The reciprocal influences of psychology and cerebral dysfunction are appre-

ciated. Both processes are, of course, brain related; however, each has its own unique and significant influence on behavior. Localization of signs and symptoms in the brain takes precedence over standard psychiatric diagnoses. Therefore, a more comprehensive and flexible assessment of mental status is undertaken.

The neuropsychiatric assessment is data driven. The collection of the data and their synthesis into a coherent formulation serve to establish neuropsychiatry as a unique clinical discipline. In this chapter, I provide an overview of the neuropsychiatric assessment of the geriatric patient, emphasizing the relationship between functional neuroanatomy and neuropathology. The basic framework of this assessment includes taking a history, doing a mental status examination, performing a physical examination, and making a formulation.

## ■ Clinical Interview

The geriatric neuropsychiatry clinical interview has unique aspects. Patients commonly experience hearing impairment, diminished cognitive efficiency, attentional im-

pairments, lack of insight, impaired memory, and dysphasias, all of which challenge the skills of the interviewer. In addition, the caregiver must be an integral source of historical information. Caregivers play an increasingly important role as the patient experiences functional declines and requires increasing assistance. The presence of impaired memory and insight may interfere with the gathering of the history to such an extent that the caregiver provides the essential collateral information.

Further, the ongoing responsibility of taking care of an impaired individual can lead to demoralization, isolation, and depression, which serve to diminish the effectiveness of the caregiver. This can result in a possibly preventable accident, such as falling and fracturing a hip, nursing home placement, or even elder abuse. Thus, inquiring as to how the caregivers are dealing with their own stresses is part of the geriatric neuropsychiatric assessment.

The neuropsychiatric history explores two interrelated realms of human existence—the development of a central nervous system and the development of a person. As such, our exploration begins before conception, with the *genetic history of the parents*, through gestation and birth, up to the day of the examination. The clinical interview below has been organized along a time line in order to address issues of psychological development along with the typical starting points for important behavioral and neurological considerations, such as occurrence of depression or onset of Parkinson's disease, for example. It emphasizes that the patients are products of their past experiences regardless of the presenting complaint. The completed history will establish a qualitative functional baseline, along with an appreciation of inherited and acquired influences on development, their impact, and the role of biological and psychological attempts at compensation (see Table 5-1).

## Gestation and Birth

The central nervous system develops in an orderly sequence notable for the germination, migration, and differentiation of neurons and glia throughout gestation. During this period, cerebral and somatic development are vulnerable to numerous perturbations from many causes. Maternal drug use, infection, and injury can negatively influence the developmental process. Labor and delivery impose additional stresses on the neonatal brain. Fetal distress from maternal hemorrhage, circulatory impairment, and cranial trauma can result in hypoxic injury, cerebral contusions, and intracerebral hemorrhage, all of which may negatively affect neurodevelopment.

The *gestational and birth history* is not generally accessible with geriatric patients. Ideally, higher functioning pa-

tients or caregivers can provide this information. When not available, several clues in the history and physical examination may raise the index of suspicion. Early hemispheric damage often leads to subtle contralateral hemiatrophy. Careful observation of the face or comparison of the hands can reveal somatic asymmetry and developmental anomaly. For example, manifestations of fetal alcohol syndrome include facial changes with epicanthal eye folds, poorly formed concha, small teeth with faulty enamel, and microcephaly with mental retardation (Streissguth and Landesman-Dwyer 1980). Delays in the timely *achievement of developmental milestones* are another possible sign of inherited or acquired dysfunction. Scholastic difficulties with speech, language, and arithmetic may reflect left hemispheric anomaly. In addition, Rourke (1989) has described a syndrome of social impairment and dysprosodia localized to the right hemisphere.

Ovsiew (1997) listed several additional signs that may suggest developmental abnormality. These include an abnormal head circumference, fine "electric" hair, more than one hair whorl, abnormal epicanthic folds of the eyes, abnormal interorbital distance, low-set or malformed ears, high palate, and furrowed tongue. Peripheral signs include curved fifth finger, single palmar crease, wide gap between first and second toes, partial fusion of the toes, and third toe longer than second toe.

Handedness is a variable that may reflect anomalous cerebral development. Geschwind and Galaburda (1985) have proposed a model of handedness based on intra-

**TABLE 5-1. Elements of the clinical interview**

Behavioral and cognitive baseline
Occupational history
Medical and surgical history
Medication regimen
Review of systems
Survey of the vegetative functions
Assessment of activities of daily living
History of recent changes in behavior and cognition

---

uterine influences on development. They describe a continuum of handedness ranging from strongly right-handed to ambidextrous to strongly left-handed and suggest that the degree of left-handedness reflects compensation for negative intrauterine influences on left hemisphere development.

## Childhood

The challenges of childhood include refining social and scholastic skills. School represents an intellectual and behavioral laboratory where deficits may be revealed, and the *school history* requires thorough probing. It is important to obtain information about any remedial classes or a history of being held back. Often, formal testing was done and a report may be available. This is a more recent development in United States education, however, and such information may not be obtainable for elderly persons.

A *history of disciplinary troubles* may reflect the presence of attention-deficit/hyperactivity or disruptive behavior disorders. Asking patients to describe their behavior in the classroom is a helpful probe, if recall is sufficient. Signs of inattention in the classroom include making careless mistakes, failing to finish schoolwork, easy distractibility, and forgetfulness in daily activities. Signs of hyperactivity and impulsivity include fidgeting, frequently leaving the seat, intrusiveness, and running about excessively. Attention-deficit/hyperactivity disorder is believed to continue into adulthood in some cases (Wender 1981; Zametkin et al. 1990). The presentation in adults is somewhat different and includes difficulty being organized, low frustration tolerance, impulsivity, restlessness, and mood swings (Woods 1986). It is not known whether residual attention-deficit/hyperactivity disorder extends into senescence.

Behavioral patterns are typically established in childhood. A repetitive pattern of aggression to people and animals, destruction of property, deceitfulness or theft, and serious violations of social norms is evidence for a conduct disorder (American Psychiatric Association 1994). Conduct disorder may represent the presence of developmental anomaly (Nachson 1991). One must inquire about any *history of violence or criminal behavior* beginning in childhood and adolescence. Violent behaviors can also appear as sequelae to numerous central nervous system disorders (Elliott 1992).

Many neurological disorders that may be relevant later in life occur during childhood, including Gilles de la Tourette's syndrome, epilepsy, meningitides, and closed head injury. These conditions are often associated with cognitive and behavioral sequelae that may persist into senescence. Older individuals may have contacted many neu-

rological diseases now considered to be rare, such as poliomyelitis, dementia paralytica, or encephalitis lethargica.

## Adolescence

During adolescence, individuals develop a social identity and begin to form strong attachments outside the family. They may also join the workforce. Maladaptive patterns of behavior established during childhood can continue into adolescence. Adolescents also begin to experiment with drugs, occasionally resulting in substance abuse and dependence. Risk-taking behaviors, such as reckless driving, are not uncommon. Injury is a common cause of morbidity in adolescence. A *history of head injury* should be elicited. Many head injuries do not result in gross cerebral trauma. Asking patients if their ability to think was affected by an injury can often elicit evidence of subtle cerebral pathology. Lishman reported that the degree of anterograde and retrograde amnesia after a head injury is a predictor of postinjury cognitive sequelae (Lishman 1987). The history should define the window of amnesia preceding and subsequent to the injury.

A thorough review of *past psychiatric history* is an essential part of the neuropsychiatric history. Numerous psychiatric illnesses have their onset during adolescence, including anxiety, mood, and thought disorders. Psychiatric illness can reflect neurobiological anomaly and certainly affects psychological development. Schizophrenia is believed to result from structural abnormality in the brain. One line of evidence supports an abnormal migration of hippocampal neurons during gestation (Roberts 1990). Other investigations have focused on prefrontal and temporal heteromodal association cortex pathology rendering an individual vulnerable to hallucinations and psychosis (Shenton et al. 1992; Weinberger 1988). Mood disorders are associated with diminished metabolism in prefrontal and subcortical regions (Ketter et al. 1996; Mayberg et al. 1997).

The *substance abuse history* must be thoroughly explored. Substance abuse can lead to acquired neurological insult and chronic symptoms. Intoxication with alcohol or other substances increases the risk for accidents and head injury. Alcohol and prescription drug abuse in the elderly are often missed by clinicians. Use of cocaine can precipitate stroke (Levine et al. 1990). The use of the designer drug 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP) led to an acute parkinsonian syndrome (Tetrud et al. 1989). Lysergic acid diethylamide (LSD) use is occasionally associated with recurrent visual hallucinatory experiences, known as hallucinogen persisting perception disorder (American Psychiatric Association 1994). Sharing

hypodermic needles exposes individuals to numerous infectious agents, including human immunodeficiency virus, which can cross the blood-brain barrier and affect cognition (Gibbs et al. 1990; Tross and Hirsch 1988) while also predisposing the user to opportunistic central nervous system infections.

## Adulthood

Adulthood heralds the establishment of a stable *pattern of behavior and cognitive performance*, representing an important baseline. Elderly individuals typically present for neuropsychiatric evaluation after a decline from these prior levels of functioning, so this baseline must be clearly identified in the history. Patients establish an *occupational history* during adulthood that should be explored for continuity, stability, and possible exposure to toxic substances.

The persistence of maladaptive behaviors from adolescence into adulthood introduces an element of chronicity that may have relevance for the neuropsychiatric evaluation. Chronic use of alcohol is thought to result in an alcoholic dementia (Charness et al. 1989; Lishman 1990). Malnutrition associated with heavy alcohol use can precipitate thiamine deficiency and the Wernicke-Korsakoff syndrome (Greenberg and Diamond 1986). A pattern of poorly managed aggression and violence can lead to traumatic brain injury, creating a downward spiral of further maladaptive behaviors and cognitive impairment.

Neurological problems that have particular relevance to the neuropsychiatric evaluation, and typically arise before the age of 65, include brain tumors, Huntington's disease, inflammatory disorders such as lupus erythematosus, and multiple sclerosis. Health habits such as nicotine dependence that place an individual at risk for cerebrovascular disease, along with the onset of medical conditions such as hypertension, diabetes mellitus, and hypercholesterolemia, are also noted during adulthood.

## Senescence

The elderly person presenting for neuropsychiatric evaluation has a wealth of life experiences that contribute to current functioning. Erikson et al. (1994) described the primary challenge of this life epoch as consolidating these experiences into a cohesive sense of integrity. The alternative is a feeling of despair that goals have not been accomplished, dreams have not been realized, and that time is running out. Neuropsychiatric disorders represent a significant threat to this sense of integrity. Important neurological conditions that arise in senescence, in addition to

those previously listed, include Parkinson's disease and the various cortical degenerative disorders such as Alzheimer's disease, frontotemporal dementias, dementia with Lewy bodies, normal pressure hydrocephalus, and subdural hematoma.

Elderly persons are far more likely to have chronic medical problems and to be prescribed multiple medications. The history should include a *comprehensive medical and surgical history*, along with a thorough *review of systems*, to screen for any current medical conditions such as urinary tract infections, endocrine disorders, acute neurological deficits, cardiac symptoms, or respiratory conditions that may precipitate an acute confusional state. The presence of bowel or bladder incontinence should be determined. Elderly patients often report somatic and cognitive symptoms in the context of major depressive disorder. The review of systems should include a *survey of the vegetative functions* affected by mood disorder including sleep, appetite, libido. At times, an alteration in the vegetative functions may be the only way to differentiate between a primary psychiatric diagnosis such as depression and a neuropsychiatric syndrome such as acquired apathy. Individuals with depression would have sleep and appetite changes, whereas patients with apathy syndromes, also known as pseudodepression, will eat when presented with food and do not experience significant sleep disruption. Recent changes in a patient's *medication regimen* can precipitate a confusional state or ataxia and should be documented. Any medication capable of crossing the blood-brain barrier has the potential to cause myriad central nervous system side effects in the elderly.

Many elderly patients are functioning well with a "pre-clinical" dementia but lose their functional reserve and appear to have frank dementia or a depressive disorder in the context of acute medical conditions. The aging brain, with a limited cortical reserve and an often tenuous blood supply, is quite vulnerable to acute dysfunction from systemic illness and is more susceptible to cognitive and behavioral toxicity of many commonly prescribed medications. Recovery from these confusional states is often slow to proceed. The "acute dementia" or "acute depression" will slowly resolve upon adequate treatment of the underlying condition.

The clinical interview of the geriatric patient should also include an *assessment of activities of daily living* to explore functional status. These activities include cooking, dressing, performing household chores, shopping, driving, maintaining personal hygiene, and paying bills. Several instruments have been developed to assess functional status in the elderly (Applegate et al. 1990). They provide the clinician with useful measures to document and monitor a

person's level of independence. The degree of autonomy and effectiveness at functioning in one's environment is a crucial historical domain that must be thoroughly assessed.

Historical information, particularly a *history of recent changes in behavior and cognition*, must be organized in order to direct the focus of the mental status and physical examinations. The various neural systems in the brain are associated with rather discrete behavioral and cognitive functions. The signs of neuropsychiatric illness reflect dysfunction in these neuronal networks. The neuropsychiatric examination must, therefore, have localizing value. Through an understanding of functional neuroanatomy and neuropathology, the neuropsychiatrist will be able to clarify problems identified in the history and expand upon them through strategic use of bedside testing to arrive at a more complete understanding of the clinical problem.

## ■ Major Neuropsychiatric Syndromes of the Elderly

Elderly patients frequently present for neuropsychiatric evaluation with chief complaints of forgetfulness, personality change, or mental status change. The differential diagnosis for these symptoms includes virtually all medical conditions prevalent in the elderly. Careful neuropsychiatric evaluation can assist the clinician by discriminating between a depressive disorder, a confusional state, a benign condition of age-related cognitive decline, or intellectual impairment caused by more significant cerebral or somatic dysfunction. Major neuropsychiatric syndromes affecting cognition will typically involve, in addition to memory, other cognitive domains, as well as the executive, motor, and limbic systems. These syndromes are described below to assist in the focus of the clinical interview and to begin to structure the approach to the mental status examination.

### Clinical Characteristics of Age-Related Cognitive Changes

Cognitive decline is not an inevitable consequence of aging. However, numerous studies have demonstrated intellectual impairment of mild to moderate severity in a significant proportion of elderly individuals not diagnosed with a dementia (Ebly et al. 1995; Peterson et al. 1992; Rapp and Amaral 1992). The cognitive domain that is primarily affected appears to be memory and, in particular, acquisition or learning (Petersen et al. 1992). Elderly individuals appear to acquire less information but retain the ability to store and recall the learned material.

The issue of when aging ends and disease begins re-

mains to be resolved. A longitudinal study of healthy, independent seniors with an isolated, mild memory impairment showed that approximately 10%–15% of these individuals experienced progression to clinically diagnosable dementia of the Alzheimer type each year (Petersen et al. 1997). Age-associated memory impairment is discussed in greater detail elsewhere in this text.

### Clinical Characteristics of Prefrontal Systems Dysfunction

Prefrontal systems dysfunction is recognized as a condition that can cause gross disruption of behavior while sparing basic motor, sensory, and cognitive functions. The metacognitive functions subserved by prefrontal systems are essential for adaptive functioning in one's environment. Despite their vital role in human behavior, the so-called executive cognitive functions are not routinely tested in common cognitive screening instruments such as the Mini-Mental State Exam (Folstein et al. 1975) or the Short Portable Mental Status Questionnaire (Pfeiffer 1975). However, an understanding of their contributions to adaptive behavior, together with an appreciation of the cardinal signs of prefrontal dysfunction, can lead to a proper diagnosis and treatment plan. Signs of prefrontal systems dysfunction range from the dramatic personality changes associated with orbitofrontal and mesial frontal dysfunction to a perplexing inability to function well in the presence of only mild motor, sensory, or cognitive impairment, as is often seen with dysfunction of the dorsolateral convexity network (Table 5–2).

**Dorsal convexity dysexecutive syndrome.** The high-level cognitive functions mediated by the dorsolateral prefrontal lobe and its connections include cognitive flexibility, temporal ordering of recent events, planning ahead, regulating actions based on environmental stimuli, and learning from experience (Goldman-Rakic 1993). Patients exhibiting dysfunction in these cognitive domains are concrete and perseverative and show impairment in reasoning and flexibility. The examiner should probe the ability to pay bills on time, organize daily activi-

**TABLE 5–2. Regional prefrontal syndromes**

Region	Cardinal signs
Orbitofrontal system	Behavioral disinhibition Environmental dependency
Dorsolateral convexity system	Cognitive disorganization
Mesial frontal system	Apathy syndrome

ties, such as going to the bank or market, keep a tidy house, or cook balanced meals. The “tea and toast” diet frequently results from loss of the organizational capacity to purchase diverse groceries in response to dwindling home supplies and to plan and prepare a meal consisting of several items. In addition, such patients are characterized by a paucity of spontaneous behavior. They often appear apathetic and may become irritable during mental status testing when fatigue easily ensues.

**Orbitofrontal disinhibition syndrome.** The orbitofrontal cortex has discrete connections with paralimbic cortex and thus plays a role in the elaboration and integration of limbic drives. This area receives highly processed information concerning the individual’s experience of an environmental stimulus and the anticipated consequences of various behavioral responses to it (Malloy and Duffy 1992). This process allows a person to maintain consistent behavior in keeping with his or her self-concept. Patients with orbitofrontal damage often exhibit poor impulse control, explosive aggressive outbursts, inappropriate verbal lewdness, jocularity, and a lack of interpersonal sensitivity. The fatuous behaviors observed with orbitofrontal system dysfunction are known as *moria* or *witzelsucht*. The stimulus-bound behaviors noted with this syndrome are commonly noted in nursing homes, where residents frequently wander and happen upon numerous stimuli. A doorknob will be turned and a room entered. A sleeve hanging from a drawer is an invitation to disrobe and put on the newly discovered clothes. A shower stall is an open invitation for a shower. These patients often become agitated and aggressive when interfered with. The diagnosis of the orbitofrontal disinhibition syndrome is primarily clinical. Such gross disruption of behavior often leads to a misdiagnosis of mania. Careful review of the history will not, however, demonstrate insomnia, pressured speech, religiosity, or grandiose delusions.

**Mesial frontal apathetic syndrome.** Mesial frontal pathology affects the functional balance between the cingulum and supplementary motor area. Disruption of this network leads to a dysmotivational syndrome ranging from apathy to akinetic mutism (Duffy and Campbell 1994). These patients often appear depressed, yet they lack the dysphoria, negative cognitions, and neurovegetative signs of a major depression. The diagnosis of a mesial frontal apathy syndrome is entirely clinical. One patient, after a gunshot wound to the frontal lobes, lapsed into a state of inertia when left alone. When questioned, he related an awareness of a personality change. He denied boredom and described it as a “loss of motivation” in that he entertained

numerous ideas for activities, but felt no impetus to act on them. His facial expression was one of casual indifference, and he would often respond with simple gestures instead of speaking. Caregivers for patients with apathy syndromes are commonly frustrated with what they incorrectly perceive as willful indifference to the home environment.

### **Clinical Characteristics of Generalized Cortical Systems Disorders**

The neurodegenerative disorders that compose the classic dementias typically affect the cerebral cortex in regional patterns. Alzheimer’s disease appears to preferentially affect heteromodal association cortex and the limbic system (Hyman et al. 1984; Pearson et al. 1985). Mesencephalic projection nuclei including dopaminergic, cholinergic, serotonergic, and noradrenergic systems are variably involved (Jellinger 1987). Common clinical findings include amnesia, aphasia, apraxia, agnosia, and visuospatial impairment. The degree of involvement of these cognitive domains is quite variable between patients. Dementia with Lewy bodies may represent a clinicopathological variant of Alzheimer’s disease. Patients present with a mixed picture of cortical and subcortical pathology, characterized by global cognitive impairment along with fluctuating attention, visual hallucinations, and spontaneous motor features of parkinsonism (McKeith et al. 1996). Frontotemporal dementias involve limbic and paralimbic degeneration in the prefrontal and temporal regions. Clinical signs of frontotemporal dementia include gross disruption of social comportment with an eventual transition to an apathetic state (Chang Chui 1989).

### **Clinical Characteristics of Focal Cortical Dementia Syndromes**

Focal degeneration syndromes can present in a slowly progressive manner and are regularly noted. Their etiology is not well understood, but autopsy findings in some cases reveal hallmarks of generalized cortical dementias, including senile plaques, neurofibrillary tangles, Pick’s bodies, and Lewy bodies (Benson and Zaras 1991; Brun 1987; Hof et al. 1989; Morris et al. 1984). Thus, these syndromes may represent uncommon presentations of more common disorders. Caselli (1995) identified four general syndromes, including progressive frontal lobe syndromes, progressive aphasias, progressive perceptual motor syndromes, and progressive bitemporal syndromes. The progressive frontal lobe syndromes are described above.

**Progressive aphasias.** The progressive aphasias described in the literature include fluent and nonfluent

types, as well as anomic and mixed types. Fluent aphasia, also known as Wernicke's aphasia, receptive aphasia, and posterior aphasia, is characterized by effortless, yet incomprehensible speech, together with difficulty comprehending the speech of others. This aphasia is most commonly caused by damage to unimodal association cortex in area 22 of the left hemisphere (A. R. Damasio 1992). This area is located in the superior temporal gyrus in the posterior regions adjacent to the supramarginal gyrus.

Nonfluent aphasia is also known as Broca's aphasia, expressive aphasia, and anterior aphasia. This aphasia is notable for effortful, agrammatic or telegraphic speech in which the patient has great difficulty using words such as "if," "and," "or," "but," "to," "from," and so on. Anterior aphasia results from damage to the inferior left frontal gyrus in the left hemisphere. Deficits in anomic aphasias are limited to word finding and naming. Anomic aphasia can result from damage to numerous sites in the left hemisphere. The mixed aphasia syndrome appears to involve numerous aspects of language function and is associated with degeneration in the left temporal and perisylvian regions. Other commonly noted aphasia syndromes such as global aphasia, conduction aphasia, transcortical aphasias, and pure word deafness are typically vascular in origin and are not commonly the product of progressive cortical degeneration (H. Damasio 1989).

**Progressive perceptual-motor syndromes.** The progressive perceptual-motor syndromes are divided into visual syndromes and motor syndromes. The progressive visual syndromes involve occipitoparietal and occipitotemporal networks and include progressive asimultanagnosia, Balint's syndrome, and visual agnosia.

Focal pathology in the occipitoparietal system bilaterally affects higher order processing of visual information into a coherent whole. Consequently, asimultanagnosia describes the inability to adequately appreciate important aspects of a visual scene, a problem known as visual disorientation. Patients can describe certain details but cannot integrate the entirety of the information (A. R. Damasio 1985). Balint's syndrome consists of asimultanagnosia along with optic apraxia, an impairment of voluntary gaze, and optic ataxia, an inability to point accurately at a target under visual guidance (Balint 1909). Bilateral dysfunction in the occipitotemporal system results in visual agnosia, an inability to name visualized objects. Prosopagnosia is a particular type of visual agnosia with a circumscribed deficit of facial recognition (A. R. Damasio et al. 1982).

Two progressive motor syndromes have been described that involve the parietofrontal junction (Caselli 1995). The syndromes are not specifically named. The first

consists of hemispasticity, hemiparesis, and hemisensory impairment in the form of astereognosis or agraphesthesia, and myoclonus. The second motor syndrome is defined by a mixed apraxia, or disorder of higher order motor integration, consisting of limb apraxia, gestural apraxia, dressing apraxia, constructional apraxia, and writing apraxia. Limb apraxia is characterized by difficulty executing simple motor tasks such as combing the hair or brushing the teeth. Gestural apraxia is a form of limb apraxia in which the patient has great difficulty imitating symbolic movements. Dressing apraxia is the inability to dress despite absence of significant sensorimotor disturbance. Constructional and writing apraxias involve impaired ability to draw or write.

**Progressive bitemporal syndromes.** The progressive bitemporal syndromes include progressive amnesia, progressive prosopagnosia, and Klüver-Bucy syndrome. The Klüver-Bucy syndrome results from bilateral destruction of the amygdalae and is characterized by hyperorality, emotional placidity, hypersexuality, compulsive exploration of the environment, known as hypermetamorphosis, and psychic blindness (Klüver and Bucy 1939; Lilly et al. 1983).

## Clinical Characteristics of Subcortical Systems Disorders

**Basal ganglia dysfunction.** The basal ganglia have a significant functional relationship with specific regions of frontal cortex. Alexander and Crutcher (1990) identified five independent neural loops uniting striatum, globus pallidus, dorsomedial thalamus, and frontal cortex. The physical integrity of these loops appears to be critical to optimal functioning of the behaviors unique to each circuit. The supplementary motor area participates in a circuit responsible for the integration of motor function. Similarly, a loop involving the frontal eye fields subserves oculomotor function. The dorsolateral prefrontal, lateral orbitofrontal, and anterior cingulate areas participate in discrete circuits subserving cognitive organization, social comportment, and motivation, respectively (Duffy and Campbell 1994). These circuits have particular relevance to neuropsychiatry because of their essential roles in adaptive behavior. The cardinal signs of basal ganglia pathology represent suboptimal participation of the striatum in these networks, resulting in cognitive impairment, motor dysfunction, and mood disorders.

The motor signs of basal ganglia dysfunction may be readily apparent during the clinical interview. The classic triad of movement disorder includes tremor, rigidity, and

akinesia. It is helpful to observe the gait when the patient first arrives. A shuffling gait may represent an early clue. Other signs include a bland expression with infrequent blinking, difficulty sitting down with ease, and a paucity of movement. “Striatal hand” may be evident and is characterized by an ulnar deviation with flexion of the fingers at the metacarpal phalangeal joints. A “pill rolling” tremor of 4–7 Hz involving the thumb and forefinger is frequently noted. When these signs are noted, the examiner should probe further for progressive symptoms of stiffness, loss of agility, involuntary movements, or difficulty walking. Chorea may be observed with other striatal disorders such as Huntington’s disease. Patients often attempt to mask these involuntary movements by quickly stroking their hair or adjusting an article of clothing.

Controversy exists over the presence of cognitive impairment associated with basal ganglia pathology (McHugh 1989). Carefully conducted studies have, however, identified the presence of a pattern of deficits that appears to reflect derangement of the frontal-subcortical contribution to cognition (Brown and Marsden 1990). Albert et al. (1974) and McHugh and Folstein (1975) have described a “subcortical dementia” consisting of mental torpor, cognitive dilapidation, apathy, and depression, without impairment of learning, speech and language, or other “cortical” functions such as praxis or mathematical calculating. The ability to retrieve stored material is often impaired (Brown and Marsden 1990). Patients will require prompts to produce historical information such as the names of recent presidents. The number of prompts required to recall material is a good indicator of the degree of the retrieval deficit. Other signs of subcortical dementia notable during the mental status examination include imperistence and slowed completion of tasks. Pathological conditions that involve the basal ganglia include Parkinson’s disease, Huntington’s disease, *état lacunaire*, tumors, progressive supranuclear palsy, multisystem atrophy, Wilson’s disease, and corticobasal degeneration.

Vascular dementias are a heterogeneous group resulting from cerebral infarctions of any etiology. Wallin and Blennow (1994) organized the vascular dementias into multi-infarct, strategic-infarct, and subcortical white matter subtypes. They found a reliable clinicopathological correlation between subcortical white matter dementia and a subcortical dementia pattern. The clinical presentation of multi-infarct- and strategic-infarct-related dementias varies widely in accordance with extent of involvement and lesion location. The concept of vascular dementia is currently being reexamined with the hope of refining clinicopathological relationships (Erkinjuntti and Hachinski 1993).

## ■ Mental Status Examination

The mental status examination is an assessment of brain function. A proper assessment should enable the examiner to estimate a patient’s cognitive capacities in terms of domains of relative strength and impairment. Several general cognitive screening instruments are commonly used by clinicians to investigate intellectual impairment. These include the Mini-Mental State Exam (Folstein et al. 1975), Cognitive Capacities Screening Examination (Jacobs et al. 1977), and the Short Portable Mental Status Questionnaire (Pfeiffer 1975). Screening instruments developed to assess dementing processes include the Dementia Rating Scale (Mattis 1973), Blessed Dementia Scale (Blessed et al. 1968), and the Alzheimer Disease Assessment Battery (Devenny et al. 1992). The Executive Interview (Royall et al. 1992) and Frontal-Subcortical Assessment Battery (Rothlind and Brandt 1993) have been developed to more specifically assess frontal systems dysfunction.

Malloy et al. (1997) have reviewed the merits of these instruments as cognitive screens. However, the geriatric patient presenting for neuropsychiatric evaluation requires a flexible and comprehensive cognitive assessment not permitted by these standard instruments. No single instrument surveys the commonly assessed cognitive and metacognitive domains adequately. The principal drawbacks include substantial false-negative rates, indicating a lack of sensitivity for mild dementia, and inadequate evaluation of right hemisphere and frontal systems function (Nelson et al. 1986).

The clinical assessment of cognition is an area of significant neglect. In a recent survey of neuropsychiatric clinicians, only 57% of respondents reported the use of formal assessment of cognitive status (Coffey et al. 1994). Many respondents routinely requested formal neuropsychological testing as their primary means for assessing cognition. This approach is neither clinically nor economically acceptable. Bedside mental status testing has been demonstrated to be a reasonable clinical indicator of cognitive impairment as a result of cerebral dysfunction of many etiologies (Malloy et al. 1997).

Neuropsychological (NP) assessment should be considered as an adjunct in the geriatric neuropsychiatric assessment. Formal NP testing is an expensive and time-consuming process that can be very helpful for certain indications. When not indicated, however, NP testing frequently does not provide any additional information to assist in treatment planning. Proper indications include the establishment of a quantitative cognitive baseline to track over time, clarification of confusing or variable find-

ings at the bedside, more thorough assessment of specific cognitive domains, or addressing a question of malingering or conversion disorder. It is helpful to compare closely the bedside cognitive findings with those of the NP testing. NP findings should concur with the findings of the bedside assessment. A common cause of discrepancy is suboptimal bedside technique or misinterpretation of the bedside findings. In these situations, the neuropsychologist can assist the bedside examiner by reviewing the technique or recommending other more reliable tests to add to the bedside armamentarium.

## ■ Cognitive Assessment

A thorough approach to bedside cognitive testing is provided elsewhere in this text. Throughout the administration of the cognitive tasks, the examiner should consider the performance in terms of quality, localizing value, and functional status. The popular cognitive screening instruments provide numerical scores as a reflection of cognitive capacity. However, cognitive performance falls on a qualitative continuum. All results must be considered in terms of an expected level of performance. Simply relying on a numerical descriptor may result in a false-negative assessment for many patients, particularly those with significant cognitive strengths, who are left with ample reserve despite cognitive decline.

Furthermore, the diagnosis of most dementing disorders is primarily clinical. No laboratory assays exist to confidently differentiate Alzheimer's disease from most other dementias, and brain biopsy is not part of a general workup of progressive cognitive dysfunction. Neuropsychiatric syndromes in the elderly typically involve either widespread pathology or more focal lesions. The pattern of deficits can thus differentiate between a generalized process such as Alzheimer's disease and a focal process such as a left parietal lobe infarction. Organizing the cognitive examination to assess regional functions can assist with this process.

The findings of the neuropsychiatric evaluation should fit with the person's functional status in his or her usual setting and help to explain and understand current difficulties. In some instances, the findings may conflict with the history. A common scenario is finding a patient who appears to be cognitively intact, but who reports an obvious decline in ability to function effectively at home. This is likely the result of a so-called dysexecutive syndrome. The structure of the office provides an artificially optimal environment for cognitive assessment. Patients having executive dysfunction will benefit from this external structure and may appear much less impaired on mental

status testing unless frontal systems are carefully assessed. In addition, the tasks that make up the mental status examination are rather arbitrary and do not necessarily assess the neural networks relied upon for daily living, which have evolved over millions of years without being shaped by the environmental stressor of mental status testing.

## ■ Neurobehavioral Assessment

Formal assessment of mental status includes a review of pertinent domains of psychiatric functioning including mood and affect, anxiety, compulsive and repetitive behaviors, personality changes, thought process and content, and perceptions. Upon completion of the clinical interview, the examiner will have acquired numerous clues to guide more thorough exploration of these areas.

### Assessment of Mood and Affect

Depressive symptoms are more commonly encountered in the elderly than in individuals under 65 years of age. Despite this, major depressive disorder, as defined by DSM-IV (American Psychiatric Association 1994), has a lower prevalence among the elderly. In addition, common neuropsychiatric disorders such as stroke (Robinson and Price 1982) and Parkinson's disease (Starkstein et al. 1990) are associated with a higher incidence of depressive illness. Bipolar disorder is occasionally encountered after stroke and traumatic brain injury (Robinson et al. 1988).

Affect is the outwardly directed manifestation of mood and serves as a nonverbal communication of one's emotional state. In neurologically intact individuals, affect remains congruent with the mood state. Neuropsychiatric disorders can disconnect affect from mood and thus disrupt a person's ability to effectively and accurately communicate their prevailing mood. Right hemisphere pathology can produce an expressive dysprosodia through which facial expression, gesticulation, and speech inflection become limited. Such persons often appear depressed despite denying feelings of dysphoria (Ross 1985). Frontal systems dysfunction resulting in apathy syndromes and Parkinson's disease are also associated with limited affective expression of internal mood states. Pseudobulbar palsy presents with excessive displays of affect in response to minimal emotional stimuli and results from bilateral damage to corticobulbar tracts, generally in the setting of cerebrovascular disease.

## Assessment of Anxiety

Anxiety is often evoked during the neuropsychiatric evaluation and can affect a person's ability to concentrate and perform optimally on cognitive examination. The examiner should promptly identify signs of anxiety and make efforts to moderate the patient's distress. Gentle reassurances are usually all that are required for the patient to continue with the examination. The examiner should also inquire about the presence of any specific or recurrent worries that the patient experiences. Anxiety disorders are among the most common psychiatric syndromes in the elderly. Blazer et al. (1991) reported a 6-month prevalence of 19.7% for any anxiety disorder in the elderly.

## Assessment of Compulsions and Repetitive Behavior

Obsessive-compulsive symptoms are occasionally sequelae of neuropsychiatric illness. Positron-emission tomographic studies of symptomatic individuals have shown disturbances in orbitofrontal-basal ganglia networks (Baxter et al. 1988). Disorders affecting the basal ganglia can be associated with symptoms of obsessive-compulsive disorder, including intrusive thoughts, repetition, preoccupation with cleanliness, and ruminations (Tomer et al. 1993).

## Assessment of Personality Changes

Personality changes detailed above are commonly encountered in the setting of frontal systems dysfunction. Affected individuals often lack awareness of any change in social comportment. The inquiry into pertinent personality changes should therefore include the caregiver's perceptions of change. Ott et al. (1996) found that right hemisphere pathology is associated with a reduction in insight.

## Assessment of Thought

Disordered thinking is a common symptom in the elderly. Both thought process and thought content are vulnerable to derangement by numerous neuropsychiatric conditions (Cummings 1985b). The influence of primary psychiatric diagnoses such as mania and schizophrenia on thought process is well known. However, frontal systems dysfunction can mimic these presentations by disrupting the ability to screen out irrelevant stimuli and maintain a given behavioral set. Consequently, stimulus-bound individuals may reveal tangential thinking or flight of ideas. Patients with apathy syndromes may appear to have a poverty of thoughts. Their paucity of speech precludes confident assessment of the thought process. Damage to the posterior

language areas can present as rambling, incoherent speech, which may be misdiagnosed as thought derailment.

Disorders of thought content are known to arise late in life. Monosymptomatic or content-specific delusions, in particular, have been reported as sequelae of a number of generalized and focal neurological conditions affecting the brain (Malloy and Richardson 1994). The delusional themes include the duplication of person (Capgras's syndrome) or place (reduplicative paramnesia), sexual themes of infidelity (Othello syndrome) or love (de Clerambault syndrome), or physical changes such as being infested with parasites (Ekbom's syndrome) or being dead (Cotard's syndrome). Lesions affecting the heteromodal association cortex of the right hemisphere appear to be especially likely to result in the occurrence of monosymptomatic delusions (Cutting 1991).

## Assessment of Perceptions

Disordered perception in the elderly typically presents as illusions or hallucinations. Illusions are a misperception of a sensory stimulus, such as mistaking a shoe for a cat, and are often experienced by cognitively impaired individuals with diminished vision or hearing, especially at night. These problems are readily treated with correction of the visual problem, use of a hearing aid, or improved lighting. Hallucinations, the experience of a sensory perception in the absence of a stimulus, may indicate the presence of encephalopathy and can occur with any sensory modality.

## ■ Sensorimotor Examination

Sensorimotor impairments significantly affect functional status in the elderly and require thorough assessment. The major neuropsychiatric syndromes described above are often associated with sensorimotor findings. Careful identification of sensorimotor impairments is necessary to provide remedial interventions. Elderly individuals with gait impairment are at increased risk for falls, which may be prevented by some form of ambulatory assistance such as a cane or walker, by avoiding doses of medication known to cause ataxia, or by optimizing treatment of the underlying cause, such as Parkinson's disease. In addition, in situations where the cognitive examination reveals a focal pattern of deficits, sensorimotor signs can further refine the bedside localization of cerebral pathology. For an outstanding review of the neurological examination, the reader is referred to Haerer (1992). The examination discussed below is limited to information that is more directly applicable to the neuropsychiatric assessment.

## Observation

A great deal of information can be gleaned from the patient through simple observation. The gait can be scrutinized as the patient walks to the examiner's office. The posture may reveal the simian stance of Parkinson's disease or spinal abnormalities such as kyphosis, lordosis, or scoliosis brought on by osteoporosis. Diminished arm swing may be a sign of Parkinson's disease. Frontal systems disease is often associated with a gait apraxia in which the patient's feet appear to stick to the floor like magnets. Circumduction of one leg may be caused by spasticity resulting from an upper motor neuron lesion. Ataxia is frequently noted as a side effect of many psychotropic medications with anticholinergic or antidopaminergic properties. Walking heel-to-toe can elicit dystonic posturing of a hand and arm, suggesting contralateral hemispheric injury. Impaired tandem gait can also be a result of peripheral sensory loss, pain, or focal weakness.

Observation of the face during the neuropsychiatric examination may reveal a Horner's syndrome resulting from ipsilateral carotid atherosclerosis. The full Horner's syndrome includes unilateral ptosis, meiosis, and anhidrosis. A flattened nasolabial fold can indicate a facial plegia from a contralateral lesion such as a stroke. A masked, bland facies with diminished blinking is a common sequela of Parkinson's disease. Exophthalmos may be a sign of hyperthyroidism.

Failure to shave or apply cosmetics to the left side of the face is often seen with left hemineglect as a result of a right hemisphere lesion.

## Vision and Hearing

Vision and hearing should be assessed. Elderly patients may not be fully aware of a gradual decline in these sensory modalities and often present with significant impairment. Providing elderly patients with proper eyeglasses and hearing aids can immediately improve functional status and diminish risk of accidents. Ocular and ear diseases are also associated with increased risk for modality-specific release hallucinations (Hammeke et al. 1983; White 1980). Anterior visual pathology can lead to the Charles Bonnet syndrome, characterized by well-formed visual hallucinations (Berrios and Brook 1984). Diminished ability to discriminate others' speech may exacerbate a tendency toward paranoia in susceptible individuals (Cooper and Curry 1976).

## Oculomotion

Examining eye movement provides a wealth of information with localizing value. Patients who cannot track the

examiner's moving finger without also moving their head may be stimulus bound from frontal systems disease. A unilateral lesion of the frontal eye fields will lead to an ipsilateral gaze preference. The pupils will not cross the midline with voluntary gaze to the contralateral hemispace. Difficulty with voluntary saccades can be an early sign of Huntington's disease in susceptible individuals (Grafton et al. 1990). Internuclear ophthalmoplegia reflects brainstem pathology, commonly a result of multiple sclerosis. Damage to the right medial longitudinal fasciculus will cause failure of the left eye to cross the midline to the right, while the right eye will track normally but exhibit monocular nystagmus. Inability to track a downward moving finger below the midline may be a sign of progressive supranuclear palsy. Lid lag with downward gaze may be a sign of hypothyroidism.

Examination of the visual fields by confrontation can help to localize temporal, parietal, and occipital lesions from damage to the optic radiations. Visual information from the superior quadrants is carried by the inferior aspect of the optic radiations, known as Meyer loop. Temporal lobe lesions will produce a contralateral superior quadrantanopia. Inferior parietal lesions can cause a contralateral inferior quadrantanopia. Patients with left hemineglect caused by a right hemisphere lesion may appear to have a complete contralateral hemianopia. However, visual fields testing in this situation is very difficult because of the strong tendency to neglect left-sided stimuli.

## Extrapyramidal Motor Examination

Diseases of the basal ganglia are commonly encountered in geriatric neuropsychiatric practice. The clinical assessment of extrapyramidal motor function is an essential element of proper diagnosis and treatment. The typical gait and tremor of a patient with Parkinson's disease has been described above. In addition to the shuffling quality of the gait, festination is noted, whereby the patient will tend to increase speed and fall forward. Patients cannot turn around easily and tend to turn slowly by shuffling in place. Extrapyramidal muscular rigidity is present throughout the entire range of motion of the neck, trunk, and extremities. A jerky yielding of resistance known as cogwheeling is often noted when examining nuchal, truncal, or limb flexor tone. Repeated rapid opening and closing of the hands will demonstrate a gradual reduction in speed and amplitude. Diffuse increases in tone are noted with lacunar states, but are not associated with cogwheeling unless a parkinsonian tremor is also present.

An additional sign of upper motor neuron and extrapyramidal pathology is *gegenhalten*, a direct resis-

tance to passive changes in position and posture. Patients who actively move their limb with the examiner despite requests to remain passive demonstrate *mitgehen*, a finding often noted with frontal systems dysfunction. The pronator drift test can often elicit subtle changes in motor tone as a result of hemispheric dysfunction. A slow pronation of the contralateral wrist with slight flexion of the elbow and fingers along with downward and lateral drift of the hand is noted. After the pronator drift test, the patient can be examined for propulsion and retropulsion by giving the patient a sudden push in either direction. Patients with Parkinson's disease cannot rapidly execute counteractive muscle groups and will stumble in the direction of the push.

## Reflexes

Examination of muscle stretch reflexes, and in particular, the biceps, triceps, brachioradialis, patellar, and Achilles reflexes, not only assesses the integrity of the sensory and motor systems, but also has localizing value. Focal lesions involving upper motor neurons originating in the precentral gyrus or their axonal tracts coursing caudally through the internal capsule to form the corticospinal tract can cause a contralateral increase in reflex response. The presence of a Babinski sign, dorsiflexion and fanning of the toes in response to stimulating the sole of the foot, is an additional important lateralizing sign of corticospinal pathology. Geriatric patients with dementia are often variably cooperative with neuropsychiatric testing. However, the reflexes can be reliably tested despite a lack of complete cooperation by the patient.

The value of frontal release signs in neuropsychiatry tends to be overstated. The integrity of the frontal systems is reflected by the quality of the person's behavior over time. A clinical history of behavioral change as noted above, along with impaired performance on bedside tests of frontal functions, is sufficient to offer a diagnosis of executive impairment. The absence of snout, glabellar, and palmomental reflexes in this situation would not exclude the diagnosis. Further, the presence of these reflexes in the absence of behavioral changes or impairment with frontal tests does not suggest the presence of frontal systems dysfunction.

## Formulation: Localizing the Findings

An important aspect of the biological domain of the formulation is to place the findings in the brain. The diagnostic necessity for this is discussed earlier in the context of wide-

spread impairments in the cortical dementias. However, patterns of deficits are commonly noted. These patterns often reflect regional impairments caused by localized pathology such as a stroke or a tumor. The data from the clinical interview, mental status examination, and sensorimotor examination can be organized in a regional fashion. Table 5-3 is intended to assist the reader with neuropsychiatric localization. The table illustrates the relationship between the three areas of inquiry and can serve as a rough guideline for the cardinal signs and symptoms of regional cerebral dysfunction.

## Summary

The neuropsychiatric formulation is the synthesis of the collected data into a cohesive clinical picture. The data are best organized in terms of the biopsychosocial model (Engel 1980). Biological deficits always have some psychological response. Furthermore, the patient's support persons will have a response of their own to the patient, which influences the effectiveness of the patient's attempts at adaptation. A case example follows.

An elderly woman presented to the neuropsychiatry clinic with the complaint of progressive memory impairment. She noted a significant decrease in her ability to manage the household. Her husband had taken up many chores formerly done by the patient. She believed that the need for assistance meant that she was "a failure" and that she was "a burden on her husband." He tended to downplay the patient's memory problem and believed she was being "lazy." Her sleep and appetite were diminished, and she experienced less interest in pleasurable activities. She had a history of poorly controlled hypertension.

Mental status testing demonstrated difficulty with alternating motor sequences as described by Luria (1980), mirroring the examiner's movements on a go/no-go task, and perseveration when copying an alternating design. She also had diminished storage and retrieval of new verbal information and required prompting to complete a chronological list of recent presidents. The sensorimotor examination revealed a mild bilateral increase in muscular tone and reflexes, greater on the right side. Computed tomography of the brain showed mild to moderate generalized cortical atrophy along with several lacunar infarcts in the basal ganglia bilaterally.

Without going into further clinical detail, *biologically*, the patient had acquired a syndrome of impaired cognition and depressed mood. Her cognitive and neuroimaging findings suggested frontotemporal systems dysfunction of a possibly mixed cortical degenerative and subcortical vascular pattern, exacerbated by the depressive syndrome.

**TABLE 5-3.** Localizing neuropsychiatric findings

Region	History	Mental status	Sensorimotor
<b>Frontal</b>	Disorganization Disinhibition	High-level attention deficit Luria motor sequences deficit Go/no-go task deficit Decrease in verbal fluency Perseveration Losses of set Confabulation Witzelsucht	Gait apraxia Mitgehen Ipsilateral gaze preference Primitive reflexes
	Apathy	Dilapidation	Hypokinesia
<b>Subcortical</b>	Motor impairment Social withdrawal Cognitive impairment	Dilapidation Mental torpor Retrieval deficit	Hypokinesia Masked facies Simian stance Festinating gait Adventitious movement Muscular rigidity Cogwheeling Gegenhalten Downward gaze palsy
	<b>Right hemisphere</b>	Confusional state Delusions Spatial disorientation Neglect Denial of deficit Dressing difficulties Left-sided motor impairment	Dysprosodia Visuoconstructive deficit Spatial analysis deficit Left hemineglect Visual memory deficit Dressing apraxia Posturing of left hand/arm with tandem gait Left pronator drift Left quadrantanopia
<b>Left hemisphere</b>	Right-sided motor impairment Language impairment Math impairment	Ideomotor apraxia Dysphasia Dyslexia Dyscalculia Dysgraphia Right/left disorientation Finger agnosia	Right hypertonus Right Babinski sign Right astereognosis Right dysgraphesthesia Posturing of right hand/arm with tandem gait Right pronator drift Right quadrantanopia
<b>Bitemporal</b>	Placidity Hyperorality Hypersexuality	Amnesia Agnosia Visual: right Auditory: left Anomia Prosopagnosia	Superior quadrantanopia
<b>Biparietal</b>	Spatial disorientation	Asimultanagnosia	Inferior quadrantanopia Ocular apraxia Optic ataxia

*Psychologically*, she equated being an effective household manager with being a good person. The executive deficits threatened her fragile sense of self-esteem. She also experienced a significant threat from the diminished autonomy

associated with her deficits and the need to rely on her seemingly unempathic husband. Her husband appeared to deny the possibility of a progressive dementing syndrome, which may have protected him from acknowledging the

potential loss of his partner through dementia. *Socially*, her husband struggled with assisting her, which compounded her dysphoria by making her feel like a burden. Her depressive syndrome made her anergic and even less able to meet the demands of household management.

Once a case is summarized in this fashion, the treatment plan can be constructed to address the depression, dementia, issues with the partner, the partner's issues with the patient's deteriorating condition, and the couple's suboptimal communication.

## ■ Conclusions

Geriatric neuropsychiatry provides clinicians with a comprehensive approach for understanding and helping elderly persons with cerebral dysfunction of any etiology. The progressive increase in longevity of the United States population means that an increasing proportion of the populace will be at risk for acquiring a neuropsychiatric syndrome. The ability to diagnose these varied conditions in their early stages and institute aggressive therapeutic and remedial measures will prolong the independent functioning of our patients, improve the quality of their lives, and diminish the significant expense of caring for elderly persons unable to function autonomously. Recent advances in understanding the brain function in healthy and pathological states will provide us with opportunities to offer more effective treatments in the future. However, the time-honored skills of inquiry, listening, and physical examination will remain the cornerstone of the practice of our specialty.

# Mental Status Examination

David L. Sultzer, M.D.

**M**ental status examination is a critical part of the neuropsychiatric assessment of older patients. The examination reveals the integrity of cognitive skills, which are those intellectual abilities that facilitate thinking, perception, communication, and problem solving. Several cognitive domains are assessed, including attention, memory, language, visuospatial skills, calculation, and executive skills.

Cognitive evaluation adds an important dimension to neuropsychiatric assessment. The psychiatric examination reveals abnormal experiences, thoughts, interpersonal skills, and behavior. The neurological evaluation focuses primarily on the motor and sensory system. The cognitive mental status examination assesses the integrity of a broad range of brain structures and can reveal the presence of cerebral pathology that contributes to the expression of psychiatric symptoms or intellectual deficits. Although a trichotomy is implied, the psychiatric, cognitive, and neurological examinations overlap considerably. Together they identify a pattern of neuropsychiatric signs that the clinician uses to formulate a differential diagnosis, direct further evaluation, and monitor change over time.

Assessing cognitive skills is particularly important in older patients because the prevalence of delirium, demen-

tia, and psychiatric symptoms related to neurological conditions increases with age. Other goals of mental status assessment in older patients include

1. Distinguishing cognitive changes of normal aging from deficits resulting from dementia;
2. Distinguishing cognitive changes of dementia from those associated with depression or delirium;
3. Promoting early recognition and treatment of dementia because even moderate cognitive decline is often not detected by family members (Ross et al. 1997) or the primary physician (Callahan et al. 1995; Eefsting et al. 1996);
4. Identifying and localizing cerebral pathology that is neurologically silent;
5. Monitoring response to treatment for dementia and other cognitive disorders; and
6. Identifying cognitive strengths in patients with mild overall impairment. Use of preserved cognitive skills can maximize a patient's functional skills.

Mental status assessment is not exclusively reserved for neuropsychologists or other subspecialists. Although complex cases may benefit from referral to a specialist, the basic

examination can be performed efficiently by many practitioners. Thoughtful, focused evaluations can rapidly and accurately reveal the necessary information for diagnosis and treatment.

In this chapter, I review the technique of clinical mental status examination, the regional neuroanatomical pathology associated with cognitive deficits, common syndromes of cognitive impairment, and the use of rating scales for cognitive assessment. Individual neuropsychiatric syndromes in the elderly are described in Sections III and IV of this volume and an overview of the neuroanatomical and neurochemical underpinnings of human cognition and emotion is provided in Chapter 4 this volume. The role of mental status assessment in the diagnosis of dementia has been described in several recent clinical guidelines (American Psychiatric Association 1997; Costa et al. 1996; Small et al. 1997; U.S. Department of Veterans Affairs 1997).

## ■ Clinical History

The mental status examination begins with a historical review of symptoms. The patient should be invited to describe current or past difficulties with memory and thinking, such as problems concentrating, forgetting recent events, forgetting where things are located, difficulty finding the right word to say, difficulty understanding what others are saying, getting lost in previously familiar places, or difficulty with routine financial transactions or record keeping. Specific features and time course of the difficulties are diagnostically relevant and point toward those cognitive domains that should be explored in more detail during the examination. A history of head trauma, meningitis, encephalitis, seizure disorder, psychiatric symptoms, neurological symptoms, or substance abuse should be identified.

Because memory or language impairment can interfere with the patient's ability to provide an accurate history, information from a family member or close friend is useful. Family members may feel uncomfortable discussing difficulties with the patient present; if so, a separate interview should be conducted. The patient's age, educational background, cultural background, occupation, and handedness should be noted because these factors affect the interpretation of cognitive performance.

## ■ Examination Technique

The length and depth of the mental status evaluation depends on the clinical circumstances and the specific goals

(e.g., screening of elderly persons without obvious neuropsychiatric illness, evaluating suspected dementia, or monitoring response to treatment for a cognitive disorder). All patients with suspected neuropsychiatric illness require at least a brief screen for competence in each cognitive domain. In some cases, the history of symptoms or the results of a screening evaluation point toward a cognitive area that needs to be investigated in detail or warrants formal neuropsychological assessment. Rating scales can be particularly useful for diagnostic screening or for following a patient's symptoms over time.

The examiner develops and tests hypotheses during the course of the examination, beginning with observations of behavior and language during the history taking. Observing how the patient behaves during the assessment and how he or she approaches cognitive challenges is essential. Throughout the examination, the *kind* of errors that occur is as important as the *presence* of errors.

A patient may become anxious or defensive during the evaluation. A brief description of the purpose and content of the examination at the beginning usually helps reduce anxiety. The patient should be reminded that "some of these questions may seem relatively easy and others may be very difficult." The evaluation is not an interrogation; an empathic approach improves the interpersonal quality of the interview and increases the reliability of the assessment. In some circumstances, completing the assessment over several brief meetings is preferable to one long examination.

The principal cognitive functions are listed in Table 6-1. These domains are not hierarchical, but competence in some domains is required for adequate performance in others. Adequate *attention* (arousal and concentration) is required for optimal performance of all other cognitive tasks. A patient who is stuporous or markedly distractible will have difficulty with other tasks. Some *executive skills* require competence in other cognitive areas because integrating several elementary cognitive abilities may be necessary. As a result of these two principles, attention is usually assessed at the beginning of the evaluation, and executive skills are often assessed at the end.

## ■ Clinical Mental Status Examination

### Attention

Attention is the ability to focus, sustain, and appropriately shift mental activity. Arousal and concentration both contribute to attention. *Arousal*, alertness, and "level of consciousness" are terms that describe the patient's awareness

**TABLE 6-1. Cognitive domains assessed in the mental status examination**

of stimuli. Level of arousal is evident during the interview and falls along a continuum from fully alert to comatose. Intermediate levels of arousal include lethargy, obtundation, and stupor (Plum and Posner 1982), and these levels are defined by the amount of stimulus required to maintain an awake state. A patient with mild impairment of arousal appears drowsy or may fall asleep during the interview. Marked impairment of arousal can be monitored using the Glasgow Coma Scale (Teasdale and Jennett 1974).

Poor *concentration* is manifest as difficulty focusing on a conversation or task. The patient may be easily distracted by extraneous events in the room, the television, or a sound outdoors. Concentration is further assessed by testing:

1. *Digit span*. The patient is asked to repeat a string of digits that is presented by the examiner at a rate of one digit per second. A string of three digits is initially presented, followed by a string of four digits, then five digits, etc. Repeating a string of at least five digits correctly is considered normal performance.
2. *Reverse digit span*. The examiner presents a string of digits, and the patient is asked to repeat the string in reverse order. Normal aging is associated with a mild decline in the ability to perform reverse digit span, but forward digit span is relatively unaffected by age

(Lezak 1995). Normal elderly can reverse a string of at least three digits.

3. *Serial 7s*. The patient is asked to subtract 7 from 100, and to continue subtracting 7 from the result. Arithmetic skills are a prerequisite for accurate performance, and the patient's educational background and occupation provide clues to the expected level of performance.
4. *Reverse sequences*. The patient is asked to state the days of the week, or the months of the year, in reverse order (e.g., "December, November, October, . . ."). These tasks may be preferable for patients who have limited education or do not routinely work with numbers.
5. *Continuous performance*. The patient is asked to tap the table "each time you hear the letter A." The examiner then presents a string of random letters that contains embedded A's. Letters are presented at a rate of one per second, and the task continues for at least 30 seconds. Errors of omission (not tapping for an A) and errors of commission (tapping for a non-A) are noted. Normally no errors occur.

Arousal is maintained by the reticular activating system. This system originates with cells of the pons and midbrain and projects diffusely to cortical and subcortical regions of the brain via the thalamic projection system. Concentration requires an intact reticular activating system as well as intact cortical (particularly frontal) and limbic structures that focus and modulate attention. Specific disorders of attention are discussed later in this chapter. Patients with impaired arousal or concentration have difficulty with other cognitive tasks because attention is required to stay awake, understand directions, and maintain the mental control required for optimal performance. Thus, all cognitive deficits must be interpreted cautiously when attention is impaired. Diagnoses of dementia or amnesia cannot be reliably made when there is marked disturbance of arousal or concentration.

## Memory

Recent studies have helped to clarify the neuropsychology and neurobiology of memory. The synaptic changes and neuroanatomic systems responsible for various aspects of memory function have been defined (Kupfermann 1991; Tranel and Damasio 1995), and neuropsychological constructs of memory processing and memory subtypes have been elaborated (Baddeley 1995). However, although strategies to assess specific aspects of memory function are available (Lezak 1995), such techniques may be complex

and require instruments not available in typical clinical settings.

For the purpose of routine clinical assessment, memory can be divided into the ability to learn, retain, and recall information. Learning and recall can be assessed using a *word list test*. A list of words is read aloud to the patient who is asked to immediately recall as many words as possible from the list. The process is repeated, using the same list, three or four times. This strategy assesses the patient's immediate or working memory, which requires intact attention. Immediate recall of more words on subsequent trials indicates that learning is occurring. Later in the mental status examination, the patient is asked to recall the word list. Patients with normal memory recall the majority of the words. The examiner should give the patient category clues for those words that are not recalled spontaneously (e.g., "an article of clothing"), followed by multiple choices for words that are not recalled with category clues (e.g., "Was the word 'hat,' 'belt,' or 'shoes'?"). Poor free recall of the word list and inability to recognize the words with clues indicate that the information has not been learned and retained. Poor free recall but accurate recognition of many of the words when given clues suggests dysfunction of the memory retrieval process and indicates that some learning and retention has occurred. Although a word list containing 3 words may suffice for cognitive screening, a longer list of 8–10 words can demonstrate the learning curve and can provide a more sensitive and specific test of learning and recall. *Orientation* questions to test learning and recall of the date and location also assess memory function.

Learning requires the integrity of limbic structures: the medial temporal lobes, the fornix, the dorsomedial thalamic nuclei, and the mammillary bodies (Squire 1987; Tranel and Damasio 1995). Severe memory impairment is usually a result of bilateral or midline brain dysfunction; unilateral brain pathology (often a medial temporal lobe lesion) can cause mild memory impairment. Preferential impairment of verbal memory occurs with left hemisphere dysfunction, whereas impairment in visuospatial memory often occurs with right hemisphere dysfunction (Signoret 1985). Verbal memory is assessed with the word list test. Visuospatial memory can be assessed by asking the patient to reproduce drawings, either immediately after a brief presentation (working memory) or later in the examination (learning, retention, and recall). Alternatively, visuospatial memory can be assessed by asking the patient to locate objects that were previously hidden in the room while the patient observed. Assessing visuospatial memory is particularly important in patients with significant aphasia who may fail verbal memory tests on the basis of language, not memory, deficits.

Tests of *remote memory* assess the ability to recall information that was learned in the distant past. Accurate remote memory requires the integrity of diffuse cortical systems that are required for storage and recall of data. Patients with limbic dysfunction who are unable to learn new information (as in Korsakoff's syndrome or after head trauma or herpes encephalitis) may be able to recall information that was learned before limbic disturbance. Remote memory is assessed by asking the patient to recall historical data: birthplace, family birthdays, work history, past presidents, or details of important historical events. For reliable assessment, the correct information must have clearly been learned in the past by the patient (and be known by the examiner). Therefore, it is helpful to validate remote memory loss with collateral sources.

## Language

Language skills are essential for human communication. Language competence is also required for accurate performance in other cognitive domains because most of the information essential to routine cognition is verbally mediated. Right- or left-*handedness* should be noted in the examination because handedness predicts which hemisphere is dominant for language. Nearly all right-handed individuals and the majority of left-handers are left hemisphere dominant for language. Some left-handers, particularly those with a strong family history of left-handedness, have language function distributed across both hemispheres.

Language assessment explores four principal areas: spontaneous verbal output, comprehension, repetition, and naming. *Spontaneous verbal output* is evaluated during the clinical interview by listening to the linguistic features of the patient's discourse. Dysarthria, a motor disorder of speech, is distinguished from aphasia, a disorder of language. Two categories of aphasia in the patient's spontaneous verbal output are considered. In *fluent aphasia*, language output is generally effortless, with normal or increased number of words per minute, normal melody and inflection (prosody), and normal phrase length. Paraphasias, or intrusions of incorrect words or phonemes, can occur (e.g., "I was *leading* the newspaper"). The information content, or "efficiency" of language, is usually low: long sentences may contain many grammatical connecting words, nonspecific nouns ("thing," "the other one"), and limited meaning ("empty speech"). *Nonfluent aphasia*, in contrast, is characterized by effortful but reduced word output, short phrase length, and dysprosody. Dysarthria is often present and sentences efficiently convey meaning with few words. Grammar and syntax are usually abnormal.

Fluent aphasia occurs with lesions of the posterior left hemisphere, whereas nonfluent aphasia occurs with lesions of the left frontal cortex or underlying white matter.

*Comprehension* is assessed by asking the patient to

1. *Follow simple commands.* Single-step or multiple-step commands are given, such as “Point to your nose” or “Point to the window, then to the floor, and then to the chair.”
2. *Follow commands, using objects.* Several items are placed on the table (e.g., a pen, a key, a paper clip, and a nickel). The patient is asked to follow instructions, such as “Touch the pen, then pick up the paper clip,” or “With the key, touch the nickel, then point to the floor.”
3. *Answer yes/no questions.* Examples are “Does a rock float on water?” and “Do you put your shoes on before your socks?”

Reading comprehension can be assessed by presenting similar commands and questions to the patient in writing. Reduced hearing in the elderly can contribute to impaired performance with spoken commands. Language comprehension deficits occur with dysfunction of the left posterior temporal or parietotemporal cortex.

*Repetition* is assessed by asking the patient to repeat sentences of increasing length and linguistic complexity. Abnormal repetition occurs with disruption of perisylvian structures of the left hemisphere.

A disturbance of *naming* may be evident as word-finding difficulty in the course of spontaneous speech. Naming is further assessed by asking the patient to identify objects or parts of the body. Both high-frequency names (elbow, nose, shoe, watch, pen) and low-frequency names (eyebrow, earlobe, sole of the shoe, watch crystal) are tested. Poor naming may result from focal brain lesions (usually the left inferior parietal lobule) or with diffuse hemispheric dysfunction. Other tasks, such as *verbal fluency* (asking the patient to name as many animals as possible in 1 minute), *reading skills*, and *writing ability*, can help identify specific aphasic disorders and can provide additional information on regional brain function (Strub and Black 1993). The syndromes of aphasia are discussed later in this chapter.

## Visuospatial Skills

Visuospatial impairment is one of the most sensitive indicators of brain dysfunction. Patients with mild delirium or with posterior brain lesions that are otherwise neurologically silent may have marked visuospatial deficits. In con-

trast, patients with primary psychiatric illness usually have minimal difficulty with visuospatial tasks.

Visuospatial skills include visually guided attention, perception, use of internal visual images, visuospatial memory, and constructional abilities. The history can reveal important evidence of visuospatial impairment: getting lost in previously familiar environments, difficulty estimating distance, or difficulty orienting objects to complete a task. Visuospatial skills can be clinically assessed by asking the patient to copy drawings provided by the examiner or by asking the patient to spontaneously draw a clockface, a house, or a person. Drawings to be copied should include a simple geometric shape, a design that is not easily verbally described, and a complex drawing with three-dimensional perspective. Examples are shown in Figure 6–1. The patient’s drawings may reveal a variety of visuospatial errors: poor use of the space available to draw, hemineglect, unusual drawing strategy (focusing on detail while missing overall layout), overlapping or “closing in” on the stimulus drawing, loss of details, loss of three-dimensionality, or poor spatial relationships among elements of the drawing (reversals, rotations, inaccurate angles). Examples of inaccurate reproduction drawings are shown in Figure 6–2. Asking the patient to draw a clockface and put hands on the clock to indicate a particular time may rapidly reveal a visuoconstructive deficit (Mendez et al. 1992) and may reveal impaired executive skills (Royall et al. 1998). Visual acuity and motor skills are obviously required for accurate drawing. Complete understanding of visuospatial deficits may require formal neuropsychological assessment using standardized tests of block design, object assembly, and line orientation (Lezak 1995).

Visuospatial impairment is more common and usually more severe among patients with a focal brain lesion in the posterior hemisphere (Black and Strub 1976). Patients with right hemisphere lesions more often have visuospatial deficits than those with left hemisphere lesions. Characteristic visuoconstructive deficits that depend on the laterality of brain injury have been identified, although the specificity of these findings is limited (Benson and Barton 1970). Features of the deficits associated with lateralized lesions are shown in Table 6–2. Executive skills, in addition to visuospatial abilities, are apparent in the organizational strategy used by the patient to draw a figure (e.g., Figure 6–2, *panel B*).

Among the elderly, visuospatial disturbance is a sensitive indicator of *delirium* and can occur in any *dementia* syndrome. Patients with *Alzheimer’s disease* typically have visuospatial impairment early in the course of illness. Visuospatial impairment may also occur with a *focal brain lesion* resulting from cortical infarction or tumor.

**FIGURE 6-1.** Examples of designs to be reproduced to assess visuospatial skill. *Panel A:* Simple geometric shapes. *Panel B:* Designs that are not easily verbally described. *Panel C:* Three-dimensional designs.

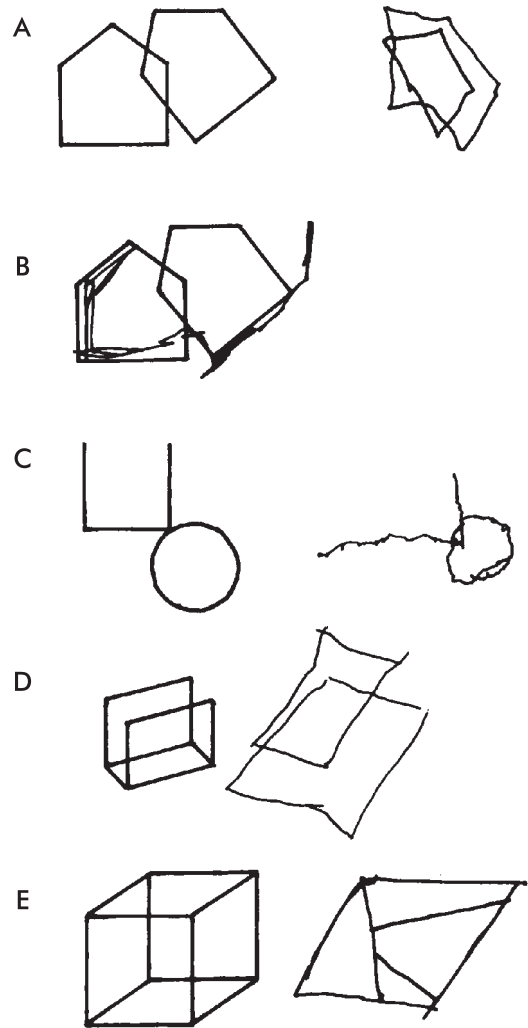

## Calculation

Calculation skill is assessed by asking the patient to perform simple addition and multiplication (e.g.,  $7 + 6$ ,  $5 \times 7$ ,  $8 \times 9$ ) and then more difficult arithmetic (e.g.,  $18 + 29$ ,  $15 \times 7$ ) without using paper and pencil. Calculation is further assessed by asking the patient to answer arithmetic questions with paper and pencil (e.g.,  $129 + 87$ ,  $423 \times 18$ ). The ability to perform calculations requires attention, an understanding of mathematic operations (addition, subtraction, multiplication, division), memorized knowledge of simple sums and the “times table,” and the visuospatial ability to maintain number alignment. The patient’s educational background and premorbid arithmetic skills must be considered in assessing current performance.

Dyscalculia may result from a variety of neurological conditions. Patients with impaired concentration as a result of delirium usually perform poorly, as do patients with diffuse degenerative brain conditions such as Alzheimer’s disease. Dyscalculia has been demonstrated in patients with focal involvement of a wide range of brain regions, although it often occurs in association with aphasia and is most common with lesions of the dominant parietal lobe (Luria 1980).

## Executive Skills

Executive skills are those mental abilities that facilitate performance of complex cognitive tasks or behaviors. A con-

**FIGURE 6-2.** Examples of inaccurate reproduction drawings. The design to be reproduced is shown on the left; the patient’s reproduction is to the right. *Panel A:* Inaccurate angles and rotation of one of the pentagons; patient with delirium. *Panel B:* Stimulus boundedness; the patient’s drawing overlaps the stimulus figure; patient with Alzheimer’s disease. *Panel C:* Missing parts of the design and evidence of tremor; patient with Alzheimer’s disease. *Panel D:* Missing parts of the design and loss of three-dimensionality; patient with vascular dementia. *Panel E:* Simplified drawing with loss of three-dimensionality; patient after resection of a left occipital astrocytoma.

stellation of skills that extend beyond memory, language, and visuospatial competence is included: planning strategies to accomplish tasks, implementing strategies, adjusting strategies as needed, monitoring performance, recognizing patterns, appreciating time sequence, and formulating abstract ideas (Duffy and Campbell 1994; Tranel et al. 1994). Such skills are critical for routine daily activities. Executive deficits are associated with disruptive

**TABLE 6-2. Visuoconstructive deficits characteristic of left-hemisphere versus right-hemisphere brain lesions**

**Left-hemisphere lesions**

- Few lines in drawings
- “Simplified” drawings with few details
- Preserved symmetry of drawings
- Drawing is done slowly
- Drawing skill improves with practice

**Right-hemisphere lesions**

- Complicated structure and elaborate details
- Extra lines in drawings; extraneous scribbling
- “Piecemeal” approach to drawing
- Particular impairment of three-dimensional drawings
- Left hemineglect
- Drawing is done rapidly
- Drawing skill does not improve with visual cues or

behaviors and self-care limitations among patients with Alzheimer’s disease (Chen et al. 1998) and among heterogeneous groups of community-dwelling and institutionalized elderly (Royall et al. 1992).

Executive skills can be divided into four categories: drive, programming, response control, and synthesis (Table 6-3). These categories provide a useful framework for assessing executive function, although there is overlap among the categories. Executive skills can be adequately assessed in the clinic, although an informant’s description of the patient’s ability to accomplish tasks, negotiate social situations, and respond to environmental contingencies can be particularly revealing (Malloy and Richardson 1994).

Drive includes the initiation of cognitive activity and sustained motivation to perform tasks. Drive is subjectively assessed during the mental status examination. Reduced drive usually has a marked impact on performance in other cognitive domains.

Programming is the ability to recognize patterns and to generate motor programs to perform motor sequences. Two ways that programming skill can be assessed include

1. *Alternating programs.* The examiner provides the patient with an alternating pattern. The patient is asked to copy the pattern and continue the pattern across the page. Examples of inability to generate or maintain a pattern are shown in Figure 6-3.
2. *Hand sequences.* The patient is asked to perform a three-step hand sequence: “slap” (palm down on the

table), “fist” (hand in a fist on the table), and “cut” (side of the hand on the table) (Christensen 1975). The examiner demonstrates the sequence, and then the patient attempts to produce the sequence. Normally, a subject will learn to perform the pattern smoothly after about five trials. If there is difficulty, the patient is encouraged to “say the words out loud as you do each step” (“slap,” “fist,” “cut”). Inability to produce smooth three-step sequences and verbal-manual dissociation (saying “fist,” while doing “slap”) are noted.

Response control is the ability to plan and efficiently execute a strategy to complete a complex cognitive task. Mental flexibility and a balance between independent thought and use of environmental cues are required for response control. Tasks that assess response control at the bedside include

**TABLE 6-3. Categories of executive skills**

Category	Executive skills
<b>Drive</b>	Spontaneous initiation of activity Motivation Sustained performance
<b>Programming</b>	Recognizing patterns Recognizing timing sequence Fluid output of alternating or rhythmic patterns
<b>Response control</b>	Divided attention Inhibition of incorrect responses Nonperseverative responses Cognitive speed and fluency Planning; ordering the steps to accomplish a task Mental flexibility: changing strategies, as required Use of memory to adjust performance Use of feedback to adjust performance Freedom from environmental dependence: ability to resist imitation, utilization, or stimulus-bound behavior
<b>Synthesis</b>	Abstraction Similarities Proverb interpretation Monitoring cognitive performance Anticipation

**FIGURE 6-3.** Alternating patterns. The patient is asked to copy the pattern (shown at the top of each example) and to continue the pattern across the page. *Panel A:* The patient's drawing initially moves toward the stimulus and the alternating pattern deteriorates as it continues across the page. *Panel B:* The patient's drawing "closes in" on the stimulus and is not continued after the stimulus ends. The patient, with mild dementia and severe bifrontal hypoperfusion on SPECT scan, was able to understand and repeat the instructions. *Panel C:* Marked inability to maintain the alternating pattern.

1. *Divided attention.* The patient is asked to continue the sequence, "1-A, 2-B, 3-C, . . ."
2. *Verbal fluency.* The patient is asked to name as many animals as possible in 1 minute. Alternatively, the patient is asked to name as many words as possible that begin with the letter "F." Initiation, strategy, and perseveration are noted. Normal performance is at least 12 animals or 10 "F" words in 1 minute.
3. *Reciprocal programs and "go/no-go."* The patient is asked to tap the table twice if the examiner taps the table once and to tap once if the examiner taps twice (reciprocal programs). The examiner then randomly taps once or twice and notes the patient's response. When this task is mastered (usually after only a few presentations), the patient is told, "Now I am going to change the rule. If I tap once, you tap twice, but if I tap twice, you should not tap at all" (go/no-go). The patient's ability to respond to the rule change and to resist the impulse to tap is noted.
4. *Multiple loops.* The patient is asked to draw a set of loop figures with the same number of loops as drawn

by the examiner. Perseveration of loop drawing is noted, as shown in Figure 6-4.

5. *Clock drawing strategy.* The patient is asked to draw a clockface. The spontaneous reproduction reveals executive function, as well as visuospatial ability. Planning and organization are observed. Poor spacing of clockface numbers or perseveration can occur (Figure 6-5), as well as incorrect representations on the clockface (Figure 6-6).
6. *Stimulus boundedness.* The patient is asked to draw the hands on a clockface as they would appear when the time is 11:10. The patient may be unable to resist placing the hands on the stimulus numbers (11 and 10) (Figure 6-7). In another task, the examiner writes the word "brown" in large black letters. The patient is asked to name the *color* that the word is written in. The patient may be unable to ignore the *word* "brown." Stimulus boundedness may also appear in a patient's reproduction drawings with over-drawing of the stimulus figure (Figure 6-2, *panel B*).
7. *Imitation behavior.* The examiner rapidly flexes and extends her or his thumb, while pointing to it with the other hand. The patient is asked, "What is this finger called?" Spontaneous movement of the patient's thumb is noted.

**FIGURE 6-4.** Multiple loops. The patient is asked to draw loop figures that contain the same number of loops as the examples provided by the examiner (*top*). The patient, who had recently undergone resection of a left frontal astrocytoma, had great difficulty terminating each loop figure drawn with her right hand, which felt "out of control" (*panel A*). She was able to draw the correct number of loops with her left (nondominant) hand (*panel B*).

**FIGURE 6-5.** Poor planning and perseveration on the clockface drawing. The patient, with moderate subcortical dementia and parkinsonism, was asked to put numbers on the clockface in their appropriate places. The spacing between numbers on the patient's drawing is not correct for 12 evenly spaced numbers, and there is perseveration of micrographic number writing up to 40. The patient was able to correctly state that a clock has 12 numbers on it and was able to put all 12 numbers in correct position on a clockface (not shown), when the examiner dictated the numbers to him one by one in random order.

**FIGURE 6-6.** Intrusion on the clockface drawing. The patient's clockface has a "12" at the top but then includes representations of time in digital format. The intrusion of digital time and the mismatch between time as conventionally written and the true appearance of a clockface reflect the executive deficit. Numbers are also incorrectly located on the clockface and the sequence continues beyond 12:00. The patient has a history of heavy alcohol use and moderate dementia.

Synthesis is the ability to appreciate metaphoric meaning, form an intellectual gestalt, and monitor cognitive performance. These skills are influenced by educational background. Clinical assessment includes evaluation of

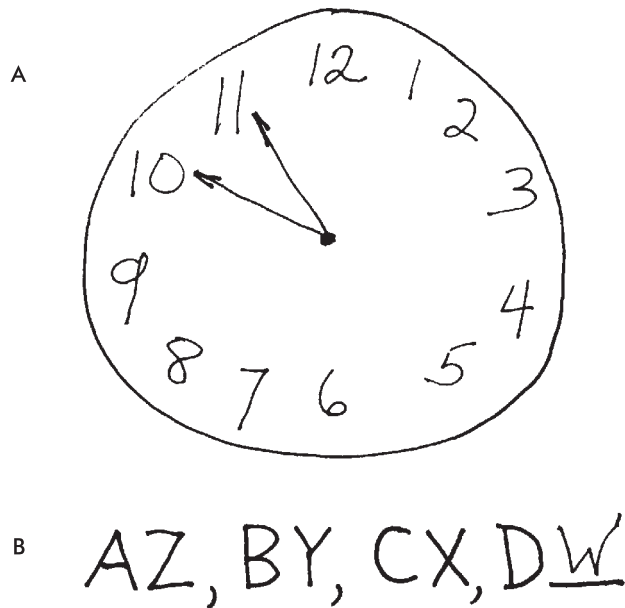

1. *Similarities.* The patient is asked to describe how a pair of words are alike. Examples are: rabbit/elephant, bicycle/train, watch/ruler.
2. *Proverbs.* The patient is asked to describe the meaning of a proverb, such as "Don't change horses in the middle of a stream." The patient's appreciation of the abstract meaning is noted.
3. *Monitoring.* The patient's ability to learn from errors and to self-correct while performing cognitive tasks is observed during the examination.

Executive skills require the integrity of diffuse or multifocal neuronal systems. Drive, programming, and response control depend on intact function of discrete circuits that include the frontal cortex, basal ganglia, thalamus, and connecting white matter tracts (Malloy and Richardson 1994; Mega and Cummings 1994). These skills are often impaired with frontal lobe damage (Grafman

1994; Mesulam 1986; Shallice and Burgess 1991; Stuss and Benson 1986; Stuss et al. 1994), although they may occur in patients with focal lesions or degenerative processes distant from the frontal cortex (Criepe 1996; Stuss et al. 1994; Tranel et al. 1994).

Performance on some structured tests of executive skills declines in psychiatrically healthy people after age 60 (Tranel et al. 1994). More extensive impairment of executive skills can result from a variety of conditions: toxic/metabolic disturbance, cerebrovascular disease, head trauma, cerebral neoplasm, cerebral or systemic infection, and degenerative brain diseases such as Alzheimer's disease, frontotemporal dementias, and Parkinson's disease (Duffy and Campbell 1994; Royall and Polk 1998). Older patients with schizophrenia can also exhibit deficits in executive skills (Almeida et al. 1995) (Figure 6-7). Drive, programming, and response control may be particularly impaired in older patients with dysfunction of frontal cortex, as in Pick's disease, frontal lobe degeneration, and some cases of Alzheimer's disease, or with disruption of frontal-subcortical circuits that occurs in basal ganglia disorders such as Parkinson's disease or Huntington's disease. Patients with vascular dementia as a result of cerebrovascular

**FIGURE 6-7.** Stimulus boundedness. The patient is asked to put the hands on the clock as they would appear when the time is 11:10. *Panel A:* The hands are placed on the “11” and the “10,” as the patient is unable to resist the stimulus numbers. This example was drawn by a 73-year-old man with schizophrenia, who showed no evidence of memory, language, calculation, or visuospatial deficits. Other executive skills were intact; he was able to correctly identify the letter that follows the “D” in the sequence of letters shown in *panel B*.

disease in subcortical nuclei or white matter tracts that link frontal cortex to other brain regions frequently demonstrate executive deficits (Duffy and Campbell 1994; Ishii et al. 1986).

### Other Cognitive Skills

**Apraxia.** The term “apraxia” is used with variable meaning. Generally, it refers to the inability of a patient with normal elementary motor function to execute the required sequence of skilled movements to complete a complex motor task (Luria 1980). In “dressing apraxia,” for example, the coordinated sequence of movements required to put on clothes is disrupted: the steps are out of order or coordinated simultaneous movements do not occur. This type of apraxia (*ideational apraxia*) usually reflects right parietal or bilateral diffuse brain dysfunction.

In *ideomotor apraxia*, the patient is unable to pantomime a motor task on command that can be performed spontaneously (Geschwind 1975). Ideomotor apraxia is revealed by asking the patient to briefly pantomime a motor act that involves muscle groups of the face, trunk, or limbs.

Examples include, “Show me how you blow out a match, . . . suck through a straw, . . . hold a baseball bat, . . . wave good-bye, . . . brush your teeth.” Ideomotor apraxia is an inability to smoothly perform the movement altogether or the substitution of a part of the body for the imitated object (e.g., substituting a finger for the toothbrush). Ideomotor apraxia reflects left hemisphere dysfunction or lesion of the anterior corpus callosum.

**Agnosia.** Patients with agnosia have intact primary sensation and normal perception but lack the ability to recognize or associate meaning to the sensory perception. In *visual agnosia*, the patient can “see” the outline, color, and lighting of an object but is unable to recognize what the object is or what it is used for (Benson and Greenberg 1969). Visual agnosia occurs with bilateral lesions of visual association cortex. Patients with *prosopagnosia* have normal visual perception and do not have visual agnosia, except for impaired recognition of familiar faces. In *environmental agnosia*, the patient can describe details of a familiar environment, but the scene lacks any sense of familiarity (Landis et al. 1986). In *astereognosis*, the patient with normal somatosensory perception is unable to recognize an object by tactile exploration with eyes closed (Adams et al. 1997). Agnosia in an elderly patient is usually caused by a discrete cortical infarction.

## ■ Syndromes of Cognitive Impairment

### Disorders of Attention

Abnormal attention is the hallmark of *delirium*, or acute confusional state, which is one of the most common causes of behavioral disturbance among hospitalized elderly (see Chapter 19 in this volume). Poor attention is also an important clinical feature that distinguishes delirium from dementia (see Chapters 23 and 24 in this volume).

Reduced arousal occurs on a spectrum: drowsiness, obtundation, stupor, or coma. These states occur with impairment of the reticular activating system or widespread cortical dysfunction. Conditions that cause reduced arousal in older patients include: brainstem infarction or compression, metabolic disturbances, drug intoxication, bilateral cortical infarction, brain infection, and head trauma. *Increased arousal* with anxiety, hypervigilance, and signs of autonomic activation can occur with drug intoxication (stimulants), drug withdrawal (alcohol, benzodiazepine, opioid, or barbiturate), or metabolic disturbances.

Akinetic mutism and catatonia resemble the syndrome

of reduced arousal. Patients with *akinetie mutism* appear alert and may follow stimuli with their eyes. However, spontaneous movement and speech are rare and tend to occur in brief episodes in response to vigorous stimulation (Benson 1990; Mega and Cummings 1994; Plum and Posner 1982). Akinetic mutism is caused by lesions of the midbrain, bilateral cingulate gyri, or septal area. Patients with *catatonia* can present with a variety of motor signs and alterations of attention, including reduced response to stimuli, mutism, posturing, waxy flexibility, and repetitive stereotypic movements (Taylor 1990). Catatonia may occur in patients with schizophrenia, mood disorders, diffuse neurological illness, or metabolic disorders. Focal brain lesions can also cause catatonia. Lesions of the frontal lobes or subcortical structures are most often implicated.

Unilateral *neglect* is a syndrome of inattention to half the body or half the external space. In sensory neglect, sensory input from one hemispace is neglected or extinguished. Sensory neglect can occur in a single sensory modality (e.g., somatosensory, visual) or can be multimodal. In motor neglect, movement in or toward one hemispace is reduced. Neglect of the left hemispace occurs more frequently than neglect of the right hemispace. The extent of neglect does not depend on the extent of primary sensory or motor impairment. With either sensory or motor neglect, the patient is strikingly unaware of the neglected half-space. Sensory neglect usually occurs with right parietal dysfunction, and motor neglect can occur with frontal lesions, although the neuroanatomic specificity of the sensory versus motor components of neglect syndromes is limited (Mesulam 1985).

Patients with normal arousal but poor *concentration* appear awake and alert, but they are easily distracted and have difficulty focusing on cognitive tasks. Poor concentration can result from dysfunction of the brainstem, midbrain, limbic system, or diffuse cortical systems that modulate and focus mental activity. Poor concentration can occur either with metabolic, toxic, or infectious conditions that affect brain function diffusely or with bilateral cortical lesions, as in head trauma or bilateral infarction. The prefrontal cortex and anterior cingulate appear to play important roles in modulating concentration (Knight 1991; Stuss et al. 1995). Older patients with primary psychiatric disorders such as schizophrenia, mania, major depression, and dissociative states may also have reduced ability to concentrate.

## Memory Disorders

*Amnesia* is the inability to learn new information. Patients with amnesia are often able to recall information that was

learned before the onset of the memory disorder. *Anterograde amnesia* is the inability to learn during the time that begins with cerebral insult and extends forward in time. *Retrograde amnesia* refers to the lack of recall for events that occurred during the period preceding the cerebral insult. Amnesia occurs with bilateral damage to the medial temporal lobes or midline limbic structures. Conditions that cause amnesia in the elderly include dementia, head trauma, posterior cerebral artery occlusion, anoxia, neoplasms involving midline limbic structures, herpes encephalitis, and Korsakoff's syndrome. Many of these conditions cause cognitive deficits in addition to amnesia, although those affecting only medial temporal or midline limbic structures, such as Korsakoff's syndrome, may result in isolated memory impairment. With stable neurological lesions, anterograde amnesia can improve over time and there can be concomitant shrinkage of the period of retrograde amnesia.

Age-associated memory impairment is the term applied to subtle alterations in recent memory that occur with normal aging (see Chapter 8 in this volume). The elderly often describe a subjective sense of poor memory, may require more trials to learn a word list, and may be less efficient in memory retrieval.

Memory impairment along with other cognitive deficits occurs in patients with dementia. Patients with *Alzheimer's disease* have difficulty learning new information (anterograde amnesia) as well as difficulty recalling information that was learned before onset of the dementia. The recall deficit is a result of widespread impairment of diffuse cortical systems that are required for continued storage and recall of memory and may be mild in the early stage of illness. In *frontotemporal dementias* including Pick's disease, memory impairment often occurs after the onset of behavioral changes, whereas in Alzheimer's disease, memory or language impairment is often the first indication of illness. In *subcortical dementias*, such as those associated with Parkinson's disease or Huntington's disease, memory impairment usually occurs early in the course of dementia, as in Alzheimer's disease. However, the memory impairment of subcortical dementia is characterized by improvement in recall when clues are given, spared recognition memory, and relatively spared declarative memory (facts, knowledge) compared with procedural memory (acquisition of motor skills or cognitive strategies) (Huber and Shuttleworth 1990; Tranel and Damasio 1995). The memory impairment of patients with Alzheimer's disease does not markedly improve when clues are given and deficits in declarative memory are greater than deficits in procedural memory (Cummings and Benson 1992).

## Aphasia

Syndromes of aphasia are distinguished by the pattern of specific language skills that are impaired: fluency, comprehension, repetition, or naming (Cummings 1985; Goodglass and Kaplan 1983). The principal aphasia syndromes, the specific language skills that are impaired in each syndrome, and the region of the brain involved are shown in Table 6-4. The disorders of language provide relatively sensitive and specific indications of regional brain dysfunction.

Among elderly patients with language impairment and no other cognitive deficits, the aphasia syndromes usually occur as a result of *infarction*, *hemorrhage*, or *tumor* that affects the brain regions identified in Table 6-4. Occlusion of the left middle cerebral artery causes global aphasia and right hemiparesis, if the occlusion disrupts perfusion of a wide area of the left hemisphere. If the occlusion is more distal, Broca's aphasia, conduction aphasia, or Wernicke's aphasia may occur, depending on the vascular territory that is compromised. Border zone infarctions, resulting from anoxia, hypotension, or carotid stenosis, affect the watershed regions between the vascular territories served by the anterior, middle, and posterior cerebral arteries and produce transcortical motor or transcortical sensory aphasia.

Elderly patients with dementia often have aphasia along with other cognitive deficits. The involvement of language skills depends on the distribution of brain lesions that cause the dementia. In *Alzheimer's disease*, a characteristic pattern of language disturbance occurs. Very early in the illness, word-finding difficulty and mild anomia are usually present. Subsequently, "empty speech" (language output that contains little information), mild comprehension deficit, and reduced fluency (e.g., measured as number of animals named per minute) occur. Paraphasias may be apparent in spontaneous speech. Elements of transcortical sensory aphasia occur during the course of Alzheimer's disease, reflecting the concentration of neuropathological changes of Alzheimer's disease in the inferior parietal lobe.

In *vascular dementia*, speech abnormalities are more common than in Alzheimer's disease (Sultzer et al. 1993). Language disturbance also occurs. The characteristics of language impairment depend on the brain regions affected by cerebrovascular disease. In general, patients with vascular dementia are more likely to have nonfluent aphasia than are patients with Alzheimer's disease and less likely to have naming impairments (Cummings and Mahler 1991). Marked impairment of language does not occur in patients with dementia associated with *subcortical extrapyramidal disorders* (Huber and Shuttleworth 1990).

**TABLE 6-4. Principal syndromes of aphasia**

Aphasia syndrome	Language skills				Regional brain dysfunction <sup>a</sup>
	Fluency	Comprehension	Repetition	Naming	
Broca's	Nonfluent	Intact	Impaired	Impaired	Left frontal operculum, left insular cortex, and adjacent white matter
Transcortical motor	Nonfluent	Intact	Intact	Impaired	Left supplementary motor area
Global	Nonfluent	Impaired	Impaired	Impaired	Wide area of left hemisphere convexity
Wernicke's	Fluent	Impaired	Impaired	Impaired	Posterior, superior left temporal lobe; left inferior parietal lobe may also be involved
Transcortical sensory	Fluent	Impaired	Intact	Impaired	Left inferior parietal lobule
Conduction	Fluent	Intact	Impaired	Impaired	Left arcuate fasciculus (usually in the left parietal operculum) or left insula and adjacent white matter
Anomic	Fluent	Intact	Intact	Impaired	Left angular gyrus or left posterior middle temporal gyrus

<sup>a</sup>In patients with left hemisphere dominance for language.

## Frontal Lobe Disorders

The frontal lobe disorders are particularly important in neuropsychiatric evaluation of the elderly because the brain lesions that are responsible are often not detected by the traditional neurological examination and the psychiatric symptoms that occur do not usually fit the characteristic pattern of common psychiatric disorders. Patients with frontal lobe disorders often present with unusual combinations of cognitive, psychiatric, and behavioral symptoms. Neuropsychiatric symptoms that occur in each of the three principal frontal lobe syndromes and those symptoms that are not well localized to specific frontal subregions are shown in Table 6-5 (Malloy and Richardson 1994; Mega and Cummings 1994; Salloway 1994; Stuss and Benson 1986). Symptoms may occur with a lesion in specific regions of the frontal cortex or in linked cortical or subcortical structures. Lesions in subcortical nuclei or white matter tracts may have marked effects on frontal function (Sultzer et al. 1995a). The relationship between anatomy and symptomatology is incomplete: patients with extensive frontal dysfunction may not manifest the full spectrum of "frontal" symptoms, and these symptoms may occur following lesions outside the frontal circuits.

The *medial frontal syndrome* is primarily a disturbance of motivation and includes a range of symptoms from mild disinterest to akinetic mutism (Stuss and Benson 1986). Spontaneity, blunted affect, and reduced spontaneous movement may occur. The syndrome occurs with lesions of the anterior cingulate gyrus, ventral striatum, medial dorsal thalamus, or tracts that connect these structures. More severe symptoms usually occur with bilateral lesions. Conditions that cause the medial frontal syndrome in the elderly include anterior cerebral artery occlusion, thalamic infarction, hydrocephalus, and tumors of the diencephalon or third ventricle.

Lesions of the *dorsolateral frontal convexity* produce a syndrome of disorganized cognitive performance (Fuster 1997; Malloy and Richardson 1994). Executive dysfunction often appears on the mental status examination, including perseveration (e.g., extra loops on the multiple loops, intrusion of a prior response in a new task), impaired motor programming, stimulus-bound behavior, difficulty with alternating programs or changing mental set, or reduced verbal or design fluency. Dorsolateral frontal convexity insults include head trauma, frontal infarction, frontal lobe tumor, and degenerative dementias, particularly those that preferentially affect frontal structures. Lesion of the dorsolateral caudate nucleus may produce a similar pattern of executive deficits.

The *orbitofrontal syndrome* occurs with lesions of the

inferior aspect of the frontal lobe. This region of the frontal lobe is intimately associated with the limbic system, and dysfunction often appears as a striking change of personality (Duffy and Campbell 1994). Disinhibition and aggression are common, and patients may show a marked inability to conform behavior to social customs (Salloway 1994). Mood is often expansive or irritable, affect is labile, and impulsive outbursts of jocularity can occur. When lesions are confined to the orbitofrontal cortex, there may be no formal neurological deficits or other cognitive deficits. Orbitofrontal damage occurs with head trauma, inferior

**TABLE 6-5. Neuropsychiatric symptoms that occur with lesions of the frontal lobe or related subcortical structures**

Site of lesion	Symptoms
Medial frontal	Low motivation Blunted affect Motor retardation Reduced verbal output Grasp reflex
Dorsolateral frontal convexity	Poor selective attention Deficits in working memory Perseveration Excessive stimulus dependence Impaired motor programming Motor impersistence Reduced verbal or design fluency
Orbitofrontal	Disinhibition Failure to appreciate social customs Childlike jocularity Labile affect Expansive mood Irritability Lack of empathy
Heterogeneous frontal cortical regions	Apathy Impulsivity Poor directed attention Poor sustained attention Difficulty with temporal sequencing Inability to change rules

frontal meningiomas, rupture of anterior cerebral artery aneurysms, and frontal dementias.

## ■ Screening for Cognitive Impairment

My focus in this chapter is on comprehensive cognitive assessment, but some clinical settings may not be ideally structured to complete a thorough evaluation. Detection rate for dementia in some care settings is low (Callahan et al. 1995; Eefsting et al. 1996). Screening can improve case detection and is most important when the prevalence of cases in the clinic population is high.

Efficient screening can be accomplished by asking questions related to cognitive decline in the patient's history or by very brief mental status testing. A complaint of cognitive difficulty may emerge spontaneously or the clinician can ask if the patient has difficulty learning new information, handling complex tasks, finding his or her way, or using words correctly. Functional abilities can be rapidly assessed using tools such as the Functional Activities Questionnaire (Pfeffer et al. 1982), which has good discriminant ability (Costa et al. 1996). Brief tests such as the Blessed Orientation-Memory-Concentration Test (Katzman et al. 1983) can quickly measure a patient's overall cognitive abilities and are described in the next section of this chapter. Screening techniques will not reveal all cases with cognitive impairment, particularly when deficits are mild, and do not substitute for a complete assessment, but they can facilitate recognition of cases that might otherwise be missed. When screening reveals possible impairment, the patient should undergo more thorough diagnostic assessment to determine the extent and etiology of cognitive deficits.

## ■ Rating Scales for Cognitive Assessment

Rating scales can be used to screen for cognitive impairment, provide a framework for more thorough clinical assessment, or quantify the results of a mental status examination. Measurement of cognitive deficits allows the clinician to identify changes over time or to determine the response to treatment. Structured assessment also facilitates reliable communication among clinicians.

Many different rating scales are available, and reviews of their use have been published (Camicioli and Wild 1997; Kluger and Ferris 1991; Raskin and Niederehe 1988; Siu 1991; Weiner et al. 1996). Rating scales differ in the time required for administration and the spectrum of symptoms

assessed (cognition, functional skills, psychiatric symptoms, behavior disturbance). Some scales are screening instruments; others are more comprehensive. Some scales provide subscores for individual cognitive domains, whereas others generate only an overall score. Each rating scale accomplishes a different clinical goal:

1. *Blessed Orientation-Memory-Concentration Test*, a six-item screening instrument that assesses concentration and memory (Katzman et al. 1983). Sensitivity, specificity, and diagnostic value of this brief instrument are acceptable and comparable to those of longer instruments (Stuss et al. 1996).
2. *Short Test of Mental Status*, a brief screening instrument (Kokmen et al. 1987). The eight items assess attention, orientation, memory, calculation, and visuoconstructive skill. Sensitivity has been shown to be acceptable.
3. *Mini-Mental State Examination (MMSE)*, a 30-item instrument that is widely used to screen for cognitive impairment and to assess the severity of impairment (Folstein et al. 1975). The examination takes about 10 minutes and provides a reliable overall cognitive score. Sensitivity for mild impairment is limited (Tombaugh and McIntyre 1992), and older individuals with low "normal" scores are at high risk for developing dementia over subsequent years (Braekhus et al. 1995). Age and educational level must be considered in interpreting the MMSE score (Crum et al. 1993).
4. *Neurobehavioral Cognitive Status Examination*, which assesses attention, memory, calculation, visuoconstructive skills, language, and abstraction. A subscore for each of these cognitive domains is generated (Kiernan et al. 1987). The examination requires specific testing materials and takes about 20 minutes to complete with an impaired patient.
5. *Mattis Dementia Rating Scale*, which assesses a wider range of cognitive skills, including executive abilities (Mattis 1976). The instrument requires about 30–45 minutes to complete with an impaired patient. It provides an overall cognitive score, with a maximum of 144 points.
6. *Neurobehavioral Rating Scale*, a 28-item instrument that measures psychiatric and behavioral disturbances, in addition to cognitive impairment (Levin et al. 1987). The evaluation takes about 40 minutes to complete. The instrument provides six factor scores that measure the cognitive and noncognitive symptoms (Sultzer et al. 1992); reliability and validity are acceptable (Sultzer et al. 1995b).

7. *Global Deterioration Scale*, a seven-point scale that measures the overall severity of dementia (Reisberg et al. 1988). Cognitive deficits, psychiatric symptoms, and functional impairment are all considered by the clinician in assigning the global severity score.
8. *Executive Interview*, a brief measure of executive skills (Royall et al. 1992). Measures of executive skills may help to clarify diagnosis (Royall and Polk 1998) and suggest risk for impairment in activities of daily living or behavioral disturbance (Chen et al. 1998).

## ■ Functional Assessment

The ability to accomplish functional activities at home is important information that complements the assessment of cognitive skills in the mental status examination. Reduced functional skills can be a sensitive indicator of dementia (Barberger-Gateau et al. 1992; Costa et al. 1996). Functional assessment also reveals the impact of medical problems and cognitive deficits on living skills and indicates the need for assistance with activities, which are both of prime importance to the patient and family.

At least a brief review of functional skills should be included in the assessment of each geriatric patient, and whether the patient currently drives a car should be noted. Two groups of activities are considered in functional assessment: physical activities of daily living (ADLs) and instrumental activities of daily living (IADLs) (Lawton and Brody 1969). Physical ADLs include the basic skills required for self-maintenance: dressing, bathing, toileting, transferring, and feeding. IADLs include more complex skills required for independent living: shopping, cooking, housekeeping, laundry, using the telephone, using transportation, managing money, and managing medications. An observer determines whether the patient is independently able to perform each of these activities. Rating scales such as the IADL Scale (Lawton 1988) or the Functional Activities Questionnaire (Pfeffer et al. 1982) can be used to improve the reliability of functional assessment or to screen for cognitive disorders.

## ■ Summary

The mental status examination is a fundamental part of the neuropsychiatric assessment of older patients. The examination focuses on cognitive abilities, which include perception, “thinking,” intellect, and problem-solving skills. Several cognitive domains are explored: attention, memory, language, visuospatial skills, calculation, praxis, and execu-

tive skills. The extent of cognitive assessment depends on the particular clinical circumstances and the goals of the evaluation; at least a screening evaluation is recommended for all geriatric patients. Rating scales can be used to help screen for cognitive impairment or to quantify the extent of impairment in patients with known deficits.

The pattern of deficits is used to identify syndromes of cognitive impairment, such as delirium, other disorders of attention, dementia, aphasia, amnesia, and frontal lobe disorders. The results of the mental status examination can also reveal the contribution of regional brain dysfunction to the expression of psychiatric symptoms in older patients.

# Neuropsychological Assessment

Kenneth Podell, Ph.D.

Mark R. Lovell, Ph.D.

The neuropsychological evaluation of older adults has become increasingly important over the past decade and is often a standard component of the neuropsychiatric evaluation. Neuropsychological assessment can be considered a more in-depth extension and quantification of the mental status examination (see Chapter 6 in this volume) and, as such, is focused on the psychometric assessment of cognitive processes. A thorough neuropsychological evaluation can add much to the clinical diagnostic process and can complement information gathered through electrophysiological, neuroanatomical, and functional neuroimaging technologies (see Chapters 9–11 in this volume).

In this chapter, we review the applications of neuropsychological assessment to geriatric patients and discuss relevant issues regarding the establishment of appropriate normative databases for this population. The selection and use of neuropsychological tests, the interpretation of test results, and the use of these results in the treatment planning process are specifically discussed. We also discuss the use of traditional fixed neuropsychological

test batteries and contrast them with more flexible approaches to the assessment of elderly patients.

## Goals of the Geriatric Neuropsychological Evaluation

Neuropsychological test results are used in various ways depending on the training of the neuropsychologist, the setting, the referral question, and the treatment program. However, despite differing approaches to assessment, the three primary goals of neuropsychological assessment are generally the same: 1) to establish an individual's cognitive and behavioral strengths and weaknesses, 2) to interpret findings from a diagnostic viewpoint (e.g., differential diagnosis such as depression versus dementia or age-appropriate cognitive decline versus dementia), and 3) to extrapolate treatment and rehabilitation recommendations from the neuropsychological assessment findings (La Rue 1992). In addition to providing specific information

that may be useful in differential diagnosis and the localization of brain dysfunction, the neuropsychological evaluation is relatively unique among neurodiagnostic techniques in its ability to document the functional capabilities of geriatric patients. This aspect of neuropsychological assessment has become increasingly important as a greater number of individuals are living well into their eighth decade or beyond. Clinicians are routinely faced with decisions regarding their patients' ability to live alone, operate an automobile, make competent decisions about health care, and manage their financial affairs.

## ■ Methodological Issues in Geriatric Neuropsychology

The aging process is accompanied by subtle declines in specific domains of cognitive functioning (Albert 1981; Kaszniak 1987; Wilson et al. 1997), with motor speed, speed of cognitive processing, and mental flexibility most affected (La Rue 1992). This decline is a function of the synergistic effects of the "normal aging process" in combination with the multitude of medical and psychosocial variables that affect the cognition of elderly individuals. The concept of "normal aging," particularly as it pertains to memory decline in older adults, is an extremely important issue and is discussed more thoroughly in Chapter 8 in this volume. However, a brief discussion of how this issue has affected the clinical neuropsychological evaluation of the geriatric patient is germane to the current chapter.

The clinical neuropsychological evaluation is highly dependent on appropriate comparison groups that allow the cognitive dysfunction related to pathological processes to be separated from the decline secondary to the normal aging process. The normative sample provides the basis for this comparison of individual patient performance to established standards for a given age group and is an important prerequisite to the assessment process. However, to date, the usefulness of neuropsychological testing with older adults has been limited by a relative dearth of normative data. The development of valid normative data for geriatric patients continues to be a major challenge for geriatric neuropsychology, particularly with regard to the psychometric assessment of patients over the age of 75 years. This is particularly pertinent for urban geriatric patients, in which case demographic characteristics have a significant impact on normative values. The evidence is starting to show that age, education, literacy, and ethnicity affect performance in various cognitive domains differentially. This issue is starting to be addressed with normative

data being collected on urban- and rural-dwelling patients of varying ethnic origins, educational backgrounds, and literacy levels (Hohl et al. 1999; Lichtenberg et al. 1998; Manly et al. 1999; Marcopulos et al. 1997; Strick et al. 1998).

Substantial limitations still exist in age-based normative data, with limited heterogeneity of education and health variables among normative samples (La Rue 1992) as well as poor reliability, validity, and normative data relevant to "old-old" patient groups (i.e., those 75 or older) (Kaszniak 1989). This lack of an adequate normative base has at times fostered a reliance on norms obtained on younger subject groups—a practice that can lead to an overdiagnosis of pathological cognitive impairment in geriatric patients.

In the absence of age-appropriate and current normative data, some clinicians have tended to rely on data that were collected many years earlier and from samples of geriatric subjects who may have differed significantly from the individual patient whose performance is being evaluated. Given generational differences in the availability of medical treatment, education, nutrition, and a host of other factors that can influence performance on neuropsychological tests, it is risky to compare the test performance of an elderly patient in the 1990s to normative data gathered during the 1970s or before. This cohort effect (Schaie and Schaie 1977) limits the usefulness of previously established normative data to current samples of patients.

One additional problem with using age-appropriate normative data in a geriatric population is making sure that the normative data, even if they have large sample sizes with appropriate age and education ranges, have adequate psychometric properties. This becomes extremely problematic on more difficult tests of memory and executive control, which are particularly important cognitive domains in assessing geriatric populations. For example, normative data are available for performance on the Wisconsin Card Sorting Test (WCST) extending through the eighth decade (Heaton et al. 1993). The WCST, a difficult test even for younger, more educated individuals, is extremely difficult for older, less educated patients. Because of this, the potential for a significant floor effect is very real. Even some seasoned neuropsychologists tend to ignore this problem. It has very real implications in terms of test interpretation and translation to "real world" activities or ecological validity. We believe that not only does one need to ensure adequate norming in terms of demographic variables, but that the test must accurately reflect the range of abilities in the age group and must also have appropriate psychometric properties (e.g., minimizing ceiling or floor effects).

In neuropsychology, because we often do not have predisease or baseline data on patients, we tend to use level of education (among other variables) as a marker of premorbid cognitive abilities. We use this to compare current performance to determine if there has been a meaningful decline. However, level of education for geriatric patients most likely does not have the same meaning as the educational level of someone in their 30s, for example. It has been our experience that level of education, unless very high or very low, may not have the same predictive abilities as we assume with a younger population. Therefore, in our clinic, to help predict life-long cognitive abilities, we also rely upon measures considered highly resilient to any type of central nervous system dysfunction. One such measure is single-word reading recognition and vocabulary skills (Bayles et al. 1985).

Yet another methodological issue that has affected the neuropsychological evaluation of elderly patients has been differing definitions of what constitutes the expected cognitive pattern of “normal aging.” For example, some researchers have distinguished between *usual aging*, in which the effects of the aging process are influenced by extrinsic factors such as nutrition and psychosocial factors, and *successful aging*, in which these factors play a neutral or positive role (Rowe and Kahn 1987). Still others have studied unusually healthy groups of geriatric subjects, documenting cognitive functioning in patients who are uncharacteristically free of the medical problems that often afflict the elderly (MacInnes et al. 1983). Obviously, the comparison of a patient’s performance to norms gathered from these disparate samples could lead to markedly different conclusions regarding pathological cognitive decline in a given patient. Comparison of the typical elderly patient with norms derived from a sample of unusually healthy individuals may result in an overdiagnosis of pathological cognitive dysfunction (Albert 1981).

Despite past limitations in the development of normative data on cognitive functioning in geriatric patients, there has been significant improvement in the development of neuropsychological tests that provide geriatric norms. For example, the Wechsler Memory Scale—Revised (WMS-R) (Wechsler 1987) and the Wechsler Adult Intelligence Scale—Revised (WAIS-R) (Wechsler 1981), two of the most popular tests used by neuropsychologists, have supporting normative data through age 74. Even more recently, these norms have been augmented by data specific to the old-old population that provide information on normal subjects into their ninth decade (Ivnik et al. 1992). And now with the introduction of WAIS-III and WMS-III (Wechsler 1997a, 1997b), normative data on the same tests have been collected on updated samples through

the eighth decade. Along similar lines, demographic corrections have been developed for the Halstead-Reitan Neuropsychological Battery (HRNB) (Heaton et al. 1991), and the normative data for the Hopkins Verbal Learning Test has been updated (Benedict et al. 1998), whereas others have renormed existing tests (Hohl et al. 1999; Lichtenberg et al. 1998; Manly et al. 1999). Relatively new cognitive screening instruments have also included older-age normative data that permit appropriate global mental status examinations in the elderly (Osato et al. 1989).

Medication side effects on cognitive abilities is another factor that is sometimes underappreciated and not taken into account both in terms of neuropsychological assessment and treatment. Commonly prescribed medications, such as cimetidine, can produce alterations in cognition. Similarly, the use of anticholinergic and antidopaminergic medications must be taken into consideration because of their known deleterious effects on memory (Drachman and Leavitt 1974) and executive control skills, respectively (see Fuster 1989).

Finally, a distinction between age-appropriate cognitive abilities, as defined by performance relative to normative data, and functional abilities needed for the individual’s given situation must be clearly defined and addressed in a neuropsychological evaluation. What may be age-appropriate cognitive functioning (e.g., for an 85-year-old individual), may not be sufficient for the level of independent functioning required in the individual’s living situation. For example, the same individual may be cognitively intact enough relative to age-appropriate normative data to return to live in an assistive living apartment building where she or he has some increased supervision, but may not be cognitively intact enough to live alone and be independently responsible for instrumental activities of daily living and medical management.

## ■ Neuropsychological Evaluation Process

The neuropsychological assessment is a complex process requiring the integration of knowledge from several different areas of medicine (including neurology, psychiatry, neurobiology), clinical psychology and aging, psychometrics, and, of course, neuropsychology and aging (Kaszniak 1989). The evaluation typically consists of a clinical interview, test selection, scoring and interpretation of test results (e.g., functional level, brain systems involved, and possible etiologies), diagnosis, and treatment

and rehabilitation recommendations.

The primary goal of the clinical interview should be to develop hypotheses regarding the patient's overall cognitive status, current problems and symptoms, and his or her capacity to engage in further neuropsychological evaluation. In addition, the clinical interview provides an opportunity for the examiner to develop rapport with the patient, explain the nature of the evaluation, and answer any of the patient's questions, which may help to alleviate initial anxiety.

Sometimes the elderly patient is not capable of giving a precise and thorough history. Thus, in our clinic we request that a significant other accompany the patient. After obtaining permission from the patient, we routinely interview the significant other or a relative to verify and/or obtain appropriate history. The significant other is asked to complete the Geriatric Evaluation by Relative's Rating Instrument (GERRI; Schwartz 1983). A questionnaire rating the patient's functional abilities in the realms of cognition, mood, and social abilities. A thorough interview should yield relevant demographic background information (e.g., age, education, occupational history, and handedness), a review of medical and psychiatric history (including past and present medication use), substance use or abuse, familial (both medical and psychiatric) and developmental information, current living situation, and support network. We also do a complete review of sensory and motor systems; homeostasis; and changes in cognition and affect, emphasizing recent changes in language, memory, thinking, and affect; any recent stressors (e.g., death of a spouse or loss of driving license); information pertaining to activity level and hobbies; motivation; and the patient's understanding of why he or she was referred for neuropsychological evaluation.

Through the clinical interview and direct interaction with the patient, the neuropsychologist gathers important qualitative information regarding cognitive functioning. This includes a general sense of the patient's orientation, attentional capacity, motivation, awareness of impairment, willingness to engage in neuropsychological testing, and social appropriateness. Integrity of gross language and motor function, memory capacity, and stamina should also be assessed. The older patient may have limitations that affect his or her performance during the neuropsychological evaluation, including reduced vision and hearing and the effects of overmedication (Goreczny and Nussbaum 1994; Russell 1984). As a result of these factors, the questions may need to be repeated and presented louder and at a slower rate.

Similarly, the method of test administration must sometimes be altered to conform to the patient's sensorial

limitations. For example, a subject with poor hearing but intact vision may have to read a word list presented on cue cards rather than listen to the list presented auditorily. This clearly violates standard administration. However, it allows for a "qualitative" analysis and can yield useful information for an experienced neuropsychologist. In addition, the patient should be encouraged to continue working on tasks even after specified time limits have been reached. This testing-the-limits approach can help to establish the patient's capacity to perform a cognitive task when motor abnormalities (e.g., as in Parkinson's disease) and sensory deficits might limit her or his ability to complete the testing within specified time boundaries.

The administration of neuropsychological tests usually begins directly after the clinical interview. Selection of tests should be based on the following five factors: 1) the referral question, 2) level of functioning of the patient as ascertained during the clinical interview, 3) hypotheses regarding the differential diagnosis, 4) physical limitations of the patient, and 5) the need to document cognitive deficiencies and relative strengths. The latter point has relevance to the patient's ability to function in everyday life.

The selection of tests may differ based on individual patient needs. For example, older patients with severe cognitive or medical disturbances may lack the stamina or attentional capacity to undergo an intensive neuropsychological evaluation. For these patients, the selection of tests that tap specific domains of cognitive functioning in combination with the use of a more broad-based screening instrument may be the most useful approach. In contrast, a patient with relatively preserved cognitive abilities and without serious medical complications may be engaged in a more thorough cognitive assessment involving the in-depth assessment of multiple domains of neuropsychological functioning (Russell 1984). Regardless of the estimated level of cognitive functioning or the hypothesized nature of the cognitive impairment, we recommend the use of a brief cognitive screen as part of the interview process with the older patient. This permits not only an initial assessment of the patient's general cognitive capacity, but also provides direction for the selection of instruments to be used in the neuropsychological evaluation. The use of cognitive screening instruments within the more general context of the neuropsychological evaluation also promotes the comparison of test results across different testing sessions, even when the patient has deteriorated to a degree that precludes a more comprehensive evaluation (for a discussion of representative screening instruments and rating scales, see Chapter 6 in this volume).

Although brief screening instruments are extremely useful in detecting (i.e., diagnosing) the presence dementia

(Stuss et al. 1996), they do not provide information regarding functional abilities, placement and competency issues, or recommendations. These limitations should be considered when interpreting results based solely upon a brief screening instrument.

Various demographic variables can influence performance scores on brief screening instruments. For example, advanced age and lower education can produce an overestimate of cognitive impairments on the Mini-Mental State Exam (Malloy et al. 1997; Naugle and Kawczak 1989). Some have taken the step of renorming some of the existing screening tests to take age and education into account (e.g., Dementia Rating Scale; Lucas et al. 1998) to obtain better sensitivity (van Gorp et al. 1999). Others continue to develop new, highly focused, very brief screening instruments for memory loss in dementia (e.g., Memory Impairment Screen; Buschke et al. 1999). Moreover, others have found that brief screening instruments can be somewhat insensitive to mild forms of dementia (particularly the memory component), thus increasing Type II errors (false negatives) (Benedict and Brandt 1992; Pfeffer et al. 1981). Other screening instruments, such as the Neurobehavioral Cognitive Status Examination, or Cognistat (Kiernan et al. 1987), offer better delineation of the patient's cognitive deficits, but may not offer good discrimination for dementia type (van Gorp et al. 1999). Depending on the history and referral question, the use of a brief cognitive screening instrument to solely determine the need for further testing may cause an inaccurate assessment in either direction.

## ■ Approaches to the Neuropsychological Evaluation of Geriatric Patients

As a discipline, clinical neuropsychology is generally concerned with the study of brain-behavior relationships. However, clinical approaches to the assessment of these relationships vary widely (Kane 1991). Currently well-accepted strategies for neuropsychological assessment include the use of fixed batteries of neuropsychological tests, flexible evaluation strategies, and use of a combination of both of these approaches. It appears now, with the need to better define cognitive and behavioral deficits and changes associated with different dementia types, that appropriately choosing tests to suit the individual assessment may be the most productive method (Benton 1985; Costa 1983). In this section, we review the application of these different approaches with adults 65 years old or older (see Lezak 1995 and Russell 1998 for more detailed

discussions on using fixed versus flexible battery approaches).

### Fixed Test Battery Approaches

In a fixed battery approach, the same test instruments or tests are administered to every patient in a standard manner regardless of the patient's presenting illness or referral question (Kane 1991; Kaszniak 1989). The two most popular neuropsychological batteries are currently the HRNB and the Luria-Nebraska Neuropsychological Battery (see Incagnoli et al. 1986; Lezak 1995). Advantages of the fixed battery approach to neuropsychological assessment include that it provides a comprehensive assessment of multiple cognitive domains and, because of its standardized format, that the test data can be incorporated into databases for clinical and scientific analysis. Disadvantages of the fixed battery approach include time and labor intensiveness and a lack of flexibility in different clinical situations.

**Use of fixed test batteries with geriatric patients.** A large literature exists on the psychometric properties of fixed batteries such as the HRNB (Anthony et al. 1980; Heaton and Pendleton 1981; Kane 1991; Parsons 1986; Reitan 1976; Reitan and Davison 1974; Reitan and Wolfson 1985) and the Luria-Nebraska Neuropsychological Battery (Golden and Maruish 1986; Golden et al. 1980; Kane 1991; Purisch and Sbordone 1986). However, relatively little empirical research exists regarding the psychometric properties of flexible or fixed battery approaches with the elderly population (Kaszniak 1989).

**Halstead-Reitan Neuropsychological Battery.** The HRNB represents one of the most popular battery approaches to neuropsychological assessment (Table 7-1). This battery measures cognitive functioning across a number of cognitive domains but is often too difficult for elderly individuals with more than mild cognitive impairment. Despite its widespread use in nongeriatric patients, the use of this battery with the elderly (as well as with younger patients) has been criticized (Fastenau and Adams 1996). Several studies have established age and education as important moderator variables for several of the battery's subtests (Heaton et al. 1986, 1991). Older or more poorly educated subjects were misclassified on the HRNB Impairment Index (a summary score based on seven different measures) as having brain damage more often than two other matched groups. Finally, the sample sizes for individual groups were not given in the published normative data, and evidence suggests that some of the normative groups had very few subjects in them (Fastenau and Adams 1996).

and that use of a regression model produced a higher rate of missed diagnoses (Fastenau 1998).

The principal concerns with reliance on the HRNB in assessment of older adults are 1) the HRNB may overestimate brain impairment in otherwise nonneurologically impaired older adults; 2) the amount of time and effort required to complete the HRNB may be inappropriate for elderly patients who are prone to fatigue easily; 3) the HRNB may not adequately assess both the strengths and weaknesses of the elder patient because it uses subtests that measure primarily fluid abilities (i.e., novel problem-solving, reasoning, and spatial processes) known to decline with normal aging; and 4) the HRNB potentially has poor psychometric properties, especially for older groups. For these reasons, some have argued against the use of the HRNB with the elderly (La Rue 1992).

Despite these concerns, some subtests from the HRNB are useful and included in neuropsychological evaluations. Subtests that can provide useful clinical information during an assessment include the Trail Making test (parts A and B) as a measure of cognitive flexibility and attention, the aphasia screening test as a gross measure of language, and the finger oscillation test as a measure of bilateral fine motor speed. Additionally, efforts have been made

to develop HRNB age and education corrections for older adults (see Heaton et al. 1991), and a short form of the HRNB has been developed (Storrie and Doerr 1980).<sup>1</sup>

**Luria-Nebraska Neuropsychological Battery.**

The Luria-Nebraska Neuropsychological Battery yields a number of empirically derived summary scores (Table 7-2). This battery requires less time to administer than the HRNB (which takes 2–3 hours), thus minimizing any fatigue effect in elderly patients. However, some have argued that specific administration and scoring parameters of the Luria-Nebraska Neuropsychological Battery places the geriatric patient at an undue disadvantage, as well as potentially increasing the chance of misdiagnosis (Lezak 1995).

**Flexible Approach to Neuropsychological Assessment**

In using a flexible approach to neuropsychological testing, individual tests are chosen based upon the patient's presenting illness or referral question (Goodglass 1986; Kane 1991; Kaszniak 1989; Lezak 1995; Schear 1984). Primary advantages of the flexible approach to neuropsychological evaluation include a potentially shorter administration time, economical favorability, and adaptability to differing patient situations and needs. Some (Goodglass 1986; Russell 1984) have argued that the flexible approach permits better specification of the deficits within a given cognitive domain as well as their underlying neural systems rather than simply documenting the presence or absence of brain damage. Others use the flexible approach because it permits easy evaluation of qualitative features such as the patient's use of problem-solving strategies (Kaplan 1983). Finally, the flexible approach can be modified easily and therefore is adaptable to a wide variety of clinical situations (Kane 1991).

Disadvantages of the flexible approach include the need for greater clinical experience; a lack of standardization of administration rules for some tests, as well as the tests administered; a potential lack of comprehensiveness; and limitations in establishing systematic databases (Kane 1991; Tarter and Edwards 1986). Also, examiners who use the flexible battery approach may require more extensive clinical training and experience because the interpretation of test results involves qualitative results as well as quantitative data. An understanding of developmental normal aging, age-related cognitive decline, neuropsychological principles, neuropathological conditions in the elderly, and other issues pertinent to differential diagnosis are

<sup>1</sup> Some of these tests have published normative data, independent of the HRNB normative data (Heaton et al. 1991).

particularly important when using the flexible neuropsychological assessment approach with elderly patients.

The flexible approach does not lend itself well to empirical investigation because of the individualized nature of the tasks and the difficulty comparing results across institutions or centers. However, this individualized approach to neuropsychological assessment remains popular with many neuropsychologists because of its adaptability, flexibility, clinical usefulness of qualitative information, efficiency with severely impaired patients, and applicability with patients who are vulnerable to fatigue, distress, or sensory limitations (Kane 1991; La Rue 1992). For these reasons, the flexible neuropsychological evaluation appears to be a useful, and possibly the best, approach for the clinical assessment of older adults (Benton 1985; Costa 1983).

Recently, test batteries and screening instruments have been designed specifically to address cognitive decline in the elderly patient, as well as test batteries or screens used for differential diagnosis of dementia type (Morris et al. 1989; see Lezak 1995 for a more detailed dis-

ussion). The distinction between a screening test for dementia and an extended mental status examination can be somewhat arbitrary. See Table 7-3 for a listing of a few tests used as screening instruments for dementia.

## Individual Tests of Cognitive Functioning

Even when a flexible approach to neuropsychological assessment is adopted, a broad range of cognitive processes should be evaluated. The major domains of cognitive functioning that should be assessed include attention and concentration, general intelligence, conceptual processes and executive functioning, memory and learning, visuospatial skills, language, fine motor speed, coordination, strength, and emotional status (see Albert and Moss 1988; Russell 1984). In addition, we like to include the assessment of functional abilities in terms of completing activities of daily living, or ADLs, and to obtain ratings by relatives or significant others. We find that by including these last two areas to our comprehensive geriatric neuropsychological assessment, we are better able to address issues of competency, improve our ecological validity, better address ability to live alone, and obtain a more accurate picture of the individual's current functioning. Table 7-3 lists individual neuropsychological tests that are commonly used in evaluating the major domains of cognitive functioning in older adults. (A complete review of these cognitive domains and the instruments that measure them is beyond the scope of this chapter; for excellent reviews on this topic, see Albert and Moss 1988; La Rue 1992; LaRue and Swanda 1997; Lezak 1995.)

### Assessment of Attentional Processes

After the informal assessment of the patient's basic level of arousal, alertness, and orientation, the patient's attentional capacity should be evaluated. Assessment of attention is necessary because attention is a prerequisite for successful performance in other cognitive domains (Albert 1981). If the patient appears to fatigue in the course of testing, it may be necessary to reassess attention to determine the effect of exhaustion on test performance.

Attention is not a unitary phenomenon; it is a multifactorial and complex cognitive activity. Attentional processes can be impaired in patients with delirium and with dementing disorders, but may also be significantly impaired in the geriatric patient with depression and in patients with focal brain lesions. For the purposes of the clini-

- Purdue Pegboard Test (Purdue Research Foundation 1948)
- Strength of Grip Test (see Reitan and Wolfson 1985)

cal evaluation of the geriatric patient, it is useful to evaluate both verbal and nonverbal aspects of attention, as these components of attention can be variably impaired depending on the etiology of the cognitive dysfunction.

Auditory attentional processes are most readily assessed by the use of span procedures. The WMS-R and WMS-III have span procedures that are both auditorily and visually based. A verbally based procedure, called Digit Span, asks the patient to repeat auditorily presented strings of numbers in increasing length in both forward and backward order. The nonverbal, spatially analogous version, called Visual Span, requires the patient to repeat the tapping order of progressively longer sequences of colored boxes printed on a card, after watching the test administrator do so. The patient's ability to perform this task in both forward and backward order is evaluated. Letter and number cancellation tasks (Talland and Schwab 1964) can be used to assess visual attentional processes and require the patient to cross off designated stimuli on a sheet of paper within a short period of time. Visual cancellation tests are particularly useful in patients with hearing loss but are contraindicated in patients with decreased visual acuity.

Divided attention (i.e., the ability to ignore extraneous information, while focusing on specific stimuli) can be assessed by the Stroop Test (Golden 1978; Stroop 1935). This test first involves the presentation of a 100-item list of words, which the patient reads aloud. Next, the patient is required to name the colors of a series of Xs. Finally, the patient is presented with a list of words that are printed in a different color ink than the word implies and is asked to name the color of the ink, ignoring the word. For example, the word *Red* is presented in green ink and the patient must suppress the tendency to read the word rather than name the color. This test is considered to be a measure of executive functioning, as well as divided attention. Patients with frontal lobe lesions (Holst and Villki 1988) or mild to moderate dementia (Fisher et al. 1990) have demonstrated the Stroop effect (i.e., slowing on the interference trials). However, one particular problem about using this test in the elderly population is color discrimination. Occasionally, the elderly subject is not capable of adequately discriminating between the different colors used in the Stroop Test. A simple way of determining this is to randomly select some of the color Xs and ask the subject to name the color. If they can do this correctly, they are capable of completing the test. Similarly, the elderly subject's visual acuity may not be adequate, and this can be tested by asking the subject to read some of the words from the first trial.

Once the patient's ability to focus and sustain attention has been evaluated, the patient's level of cognitive functioning in other domains can be evaluated. If the patient's

ability to attend is judged to be severely impaired, further neuropsychological assessment beyond a brief cognitive screen may not be useful.

## Assessment of Intellectual Processes

Intellectual processes are differentially affected by the aging process and by dementing disorders. Overlearned crystallized intellectual functions (Cattell 1963) such as fund of general information and vocabulary development are often preserved, whereas the ability to use abstract reasoning and cognitive flexibility (fluid intelligence) usually declines both with normal aging and with disease-associated processes. The WAIS-R and WAIS-III are the most commonly used tests of general intelligence but either may take more than 2 hours to administer to an elderly patient, making it impractical in many cases. When the complete administration of the WAIS-R or WAIS-III is not possible because of limitations in the patient's stamina or severity of cognitive impairment, the administration of selected subtests can be useful. In particular, the Vocabulary and Information subtests are relatively good indicators of the patient's premorbid level of functioning. The ability to think abstractly is most commonly assessed through the use of the Similarities subtest of the WAIS-R, the Comprehension subtest provides a sample of the patient's judgment when placed in hypothetical situations, and Block Design measures visuoconstructive abilities. The Wechsler Abbreviated Scale of Intelligence (Psychological Corporation 1999) is a two or four subtest version of the WAIS-III with normative data extending into the eighth decade.

## Memory

The evaluation of memory represents an extremely critical component of the neuropsychological assessment of the geriatric patient and can yield important diagnostic information. The patient's performance can help discriminate the effects of brain impairment from normal aging and can also help differentiate between psychiatric disorders (e.g., depression) and dementia etiology. For example, one dissociation of memory performance includes the difference between impaired free recall and recognition of recent information versus impaired free recall but relatively preserved recognition of recent information. Impaired free recall and recognition performance may be classified as a "pure amnesia" with concomitant dysfunction of encoding and storage. This type of memory loss is typically associated with medial-temporal lobe damage, particularly to the hippocampus, and is characteristic of Alzheimer's disease.

Impaired free recall with relatively preserved recognition performance suggests a retrieval deficit consistent with dysfunction of the frontal-subcortical circuitry and characteristic of subcortical dementias (Cummings 1992; Delis et al. 1991). However, some evidence shows that, when controlled for dementia severity, there may not be any difference in memory performance between Alzheimer's and multi-infarct dementia (La Rue 1989).

Both verbal and visuospatial memory should be assessed and may have relevance for the localization of brain dysfunction to either the left or right hemisphere, respectively. Verbal memory processes are most often assessed through the use of word lists that are presented a specified number of times or through the presentation of "stories" that the patient is asked to recall at some later time (i.e., immediately after presentation and after a 20-minute delay). The Rey Auditory-Verbal Learning Test (Rey 1964) and the California Verbal Learning Test (Delis et al. 1987) are commonly used list-learning tasks, although these tests are challenging because of the length of the lists (15 and 16 words, respectively) and the five required repetitions of the lists. These tests may be too difficult for geriatric patients who have more than a mild level of dementia or who have reduced stamina. The Hopkins Verbal Learning Test (HVL) (Benedict et al. 1998; Brandt 1991) and California Verbal Learning Test—Dementia Version (Libon et al. 1996) may be preferable because they use shorter word lists and, in the case of HVL, less number of repetitions. The most common story recall tasks used to evaluate verbal memory are taken from the WMS-R or WMS-III.

Evaluation of the patient's ability to learn and remember abstract spatial information is also an important component of the neuropsychological assessment process, and disruption of spatial memory relative to other test results may suggest right hemisphere dysfunction. Testing most often involves the reproduction and subsequent recall of abstract designs such as are provided by the Visual Reproduction subtest of the WMS-R or WMS-III, the Rey-Osterrieth Complex Figure Test (which is prone to floor effects in the elderly), and the Brief Visuospatial Memory Test—Revised (Benedict 1997). The Brief Visuospatial Memory Test—Revised is unique among published visuospatial memory tests in that it has multiple trials. This allows one to study the subject's visuospatial learning and thus can be compared to the subject's learning curve on a verbal word list-learning test.

In the evaluation of spatial memory, it is particularly important to dissociate the patient's ability to reproduce the designs (constructional disturbance) from memory, *per se*. One way of conveniently accomplishing this is by asking the patient to copy the design before the memory compo-

ment of the evaluation is completed, such as in the administration of the Rey-Osterrieth Complex Figure Test. Figure 7-1 provides an example of severe constructional disturbance in a 77-year-old patient with suspected Alzheimer's disease. In addition, other assessment procedures such as the Benton Visual Retention Test (Benton 1992) allow separation of constructional disturbance from impairment of spatial memory by providing normative data for both the reproduction (i.e., copy) and retention of figural information, separately. Finally, nonverbal memory can be assessed by using a recognition paradigm. Here the subject is exposed to a series of geometric stimuli. This is followed by a long series of geometric designs. Most are new (e.g., not part of the initial stimuli shown to the subject previously), but some repeat (e.g., the designs shown initially). The subject is asked to say "yes" if the stimulus looks familiar and "no" if it does not. This type of paradigm has absolutely no graphomotor component, but it also has no free recall component (Paolo et al. 1998).

Remote memory, also referred to as *tertiary memory*, refers to the recall of events that occurred during the early years of one's life (La Rue 1992). Interestingly, older adults typically report the ability to recall events from remote memory (e.g., names of grade school teachers), while complaining of anterograde memory loss for recent events (e.g., what they had for lunch that day). Traditional measures of remote memory include the Famous Faces Test or Famous Events Test (see Lezak 1995), which assess the individual's ability to recall famous faces or events during different decades of the 20th century.

As found with measures of new learning (e.g., word list learning), performance on tests of remote memory can differentiate between cortical (e.g., Alzheimer's disease) and

subcortical (e.g., Huntington's disease) dementias. The former tends to show the typical temporal gradient in recall of past events (better recall the older the event), whereas the latter tends to be equally impaired across decades. A similar explanation of poor consolidation versus retrieval, respectively, has been proposed (see Salmon and Bondi 1997). The assessment of remote memory is difficult because the examiner is usually uncertain about the amount of initial exposure or the subsequent rehearsal of this information the subject had with the stimuli ( Craik 1977). In other words, what may appear as remote memory failure in a given patient may actually be a lack of exposure to the event in question or even possibly an anterograde amnesia that developed at an earlier time. Research documents significant age differences in a comparison of remote memory (public events) between young, middle-aged, and older adults (Howes and Katz 1988). Specifically, the elderly group demonstrated significantly poorer performance in recall of remote events during the time periods when both groups had lived. However, the elderly demonstrated consistent recall across the five decades.

The issue of whether older subjects demonstrate consistent recall across decades remains a controversial issue (Squire 1974; Warrington and Sanders 1971). Overall, remote memory appears to be affected by age, but this finding should continue to be interpreted with caution because methodological differences remain across studies (La Rue 1992).

In summary, assessment of memory in the geriatric patient should be thorough, encompassing aspects of learning, retention, and recognition as well as remote memory. This is important because it aids in differential diagnosis and also because various components of memory differentially decline with age (see Lezak 1995).

**FIGURE 7-1.** Rey-Osterrieth Complex Figure Test (*panel A*) and reproduction of this figure by a 77-year-old man with suspected Alzheimer's disease (*panel B*). The patient's copy of the figure demonstrates severe impairment of visuoconstructional processes often associated with parietal lobe damage.

## Executive Functioning

Along with memory, executive control skills show significant decline with normal aging (Libon et al. 1994; see La Rue 1992). In fact, some have postulated that the cognitive changes in normal aging are most pronounced in executive control functioning (Mittenberg et al. 1989). This may be due to greater cortical (Terry et al. 1987) and neurotransmitter (Carlsson 1981; Goldman-Rakic and Brown 1981) loss in the frontal lobe, as well as a greater decline in metabolic activity (Shaw et al. 1984; Smith 1984). This indicates that age-appropriate normative data on measures of executive control are highly relevant to an older population. It also suggests that just simply “renorming” an existing test of executive control may be somewhat problematic. Renorming the test for older patients who are known to decline on that measure increases the chance of that test’s having poor psychometric properties for the older population. For example, the WCST is the typical “gold standard” for assessing executive control skills. However, it is particularly prone to floor effects in older populations and thus loses its clinical utility.

Executive control functioning is a constellation of multicompartamental cognitive skills that encompasses mental planning and organization, novel problem solving (e.g., cognitive flexibility), set development and shifting, and error monitoring. These components can be assessed individually or in combination. The WCST is used to assess cognitive flexibility (e.g., novel problem solving) and set shifting. However, as mentioned previously, it may have poor clinical utility in older patients. Tests such as Trail Making can be used to assess sequencing and visual search skills, although these skills also decline sharply with advancing age. Planning can be assessed through a qualitative analysis of how the patient approaches tasks such as the Block Design subtest of the WAIS-R or WAIS-III or the Rey-Osterrieth Complex Figure (Meyers and Meyers 1995; Osterrieth 1944) (Figure 7–1). Planning also may be evaluated formally using the Tinkertoy Test (Lezak 1983), which requires the patient to build a design using a 50-piece Tinkertoy set. The test has shown good construct validity as a measure of executive control functioning (Mahurin et al. 1993) and sensitivity to detecting dementia (Koss et al. 1998) and dementia type (Mendez and Ashla-Mendez 1991).

Two additional measures of executive control functioning that are showing promising results in the clinical assessment of elderly patients are the Executive Control Battery (ECB) (Goldberg et al. 1996) and Cognitive Bias Test (CBT). ECB was designed to quantify the qualitative features of executive dyscontrol as developed by A. R. Luria

and E. Goldberg. The ECB consists of four relatively simple subtests: Competing Programs, Manual Postures, Graphical Sequences, and Motor Programming. The subtests are quick and easy to administer and can be given individually. The battery measures perseveration, field dependency, impulsivity, and sequencing errors. The battery, or portions of it, is sensitive to prefrontal lesions (Podell et al. 1992a, 1992b; Zimmerman et al. 1994), the decline in executive control associated with advanced normal aging (Libon et al. 1994), and the differential effects of Alzheimer’s versus cerebrovascular dementia on graphomotor perseverations (Lamar et al. 1997). See Figure 7–2 for examples of graphomotor perseverations elicited on the Graphical Sequences subtest of ECB.

The CBT is an innovative computerized test that assess the subject’s response preference along a continuum of context-dependent/independent responding. For example, after being presented with a stimulus, does the subject use it as a context for which to make a subsequent judgment (context dependent)? Or does the subject make all choices independent of any context (i.e., context independent)? CBT performance is sensitive to prefrontal functions with laterality and sexual dimorphic effects (Goldberg et al. 1994; Podell et al. 1995). Research in an elderly population has shown this test’s sensitivity to the disease progression in Alzheimer’s disease (Goldberg et al. 1997).

## Visuospatial and Visuoconstructive Processes

Just as it is important to separate disorders of visual memory from difficulties secondary to impairment of constructional processes, it is also necessary to separate disorders of visuospatial analysis from those of visuoconstructive processes. This dissociation can have localizing value, aid in differential diagnosis, and address functional abilities. The separation of these different, but related, neuropsychological processes can be most effectively accomplished by comparing the results of constructional tasks such as Block Design from the WAIS-R or WAIS-III to performance on motor-free spatial tasks such as the Visual Form Discrimination Test, Judgment of Line Orientation, and Facial Recognition tests developed by Benton and his colleagues (Benton et al. 1983). The Rey-Osterrieth Complex Figure Test, used in combination with these motor-free tasks, can be useful in separating visuospatial from visuoconstructive deficits. Poor performance in copying the figure, with better performance on motor-free tests, suggests a constructional rather than visuospatial disorder. We find a clock-drawing test (command and copy trials) useful in distinguishing between visuospatial, constructional, and

**Hyperkinetic Perseverations** - The elementary motor act cannot be terminated.

**Perseveration of Elements** - The substitution, or addition, of a previously occurring element, or part of an element, into the current response.

**Perseveration of Features** - No specific component of the element is perseverated. Instead a general characteristic, or feature, of the element intrudes upon the present response.

**FIGURE 7-2.** Types of graphomotor perseverations from the Graphical Sequences subtest of the Executive Control Battery.

executive control (planning) components. This test is relatively quick and easy to administer and has been extensively studied in dementia (Freedman et al. 1994).

One caveat we would like to add addresses the issue of primary vision and assessment of visuospatial and constructional abilities. The examiner must be aware of, and sensitive to, the patient's primary visual acuity (e.g., effects from glaucoma, cataracts, and macular degeneration). We recommend a cursory visual acuity check (e.g., using a Snellen eye chart) for all geriatric patients undergoing any neuropsychological testing using visual stimuli. One must consider the utility of administering these tasks, or the need for using enlarged stimuli, if the patient's primary visual acuity is poor.

## Speech and Language

Clinical evaluation of speech and language processes is also a necessary component in the neuropsychological evaluation of geriatric patients. Language processes in the elderly

can be affected by the normal aging process (Albert and Moss 1988), depression (Speedie et al. 1990), and dementia (Hill et al. 1989), and a thorough evaluation of language can help differentiate these disorders clinically. In particular, disorders of object naming (tested by presenting the patient with pictures of common objects) have been found to be associated with dementing illness (Albert 1981; Hill et al. 1989) and, to a lesser degree, with cognitive impairment secondary to depression (Speedie et al. 1990).

Other aspects of language should also be assessed during the neuropsychological evaluation, including comprehension and verbal fluency, as well as reading and writing. Verbal fluency can be easily assessed via the Animal Naming subtest of the Boston Diagnostic Aphasia Examination (Goodglass and Kaplan 1972) or the Controlled Oral Word Association Test (Benton and Hamsher 1978). Both types of verbal fluency tests provide the patient with 1 minute to produce as many words that fall under the category of "animals" or that begin with a specific letter. The total number of words generated by the patient in 1 minute

represents a total verbal fluency score and is compared to age-appropriate normative data. Comparison between the two fluency tasks can distinguish between a primary deficit in lexical-semantic accessing versus an impairment in executive control functioning. For example, impaired performance on novel fluency (e.g., a specific letter) but intact semantic fluency is an indication of executive dyscontrol (e.g., poor novel generation). The converse, intact fluency for a novel cue but impaired animal naming, is indicative of impaired lexical-semantic accessing skills. The Aphasia Screening Test (Halstead and Wepman 1959) from the HRNB is also useful and provides a brief assessment of multiple aspects of language, as well as allowing an evaluation of basic reading, writing, and calculation abilities.

### **Motor Processes and Psychomotor Speed**

Although motor speed and coordination decrease with normal aging, impairment of motor processes can also signal underlying neuropathological process. Decreased motor strength or speed can suggest a lateralized brain lesion, such as a stroke, tumor, or metastases, or may occur as part of a dementing disorder. In addition, a disruption in the ability to produce complex motor acts (e.g., dressing and eating) may represent an apraxia and may point to dysfunction of specific brain systems. Finally, evidence indicates that tests of impairments in fine and complex motor skills are almost as sensitive as other cognitive measures in differentiating between healthy normal and the mild, early stages of dementia (Kluger et al. 1997).

Motor speed is most commonly evaluated through the use of the Finger Oscillation Test (Finger Tapping) from the HRNB, the Grooved Pegboard Test (Matthews and Kløve 1964), or Purdue Pegboard Test (Purdue Research Foundation 1948). In general, better performance is expected of the dominant (usually right) hand relative to the nondominant hand, and the reversal of this pattern can help to localize a brain lesion to the contralateral hemisphere. The cautions concerning the use of age-appropriate norms are particularly germane to a discussion of the evaluation of motor processes. Comparison of an elderly patient's performance on a motor task to that of a younger normative group will result in spurious and misleading information. Finally, the examiner must be attuned to the contribution of peripheral factors upon motor performance. Peripheral, or non-central nervous system, diseases such as gout, arthritis, or peripheral neuropathies all effect motor performance and, if not taken into consideration, can lead to erroneous and incorrect interpretations.

### **Daily Functional Abilities**

Direct assessment of functional abilities (i.e., instrumental activities of daily living, or IADLs) has become increasingly more important in neuropsychological test batteries. Therefore, some clinicians now advocate the assessment of functional capacity by using instruments specifically designed for this purpose (La Rue and Swanda 1997). Additionally, such instruments play an important role in determining level of legal competency, which has become an increasingly more frequent referral question in neuropsychological assessments of older adults (Grisso 1994).

Functional abilities can be assessed through individual or collateral interviews or questionnaires (e.g., the Instrumental Activities of Daily Living Scale [Lawton and Brody 1969] and the Blessed Dementia Rating Scale [Blessed et al. 1968]) or by direct evaluation of the patient. However, evidence indicates that individual or collateral reports do not correlate well with actual performance (see Grisso 1994). Having a subject actually perform the given tasks or the requisite skills needed for the task is a more accurate and valid assessment of his or her functional abilities.

In our clinic, we have recently incorporated the direct assessment of functional abilities as part of our standard geriatric assessment. Specifically, we have used the Independent Living Scales (ILS) (Loeb 1996). Through a series of verbal responses and actual task completion (e.g., writing a check or using a telephone), the ILS assesses several different areas—Memory/Orientation, Managing Money, Managing Home and Transportation, Health and Safety, and Social Adjustment—vital to independent functioning and competency. The instrument is well normed and has been extensively validated on several different populations. In fact, unpublished data from our clinic (Baird et al. 1999) has shown a strong correlation ( $r = .73$ ) between performance on the ILS and level of dementia as assessed on the Dementia Rating Scale.

### **Use of Neuropsychological Testing in Differential Diagnosis**

As highlighted throughout this chapter, geriatric patients are at risk for a number of neuropathological disorders that affect cognitive functioning, which are often difficult to distinguish clinically. Although the neuropsychological evaluation can often be helpful in the differential diagnosis of neurological disorders, it must be emphasized that the results of neuropsychological testing should not be interpreted “in a vacuum,” but should be integrated with other diagnostic information gathered within the broader con-

text of the neuropsychiatric evaluation. This should involve a thorough medical, social, and psychiatric history; mental status examination; the application of appropriate neuroimaging technologies; and appropriate laboratory studies. With these guidelines in mind, we briefly review the use of neuropsychological testing in the differential diagnostic process. For a more detailed review, see La Rue 1992.

## ■ Dementia

Dementing disorders are not a homogeneous group of conditions; they vary greatly with regard to etiology, neurological substrate, disease course, and treatment (see Chapters 19, 20, and 24 in this volume). Therefore, it is not surprising that different types of dementia are associated with different neuropsychological profiles (Table 7–4).

One of the more recent developments in the differential diagnosis of dementia is a new classification of individuals who do not conform to a formal diagnosis of dementia (i.e., impairment in multiple cognitive domains) but have a circumscribed memory impairment greater than what can be expected for their age and background. This classification has been termed *mild cognitive impairment* or MCI (Flicker et al. 1991; Petersen et al. 1999). MCI is considered a transitional period between normal aging and the

development of dementia (usually the Alzheimer's variant). However, there is debate whether all individuals diagnosed with MCI develop dementia.

The neuropsychological profile of Alzheimer's disease is most often characterized by impairment of memory, executive control, visuospatial processes, intellectual processes, complex motor skills, and language, although impairment in all of these areas may not be present in every patient, particularly early in the disease. Memory impairment is usually the first sign of the disorder, although detailed neuropsychological evaluation may reveal subtle deficits in other areas (e.g., executive functioning). Dysnomia, decreased verbal fluency, and poor semantic processing are also common, even early in the disease process. The memory impairment is characterized by a relatively spared span of apprehension (as measured by the Digit Span procedure) but marked impairment in the retention of newly learned material. Intrusive errors (i.e., the inclusion of extraneous items, usually semantically related) are common both on list learning (Delis et al. 1991) and story recall tasks.

Early in Alzheimer's disease, often subtle impairment of mental flexibility and executive functioning may be viewed by the patient (and by his or her family) as being part of the normal aging process. Visuospatial impairment may be evident in the patient's drawings and may range from mild distortions of designs to a complete inability to repro-

**TABLE 7–4. Profiles of neuropsychological dysfunction in elderly patients**

Syndrome	Neuropsychological profile
Alzheimer's disease	Impaired recent memory, intrusive errors on list-learning tasks, poor performance on memory recognition and retention measures, impaired naming and other signs of aphasia, visuospatial processing deficits, general intellectual decline, apraxia, and agnosia (in advanced illness)
Frontotemporal dementias	Executive functioning deficits (perseveration, impaired planning, stimulus boundedness, impaired synthesis, impaired mental flexibility), reduced fluency (verbal and nonverbal), impaired insight, marked personality change early in illness characterized by apathy and inertia, impaired selective attention, and relatively preserved memory
Vascular dementia	"Patchy" pattern of deficits depending on location of infarcts, general intellectual decline over time, stepwise decline in cognitive functioning over time, and lateralized cognitive deficits depending on site of infarct or infarcts
Subcortical dementias	Psychomotor slowing, prominent memory impairment, speech or motor-system difficulties, impaired concept formation and mental flexibility, impaired insight, and depression
Dementia with Lewy bodies	Progressive insidious cognitive decline; pronounced fluctuations in attention and arousal; recurrent, well-formed, and detailed visual hallucinations; motor features consistent with parkinsonism; and usually neuroleptic sensitivity
Dementia syndrome of depression	Mildly impaired naming, impaired attentional processes, and immediate memory but intact depression retention of new material, normal primacy effects on memory tasks, normal learning curve on list-learning tasks, normal retrieval and recognition of material, and intact visuospatial processing

duce even simple two-dimensional copies. At later stages in the disease, more severe impairment of intellectual processes is observed, and agnosia and apraxia are often seen. Severe visuospatial impairment may take the form of an inability to tell time on an analogue clock or by spatial disorientation. This problem can become so severe that the patient is unable to find his or her room consistently. Personality and affective changes are common, especially in the later stages. Sundowning is often associated with Alzheimer's disease in the mid to late stages of the disease.

The label *frontotemporal dementia* is used to describe a number of disorders (such as Pick's disease, progressive subcortical gliosis, and dementia of the frontal lobe type) that primarily affect the prefrontal and temporal regions of the brain. Frontotemporal dementia is most often characterized by marked insidious personality change and impairment of executive functioning affecting all aspects of cognition (Cummings 1992; Moss et al. 1992). Although memory impairments can be present, they are usually associated with a preponderance of an executive control impairment (e.g., poor retrieval).

Unlike dementia of the Alzheimer type, the first signs of frontotemporal dementia are usually neuropsychiatric rather than cognitive in nature. Personality changes can be characterized by two distinct behavioral syndromes: apathy and behavioral inertia in the dorsolateral syndrome or hypomanic-like, puerile, sometimes irritable disinhibition in the orbitofrontal variant (Fuster 1989). Executive functioning impairment takes the form of perseveration, abulia or lack of initiation, stimulus boundedness (or field dependency), impaired synthesis and planning, and poor error monitoring. In contrast to those with the dementia of Alzheimer's disease, patients with frontotemporal dementia often have preserved visuospatial abilities and relatively better preserved memory functions (Neary and Snowden 1991). Although basic motor processes are usually intact, executive processes that involve a significant motor component are typically impaired. Language comprehension and expression are often preserved, but echolalia and a progressive expressive aphasia can develop. The neuropsychiatric and cognitive difficulties seen in frontotemporal dementia can become so severe as to limit the patient's ability to complete a comprehensive evaluation. Short bedside procedures are often useful and should be part of the mental status examination (see Chapter 6 in this volume).

Vascular dementia refers to a group of dementing disorders of a cerebrovascular nature consisting of an abrupt onset with a stepwise decline over time. Vascular dementia is characterized by "patchy" performance on neuropsychological measures with islands of preserved and impaired performance, depending on the site of the infarct(s) or

ischemia. As the disease progresses, a stepwise decline in cognitive functioning is typically observed and can be documented through serial neuropsychological evaluations. Left hemisphere lesions often result in language and verbal memory impairment, whereas right hemisphere lesions result in greater impairment of visuospatial processes and visual memory. Small infarcts that do not affect motor or speech areas may go unnoticed by the patient or family but can be documented through neuroimaging and neuropsychological evaluation.

The subcortical dementias are a group of disorders that are characterized by primary dysfunction in subcortical brain areas. Unlike dementing conditions that primarily affect cortical areas, leading to aphasia, apraxia, agnosia, and anomia, subcortical dementia features motor dysfunction, speech impairment, memory dysfunction, characterized primarily by deficits in retrieval (Delis et al. 1991), executive disorders, and disturbances in mood and personality (Cummings 1985). Subcortical dementia occurs with extrapyramidal syndromes such as Parkinson's disease, Wilson's disease, progressive supranuclear palsy, multisystems atrophy, and Huntington's disease. Although there is often a general decline in intellectual processes over time, this decline is usually much less severe than in other dementing disorders. Performance on neuropsychological testing in Parkinson's disease varies across patients, but deficits are often found on tests that require psychomotor speed, visuospatial processing, executive functioning, and memory (Pirozzolo et al. 1982). In addition, performance may be impaired on tests that measure concept formation and problem solving in new situations (Matthews and Haaland 1979), category fluency, and mental flexibility (Beatty et al. 1989).

Patients with Huntington's disease often exhibit executive functioning impairment that involves difficulty with mental flexibility and abstraction but with relatively preserved "overlearned" verbal skills (i.e., on the Information and Vocabulary subtests on the WAIS-R). Memory impairment also commonly occurs with Huntington's disease and is characterized by impairment in the acquisition and retrieval of new information, as well as by impaired remote memory later in the disease process (Albert et al. 1981). In contrast with patients with Alzheimer's disease, who are characterized by dysnomia, patients with Huntington's disease can exhibit normal performance on confrontation naming tests (Butters et al. 1978).

Dementia with Lewy bodies (DLB) is a progressive, degenerative dementia that is often overlooked when making a differential diagnosis of dementia type, but one that has important implications for appropriate treatment (McKeith et al. 1996; for a review, see Hansen and Galasko

1992). As many as 15%–25% of patients undergoing autopsy may have Lewy bodies present in the brainstem and cerebral cortex. The core cognitive features include progressive, insidious cognitive decline with pronounced fluctuations in attention and arousal; recurrent, typically well-formed and detailed visual hallucinations; and motor features consistent with parkinsonism. Memory deficits may not be evident in the early stages, but impairments in executive control and visuospatial and visumotor skills are mostly likely early prominent features. Other supportive features include syncope, repeated falls, hallucinations in various modalities, and fixed delusional system(s). Patients with DLB are usually neuroleptic sensitive, which in fact is considered a core feature in diagnosis. This is very important in terms of psychiatric treatment. Elderly patients who present with recent onset of a fixed delusional system with visual hallucinations should be considered for a diagnosis of DLB, and the use of a neuroleptic should be carefully considered (see McKeith et al. 1996).

### **Depression-Related Cognitive Dysfunction**

It is estimated that from 10% to 20% of patients with depression have significant cognitive impairment (Reynolds and Hoch 1988). In addition, depression frequently accompanies neurological disorders such as Alzheimer's disease (Kaszniak 1987), stroke (Robinson and Price 1982), and extrapyramidal diseases such as Parkinson's and Huntington's (Cummings 1985). The labels *pseudodementia* (Kiloh 1961), *dementia syndrome of depression* (Folstein and McHugh 1978), *depression-induced organic mental disorder* (McAllister 1983), and *depression-related cognitive dysfunction* (Stoudemire et al. 1989) have been used to describe the reversible cognitive impairment in elderly patients with depression. Since Kiloh's initial characterization of pseudodementia (1961), numerous articles have described the clinical features of cognitive impairment secondary to depression and its differentiation from progressive and irreversible conditions such as Alzheimer's disease (Bulbena and Berrios 1986; Cummings 1989; Jeste et al. 1990; Kaszniak 1987; see Christensen et al. 1997 and Veiel 1997 for reviews). Although the concept of depression-related cognitive impairment is well accepted and has had value in identifying potentially treatable forms of dementia, the term *pseudodementia* has come under criticism (Arie 1983; Lamberty and Bieliuskas 1993; Reifler 1982; Shraberg 1978, 1980). These criticisms have stemmed primarily from the implication that cognitive dysfunction secondary to depression does not represent a "real" or "organic" phenomenon. Additional criticisms have been based on the

lack of diagnostic specificity of the term and from the lack of utility of the concept in predicting response to treatment.

Understanding of the complexity of cognitive dysfunction in elderly patients with depression has increased substantially over the last decade, and an increasing number of systematic studies have been designed to assist in the separation of the potentially reversible (and treatable) dementia of depression from irreversible and often progressive conditions such as Alzheimer's disease and vascular dementia. Although currently no universally accepted neuropsychological template exists for the differentiation of depression-related cognitive dysfunction from cognitive impairment secondary to specific brain disease, research has suggested that neuropsychological test results may be useful in this regard. For example, several studies have pointed to the usefulness of confrontation naming tests, such as the Boston Naming Test (Kaplan et al. 1983), in the differential diagnostic process (Caine 1981; Hill et al. 1989; Petrick and Mittenberg 1992), although this finding has not been found by all researchers (Speedie et al. 1990). Further complicating the issue is research suggesting that depression might represent an early marker for later developing progressive dementia (Kral and Emery 1989; Nussbaum et al. 1991; Reding et al. 1985). Others have recommended that detailed historical information and behavioral features, along with qualitative aspects of neuropsychological performance, are helpful in making a differential diagnosis (Kaszniak and Christenson 1994).

Christenson et al. (1997) recently performed a meta-analysis of studies looking at the cognitive effects of depression. Two types of studies were analyzed: patients with depression versus psychiatrically healthy control subjects and patients with depression versus patients with Alzheimer's disease. Essentially, patients with depression show impaired performance across all cognitive domains with very little intact cognitive skills. One of the greatest effect size was in executive control skills. However, relative to psychiatrically healthy control subjects, patients with depression were mostly impaired on speeded tasks and vigilance tasks. No difference in the effect size was found when comparing free recall to recognition memory, semantic processing, or using verbal versus nonverbal material. Patients with depression were equivalent to those with Alzheimer's disease on recall compared with recognition and verbal compared with nonverbal processing and were significantly better in all other cognitive domains. The notion that the difference between depression and dementia (especially that of the Alzheimer's type) is a result of effortful (including speeded tasks) versus noneffortful tasks received some support in the meta-analysis. Thus, patients with de-

pression being impaired only on effortful (and speeded) tasks, but patients with dementia being impaired on both effortful and noneffortful tasks (Hartlage et al. 1993), may have important use in the differential diagnosis between depression and dementia. But not all noneffortful tasks discriminated well. Also, the notion that recognition versus recall distinguished depression from dementia was not supported by the meta-analysis. The possibility that speed of processing or attentional components might distinguish depression from dementia was proposed by the authors. This was also supported by another meta-analysis that compared younger patients with depression to psychiatrically healthy control subjects (Veiel 1997). The issue of cognitive dysfunction in elderly patients with depression is a complicated one that deserves further study.

## ■ Ecological Validity of Neuropsychological Tests

Because neuropsychologists are increasingly asked to render decisions about functional capacity and competency of the elderly patient, ecological validity of standard neuropsychological tests is a central and important issue. Indeed, the utility of neuropsychological assessment lies not only in its ability to aid in the diagnostic process, but also in its capacity to provide information regarding the patient's ability to function in his or her natural environment. Neuropsychological test performance and outcome measures have only a moderate relationship (Acker 1990; Chelune and Moehle 1986), but have a greater predictive accuracy for functional skills demanding complex information processing, such as writing a check, than for basic functional capacity, such as performance of a personal hygiene skill (Baird et al. 1999; Goldstein et al. 1992; Loeb 1996; McCue et al. 1990; Rogers et al. 1994).

Even with the good predictive validity neuropsychological tests have for general functional abilities, little direct evidence indicates that neuropsychological test results can predict specific functional abilities such as driving or appropriate residential placement (see Blaustein et al. 1988; Kaszniak and Nussbaum 1990). Unfortunately, relatively few empirical data exist to support the predictive validity of neuropsychological test performance on these functional domains in older patients. The development of new neuropsychological tasks that more closely parallel ADLs is much needed (Zappala et al. 1989). Currently, decisions are more often based on estimates of the patient's performance on more traditional neuropsychological measures that have no direct corollary "in real life." In particu-

lar, decisions regarding the patient's ability to drive are often based on performance on visuospatial, attentional, memory, and executive functioning tasks, as these processes are generally thought to be requisite to the safe operation of an automobile. The development of ecologically valid neuropsychological tests to more directly assess the patient's ability to perform real-life activities requires continued attention and represents one of the biggest challenges for the field of geriatric neuropsychology. To this end, we see the direct assessment of functional abilities (such as the Independent Living Scale) as one method for trying to fill this void. We find that we are better able to address the issues of functional capacity and level of competency by using standardized neuropsychological tests in conjunction with the direct assessment of functional abilities. Although not a perfect solution, this certainly is a step in the right direction.

## ■ Conclusions and Future Directions

In this chapter, we have reviewed several important issues related to the neuropsychological assessment of older patients. First, the use of a flexible, individualized approach to neuropsychological assessment with older patients is advocated because it typically requires less time than standard fixed batteries, is cost-effective, and is patient driven, thus providing the opportunity to address specific cognitive deficits. Second, despite recent developments in geriatric neuropsychology, a continued need exists for empirical-clinical investigation of the utility of different evaluation approaches to the assessment of older adults. Third, age-appropriate normative data for individuals over the age of 74 are still inadequate. Although progress has been made in this area, a need for normative data for individuals in this age group remains. Fourth, the use of neuropsychological testing in the differential diagnosis of dementing illnesses, particularly subcortical versus cortical dementia and depression versus dementia, remains an important area deserving of continued attention. Fifth, the ecological validity of neuropsychological assessment is a relatively new area of concern that deserves sophisticated empirical investigation. Cognitive tests that predict the functional capacity of older patients are just being developed and incorporated into the formal neuropsychological test battery. They have the potential of adding valuable information in addressing a wide range of referral questions. Finally, continued specialized training of the clinical neuropsychologist in the assessment and treatment of older patients is needed.

# Age-Associated Memory Impairment

Graham Ratcliff, D.Phil.

Judith Saxton, Ph.D.

In this chapter, we review the memory changes associated with aging, paying particular attention to the phenomenon of age-associated memory impairment (AAMI). We begin the chapter with a brief overview of what is known about memory loss in older adults and a discussion of some current theoretical interpretations of these data. We then turn to the specific, well-defined phenomenon of AAMI, reviewing and critiquing proposed diagnostic criteria for this condition, exploring its clinical significance, and considering alternate constructs. We make the points that age-related memory changes can be conceptualized in a number of different ways and that different constructs, associated with different sets of diagnostic criteria, are appropriate for different purposes. We consider the prime distinguishing feature of currently available constructs to be the comparison group (young adults or the elderly individual's age peers) with reference to which memory is compared, approaches that we see as relevant to the study of normal aging and pathological aging, respectively.

We then undertake a brief review of the characteristics

of individuals who exhibit age-related memory changes and explore some possible biological bases for these conditions. Finally, we discuss some principles and practical considerations relating to clinical memory assessment in elderly individuals and describe some of the tests available for this purpose.

## Background

Solid, converging evidence exists from a variety of sources that some otherwise healthy, normally aging individuals experience a deterioration in memory as they grow older (Kaszniak et al. 1986; Poon 1985). The literature of experimental psychology suggests that this decline typically affects secondary memory, also known as *long-term* or *recent memory*, more than it affects primary (*short-term* or *immediate*) memory or tertiary (*remote*) memory (Schacter et al. 1991). Age effects also sometimes appear in working memory (Baddeley 1986), tasks that require the individual not only to hold information in mind for a short time, but also

to perform some mental operation on that information or perform another task simultaneously (Bromley 1958; Craik 1977; Dobbs and Rule 1989; Salthouse et al. 1989).

The net main effect of these changes is to reduce the ability to encode new information into memory, hold it over time, and recall it after an interval. Although the processes involved in remembering, particularly encoding and retrieval, become less effective as we grow older, the content of our memories—our knowledge base—can continue to increase (Perlmutter et al. 1987). Older people may, therefore, perform nearly as well as young people on tests such as digit span (in which information need only be held temporarily in a short-term memory store) or on tests assessing general knowledge or vocabulary (which assess well-learned factual or semantic knowledge rather than memory for specific events). Older people are likely to perform less well on tests such as backward digit span or delayed recall of recently presented material exceeding their immediate memory spans.

Psychometric evidence confirms that the decline of memory with increasing age is of substantial proportions. Performance on standard tests of secondary memory declines with age such that the norms for people 70–74 years old on the Wechsler Memory Scales (WMS-R [Wechsler 1987]; WMS-III [Wechsler 1997b]) call for scores up to 50% lower than those expected of young adults, and further declines are seen in individuals age 75 and older (Ivnik et al. 1992b). Age seems to have a more deleterious effect on the subtests involving memory for nonverbal material than on memory for verbal material, recall is more affected than recognition memory, recollection of detail declines more than recall of the general theme in memory for narrative, and the decline on verbal list learning is greater than that for narrative recall (Wechsler 1997b).

In the clinical literature, the phenomenon of “benign senescent forgetfulness” (Kral 1958) has been recognized for more than 30 years. The disorder was described as being the forgetting of details of events without loss of awareness of the events themselves. Remote memories were more affected than recent memories and people who had this disorder were aware of their problem and attempted to compensate for it. Kral et al. (1964) thought that this relatively mild and inconsistent memory impairment was nonprogressive and originally attributed it to normal aging (Kral 1962). They distinguished it in these respects from the “malignant” forgetfulness of the organic amnesic syndrome and dementia.

However, although this general picture is easily discerned and consistent from several viewpoints, the details are less clear and more controversial. In one view, for example, age-related changes in memory are secondary to other

cognitive changes. Thus, reduced speed of information processing with increasing age has been held to play a major role in the memory changes associated with aging and accounts for a substantial proportion of age-related variance in memory tasks (e.g., Luszcz et al. 1997; Salthouse 1996). Similarly, Craik (1990, 1991; Craik and Jacoby, 1996) has argued that the degree of age-related impairment on memory tasks depends on the degree to which the task demands more active, less routine, and more internally organized processing on the part of the subject rather than on the type of memory involved. Older subjects have more difficulty with, or are less inclined to use, this kind of processing and perform less well on tasks that require it.

Other studies have highlighted the relationship between age-related memory changes and the executive functions subserved by the frontal lobes. The frontal lobes may be particularly vulnerable to aging both structurally (Coffey et al. 1992) and functionally. Frontal lobe functions have been reported to be impaired in individuals with AAMI (Hallikainen et al. 1995), and some organizational aspects of memory test performance in the elderly resemble that of younger individuals with frontal lobe lesions (Stuss et al. 1996). Age-related changes in source memory, which has been related to frontal lobe function, have also been reported (Degl’Innocenti and Backman 1996), and performance on tests of executive function explains a significant amount of age-related variance in memory test scores (Troyster et al. 1994).

Certainly, some of the factors that affect the degree of age-related decline on memory test performance affect performance on other cognitive tasks in a similar way. For example, the differential difficulty of verbal and visuospatial memory tests for elderly patients is mirrored in differential rates of decline on the verbal and performance subtests of the Wechsler Adult Intelligence Scales (WAIS-R [Wechsler 1981]; WAIS-III [Wechsler 1997a]), and it may be that the decline in visuospatial memory can be more usefully regarded as a facet of impaired visuospatial ability rather than as a problem primarily of memory (Koss et al. 1991). Similarly, the changes in working memory may be regarded primarily as information-processing deficits rather than as memory impairments, per se, and the age effect seems to appear only when certain kinds of processing are required (Salthouse et al. 1991).

In this view, memory can be regarded as just one aspect of cognition, an emergent property of the human information processing system, which, like other aspects of cognition, is affected by changes in the efficiency of that system. For a further review of these and other resource theories, see A. D. Smith (1996). The implication is that we may learn more about age-related changes in cognition if we do

not think of them as changes in memory, perception, attention, and so on, but instead attempt to analyze the memory, perceptual, and attentional tests we use to identify the information-processing requirements involved. Nevertheless, the important end-product for the clinician is that memory, as assessed by clinical memory tests, declines with age in well-established ways.

Just as the magnitude of the age-related decline in memory and the nature of the underlying cognitive processes affected are less well established than the fact of a decline in memory performance, so the defining characteristics, epidemiology, and clinical significance of benign senescent forgetfulness have not been well delineated although the existence of the disorder is recognized. Kral (1958) described some of the characteristics of his subjects' forgetfulness, but he did not define operational criteria for diagnosing the disorder and he did not objectively quantify the impairment. Although he initially regarded the disorder as a part of normal aging (Kral 1962), his subjects were nursing home residents and patients in a psychiatric hospital. More than half of them exhibited neurological signs suggesting lesions in the brain, as did nearly half of his unimpaired subjects. His subjects were thus certainly not drawn from a "normal" population, and Kral himself subsequently speculated (Kral et al. 1964) that benign and malignant forgetfulness might differ only in degree and both might be reflections of a single underlying pathological process. Of course, this would not necessarily make them "abnormal" if the "usually aging" individual who exhibits the range of physiological and even pathological changes typically associated with aging (D. B. Caine et al. 1991), rather than the optimally healthy "successfully aging" individual (Rowe and Kahn 1987), is accepted as the norm.

## ■ Constructs of Age-Related Memory Decline

### Definitions

Before discussing the specific construct of AAMI (Crook et al. 1986a) in detail, we need to define some of the terms used in this chapter. Our purpose in doing so is emphatically not to introduce yet more terms into the literature; we only wish to simplify communication for the purposes of this review. Many of the apparent disagreements about age-related memory changes are attributable to the inconsistent use of terms. To this end, *age-associated memory impairment* (AAMI) is used in this chapter strictly as defined by Crook et al. (1986a) and designates only phenomena

meeting all the National Institute of Mental Health (NIMH) work group's diagnostic criteria. We also at times refer separately to the NIMH "psychometric criteria for AAMI." By these we mean the conditions set out in criteria c, d, and e, which define memory impairment but not the population eligible for diagnosis (see next section). We also make a general distinction between "age-appropriate forgetfulness," implying a decline in memory from young adult levels (of which AAMI is a specific example), and "age-inappropriate forgetfulness," implying memory impairment in comparison with age peers. The distinction between age-appropriate and age-inappropriate forgetfulness was recognized by Blackford and La Rue (1989) in their definitions of *age-consistent memory impairment* (ACMI) and *late-life forgetfulness* (LLF), the terms apparently being chosen for their similarity to those designating the similar constructs of AAMI and benign senescent forgetfulness, respectively; but we use their terms only to refer to phenomena meeting their specific diagnostic criteria. Finally, we use the general phrase *age-related memory decline* as an all-embracing, vaguely defined term to refer to any and all changes in memory allegedly associated with aging.

### Diagnostic Criteria for Age-Associated Memory Impairment

The construct of AAMI was introduced by a NIMH work group (Crook et al. 1986a). It was the group's declared intention to facilitate communication and stimulate research into late-life memory loss, particularly its treatment, by introducing research diagnostic criteria, with the expectation that the criteria would be modified as research in the area developed. Modifications have indeed been suggested (Blackford and La Rue 1989; Larrabee and McEntee 1995, 1996; Rosen 1990; G. Smith et al. 1991), but have not yet been universally agreed on. The NIMH work group made a great contribution by providing a focus for discussion and emphasizing the importance of a detailed operational definition of the construct with which they were dealing. Their original criteria for AAMI are summarized as follows:

- a. Age 50 years or over;
- b. Complaint of memory loss affecting everyday functioning with gradual onset;
- c. Memory test performance at least 1 SD below the mean established for young adults on a standardized test of secondary memory with adequate normative data;
- d. Adequate intellectual function as determined by a scaled score of at least 9 on the Vocabulary subtest of

the Wechsler Adult Intelligence Scale (WAIS) (Wechsler 1955);

- e. Absence of dementia as determined by a score of 24 or higher on the Mini-Mental State Exam (MMSE) (Folstein et al. 1975); and
- f. Exclusion criteria including absence of a number of medical conditions, depression, risk factors for stroke, history of repeated minor or single major head injury, drug or alcohol abuse, or recent use of psychotropic medications that might affect cognitive function together with, in many cases, guidelines for determining whether these conditions were present.

Also, it should be noted that this definition of *age-associated memory impairment* differs from Kral's concept of *benign senescent forgetfulness* (Kral 1958) in several important respects. First, these criteria are attempting to capture a different phenomenon than that described by Kral, and the comparison group is different in the two cases. The AAMI criteria define *impairment* with respect to healthy young adult levels, not to those of the older individual's age peers as was implied in the description of benign senescent forgetfulness. Thus, it would logically be possible for all older individuals to meet criteria for AAMI, by exhibiting poorer memory than young adults, without exhibiting benign senescent forgetfulness in the sense of poorer memory than would be expected of a psychiatrically healthy older individual. Conversely, except for those who failed the AAMI exclusion criteria (including at least 53% of Kral's original group), cases of benign senescent forgetfulness would generally meet criteria for AAMI unless the clinical evidence of forgetfulness was not substantiated by poor performance on standardized memory tests. In practice, this is probably relatively infrequent if the judgment is based on a reasonably thorough clinical evaluation and not just a subjective report of memory impairment. With these provisos, *benign senescent forgetfulness* can be regarded as a subset of *age-associated memory impairment*, but the terms are not equivalent.

Second, the term *age-associated memory impairment* is "non-specific with regard to etiology and does not necessarily imply that the disorder is non-progressive" (Crook et al. 1986a, pp. 269–270). Thus, patients whose memory impairment is subsequently shown to be the earliest stage of a dementing illness are not necessarily excluded from the category of AAMI, and it is sensible to ask how often AAMI is, in fact, a dementia prodrome. This also implies that AAMI is not necessarily to be regarded as nonpathological, although the lengthy and detailed exclusion criteria clearly indicate that Crook and his colleagues had an optimally healthy cohort in mind when they defined it.

## Utility of the Construct of Age-Associated Memory Impairment

The construct of AAMI can be criticized on several grounds. First, is the phenomenon it attempts to identify—decline from presumed young adult levels rather than an age-inappropriate impairment of memory relative to older individuals' age peers—the appropriate one to define? Second, if so, do the proposed criteria actually capture it clearly? Third, is the term *age-associated memory impairment* appropriate, and should it be regarded as a diagnosis? Finally, although the specification of diagnostic criteria has undoubtedly helped clarify some issues, is a focus on classification and diagnosis the best way of investigating and describing the changes in memory associated with aging?

When we rate the memory of elderly people, should we compare their memory with the presumably better memory of young adults as Crook et al. (1986a) suggested, or should we compare older adults with each other to identify a subgroup with poorer memory more in the spirit of Kral's benign senescent forgetfulness? Both approaches are feasible and have their merits, but both have practical and theoretical disadvantages. Only the former approach can tell us whether the memories of older people are, in fact, worse than the memories of younger people. However, it is difficult to be sure that the memory of a given older individual has changed over time without reference to test scores obtained from that individual in youth. Cross-sectional studies comparing older individuals' data with normative data collected from young people suffer from the obvious risk of cohort effects, as well as the more general problems involved in referencing performance to published norms based on populations whose demographics are incompletely specified or frankly different. Conversely, only the latter approach can tell us whether an individual has an abnormally poor memory given his or her age, but normative data on cognitive test performance in the old-old has, until recently, been virtually nonexistent, although some progress is being made in this regard. A number of studies from the Mayo Clinic, for example, are useful in the psychometric assessment of the elderly (Ivnik et al. 1992a, 1992b, 1992c), and the most recent version of the Wechsler Memory Scale (WMS-III) (Wechsler 1997b) includes norms for individuals up to 89 years old.

As is often the case, the answer depends on what question one is interested in. Arguing for the "decline from young adult" model, Crook and Ferris (1992) pointed out that elderly people typically complain that their memories are worse than they used to be, not that their memories are worse than those of their age peers, and that the decline is

sufficiently common and sufficiently severe to justify therapeutic trials, whether it is normal or not. These researchers compared the situation to other conditions, such as presbyopia, which are “defined by reference to normative standards for young adults and . . . so common among the elderly as to be considered ‘normal.’ Nevertheless, few clinicians would compare the vision of an 80-year-old with norms established for other people of the same age and prescribe corrective lenses only to those whose visual performance falls outside those norms” (Crook and Ferris 1992, p. 714). If the primary purpose is to select subjects for trials of treatments for a potentially normal age-related decline in memory, the NIMH concept of AAMI is appropriate and the strict exclusion of other possible causes of memory impairment is necessary.

### **Alternative Approaches to Age-Related Memory Decline**

On the other hand, if one is interested in defining a disease state, identifying a dementia prodrome, or performing clinical evaluation of the mass of elderly individuals who are referred for neuropsychological assessment, the “impaired relative to age peers” approach may be more appropriate or, at least, provide a useful additional conceptual framework. Several different ways of defining an age-inappropriate memory impairment have been proposed, and, where the evidence is available, these do seem to identify abnormal memory functioning, although whether the condition is benign has not been conclusively established. In this vein, Larrabee et al. (1986) identified individuals with “senescent forgetfulness” on the basis of memory test performance significantly worse than performance in other cognitive domains and significantly below an age-residualized mean (i.e., they conceptualized it as an age-atypical deficit specific to memory without necessarily implying change from a higher level earlier in life). Senescent forgetfulness defined in this way did not seem simply to be one end of a continuum of memory function because memory test performance in their sample was bimodally distributed, raising the possibility of some causative disease process. Larrabee and Crook (1989) also identified a subgroup of AAMI subjects whose performance on more ecologically valid, everyday memory tests was impaired relative to an age-residualized mean. In both studies, the prevalence of age-inappropriate memory impairment actually increased with increasing age, suggesting that the pathological process involved, if any, is age related. Larrabee and Crook (1989) also pointed out that their age-residualized, cross-sectional data suggest that this form of memory impairment is not evenly distributed across the adult age

range (i.e., those individuals who are shown to be abnormally forgetful after age 65 are not all likely to have been abnormally forgetful earlier in life).

### **Clinical Significance of Age-Inappropriate Forgetfulness**

The value of the construct of an age-inappropriate, selective impairment of memory lies chiefly in its clinical significance, particularly whether it is a correlate of disease and whether it is truly benign or heralds an impending dementia. The evidence on this point is, as yet, inconclusive, although the topic clearly deserves further investigation. Larrabee et al. (1986), for example, failed to find any progression of memory deficit in their subjects with age-inappropriate “senescent forgetfulness” at 1-year follow-up, whereas Katzman et al. (1989) reported that 37% of the “functioning individuals with memory impairment [who] might well have been considered to have benign senescent forgetfulness” in their sample of elderly volunteers had dementia at 5-year follow-up and Parnetti et al. (1996) concluded that some subjects with AAMI may have early Alzheimer’s disease. Further, O’Brien et al. (1992) reported an intermediate rate of progression to dementia of 8.8% in a group of 68 patients with benign senescent forgetfulness followed for an average of 3 years. However, these researchers based the diagnosis of forgetfulness entirely on subjective report, specifically excluding subjects who showed objective evidence of memory impairment on psychological tests. This is a different construct from the senescent forgetfulness of Larrabee et al. (1986), which was objectively demonstrable, and highlights the importance of the use of comparable terms in diagnostic criteria.

Another important aspect of the concept of age-inappropriate forgetfulness advanced here and by Larrabee et al. (1986) is that memory should be selectively impaired, or at least disproportionately affected, in comparison with other cognitive functions. This is another difference from the NIMH concept of AAMI, in which the memory impairment could be associated with age-related decline in other cognitive functions, provided that these were not sufficient to justify the diagnosis of dementia and did not substantially affect vocabulary test performance. The disproportionately severe impairment of memory in comparison with other cognitive functions may also distinguish the concept of age-inappropriate forgetfulness advanced here in principle, although possibly not in practice, from other concepts of “mild cognitive impairment not amounting to dementia” (World Health Organization 1978) or “questionable dementia” as used in the Clinical Dementia Rating Scale (Hughes et al. 1982) in which the

preservation of nonmnemonic cognitive functions is either not required or only implied. More recently, Petersen and colleagues have proposed broad criteria aimed at identifying individuals with mild cognitive impairment (MCI) who are thought to be at risk for developing dementia (Petersen et al. 1996, 1999). These criteria are broadly similar to age-inappropriate memory decline in that the individual is required to exhibit a significantly abnormal memory performance compared with age-matched peers with relatively normal general cognitive functioning. Although there is still considerable uncertainty regarding the diagnostic criteria for MCI, it had been reported that individuals with MCI progress to Alzheimer's disease at a rate of 12% per year (Petersen et al. 1999) and that those with focal memory impairment, and carrying the APOE-epsilon 4 allele, have increased risk of developing Alzheimer's disease (Petersen et al. 1996). These conversion rates suggest that not all individuals meeting MCI criteria progress to Alzheimer's disease. Indeed, some individuals appear to remain in a plateau for many years, and some may never progress to dementia (Miceli et al. 1996). On the whole, studies using these kinds of classifications seem to find rather higher rates of progression to dementia than those attempting to isolate senescent forgetfulness, although the line of demarcation is not well defined (Dawe et al. 1992). It is not certain for example, to what extent the baseline impairment in Katzman et al.'s subjects (1989) was specific to memory. Although Reisberg et al. (1986) found that the extent to which subjects deteriorated was dependent on initial degree of impairment (i.e., the more impaired subjects tended to show more deterioration), this was based on a global assignment of "magnitude of cognitive decline" rather than on an assessment of memory performance in comparison to other cognitive functions.

The essential difference between the two principal concepts of age-related memory decline discussed so far has been the standard against which memory is compared—the young or the healthy elderly. A third approach is to look for qualitative rather than quantitative differences between the memory of healthy older individuals and the other groups of interest. Generally, the memory of individuals with dementia is much worse than that of healthy elderly people, but not qualitatively different (Huppert 1994). However, Grober and colleagues (Grober and Buschke 1986; Grober et al. 1988) have suggested that a failure to benefit to the normal extent from semantic cuing may distinguish the memory impairment of dementia and this, rather than absolute score, may also be a way of identifying age-inappropriate memory impairment in individuals without dementia.

The significance of abnormal rates of forgetting

(Cullum et al. 1990), the severity of memory impairment compared to other cognitive functions (Cullum et al. 1995), overall pattern of neuropsychological test performance (Hänninen et al. 1995), and slow rates of learning (Petersen et al. 1992) have also been emphasized. Although such studies of qualitative aspects of memory in aging are important, we do not believe that they should be incorporated into the diagnostic criteria. The memory of individuals with AAMI may be qualitatively different from the memory of young adults, as well as quantitatively worse; however, the construct of AAMI is not defined by that difference.

To summarize, there are two distinct concepts of age-related memory decline, and both are useful. The concept of a potentially normal age-related decline from young adult levels envisaged by the NIMH criteria for AAMI is appropriate for studies of normal aging and memory. On the other hand, the phenomenon of selective, age-inappropriate forgetfulness in elderly people does appear to exist (Larrabee et al. 1986), and this concept is likely to be more useful in clinical evaluations and research looking for the antecedents of dementia (Barker et al. 1995; Blackford and La Rue 1989; O'Brien and Levy 1992; G. Smith et al. 1991).

### **Applicability of the Original Diagnostic Criteria for Age-Associated Memory Impairment**

Several criticisms of the NIMH criteria for AAMI (Bamford and Caine 1988; Barker et al. 1995; Blackford and La Rue 1989; O'Brien and Levy 1992; Rosen 1990; G. Smith et al. 1991) were reviewed in detail in the first edition of this volume. As Larrabee and McEntee (1995) have pointed out, many of these criticisms referred to psychometric problems that have psychometric solutions, and these issues have become less contentious in the last 5 years. Nevertheless, the issue of precise diagnosis is so important that we review these criticisms briefly here. The reader is referred to the earlier version of this chapter (Ratcliff and Saxton [1994]) and to Larrabee (1996) and Larrabee and McEntee (1995) for further discussion.

First, the criticism of memory test performance 1 SD below the mean for young adults does not make adequate provisions for individuals whose memory functioning as a young adult was substantially above or below average. The former could experience significant deterioration in memory without meeting criteria for AAMI, whereas the latter would meet criteria on reaching age 50 without necessarily experiencing any decline in memory. Similarly, the inclusion criteria of a vocabulary score of at least 9 renders

around half of normal adults over the age of 70 ineligible for the diagnosis, and no a priori reason seems to exist to suppose that individuals whose level of intellectual functioning is in the lower half of the average range should not experience age-related declines in memory.

Several authors have suggested ways of overcoming these problems by adjusting memory test scores for presumed level of intellectual function using vocabulary or education as an index and comparing the memory of older individuals with that of young people of an equivalent intellectual level (Goodman and Zarit 1994; Larrabee 1996; Larrabee and McEntee 1995; Ratcliff and Saxton 1994; Rosen 1990). Generally, the effect of these modifications has been to identify a group that seems to reflect the intended construct of AAMI more effectively than the original criteria.

Other criticisms involve the connotation of the term "impairment" in this context (G. Smith et al. 1991), the exclusion of individuals with medical conditions that may be normative in the elderly (Malec et al. 1993; Ratcliff and Saxton 1994), and the use of an MMSE score of 24 as a cut-off for dementia (Ratcliff and Saxton 1994).

A final main criticism of the original NIMH criteria involves the requirement for complaints of memory loss affecting everyday life with gradual onset and without sudden worsening in recent months, and this deserves discussion in more detail. Subjective report of memory impairment has been associated with depressed mood (Kahn et al. 1975; Popkin et al. 1982), neuroticism (Poitrenaud et al. 1989), age stereotypes of failing memory to which the complainant subscribes (Scogin et al. 1985; Zarit et al. 1981), and self-reported health status and number of functional limitations (Cutler and Grams 1988), as well as actual memory impairment (Zelinski et al. 1980).

The frequency with which older individuals "complain" of memory problems is probably also crucially dependent on how the question is asked. Only about half of Cutler and Grams's 14,564 subjects (1988) reported trouble remembering things "frequently" or "sometimes" as opposed to "rarely" or "never," whereas Sunderland et al. (1986) reported a "universal belief" among their elderly subjects that their memories failed them more frequently "now" than "when age 30." Sunderland and colleagues did find evidence of age-related memory impairment on objective tests in their group, but the frequency of reported memory failures was related to performance on only a few of the memory tests, and very few subjects regarded memory failures in everyday life as "even a minor handicap." Sunderland et al. (1986) also reported only moderate agreement between different subjective methods of memory assessment, and their questionnaire (although carefully

designed and based on one that had been used effectively with younger individuals with memory impairment resulting from head injury and with their families [Sunderland et al. 1983]) showed low test-retest reliability. Even though studies involving clinical samples show more relationship between complaint and performance than do community-based studies, and progress is being made in the design and selection of appropriate instruments (Zelinski and Gilewski 1988), these observations cast serious doubt on the validity of current methods of subjective memory assessment and imply that subjective complaints of memory impairment should not be uncritically accepted at face value. Nevertheless, they may have a place in the diagnostic criteria for age-related memory decline.

Larrabee and McEntee (1995) point out that the requirement of both subjective complaint and objective deficit may exclude, on the one hand, those individuals who have always functioned at the low end of the normal range throughout adulthood but had noticed no recent decline in memory; whereas, on the other hand, individuals who report memory impairment secondary to psychological factors will not meet the objective-memory test criterion. Neither group constitutes having age-related memory decline. In support of this argument, Larrabee and McEntee quote the data of Koivisto et al. (1995), who found in a large epidemiological study that 76.3% of their sample reported subjective memory impairment and 78.4% were impaired on objective tests, but only 53.8% met both criteria. This appropriate self-exclusion of relatively low-functioning individuals whose memories have not declined probably occurs on a less formal basis in clinical practice, as it is the perception of memory loss rather than poor memory test performance that usually brings patients to the clinic.

It should also be noted that laboratory memory tests may not themselves be good predictors of real-life memory function. Thus, the failure to find correlations between subjective report of memory impairment and poor performance on standard memory tests may be attributable to the fact that laboratory memory test performance does not reflect the everyday memory abilities that are accurately reported by the subjects. In at least one study (Larrabee et al. 1991), good correlations were obtained between performance on a battery of computerized memory tests ingeniously designed to simulate everyday memory functions (Crook et al. 1986b) and responses to a subjective memory questionnaire with good psychometric properties (Crook and Larrabee 1990). Unlike many previous authors, Crook and Larrabee did not find that subjective memory complaint was related to depressed mood. Nevertheless, in spite of this result, subjective reports of memory impair-

ment are currently so difficult to interpret that they should be treated with extreme caution.

### Differential Sensitivity of Memory Tests

Even if general diagnostic criteria are agreed upon, the differential sensitivity of different memory tests to aging indicates that the particular test used will determine the size of the population defined. G. Smith et al. (1991) found that at least twice as many of their two groups of elderly subjects met NIMH psychometric criteria for AAMI when a less verbal memory test—Visual Reproduction from the Wechsler Memory Scale (Wechsler 1945) or WMS-R, rather than Logical Memory from the same tests—was used as the index of memory impairment. Even when two verbal tests with a different format (Logical Memory and the Rey Auditory Verbal Learning Test [RAVLT] [Rey 1964]) were compared (Lezak 1983), the proportion of cases identified varied by a factor of more than 4 (20%–96% in one group and 11%–58% in the other). Similar results were reported by Raffaele et al. (1992) with classification rates varying from 22.7% for immediate Logical Memory to 53% for delayed Visual Reproduction. The general tendency is for more subjects to be classified as “impaired” by visuospatial tests than by verbal tests, by delayed recall than by immediate recall, and, at least within the verbal domain, by list learning tasks than by narrative recall. The difference in sensitivity appears to be attributable partly to the modality involved, but also to the psychometric properties (e.g., ceiling effects) of the tests themselves (Raffaele et al. 1992).

Blackford and La Rue (1989) addressed the issue of differential sensitivity of memory tests by requiring that the test battery include at least four memory tests and recommended a number of instruments from which the clinician may select. They defined three levels of impairment on the basis of such a battery: AAMI (performance at least 1 SD below the mean established for young adults on one or more tests); ACMI (performance within + 1 SD of the mean established for age on 75% or more of the tests administered); or LLF (performance between 1 and 2 SD below the mean established for age on 50% or more of the tests administered). Although this reduces the problem of differential sensitivity, it does not eliminate it, as studies using, for example, the four secondary memory tests from the WMS-R would still be expected to yield different rates of LLF than would those including a list learning task like the RAVLT.

A possible compromise is to use a composite score based on the weighted averages of scores on a group of individual tests (rather than looking at the percentage of tests

on which performance falls below a certain level). The General Memory Index and Delayed Recall Index derived from the WMS-R are based on such weighted averages of four tests, including both verbal and nonverbal material, and a composite score based on these tests is considerably more sensitive than each of the component tests individually (G. Smith et al. 1991). Though it may be premature to specify the particular tests that should be used in assessing age-related memory decline as G. Smith et al. (1991) suggested, the WMS-R meets some of the requirements and has the advantages that it is widely used and that normative data for the older old are becoming available.

### Age-Associated Memory Impairment as a Diagnostic Entity

It was not the stated intention of the NIMH work group to imply that AAMI was a disease or that it was necessarily abnormal or that it had a known and defined pathological basis for which a diagnostic laboratory test might, in principle, be developed. Instead, as stated above, they proposed to introduce a “diagnostic term” (Crook et al. 1986a) and associated diagnostic criteria to facilitate communication and promote research, particularly into pharmacological treatment for the condition they defined. Nevertheless, a number of subsequent authors have objected to the term on the grounds that it does imply a clinical diagnosis, which in turn implies a disease, although the phenomenon it denotes does not merit such a status (Bamford and Caine 1988; O’Brien and Levy 1992; Rosen 1990). Perhaps because of these kinds of criticism, future diagnostic systems are likely to modify the construct (Caine 1992), distinguishing between age-appropriate and age-inappropriate impairments on the one hand and between those associated with and independent of other systemic or central nervous system disease on the other.

Even if AAMI (or LLF or any other form of age-related memory decline) does constitute a diagnostic entity, one can ask whether the construct is appropriately named and whether it is likely to be useful. Just as the term *benign senescent forgetfulness* can be criticized because it is not clear that the implication of nonprogression is necessarily justified, so the term *age-associated memory impairment* has been criticized because *impairment* connotes abnormality, which is not a necessary part of the AAMI construct (G. Smith et al. 1991). *Decline* or *loss*, which connote deterioration from a previously higher level but not abnormality, might be better. Ironically, the more descriptive and less evaluative term *forgetfulness* has been used in two contexts (*benign senescent forgetfulness* and *late-life forgetfulness*) in which abnormality is implicitly or explicitly involved.

## Possible Biological Bases of Age-Related Memory Decline

A number of neuroanatomical and neurochemical changes are known or suspected to occur with aging, and some of these might plausibly be related to deterioration in memory. Modest age-related decreases are known to occur in the size of the mammillary bodies (Raz et al. 1992) and temporal lobe structures (Coffey et al. 1992). Both these brain areas are known to be involved in memory. Hippocampal volume has been reported to be correlated with memory test performance in psychiatrically normal elderly subjects (Golomb et al. 1994) and to be reduced in patients with amnesia (Press et al. 1989) and in patients with Alzheimer's disease (Kesslak et al. 1991; Seab et al. 1988), although Seab and colleagues did not find that the degree of atrophy was related to severity of memory impairment. The possible relationship to frontal lobe function is discussed above. It is also noted above that the majority of the elderly are not completely healthy, and a wide range of comorbidities probably influence memory and other cognitive functions in the elderly. We have found, for example, that individuals with cardiovascular disease even at subclinical levels (Kuller et al. 1994) performed less well on memory tests and on tests of speed, attention, and working memory than did those free of such disease. Cognitive test performance was also related to relatively rare diseases such as diabetes and emphysema. Poor performance on tests of attention, visuospatial ability, and delayed recall from the WMS-R was also associated with history of bypass surgery.

The presence of the APOE-epsilon 4 allele may help distinguish the small subset of individuals whose memory impairment may represent an early, monosymptomatic stage of Alzheimer's disease (Blesa et al. 1996; Petersen et al. 1995). White matter changes documented by computed tomography or magnetic resonance imaging are a frequent incidental finding in the elderly (Coffey et al. 1992). Whereas some authors have found that these are both more severe and related to severity of cognitive impairment in individuals with dementia, this is certainly not universally agreed to be the case (Kozachuk et al. 1990). Similarly, changes in cholinergic neurotransmitter systems are well documented in Alzheimer's disease and may also be found in normal aging (Morgan 1992). These changes have been suggested as a possible basis for AAMI (Bartus et al. 1982). Crook and Larrabee (1988) have reviewed other potential underpinnings of AAMI and recommended trials of pharmacotherapy on this basis, although this approach has not been generally agreed upon.

These and other potential causes of AAMI deserve further study, but to date we are not aware of a consistent body

of empirical evidence that conclusively links age-related memory decline to specific neurochemical or anatomical changes. In the search for such evidence, it will be necessary to bear in mind the distinctions between age-appropriate and age-inappropriate forgetfulness and, consequently, to look for correlates in both successfully and unsuccessfully aging individuals.

## Future Research Strategies

The availability of diagnostic criteria for AAMI should not thwart the pursuit of other goals for aging research or other approaches to the study of age-related memory decline. As discussed above, memory can be regarded as an emergent property of the human information-processing system as well as a cognitive domain in which an individual may or may not exhibit impaired functioning. The information-processing system could be affected in a number of different ways, any or all of which could cause the individual to meet criteria for AAMI but have different theoretical, prognostic, and, possibly, therapeutic implications. A different kind of research focused on the processes involved in remembering is required to determine what age-related memory decline is, rather than simply whether it is present in a given individual.

We also need to supplement AAMI-oriented research with studies of aging individuals in which some form of psychometrically defined age-related memory decline is the independent variable and medical conditions, demographics, and subjective report are treated as dependent variables rather than as exclusion criteria. Certainly, it is important to know what proportion of the community-resident elderly exhibits a decline in memory and, for those that do, what the typical causes or, at least, correlates of that decline are. As we have seen, the NIMH exclusion criteria render a large proportion of the population ineligible for the diagnosis of AAMI, and many of these individuals do not exhibit memory impairment in spite of the "threats to memory" (G. Smith et al. 1991) represented by the condition causing their ineligibility. Conversely, it is likely that some of the ineligible individuals who do exhibit memory impairment do so because of age-related changes, rather than because of their medical conditions. It is our impression that, in community samples, rather than patient groups, the adverse effect of medical and psychiatric illness on cognition is minimal, although it may be demonstrable in large group studies. In our sample of community-resident elderly individuals (described above), we evaluated self-reported depressive symptomatology in the previous week using the Center for Epidemiological Studies Depression Scale (CES-D) (Radloff 1977) and assessed

memory using the WMS-R. Although a significant correlation was found between depression score and Delayed Recall weighted raw score, this accounted for less than 3% of the variance. Furthermore, individuals with CES-D scores exceeding a conventional cutoff score of 17, raising the possibility of clinically significant depression, were found only slightly more frequently among individuals meeting psychometric criteria for AAMI (11% compared with 7% of individuals not meeting these criteria).

## ■ Clinical Memory Assessment in the Elderly

The way in which the clinician investigates the memory of the elderly patient and the thoroughness of the assessment will depend on the purposes and circumstances of the evaluation. It is clear that the assessment must involve some form of objective memory test, rather than relying on subjective report. The minimum requirement for such a test is that it involve the delayed recall of recently presented information and be sufficiently difficult that it is not subject to a marked ceiling effect. The word list learning test used by the Consortium to Establish a Registry of Alzheimer's Disease (CERAD) (Morris et al. 1989) meets these minimal requirements, but the three words from the MMSE (Folstein et al. 1975) do not, as the test is too easy to be sensitive to mild or even moderate memory impairment. Preferably, the test should also involve multitrial learning as well as memory, providing a way of comparing the ability to encode, retain, and recall information (e.g., immediate and delayed recall trials); use both verbal and nonverbal material; and have norms for elderly individuals. A combination of measures is probably required if all these requirements are to be met adequately, and some suggestions were made by Blackford and La Rue (1989). A selection of memory tests was also reviewed by Lezak (1983) and by Spreen and Strauss (1998), and the subject was discussed more extensively in *Clinical Memory Assessment of Older Adults* by Poon (1986).

Although it is not ideal, our usual practice is to base routine memory assessments on the Logical Memory and Visual Reproduction subtests of the WMS-R or WMS-III supplemented by a learning task, typically the RAVLT or the revised version of the Hopkins Verbal Learning Test (Benedict et al. 1998). As noted above, the WMS-R and the WMS-III go some way toward overcoming the problem of differential sensitivity of different tests by providing summary scores based on the weighted averages of subtests involving immediate and delayed recall of verbal and nonver-

bal material. It is true that the more age-sensitive list-learning type of task is underrepresented in these weighted averages, but this is partially compensated by the fact that the Logical Memory subtest (recall of short passages of prose, similar to news items) weighs heavily and is one of the more ecologically valid memory tests in common clinical use (Sunderland et al. 1983). If prediction of everyday memory function is crucial, however, it would be more appropriate to use the Rivermead Behavioral Memory Test (Wilson et al. 1985) or a research instrument of the kind described by Crook et al. (1986b). The WMS also allows one to compare verbal and nonverbal memory, although the tests are not terribly well matched. Norms for the older old are now available for the WMS-R (Ivnik et al. 1992b) and are included in the manual for its recent successor, the WMS-III (Wechsler 1997b). We do not yet have sufficient experience with the WMS-III to form a definite opinion, but it is likely that similar considerations will apply, although the test, while improved in several respects, is more cumbersome to use and it may be more efficient to extract relevant subtests. If so, we would recommend substituting the RAVLT for the list learning and paired associate subtests of the WMS-III on the grounds of greater sensitivity. The addition of a Working Memory Index may also prove very useful.

Summary scores should be used with caution because information is lost and important discrepancies between individual component scores can be concealed. Nevertheless, summary scores can be convenient and, when one is required, we favor the Delayed Recall weighted raw score over the Immediate Recall weighted raw score because it incorporates a delay and can be expected to be more sensitive to memory impairment in general and age-related memory decline in particular. We prefer the weighted raw scores in some circumstances to the indexes, which can be derived from them, because the former are not age corrected so that an individual's scores can be compared with other individuals of any age.

We also find the Rey-Osterrieth Complex Figure (ROCF) (Osterrieth 1944; Rey 1941) to be extremely useful. It is our practice to administer copy, immediate, and 30-minute delayed recall conditions because the comparison of performance on all three stages provides a wealth of information. For individuals too impaired to complete the original ROCF, we have developed a simplified version and have published norms for healthy elderly and individuals with Alzheimer's disease (Becker et al. 1987; Saxton and Becker, in press).

Finally, we usually use the delayed recall scores rather than a forgetting score calculated by subtracting delayed from immediate recall because we believe that, in most

populations, it will be more sensitive to memory impairment without sacrificing specificity to an unacceptable degree. The rationale is as follows: whatever aspect of memory is involved (encoding, retrieval, rate of forgetting, and so on), delayed recall will be affected. It is true that other disorders (e.g., aphasia) may cause low delayed recall scores by impairing the ability to process the information to be remembered. These disorders can then masquerade as memory impairments, a state of affairs that could be avoided by use of an immediate-recall-minus-delayed-recall criterion that would reveal that the information had not been encoded into memory at the outset. However, as the memoranda on the WMS-R and most other standardized memory tests exceed memory span, moderate memory impairments may affect immediate, as well as delayed, recall and therefore would not be fully reflected in an immediate-recall-minus-delayed-recall measure of forgetting. In community-resident populations, the incidence of false negatives of this kind is likely to exceed the incidence of false positives secondary to inability to adequately process the stimulus material. Further, in clinical evaluations one should never consider any test score in isolation, always remembering that any test, however well designed, can be failed for multiple reasons. When false negatives do occur, usually independent evidence of the responsible disorder will be present to help the clinician interpret the results.

The assessment of memory in the elderly, like neuropsychological evaluation in all other circumstances, therefore involves weighing an individual's current memory function against the level that would be expected for that individual on the basis of age, education, and level of intellectual functioning and against his or her functioning in other cognitive domains. As we acquire more data on the natural history of aging and memory and learn more about the significance of age-inappropriate forgetfulness, we will be better able to set the balance and interpret the results.

## ■ Summary and Conclusions

To what extent does our research and review of the recent literature enable us to amplify or modify the generalizations with which we began this chapter? First, the recent evidence, spurred by the provision of psychometric criteria for AAMI, confirms that memory test performance is typically poorer in the elderly than in the young. Age affects delayed recall more than it affects immediate recall, and visuospatial material is typically less well recalled than verbal material. Accordingly, estimates of the prevalence of AAMI vary widely depending on which kind of material and what form of test is used. Our view is that the great ma-

majority of elderly people are affected to some degree, but that the decline reaches significant proportions only in a subset, the size of which varies widely depending on the criteria used, and is perceived as a significant problem by only a small minority.

Second, there is sufficient evidence to justify distinguishing age-appropriate and age-inappropriate forms (or levels) of age-related memory decline. The former, of which AAMI is an example, represents a normal age-related phenomenon, whereas the latter, the true descendent of benign senescent forgetfulness, is by definition abnormal and, possibly, pathological. Whether age-inappropriate forgetfulness is progressive, whether it can be distinguished from other concepts of mild cognitive decline by virtue of being specific to memory, and whether it is qualitatively different from normal memory or merely worse is not yet certain. The prevalence of age-inappropriate forgetfulness is also undetermined, but it is certainly less common than the age-appropriate form.

Completely satisfactory diagnostic criteria do not yet exist for AAMI or any other concept of age-related decline in spite of valiant efforts (Blackford and La Rue 1989; Crook et al. 1986a). Improved criteria would take an individual's overall level of intellectual functioning or educational background into account when setting the standard against which to rate memory, distinguish age-appropriate from age-inappropriate decline, make reference to the selectivity of memory impairment, modify the requirement for subjective complaint, and recognize the possibility of a number of comorbidities, rather than impose rigid exclusion criteria. The last might be achieved by assigning a level of probability to the diagnosis much as in the research diagnostic criteria for Alzheimer's disease of the National Institute of Nervous and Communicative Disorders and Stroke and the Alzheimer's Disease and Related Disorders Association (McKhann et al. 1984). Because of the varying sensitivities of different memory tests, it may also be necessary to specify the characteristics of suitable tests, if not actually require that specific, named tests be used.

# Anatomic Imaging of the Aging Human Brain

## *Computed Tomography and Magnetic Resonance Imaging*

C. Edward Coffey, M.D.

For most of human history, life expectancy was remarkably stable at about 30–40 years (Cutler 1976, 1979). Within the past 150 years, however, advances in medical science (particularly the successful treatment of infectious diseases) have resulted in a dramatic increase in life span, so that men and women born in 1980 can now expect to live for an average of 70.0 and 77.5 years, respectively (Rowe and Katzman 1992). As such, the elderly segment of our population is growing; the number of persons 65 years old or older increased 8-fold from 1900 (3 million) to 1980 (25 million), and the number of those over age 75 (the so-called old old) has increased 11-fold during that same time period (from 900,000 to 10,000,000) (McFarland 1978).

The continued expansion of the elderly segment of our population and a growing awareness of age-related diseases such as dementia have prompted considerable interest in the study of the aging human brain. Central to this study have been efforts to characterize the spectrum and extent of changes in brain morphology that occur with “normal ag-

ing.” Such normative data are essential for an understanding of “pathological” brain aging in elderly people (Creasey and Rapoport 1985; DeCarli et al. 1990; Drayer 1988).

Investigations of age-related changes in brain morphology have used two approaches: autopsy studies and brain imaging techniques. Autopsy studies have found consistent age-related reductions in brain weight and volume (about 2% per decade), cortical volume, and regional cortical neuronal number (Creasey and Rapoport 1985; Katzman and Terry 1992; see also Chapter 3 in this volume). Ventricular dilation has also been reported, and the variance of measurements of ventricular size appears to increase with age. However, neuropathological measures of brain morphology are subject to sources of error such as selection bias, technical and fixation artifacts, and the influences of premorbid illness and cause of death (which may be different for young versus elderly cohorts). Brain imaging techniques avoid many of these problems and provide an opportunity to examine brain morphology in healthy

living subjects, with increasing anatomical resolution.

In this chapter, I review imaging studies that have examined the effects of aging on brain anatomy. I begin with a discussion of methodological issues relevant to such investigations and then summarize findings regarding the effects of age on brain ventricular and parenchymal structures. Finally, the potential relationship of these structural brain alterations to age-related changes in cognitive function is also discussed.

## ■ Methodological Issues Relevant to the Imaging Assessment of Age-Related Changes in Brain Structure

### Study Design

Imaging studies of brain aging can be designed as either cross-sectional or longitudinal investigations. In cross-sectional studies, a single imaging evaluation is performed at roughly the same time on a group of subjects whose ages differ across a range of interest. Such studies allow for relatively rapid, efficient, and economical acquisition of large amounts of data, and it is not surprising therefore that most investigations to date have used a cross-sectional design. However, cross-sectional studies may be influenced by secular effects (i.e., the possibility that brain size exhibits systematic changes over successive birth cohorts in the general population). For example, successive generations may have, on average, larger parenchymal volumes and smaller ventricular volumes. If such trends actually exist in the population at large and if they are not secondary to secular trends associated with correlates of brain morphology such as cranial size or years of education, then an assessment of the true effects of aging on brain size will require longitudinal investigation.

In longitudinal studies, imaging evaluations are repeated on the same group of subjects as they age over time. Such studies are thus free of secular effects, but they are labor intensive and may suffer from significant attrition effects (i.e., subject dropout may result in a sample at the end of the investigation that is markedly different from that at the beginning). Longitudinal studies may also outlive their usefulness (the period effect); for example, an ongoing study of ventricular size that began in the era of pneumoencephalography would not be of great interest in today's world of high-resolution computed tomography (CT) and magnetic resonance (MR) imaging.

The interpretation of both cross-sectional and longitudinal investigations must also consider the possible influences of "survivor effects" and heterogeneity within the el-

derly population (Creasey and Rapoport 1985). *Survivor effect* refers to the overrepresentation in study samples of relatively healthy subjects (the survivors) because others with preexisting illnesses may have died before study entry. Relative to younger populations, the elderly exhibit greater heterogeneity in a variety of physiological variables that could indirectly influence brain structure. In summary, both cross-sectional and longitudinal study designs have strengths and limitations: the choice of one approach over the other will depend on available resources and the specific aims of the investigation.

### Subject Selection

Brain morphology may be affected by variables in the subject sample that are associated with the aging process (e.g., concomitant medical illnesses such as hypertension, diabetes mellitus), as well as by other variables that are relatively independent of it (e.g., gender, body or head size, handedness, education, socioeconomic status, and psychiatric and drug-use history). These variables must be considered and appropriately controlled before conclusions can be reached about the effects of aging, per se, on brain anatomy. It should also be noted that the apparent effects of age on brain structure may vary depending on the age range of the sample studied. In general, aging effects have been less robust in samples with restricted age ranges (Appendixes 9-1, 9-2, and 9-3).

**Subject sample.** Selection of an appropriate subject sample is obviously a critically important first step in any investigation of aging effects on brain morphology. A sample of healthy volunteers from the community may differ markedly from a sample of medical or psychiatric *patients* with "normal" scans. Although the latter samples provide a convenient and economical source of readily available imaging data, such samples may include individuals with structural brain changes resulting from causes other than aging (Coffey et al. 1998). In addition, patient samples are generally less representative of the variability in brain morphology that exists within samples of healthy volunteers. As noted above, such heterogeneity is especially great among the elderly, a finding that may be related in part to differences between "usual aging" (i.e., no clinically obvious brain disease) and "successful aging" (i.e., minimal decline in neurobiological function in comparison to that of younger subjects) (Coffey et al. 1998; Rowe and Kahn 1987).

Thus, even within studies that examine healthy community volunteers, considerable variability in brain morphology may exist depending on the relative mix of subjects

with usual versus successful aging. Whenever possible, studies should attempt to define the extent to which their subjects fall within these two categories, based in part on thorough medical, neuropsychiatric, and neuropsychological evaluations, as well as on correlative assessments of brain function (e.g., with electroencephalography [EEG], single photon emission computed tomography [SPECT], or positron-emission tomography [PET]). Even these evaluations may fail to identify subjects with various other conditions that may affect brain morphology, including those with preclinical disease or with genetic predispositions to disease. In this chapter, I review those studies that have for the most part examined healthy volunteers from the community.

Sample size is also an important factor in interpreting results—negative findings in studies with relatively small samples may be a result of low power.

**Gender and body size.** Women are smaller (i.e., shorter and lighter) on average than men are, and, as such, their heads and brains also tend to be smaller (Gould 1981). Even within a single-gender study, however, differences in body or head size among subjects may confound apparent age-related differences. Although there is no generally accepted method of correcting for head or body size, this variable may be taken into account either through subject matching (e.g., on height), statistical analysis (e.g., analysis of covariance), or the use of ratio measures (e.g., using intracranial or total brain size as the denominator) (Appendixes 9–1, 9–2, and 9–3). The latter procedure suffers from two limitations (Coffey et al. 1998). First, the ratio approach implicitly assumes that brain size is perfectly correlated with intracranial size. Although the two variables are highly correlated, the assumption of perfect correlation is in my view untenable. Second, the ratio approach creates outcome variables that are necessarily bounded between zero and one. Such variables may have distributions poorly suited for linear regression analysis. Even after controlling for differences in head size, the literature suggests that gender may interact with the aging process to influence changes in brain structure (see below).

**Handedness.** Several studies have demonstrated differences in regional brain size or symmetry between right-handed and left-handed (or non-right-handed) individuals (Kertesz et al. 1992; Witelson 1992). Surprisingly, only a few investigations of the aging brain have specified the handedness of their subjects (Appendixes 9–1, 9–2, and 9–3). This variable should be assessed with continuous quantitative measures (Coffey et al. 1992), and its effects on brain structure should be controlled either statistically or

through subject inclusion criteria (e.g., limiting the sample to those subjects with definite motoric lateralization).

**Education and socioeconomic status.** Imaging studies have reported a relationship between brain structure and educational level or socioeconomic class (Andreasen et al. 1990; Coffey et al. 1999; Pearlson et al. 1989b). This relationship may be an indirect one, however, with both of these variables (and perhaps also IQ) serving as markers for body or head size (Pfefferbaum et al. 1990). Studies of brain aging should assess the potential impact of these variables statistically (Coffey et al. 1992, 1999) or attempt to control them through subject matching procedures when appropriate (Pfefferbaum et al. 1990).

**Psychiatric and drug-use history.** Alterations of brain morphology have been described in patients with a variety of psychiatric disorders, including schizophrenia (Pfefferbaum et al. 1990), affective illness (Coffey 1996; Coffey et al. 1990, 1993), and eating disorders (Laessle et al. 1989). Although some earlier studies failed to specify the psychiatric histories of their subjects, more recent investigations have appropriately excluded patients with such histories (Appendixes 9–1, 9–2, and 9–3). Alcohol and perhaps other drug use may also alter brain structure (Casella et al. 1991; Lishman 1990; Pfefferbaum et al. 1998), but again studies have varied in the extent to which these factors have been considered (Appendixes 9–1, 9–2, and 9–3). Although more recent investigations of brain aging have generally excluded subjects with substance abuse or dependence, the effects of subclinical drug or alcohol consumption on structural brain aging have not been thoroughly assessed. One major impediment to such efforts has been the inability to obtain reliable and accurate data about the extent of lifetime drug use.

## Imaging Technique

**Imaging modality.** Early imaging modalities provided only indirect visualization of the human brain by imaging either the skull (skull radiography), the cerebral vessels (arteriography), or the cerebrospinal fluid (CSF) spaces (pneumoencephalography). More recent developments in computer technology have now made possible in vivo visualization of brain tissue with imaging techniques such as CT and MR imaging. These techniques differ in their safety, anatomical resolution, and sensitivity to tissue contrast.

X-ray CT images are formed when X rays are passed through the brain from several different directions. Detectors opposite the X-ray source measure the extent to which

passage of the X-ray beams has been attenuated by the intervening tissues. Computers relate this information to the density of the various structures (e.g., CSF, bone, gray matter, and white matter) and then construct a series of tomographic images of the brain and cranium.

X-ray CT is a relatively quick and inexpensive imaging modality, but because subjects are exposed to irradiation (about 2 rad), serial studies in healthy individuals may not be possible. The method is also limited by relatively low spatial and anatomic resolution, partial volume effects (inaccurate averaging of tissue attenuation values), and beam-hardening artifact (false elevation of brain CT values adjacent to the skull). This latter problem limits the precision with which boundaries can be determined for structures adjacent to bone, including the temporal lobes, the apical cortex, or the inferior frontal lobes, regions of great interest to neuropsychiatrists.

MR images are formed when the alignment of ions (in medical imaging these are typically protons) in a strong magnetic field is disrupted by a brief radiofrequency pulse. When the pulse is terminated, radiofrequency energy is emitted as the protons become realigned within the magnetic field. Computers relate this emitted radiofrequency energy to various tissue (proton) characteristics, from which a series of planar or three-dimensional images can be constructed. Various imaging sequences may be used to examine different tissue characteristics, resulting in images that are relatively T1- or T2-weighted. In general, T1-weighted images provide greater anatomic resolution, whereas T2-weighted images provide higher contrast and greater sensitivity to pathological tissue changes.

Relative to CT, MR imaging provides more accurate structural information because of clear differentiation of gray matter, white matter, and CSF; the absence of beam-hardening artifact; and the capability to image in multiple planes, thereby providing optimal views of regional cerebral structures with less volume-averaging artifact (see below). Additionally, MR imaging has greater sensitivity to detect pathological tissue, particularly hyperintense foci of the subcortical white matter and gray matter nuclei (subcortical hyperintensity) that occur with increasing frequency in elderly people (Coffey and Figiel 1991). Because MR imaging does not use ionizing radiation, serial studies in healthy subjects are possible.

For these reasons, MR imaging appears to be uniquely suited to the study of age-related changes in brain morphology. It should be noted however, that accurate assessment of brain structure with MR imaging may be affected by a number of technical factors, including choice of acquisition sequence parameters (affecting tissue contrast), slice section thickness (adjacent sections that are too thin may

result in overlapping profiles and “cross-talk” artifact), and magnetic field homogeneity (inhomogeneous fields may result in spatial distortion of objects and object pixel nonuniformity) (Jack et al. 1988). Movement artifact may also be induced by pulsation of blood and CSF, especially in the limbic system where structures lie in close proximity to the ventricles and the carotid arteries—such artifact can be lessened with the use of cardiac-gating and flow-compensated pulse sequences (Pfefferbaum et al. 1990). Careful consideration of these methodological issues is needed to ensure precision of measurement with MR imaging. MR imaging is a more expensive and often more lengthy procedure than CT, and some subjects may be unable to cooperate with the long imaging time, especially if they feel confined by the scanner and develop claustrophobia; however, recent advances in imaging technology have resulted in considerable shortening of scanning time with MR imaging. Finally, MR imaging cannot be used in subjects who have a pacemaker or intracranial ferromagnetic objects such as surgical clips. Irrespective of whether CT or MR imaging is employed, the quality of the images collected may be affected by several factors.

**Plane of imaging.** The optimal orientation from which to visualize brain anatomy will vary depending on the structure of interest. For example, corpus callosum and medial prefrontal cortex are best seen on midsagittal images, axial images provide a good view of subcortical white matter and gray nuclei (i.e., thalamus and basal ganglia), and coronal sections are required for optimal views of the temporal lobes and limbic structures. With brain CT, the plane of imaging is limited by the patient’s position in the scanner: because typically the patient is supine, axial images are produced. With MR imaging, the plane of imaging can be determined simply by programming the magnetic gradients, making possible images in the coronal, axial, and sagittal planes, irrespective of patient positioning within the scanner.

Once the appropriate imaging plane has been selected, the images must be acquired in a standardized orientation so that valid comparisons across subjects are possible. Proper alignment of acquisition plane is especially critical for studies of brain asymmetry because head tilt can result in artifactual right-left differences. External landmarks (e.g., the canthomeatal line) are relatively quick and easy to establish for orientation, but they may not be consistently related to brain structure (Homan et al. 1987). Such problems may be obviated by use of internal landmarks (e.g., the anterior commissure–posterior commissure line), but these can be more technically difficult to establish and thus may add to the length of the scanning procedure.

**Slice thickness.** Image resolution is affected by section thickness, as each image data point (voxel) in the slice represents an average of slice thickness (millimeters) raised to the third power. Thus the thinner the section, the higher the resolution. However, with thin sections, a greater total scanning time is required to image a given volume, and thin sections are also associated with a reduced signal-to-noise ratio (less tissue is present to produce a signal). Furthermore, slice thickness with MR imaging is limited by certain technical factors including gradient strength, quantity of radiofrequency energy used for excitation, and the phenomenon of cross-talk artifact. This latter problem can be partially obviated by leaving space between adjacent sections (interscan gap), but this method excludes a given portion of tissue from direct assessment, thereby reducing the accuracy of volume measurements (particularly of small or irregular structures). Section interleaving is another method for reducing cross-talk artifact, but this procedure doubles scanning time.

**Phantom calibration.** Verification of the accuracy of imaging data against a known standard (phantom) should be conducted on a regular basis to ensure stability of the imaging hardware. With MR imaging in particular, image data may be affected by variations in the main magnetic field, the magnetic field gradient systems, and the radiofrequency pulse system.

**Head movement artifact.** Involuntary head movement by subjects is another source of artifact that can degrade image quality. Head movement is more likely as the length of the scanning time increases, and it may be especially troublesome in certain clinical circumstances. For example, at least some elderly subjects with arthritic conditions may be unable to lie still for more than a few minutes, making comparisons with younger nonarthritic subjects problematic. Head movement may be reduced by physical restraints (e.g., Velcro straps or fitted plastic masks) or the use of sedative medications, but the latter are rarely appropriate for use in nonpatient volunteers.

## Methods of Image Analysis

**General considerations.** The quality of imaging data is affected by several factors related to the methodology of image analysis. First, measurements can be made on a variety of different forms of imaging data including radiographs, overhead projections of radiographs, photographs of the image, or displays of the original digital image data on computer consoles (Jack 1991). Computerized digital data systems afford the greatest flexibility and permit stan-

dardization of window settings across images, thereby providing for greater consistency and accuracy of measurement than is possible from films, where window settings are fixed. Second, the interpretation of brain imaging data will be affected by the criteria used to define the structure of interest. For example, the measured size of the frontal lobes on MR imaging will vary depending on whether their posterior boundary has been defined by the optic chiasma, the genu of the corpus callosum, or the central sulcus (Coffey et al. 1992; Kelsoe et al. 1988). Anatomic non-uniformity in these landmarks across subjects will also contribute to variability in regional brain measures. Third, the reliability of the measures of brain anatomy will vary with the skill of the rater—both interrater and intrarater reliabilities should be reported for all raters, using either kappa statistics or intraclass correlation coefficients. Finally, it should be clear from the above that assessment of imaging data requires considerable subjective judgment on the part of the rater. As such, all measurements should be performed by raters who are “blind” to subject data (e.g., age, gender, and diagnostic group) or to study hypotheses that could bias such assessments.

**Types of measures.** The effects of aging on brain morphology have been assessed with both qualitative and quantitative measures. Qualitative measures consist of various scales to determine the presence and severity of parameters of interest, including, for example, cortical atrophy or ventricular enlargement. Qualitative measures are relatively inexpensive and easy to use, do not require sophisticated technological support, are frequently “clinically relevant,” and may show good agreement with more quantitative assessments (Zatz et al. 1982a). Qualitative measures have limited resolution and sensitivity, however, and their accuracy is critically dependent on the skill of the particular rater. For this reason, it is often difficult to compare results from different studies, especially when different rating scales have been used.

Quantitative measures of brain size may be either linear (distance measurement), planimetric (area measurement), or volumetric (multisection planimetric). Linear and planimetric measures are relatively quick and inexpensive and are available to researchers who lack sophisticated computerized image processing capabilities. Such measures also correlate reasonably well with volumetric measures, at least for structures of regular shape. For more complicated structures with irregular shapes, however, volumetric measures are much more accurate, especially when the sections are relatively thin (< 5 mm) and contiguous, and when they span the entire extent of the structure of interest. Volumetric measures are also more sensitive than

linear and planimetric methods for detecting subtle group differences (Gado et al. 1983; S. Raz et al. 1987). Finally, volumetric measures are especially important for assessing left-right asymmetries because single-section measures are much more susceptible to the confounding effects of head tilt and patient positioning and because bilateral structures may not be aligned in a perfectly parallel position within the left and right hemispheres. In such situations, the left and right sides of a structure could differ with regard to the particular imaging section on which they appeared larger, in which case left-versus-right comparisons based on a single section clearly would not be representative of any asymmetry in the total volume of that structure.

Among quantitative brain imaging studies, differences exist in the technique used to segment the cranial contents into bone, CSF, white matter, and gray matter compartments. Regions of interest may be outlined manually (“trace” technique) or tissue segmentation can be performed automatically by establishing threshold values of pixel intensity for each tissue compartment. These automated procedures should improve substantially test-retest reliability and the speed with which large volumes of imaging data can be analyzed, but they are less adept at segmenting regions with similar pixel intensity values (e.g., separating amygdala from hippocampus).

## Effects of Aging on Brain Structure

### Ventricular Size

Brain CT and MR imaging investigations have consistently demonstrated *enlargement of the ventricular system* with age (Appendix 9–1). The reported extent of enlargement has varied, however, depending on the way in which ventricular size has been assessed. General estimates from the literature suggest that, over the first nine decades of life, the ventricular/brain ratio (VBR) may increase nonlinearly from 2% to 17% (Barron et al. 1976; Pearlson et al. 1989a; Schwartz et al. 1985; Stafford et al. 1988), the proportion of ventricular fluid volume to brain volume may increase from 2%–4% to 4%–8% (Stafford et al. 1988), and the proportion of ventricular fluid volume to cranial volume may increase from 1%–2% to 2%–4% (R. C. Gur et al. 1991; Jernigan et al. 1990; Murphy et al. 1992; Pfefferbaum et al. 1986). These age effects appear to be similar for the lateral and third ventricles (Coffey et al. 1992; Murphy et al. 1992; Schwartz et al. 1985). The fourth ventricle is rarely reported separately from the total ventricular system (Appendix 9–1). Shah et al. (1991) and Blatter et al. (1995) found no relation between age and fourth ventricular size.

In a study of 76 healthy adult volunteers from our laboratory, we found that increasing age was associated with significantly larger volumes of the lateral ventricles and the third ventricle (Coffey et al. 1992). After adjusting for gender and intracranial size, both lateral ventricular volume and third ventricular volume were found to increase by approximately 3% per year (Figure 9–1). In a second study focusing on elderly volunteers ( $N = 330$ ) living independently in the community, we found age-specific increases in lateral ventricular volume of approximately 0.95 mL/year and in third ventricular volume of approximately 0.05 mL/year, over ages 65–95 years old (Coffey et al. 1998).

We have also conducted blinded ratings of lateral ventricular enlargement to provide a “clinical context” within which to interpret these volumetric changes (Coffey et al. 1992). We found that the frequency of at least mild lateral ventricular enlargement (Table 9–1) increased significantly with age, in agreement with numerous imaging and postmortem studies (Appendix 9–1). The odds of at least mild lateral ventricular enlargement were 0.10 at age 40 and increased by approximately 7.7% per year to 2.22 at age 80. This ventriculomegaly was typically rated as mild in severity, however; and more than one-half (54%) of our elderly subjects did not meet criteria for lateral ventricular

**FIGURE 9–1.** Increase in brain ventricular volumes with age, relative to volumes at age 30. Linear regression models for  $\log_e$  (volume), controlling for the effects of gender and intracranial size, indicated that volume increased exponentially with age for both the lateral ventricles (*line A*) and the third ventricle (*line B*). The rate of volume increase was similar for each region (3.2% per year and 2.8% per year, respectively).

enlargement (Table 9–1). These findings are consistent with the increased variation in ventricular size with age that others (Creasey and Rapoport 1985; DeCarli et al. 1990) have observed. Thus, although ventricular volume increases with age, it appears that “clinically rated” ventricular enlargement is not an inevitable consequence of advancing age.

Only a small number of longitudinal studies of age-related ventricular enlargement have been reported (Appendix 9–1). Gado et al. (1983) found a 3.7% increase in the ratio of ventricular volume to cranial volume on CT in 12 elderly subjects followed for 1 year, but no change in linear measures of ventricular size. In a sample of older adults, Shear et al. (1995) reported an average increase in ventricu-

**TABLE 9–1. Ratings of cortical atrophy, lateral ventricular enlargement, and subcortical hyperintensity**

lar system volume on CT of approximately 0.61 mL/year over an average follow-up period of 2.6 years. Mueller et al. (1998) found a 1.4 mL/year increase in lateral ventricle volume on MR imaging in elderly subjects followed for 3–9 years. In a sample of 28 healthy 21- to 68-year-old men, Pfefferbaum et al. (1998) observed increases in both lateral (approximately 5 mL, or 20%) and third ventricular volumes on MR imaging over a scanning interval of 5 years.

A significant *hemispheric asymmetry* (left greater than right) exists in the volumes of the lateral ventricles (Coffey et al. 1992; Zipursky et al. 1990), but only a few studies have examined whether the right and left lateral ventricles differ with regard to aging effects (Appendix 9–1). Most of these authors have found no differences in aging effects on the two hemispheres (Coffey et al. 1992, 1998; DeCarli et al. 1994; Murphy et al. 1992, 1996; Schwartz et al. 1985), but R. C. Gur et al. (1991) reported that the age-related increase in ratio of ventricular CSF volume to cranial volume was more pronounced in the left hemisphere than in the right, a difference they attributed primarily to elderly men.

Although *gender differences* have been described in the size, symmetry, and function of several brain structures, only a small number of imaging studies have examined the effects of gender on brain aging in nonpatient samples of living humans (see Coffey et al. 1998 for review). Most studies, including recent work from our group, have found no gender effects on the age-related increase in lateral or third ventricular volume (Appendix 9–1). Because age-related ventricular enlargement is presumed to occur as a result of shrinkage of periventricular brain matter, these results are also consistent with other studies that found no effect of gender on the age-related volume loss of structures that form the borders of the lateral ventricles (i.e., the caudate nuclei) (Krishnan et al. 1990; Murphy et al. 1996) or the third ventricle (i.e., the thalamus) (Murphy et al. 1996) (see below). In contrast, Grant et al. (1987) reported that men, but not women, exhibited a significant age-related increase in lateral ventricular volume, although this apparent gender difference was not tested. Likewise, Blatter et al. (1995) observed higher correlations in males than in females between age and lateral ventricle volume (adjusted for intracranial volume [IV]) ( $r = .444$  versus  $r = .218$ , respectively) and between age and third ventricle volume (adjusted for IV) ( $r = .634$  versus  $r = .406$ , respectively), but again these correlations were not statistically compared. Kaye et al. (1992) reported that the precipitous age-related increases in lateral ventricular volume began about a decade earlier in males than in females. Finally, Murphy et al. (1996) found that *females* actually had a greater age-related increase in the ratio of third ventricle volume/IV than did males.

## Brain Atrophy

**Generalized brain atrophy.** The effects of age on brain size have been assessed with visual estimates (qualitative ratings) of sulcal enlargement, quantitative measurements of CSF spaces, and quantitative measurements of total and regional brain size. Age has been found to be significantly correlated with visual ratings of sulcal enlargement (Coffey et al. 1992; Jacoby et al. 1980; Yoshii et al. 1988) (Appendix 9–1). The only exceptions to these observations are the reports of Laffey et al. (1984) and Wahlund et al. (1990), which limited investigation to elderly subjects.

In our study of 76 healthy adults (Coffey et al. 1992), the odds of a rating of at least mild cortical atrophy were found to increase by approximately 8.9% per year such that, by age 68, subjects had a 50% chance of having acquired cortical atrophy. In spite of this predicted high frequency, the cortical atrophy present in our subjects was typically rated as mild (Figure 9–2). Moderately severe cortical atrophy was uncommon (four [9%] of 46 elderly subjects), and none of our subjects exhibited severe cortical atrophy (Table 9–1). These data suggest that although brain volume declines with age (see below), cortical atrophy (like ventricular enlargement) 1) is not an inevitable correlate of normal aging and 2) when present is typically mild in severity and therefore relatively unlikely to be considered “clinically significant.”

Quantitative studies of sulcal CSF spaces have consistently demonstrated increased CSF volume with age (Appendix 9–1), the only exception being two relatively small studies of older adults (Tanna et al. 1991; Wahlund et al. 1990). Estimates of sulcal and cisternal volume range from 1 mL at the second decade of life to 40 mL at the ninth decade (Zatz et al. 1982a). Over the same age span, the proportion of sulcal CSF volume to cranial volume increases from approximately 3% to approximately 10% (R. C. Gur et al. 1991; Jernigan et al. 1990; Murphy et al. 1992), roughly at a rate of 1.0% per decade (Coffey et al. 1998; DeCarli et al. 1994; Pfefferbaum et al. 1994). The age-related increase in sulcal CSF volume may not be linear, however, and appears to be greatest after age 60 (Pfefferbaum et al. 1986; Zatz et al. 1982a). Variability in the measures of sulcal CSF volume also increases substantially with age (Coffey et al. 1998; DeCarli et al. 1994; Pfefferbaum et al. 1986; Zatz et al. 1982a).

Only a small number of *longitudinal studies* of age-related sulcal CSF volume increase have been reported (Appendix 9–1). Gado et al. (1983) found that the ratio of sulcal CSF volume to cranial volume increased by an average of 13% in 12 elderly subjects followed over 1 year.

**FIGURE 9-2.** Visual standards for cortical atrophy score ratings on T1-weighted coronal magnetic resonance images (repetition time = 500 milliseconds, echo time = 20 milliseconds). *Panel A:* Grade 0, 1 = none, borderline. *Panel B:* Grade 2 = mild cortical atrophy. *Panel C:* Grade 3 = moderate cortical atrophy with widening of the interhemispheric fissure. *Panel D:* Grade 4 = severe cortical atrophy, with widening of almost all sulci. This subject also exhibits moderately severe enlargement of the lateral ventricles.

Mueller et al. (1998) found a 1.5 mL/year increase in total CSF volume on MR imaging in elderly subjects followed for 3–9 years. In a sample of 28 healthy 21- to 68-year-old men, Pfefferbaum et al. (1998) observed no significant increase in sulcal CSF volume on MR imaging over a scanning interval of 5 years.

Quantitative investigations that directly measure brain size have consistently found reduced total brain volume with age (Appendix 9–2). The only negative study attempted to estimate brain volume from a single brain section (Yoshii et al. 1988). (It should also be noted that these same subjects did exhibit age-related cortical atrophy as determined from ratings of sulcal enlargement.) Over the first nine decades of life, the ratio of cerebral volume to cranial volume appears to decrease from approximately 93% to approximately 82% (Coffey et al. 1992; Jernigan et al. 1990; Tanna et al. 1991), and brain volume may decrease from an average of approximately 1200–1300 mL to approximately 1100–1200 mL (Coffey et al. 1992; R. C. Gur et al. 1991; Murphy et al. 1992). In our study of 76 healthy adult volunteers, we found that increasing age was associated with a significant decrease in total cerebral hemisphere volume of approximately 0.23% per year (Coffey et al. 1992). In a second study focusing on elderly volunteers ( $N = 330$ ) living independently in the community, we found age-specific reductions in total cerebral hemisphere volume of approximately 2.79 mL/year from ages 65 to 95 years (Coffey et al. 1998). Recent data suggest that genetic factors may contribute to individual differences in both brain parenchymal and CSF volume changes in normal aging (Carmelli et al. 1999).

Only a few *longitudinal studies* of global cerebral volume loss with age have been undertaken (Appendix 9–2). Significant reductions have been observed for whole brain volume (Fox et al. 1996; negative findings reported by Gur et al. 1998) and for total gray matter volume (Pfefferbaum et al. 1998).

Only a few studies have compared the effects of aging on the *right and left cerebral hemispheres*, and none of these has found any difference between hemispheres with regard to age-related total hemisphere volume loss (Appendix 9–2).

Recent literature suggests that *gender differences* may exist in the effects of age on cerebral hemisphere volume loss (see Coffey et al. 1998 for review) (Appendix 9–2). In our study of 330 elderly volunteers, we found that from ages 65 to 95 years males (of average IV) had an increase in peripheral CSF volume of approximately 32% compared with less than a 1% increase in females (Coffey et al. 1998) (Figure 9–3). Gur et al. (1991) also found that the ratio of sulcal CSF volume/IV was greater for elderly (55 years and older) subjects and for men. Similarly, Blatter et al. (1995)

found higher correlations between age and “subarachnoid” CSF volume (adjusted for IV) in males ( $r = .653$ ) than in females ( $r = .545$ ), although these correlations were not statistically compared. Other cross-sectional studies that examined peripheral CSF volume have found no gender effects on age-related increases (Murphy et al. 1996; Sullivan et al. 1993; Yue et al. 1997). In the longitudinal study of Mueller et al. (1998), females apparently showed greater age-related increases in total CSF volume than did males (actual data not reported).

In contrast to the gender differences observed with regard to age-related increases in peripheral CSF, we found no gender differences in the age-related decrease in cerebral hemisphere volume. Similar negative findings have been reported (Coffey et al. 1992; R. C. Gur et al. 1991; Raz et al. 1993c, 1997; Murphy et al. 1996; Sullivan et al. 1993; Yoshii et al. 1988). Although Condon et al. (1988) found that men, but not women, exhibited a significant correlation between age and the ratio of total brain volume/IV, these correlations were not statistically compared. Similarly, Blatter et al. (1995) observed higher correlations in males than in females between age and the ratio of total brain volume/IV ( $r = -.675$  versus  $r = -.539$ , respectively), but again these correlations were not statistically compared. Murphy et al. (1996) reported that males had a significantly greater age-related decrease in the ratio of cerebral hemisphere volume/IV than did females.

**FIGURE 9–3.** Effects of gender on age-specific changes in sulcal cerebrospinal fluid (CSF) volume. Hierarchical regression models for CSF volume, adjusting for the effects of intracranial volume, age, and gender, indicated a significant age-by-gender interaction. Age-specific increases in sulcal CSF volume were significantly greater in men (*dashed line*) than in women (*solid line*) (2.11 mL/year versus 0.06 mL/year, respectively).

Source. Adapted from Coffey et al. 1998.

Our finding of a significant gender effect on the age-related increase in peripheral CSF volume, in the absence of a gender effect on age-related volume loss of cerebral hemisphere brain matter, is consistent with the observations of R. C. Gur et al. (1991). Taken together, these reports suggest that although peripheral CSF volume may show a greater age-related increase in males than in females (likely as a result of cortical atrophy), such gender differences in cortical atrophy may not be apparent statistically when the size of the cortex is averaged in with a relatively larger structure such as the cerebral hemisphere. We are not aware of any studies that have examined gender effects on age-related tissue loss in the cortex per se.

**Regional brain atrophy.** Significant age-related reductions have been observed for total *gray matter* volume (Blatter et al. 1995; Guttmann et al. 1998; Lim et al. 1992; Passe et al. 1997; Schwartz et al. 1985) and cortical gray matter volume (Jernigan et al. 1991; Meyer et al. 1994; Pfefferbaum et al. 1994), as well as for specific gray matter structures such as the anterior diencephalon (Jernigan et al. 1991), caudate nucleus (Gunning-Dixon et al. 1998; Hokama et al. 1995; Jernigan et al. 1991; Krishnan et al. 1990; Murphy et al. 1992, 1996; Raz et al. 1993a, 1993c; negative findings reported by Meyer et al. 1994), and putamen or lentiform nucleus (Gunning-Dixon et al. 1998; Hokama et al. 1995; McDonald et al. 1991; Murphy et al. 1992, 1996; Schwartz et al. 1985; negative findings reported by Jernigan et al. 1991; Meyer et al. 1994; Raz et al. 1993a). Conflicting findings have been reported for the thalamus (Murphy et al. 1992, 1996; Schwartz et al. 1985; negative findings reported by Jernigan et al. 1991 and Meyer et al. 1994). The decrease in cerebral gray matter size is likely related in part to age-related neuronal loss or shrinkage or to decreased neuronal interconnectivity (see Chapter 3 in this volume).

Although most studies suggest that total *cerebral white matter* volume does not appear to change significantly with age (Blatter et al. 1995; Jernigan et al. 1991; Lim et al. 1992; Meyer et al. 1994; Passe et al. 1997; Pfefferbaum et al. 1994; Raz et al. 1993b, 1993c, 1997; Schwartz et al. 1985), age effects have been reported for total white matter volume (Guttmann et al. 1998) and for certain regions (e.g., prefrontal) (Raz et al. 1997). Aging is also associated with changes in the tissue characteristics of brain white matter (and some gray matter nuclei), an issue that will be discussed below (see Subcortical Hyperintensity). Studies are consistent in describing age-related size reductions in total and regional corpus callosum (Davatzikos and Resnick 1998; Doraiswamy et al. 1991; Janowsky et al. 1996; Parashos et al. 1995; Salat et al. 1997), an effect that we ob-

serve to be especially prominent in the anterior-most regions (Parashos et al. 1995).

Age-related reductions in brain size have also been described for the frontal lobes ([Cala et al. 1981; Coffey et al. 1992, 1998; Cowell et al. 1994; DeCarli et al. 1994; Jacoby et al. 1980; Murphy et al. 1996; Raz et al. 1997, 1998b]; others observed no age-related changes for the dorsolateral prefrontal cortex [Raz et al. 1993b, 1993c] and the anterior cingulate cortex [Jernigan et al. 1991; Raz et al. 1997]), the temporal lobes (Coffey et al. 1992, 1998; Convit et al. 1995; Cowell et al. 1994; Jack et al. 1992; Murphy et al. 1996; Raz et al. 1997; negative findings reported by DeCarli et al. 1994), the amygdala-hippocampal complex (Coffey et al. 1992; Convit et al. 1995; Doraiswamy et al. 1993; Golomb et al. 1993; Jack et al. 1992, 1997, 1998; Mu et al. 1999; Murphy et al. 1996; O'Brien et al. 1997; Raz et al. 1998b; negative findings reported by Frisoni et al. 1999; Laakso et al. 1998; Raz et al. 1997), and the parietal-occipital lobes (Coffey et al. 1992, 1998; Cowell et al. 1994; Murphy et al. 1996; Raz et al. 1993b, 1993c, 1997, 1998b) (Appendix 9–2).

A relatively small literature has examined posterior fossa structures (Appendix 9–2). Age-related size reductions have been described for the cerebellum (global or regional) (Cala et al. 1981; Deshmukh et al. 1997; Murphy et al. 1996; Oguro et al. 1998; Raz et al. 1998a; negative findings reported by Deshmukh et al. 1997; Escalona et al. 1991; Salat et al. 1997; Shah et al. 1991) and for the midbrain (Doraiswamy et al. 1992; Oguro et al. 1998; Shah et al. 1991), but not for the pons or medulla (Oguro et al. 1998; Salat et al. 1997; Raz et al. 1998a). Oguro et al. (1998) suggested that males demonstrated greater age-related reductions than females in size of midbrain tegmentum and cerebellar vermis.

In our investigation of 76 adult volunteers (Coffey et al. 1992), we observed that the relative rate of change in cerebral volume with age may differ among individual regions (Figure 9–4). Cerebral hemisphere volume, for example, declined at a rate of about 0.23% per year, a rate that agrees closely with previous postmortem (Davis and Wright 1977; Miller et al. 1980) and imaging studies (Appendix 9–2). In contrast, the rate of volume decrease for the frontal lobes (0.55% per year) was twice as great, indicating that this region may be particularly prone to volume loss associated with aging. This observation is consistent with a small number of imaging studies (Cala et al. 1981; DeCarli et al. 1994; Raz et al. 1997, 1998b) and with previous neuropathological studies demonstrating that the frontal lobes are disproportionately affected by age-related changes such as volume loss, thinning of cortical laminae, widening of superficial sulci, and alterations in neuronal cell populations (Haug 1985; Katzman and Terry 1992).

These data, taken together with findings from our study, may suggest a neuroanatomical substrate for age-related changes in frontal lobe function present in neuropsychological (Mittenberg et al. 1989) (see also Chapter 8 in this volume) and brain metabolic imaging (Alavi 1989; Warren et al. 1985) (see also Chapter 10 in this volume) studies of aging humans. The rates of volume loss for the temporal lobes (0.28% per year) and the amygdala-hippocampal complex (0.30% per year) were similar to those for the cerebral hemispheres.

Only a few *longitudinal studies* of regional cerebral volume loss with age have been undertaken (Appendixes 9–1 and 9–2). Significant reductions have been observed in frontal region (Shear et al. 1995; negative findings reported by R. E. Gur et al. 1998 and Mueller et al. 1998), prefrontal gray matter (Pfefferbaum et al. 1998), temporal lobe (Gur et al. 1998; Kaye et al. 1997; negative findings reported by Mueller et al. 1998), hippocampus (Jack et al. 1998, Mueller et al. 1998), and parietal-occipital region (Fox et al. 1996; Mueller et al. 1998; Pfefferbaum et al.

**FIGURE 9-4.** Decrease in regional cerebral volumes with age, relative to regional volumes at age 30. Linear regression models for  $\log_e$  (volume), controlling for the effects of gender and intracranial size, indicated that volume decreased exponentially with age in the cerebral hemispheres (*line A*), the temporal lobes (*line B*), the amygdala-hippocampal complex (*line C*), and the frontal lobes (*line D*). It is apparent that the rate of change in brain volume with age was substantially greater for the frontal lobes (0.55% per year) than for the other regions (range of 0.23% to 0.30% per year). For example, relative to the cerebral hemispheres, frontal lobe volume decreased at a rate of 0.32% per year ( $P < .004$ ).

*Source.* Adapted from Coffey et al. 1992.

1998; Shear et al. 1995). Kaye et al. (1997) performed annual brain MR imaging in 30 healthy elderly subjects over an average follow-up of 42 months. Volume loss in the temporal lobes (about 1.27% per year) predicted eventual development of dementia, whereas volume loss in the hippocampus (about 2% per year) or parahippocampus (about 2.5% per year) did not.

Although *hemispheric asymmetries* exist in the size of many brain regions (Bear et al. 1986; Chui and Damasio 1980; Kertesz et al. 1992; LeMay and Kido 1978; Suddath et al. 1989; Weinberger et al. 1982; Weis et al. 1989), only a few studies have examined the interactions between aging and right versus left hemisphere volume loss (Appendix 9–2). No right-left hemispheric differences have been reported for the effects of aging on total gray matter (Schwartz et al. 1985) or total gray matter plus white matter (Schwartz et al. 1985), although Murphy et al. (1992) found that older men (> 60 years old) exhibited a right-greater-than-left asymmetry in lenticular nucleus volume, whereas young men showed the reverse asymmetry. Negative findings have been described by the majority of studies examining the frontal lobes (Coffey et al. 1992, 1998; DeCarli et al. 1994; Raz et al. 1997), although two studies have reported interesting interactions with gender. Cowell et al. (1994) found that the right-greater-than-left asymmetry of frontal lobe volume was larger in females greater than 40 years old than in younger females, a difference that was not seen in males. Murphy et al. (1996) found that age-related volume loss of the frontal lobes was greater in the right hemisphere for males, whereas in females the volume loss was greater in the left hemisphere. No hemispheric differences have been described in the effects of age on the temporal lobes (Coffey et al. 1992, 1998; Cowell et al. 1994; Murphy et al. 1996; Raz et al. 1997), the hippocampus (Coffey et al. 1992; Jack et al. 1997), or the amygdala (Coffey et al. 1992; Jack et al. 1997), although Jack et al. (1997) did observe a left-greater-than-right asymmetry in the age-related volume loss of the parahippocampal gyrus.

*Gender differences* may exist in the effects of aging on regional brain tissue loss (Appendix 9–2). In our recent study of 330 elderly volunteers (Coffey et al. 1998), we found that the age-associated increase in lateral fissure CSF volume, a marker of frontotemporal (and to a lesser extent, parietal) atrophy, was greater in men than in women. For example, from ages 65 to 95 years, men (of average IV) had an increase in lateral fissure volume of approximately 80%, whereas women had an increase of only approximately 37% (Figure 9–5). Cowell et al. (1994) and Murphy et al. (1996) found that males exhibited greater age-related decreases in the ratio of temporal lobe volume/IV than did females. Similarly, Golomb et al. (1993) found that

age-related hippocampal atrophy was more common in males than in females, and Raz et al. (1997) observed greater age-related inferior temporal volume loss in males than in females. In contrast, Murphy et al. (1996) actually observed greater temporal lobe atrophy in females than in males. Despite differences in which gender is more affected, these published results suggest that gender may affect the age-related volume loss of the temporal lobe region. These findings may provide a neuroanatomic substrate for the gender differences in age-related verbal memory impairment (see Chapter 8 in this volume).

The literature is also conflicting with regard to the effects of gender on age-related changes in frontal lobe size (Appendix 9–2). Cowell et al. (1994) and Murphy et al. (1996) have both observed greater age-related frontal lobe volume loss in males than in females. In contrast, others have found no interactions between aging and gender effects (Coffey et al. 1992, 1998; Cowell et al. 1994; Raz et al. 1993c, 1997; Sullivan et al. 1993). These discrepant results may reflect differences among studies in samples and brain measurement techniques (e.g., quantitative versus qualitative measures, area measures from a single slice versus volume measures from multiple slices).

**FIGURE 9–5.** Effects of gender on age-specific changes in lateral (sylvian) fissure cerebrospinal fluid (CSF) volume. Hierarchical regression models for CSF volume, adjusting for the effects of intracranial volume, age, and gender, indicated a significant age-by-gender interaction. Age-specific increases in lateral fissure CSF volume were significantly greater in men (*dashed line*) than in women (*solid line*) (0.23 mL/year versus 0.10 mL/year, respectively).

Source. Adapted from Coffey et al. 1998.

With regard to more posterior brain regions, we recently found that the age-related decrease in parieto-occipital region area was greater for males than it was for females. For example, from ages 65 to 95 years, men (of average IA) lost approximately 15% of their parieto-occipital lobe area, whereas women lost only 4% (Coffey et al. 1998) (Figure 9–6). Using a somewhat different definition of this brain region, Cowell et al. (1994) did not find any gender effect on the age-related decrease in the ratio of the posterior cerebral hemisphere volume/IV. Murphy et al. (1996) likewise found no gender differences in the age-related decrease in parieto-occipital region volume/IV, although they actually observed worse atrophy in females for the ratio of parietal lobe volume/IV. Similarly, Raz et al. (1993c) reported that females exhibited greater age-related volume loss in the visual cortex than did males. These widely divergent findings indicate a need for additional research (Appendix 9–2).

Our data also indicate that the rates of age-related changes in regional cerebral volume are greater for ventricular regions (about 3% per year) than for the parenchymal regions described above (0.23%–0.55% per year). This finding suggests that ventricular enlargement

**FIGURE 9–6.** Effects of gender on age-specific changes in parieto-occipital region area. Hierarchical regression models for cerebrospinal fluid (CSF) volume, adjusting for the effects of intracranial volume, age, and gender, indicated a significant age-by-gender interaction. Age-specific decreases in parieto-occipital region area were significantly greater in men (*dashed line*) than in women (*solid line*) (–0.31 mL/year versus –0.09 mL/year, respectively).

Source. Adapted from Coffey et al. 1998.

may provide a more sensitive index of brain aging than does cortical atrophy. It has been assumed that age-related ventricular enlargement occurs by *ex vacuo* expansion that results from shrinkage of periventricular structures. Current work is under way in our laboratory to examine whether age-related changes in the size of these structures (e.g., caudate and thalamic nuclei) are indeed related to the increase in ventricular volume that accompanies aging.

With regard to aging effects on the *shape* of brain structure, Magnotta and colleagues (1999) observed that age was associated with more sharply and steeply curved cortical gyri, as well as with sulci that were flatter and less curved.

In summary, aging is associated with global changes in brain structure, including decreased brain volume and increased CSF volume. In addition, differential effects of aging are observed for specific brain regions and structures. Some structures (e.g., association cortices such as prefrontal) are highly vulnerable to age-related volume loss, whereas others (e.g., medial temporal region) show moderate vulnerability, and still others (e.g., occipital cortex, pons) exhibit only mild sensitivity to aging. Raz (in press) has made the interesting suggestion that this pattern of differential vulnerability follows a rule of “last (phylogenetically and ontogenetically) in—first out.” That is, those structures that evolved in more modern species and that matured late in the course of human development appear to suffer greater effects of aging than do the more ancient and mature structures. These late-evolving and maturing structures are also the ones that complete myelination relatively late in the development of the organism. The pathophysiology of these age-related volume changes is unknown, although a variety of mechanisms have been suggested including age-related changes in neurotransmitter concentration or function, excitotoxicity, subclinical inflammation, stress-induced glucocorticoid neurotoxicity, and cumulative effects of systemic illnesses such as hypertension (see Chapter 3 in this volume).

Studies are consistent in demonstrating increased variability in brain anatomic measures with aging—some subjects show marked atrophic changes, whereas others show very little change. Factors that may account for at least some of this variation include general medical health as well as alcohol and other recreational drugs. Recently, we found that education level may also explain some of the individual variation in brain aging (Coffey et al. 1999). In a sample of 320 elderly individuals living independently in the community, years of formal education was significantly associated with peripheral (sulcal) CSF volume, a marker of cortical atrophy. Each year of education was associated with an increase in peripheral CSF of 1.77 mL. Our finding of a greater age-specific increase in peripheral CSF volume

in *normal* elderly persons is consistent with the “reserve” hypothesis that such individuals are afforded greater protection from any clinical manifestations of cortical atrophy. These findings are also consistent with the few imaging studies of Alzheimer’s disease demonstrating greater regional brain atrophy and hypoperfusion in those patients with more education. These latter studies suggest that education exerts its “protective” effect, not by reducing the brain changes associated with disease or aging, but by enabling more educated individuals to resist the influence of deteriorating brain structure by maintaining better cognitive and behavioral functioning. The mechanism by which education may be related to preserved cognitive functioning in the setting of cortical atrophy is unknown but may be suggested by our observation of a lack of association between education and age-specific ventricular enlargement. This observation suggests that education is not associated with relatively greater age-related atrophy of those striatal structures (e.g., caudate nucleus) that form the lateral walls of the lateral ventricles. Preserved striatal structure may imply preserved integrity of frontosubcortical circuits critical to executive cognitive functioning, which in turn would afford the individual a greater cognitive “buffer” against any clinical manifestations of brain aging or cortical atrophy.

## ■ Neuropsychological Correlates of Age-Related Changes in Brain Structure

Aging may be characterized cognitively by generalized slowing of cognitive function and by decreased working memory (see Chapter 8 in this volume). Despite a relatively large literature on the relationship between cognitive functioning and brain structure in patients with dementia, only a few studies have examined such relationships in non-patient samples of aging healthy adult volunteers, and results have been conflicting (Appendices 9–1 through 9–4).

## Neuropsychological Correlates of Age-Related Changes in Global Brain Structure

With regard to global brain changes, six of nine studies examining *ventricular size* found no relation with a variety of measures of cognitive function (Jacoby et al. 1980; Kaye et al. 1992; Matsubayashi et al. 1992; Pearlson et al. 1989a; Sullivan et al. 1993; Wahlund et al. 1990) (Appendix 9–1). Three positive studies have been reported. Earnest et al.

(1979) performed neuropsychological testing (Trail Making Test, the Digit Symbol and Block Design subtests of the Wechsler Adult Intelligence Scale [WAIS] [Wechsler 1955], and the Visual Reproduction subtest of the Wechsler Memory Scale [Wechsler 1945]) in 59 elderly subjects who had been scanned by CT 1 year earlier (Appendixes 9–1 and 9–2). After adjustments for age, the only significant findings were negative correlations between the Digit Symbol Test and linear ( $r = -.40$ ) and planimetric ( $r = -.30$ ) measures of lateral ventricular size. In a sample of elderly subjects, Soininen et al. (1982) found a negative correlation between a composite neuropsychological test score and linear measures of ventricular size and sylvian fissure size on CT, but the effects of age were not controlled. Although Stafford et al. (1988) reported a negative correlation between a discriminant function of ventricular volume on CT and a discriminant function of neuropsychological tests of naming and abstraction, the effects of subject age on this correlation were apparently not partialled out.

Only a few studies have examined relations between global *brain parenchymal* measures and cognitive function (Appendixes 9–1 and 9–2). Jacoby et al. (1980) found no significant correlations (after adjustments for age) between a test of memory and orientation and ratings of cortical atrophy on CT scanning of elderly subjects. In contrast, Carmelli and colleagues (1999) found that within-pair differences in brain volume on MRI were associated with within-pair differences in memory function in 74 elderly male twin pairs. Two MR imaging investigations have observed relations between IQ and total and regional brain volumes in relatively young samples (Andreasen et al. 1993; Willerman et al. 1991). A third MR imaging investigation found no relation between IQ and either total or regional brain volumes in a mixed-age sample, although global cerebral asymmetry (left greater than right) did predict IQ (Raz et al. 1993b).

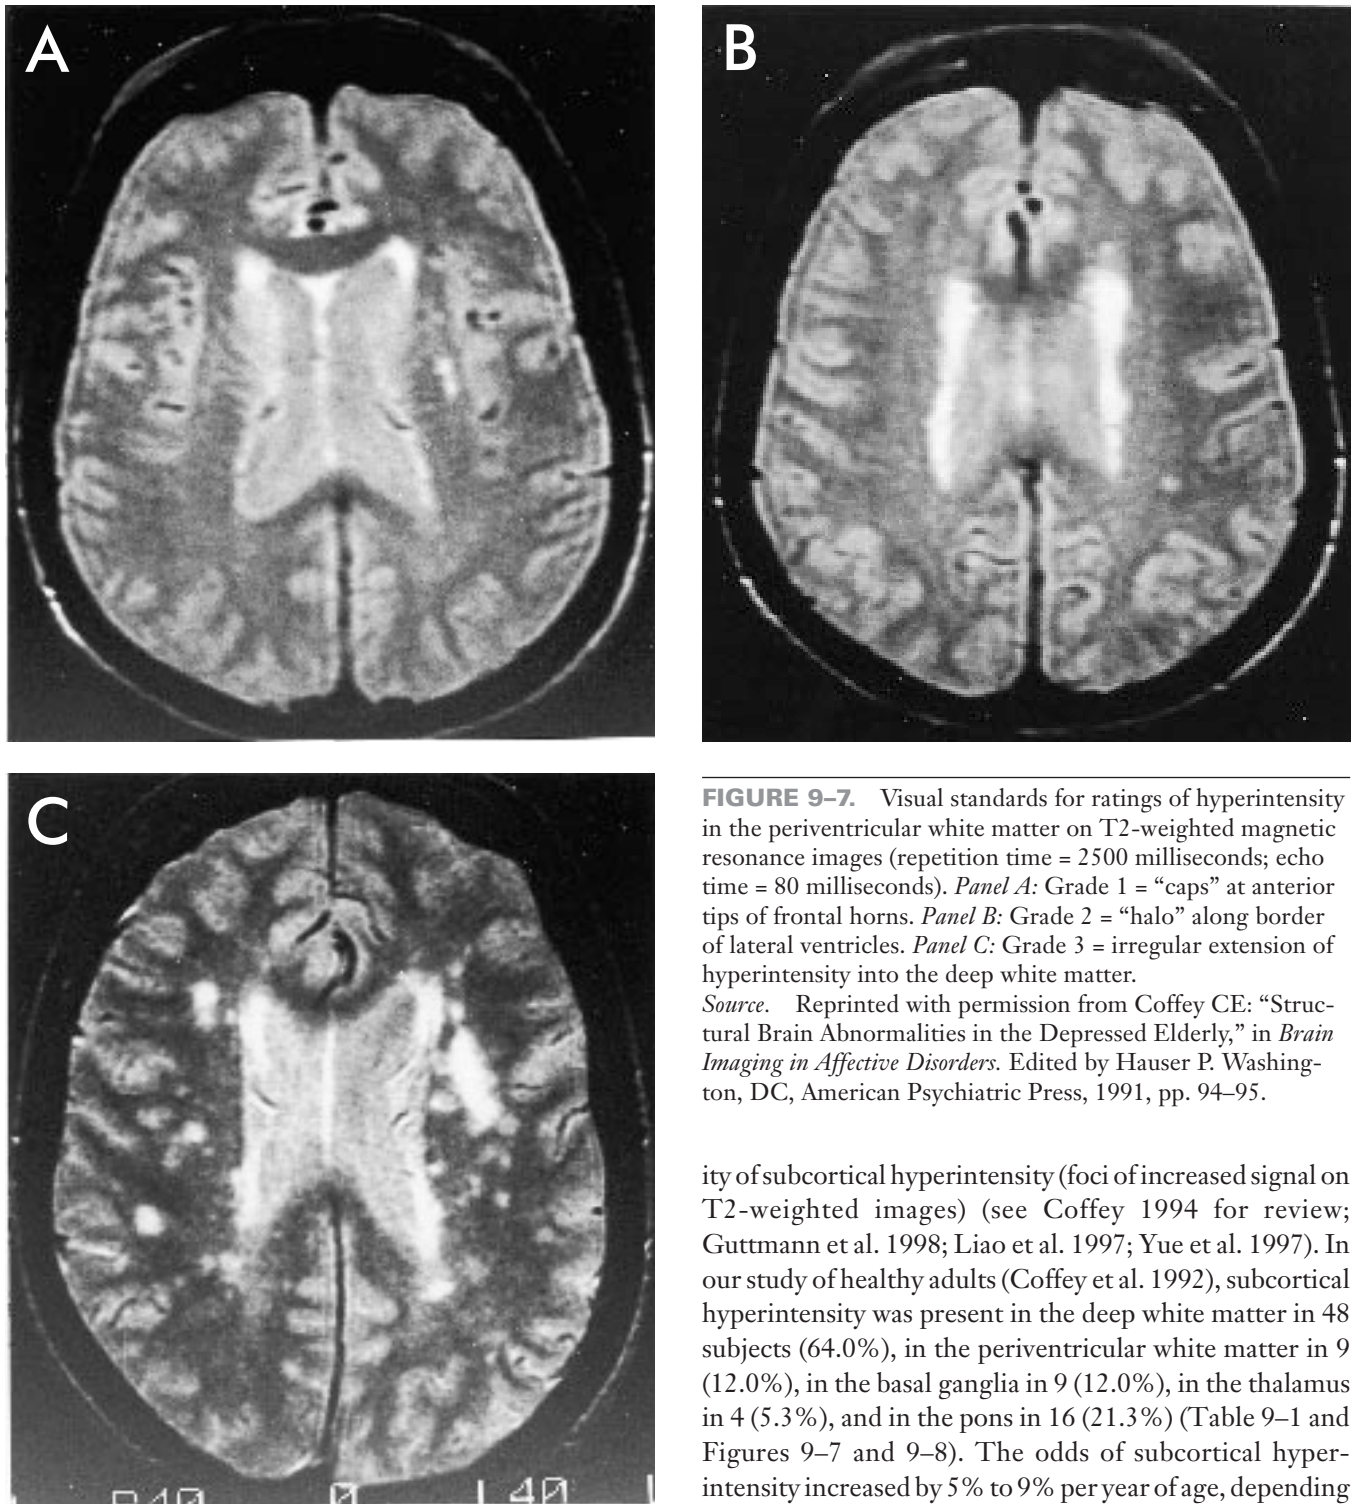

### Neuropsychological Correlates of Age-Related Changes in Regional Brain Structure

Most studies of the neuropsychological correlates of age-related changes in brain structure have focused on memory and the *temporal lobe* (Appendix 9–2). Golomb et al. (1993) found that elderly subjects with hippocampal atrophy performed worse on the recent verbal memory portion of the Guild Memory Scale, but no group differences were observed in immediate verbal memory, digit span, or recall of designs. A subgroup of these subjects was followed for a mean of 3.8 years, at which time those who had declined to a score of 3 on the Global Deterioration Scale

were found to have had smaller hippocampal volumes at baseline (Golomb et al. 1996). In a study of 40 healthy older volunteers, O'Brien et al. (1997) found a relation between the presence of amygdala-hippocampal atrophy on MR imaging and lower scores on the Cambridge Cognitive Examination (CAMCOG), a relation that was entirely a result of lower scores on the memory subscale. Kohler et al. (1998) studied 26 healthy elderly (approximately 71 years old) subjects and observed a trend for a negative association between hippocampal volume and delayed verbal recall on the California Verbal Learning Test, but no association with visual recall (Visual Reproduction Test of the Wechsler Memory Scale–Revised) or scores on the Mattis Dementia Rating Scale. Parahippocampal gyrus volume was not related to any of the three measures. Raz et al. (1998b) observed no relations between hippocampal and parahippocampal volumes on MR imaging and several memory measures in a sample of 95 healthy adults. In a study of 11 healthy elderly subjects, Lupien et al. (1998) found decreased hippocampal volume on MR imaging, as well as deficits in hippocampal-dependent memory function, in those with significant prolonged elevations of serum cortisol. The authors speculated that elevated glucocorticoid levels, which are known to be toxic to hippocampal cells in animals, may likewise cause hippocampal atrophy and dysfunction in elderly humans.

With regard to *other brain structures*, Salat et al. (1997) found a correlation between corpus callosum area and performance on the Visual Reproduction portion of the Wechsler Memory Scale in females but not males. No relations were found in either gender with scores on the Logical Memory portion of this test or with scores on the Block Design subtest of the WAIS. Hokama et al. (1995) found no correlation between IQ and volumes of basal ganglia nuclei in 15 adult male volunteers. In the MR imaging study of Raz et al. (1998b) described above, relations were observed between the volume of the visual processing areas (pericalcarine cortex) and nonverbal working memory and between prefrontal cortex atrophy and increased perseveration.

Recently, a few studies have examined the neuropsychological and brain MR imaging correlates of the apolipoprotein E e4 allele, a risk marker for Alzheimer's disease and vascular dementia (see Chapters 23 and 24 in this volume). H. Schmidt et al. (1996) found that elderly nondemented apoE carriers performed worse than noncarriers on tests of learning and memory, but the groups did not differ on measures of sulcal and ventricular widening, hippocampal and parahippocampal volumes, or extent of subcortical hyperintensity (see below). In contrast, in a study of elderly twins without dementia,

**FIGURE 9-7.** Visual standards for ratings of hyperintensity in the periventricular white matter on T2-weighted magnetic resonance images (repetition time = 2500 milliseconds; echo time = 80 milliseconds). *Panel A:* Grade 1 = “caps” at anterior tips of frontal horns. *Panel B:* Grade 2 = “halo” along border of lateral ventricles. *Panel C:* Grade 3 = irregular extension of hyperintensity into the deep white matter.

ity of subcortical hyperintensity (foci of increased signal on T2-weighted images) (see Coffey 1994 for review; Guttmann et al. 1998; Liao et al. 1997; Yue et al. 1997). In our study of healthy adults (Coffey et al. 1992), subcortical hyperintensity was present in the deep white matter in 48 subjects (64.0%), in the periventricular white matter in 9 (12.0%), in the basal ganglia in 9 (12.0%), in the thalamus in 4 (5.3%), and in the pons in 16 (21.3%) (Table 9-1 and Figures 9-7 and 9-8). The odds of subcortical hyperintensity increased by 5% to 9% per year of age, depending on the anatomical region involved (Figure 9-9).

A growing body of neuropathological evidence is defining the pathophysiological significance of subcortical hyperintensity (Coffey and Figiel 1991; Pantoni and Garcia 1997). Periventricular hyperintensities in the form of caps or rims (Figure 9-7, *panel A*) are common in healthy individuals and do not appear to constitute pathology. Histological studies suggest that these periventricular caps

Plassman et al. (1997) found no neuropsychological differences between apoE carriers and noncarriers, although the former had smaller right and left hippocampal volumes.

### Subcortical Hyperintensity

Numerous MR imaging studies have demonstrated that aging is associated with an increased prevalence and sever-

**FIGURE 9-8.** Visual standards for ratings of hyperintensity in the deep white matter on T2-weighted magnetic resonance images (repetition time = 2500 milliseconds; echo time = 80 milliseconds). *Panel A:* Grade 1 = punctate foci. *Panel B:* Grade 2 = small confluence of foci. *Panel C:* Grade 3 = large confluent areas of signal hyperintensity.

ure 9-7, *panels B and C*, and Figure 9-8), a spectrum of histological changes may be present that range from vascular ectasia and dilated perivascular spaces, to edema and demyelination, to frank lacunar infarctions. It has been suggested that these more severe changes are a consequence of chronic brain hypoperfusion stemming from some combination of advancing arteriosclerosis, hypertensive vascular disease, chronic recurrent hypotension, cerebral amyloid angiopathy, the presence of "senile" arteriolar hyaline lesions, age-related thickening of meninges, and impaired autoregulation of cerebral circulation associated with aging. Indeed, evidence on MR imaging of old cerebral "microbleeds" is reported in approximately 6% of neuropsychiatrically normal community volunteers, and is associated with more extensive subcortical hyperintensity (Roob et al. 1999). The prevalence and severity of subcortical hyperintensity are thus increased in the presence of risk factors for vascular disease (Coffey and Figiel 1991; Liao et al. 1997). As conceptualized by Awad et al.

and rims likely reflect increased water content resulting from various factors, including a loose network of axons with low myelin content, a patchy loss of ependyma with astrocytic gliosis ("ependymitis granularis"), and the normal convergence of flow of interstitial fluid within the periventricular region (Sze et al. 1986). For the more severe changes of subcortical hyperintensity, however (Fig-

**FIGURE 9-9.** Increase in the regional prevalence of subcortical hyperintensity with age. Logistic regression models indicated that the risk of subcortical hyperintensity increased significantly with age in the deep white matter (*line A*) and pons (*line B*), but not in the periventricular white matter or basal ganglia (*line C*). The odds of subcortical hyperintensity increased by approximately 6.3% per year in the deep white matter and by 8.1% per year in the pons. *Source.* Adapted from Coffey et al. 1992.

(1986), subcortical hyperintensity in otherwise healthy older subjects may reflect “wear and tear” of brain parenchyma that accompanies aging and chronic cerebrovascular disease. Recent data in twins suggest that genetic factors may also contribute to individual differences in volume of subcortical hyperintensity (Carmelli et al. 1999).

Although a growing literature exists with respect to the relation between cognition and changes in subcortical white matter in normal aging (Appendix 9-3), these results are conflicting and the studies are difficult to compare given methodological differences. Most studies find no relation between subcortical hyperintensity and scores on dementia rating scales (Austrom et al. 1990; Harrell et al. 1991; Hendrie et al. 1989; Mirsen et al. 1991; positive findings reported by Steingart et al. 1987 and Matsubayashi et al. 1992). Positive findings have generally been more common among studies using more focal neuropsychological assessment batteries, with measures of frontal lobe function appearing to show the closest relation with subcortical hyperintensity (Austrom et al. 1990; Boone et al. 1992; Carmelli et al. 1999; DeCarli et al. 1995; Rao et al. 1989; Schmidt et al. 1993, 1999; Ylikoski et al. 1993).

In a study from our laboratory (Tupler et al. 1992), we examined the relationship between subcortical hyperintensity on MR imaging and two specific neuropsy-

chological instruments—the Benton Facial Recognition Test (Benton et al. 1983) and the WAIS-R Digit Symbol. The former was chosen because it had yielded the highest level of significance of any test reported to be associated with subcortical hyperintensity; the latter, because it had been reported to be related to subcortical hyperintensity by two independent groups (Appendix 9-3). In addition, both the Benton Facial Recognition Test and the Digit Symbol subtest of the WAIS-R (Wechsler 1981) were favored a priori because subcortical pathology might be expected to disrupt visuospatial perception and visuospatial execution, respectively.

We found that performance on both tests was highly related to age and education, but not to the presence of subcortical hyperintensity. The majority of our subjects had relatively mild findings of subcortical hyperintensity, however, and it thus remains possible that more severe changes might be associated with cognitive dysfunction in otherwise healthy adults (e.g., see Boone et al. 1992; DeCarli et al. 1995; Matsubayashi et al. 1992; Steingart et al. 1987). Indeed, extensive damage to subcortical white matter tracks would disrupt frontal-subcortical circuitry and possibly provide an anatomical substrate for the mental slowing and disturbed executive functioning seen with aging.

In addition, an issue not addressed by our study was whether subcortical hyperintensity might be associated with cognitive changes in patients with various medical, neurological, or psychiatric illnesses (Coffey and Figiel 1991). In this regard, we have previously reported that subcortical hyperintensity is more common in patients with severe depression (Coffey 1991; Coffey et al. 1990, 1993), and correlative studies are currently under way to determine whether the cognitive impairment that frequently afflicts this population might be associated with these brain changes.

## Other Brain Imaging Parameters

**Intracranial calcification.** Punctate calcification appears as an area of increased density on CT but leaves a signal void on MR imaging. Intracranial calcification may occur in association with many pathological conditions and may also be noted as an incidental finding commonly involving the pineal gland, dura, habenula, petroclinoid ligament, choroid plexus, basal ganglia, and major cerebral vessels (Rhea and DeLuca 1983). Clinical experience and some research suggest that “physiological calcification” of these various structures increases with age (Cohen et al. 1980; Modic et al. 1980), but little systematic information is available in nonclinical elderly samples.

**Brain tissue characteristics.** Conflicting data exist on whether increasing age is associated with alterations in CT attenuation values (Hounsfield unit) of the subcortical white matter (Cala et al. 1981; Schwartz et al. 1985; Zatz et al. 1982b). However, patchy areas of decreased attenuation in the subcortical white matter do occur with increasing frequency on CT of the elderly (Coffey and Figiel 1991). Such changes likely reflect the effects of hypoperfusion to subcortical structures and are the CT scan equivalent of subcortical hyperintensity on MR imaging (Coffey and Figiel 1991).

Increasing age has also been reported to be associated with regional brain changes in T1 and T2 relaxation time estimates on MR imaging (Appendix 9–4), but such data must be considered preliminary given a number of methodological issues (Drayer 1989).

**Magnetic resonance spectroscopy.** Magnetic resonance spectroscopy is a noninvasive technique capable of measuring the metabolism and chemical composition of brain tissue (Keshavan et al. 1991). Age-related findings have been reported for magnetic resonance spectroscopy in animals (Herndon et al. 1998; Pettegrew et al. 1990), but this technique has only recently been applied to the systematic study of “normal or usual” aging in humans, with variable findings (Appendix 9–4). Preliminary efforts are under way to explore the role of magnetic resonance spectroscopy in age-related conditions such as dementia and cerebrovascular disease (Dager and Steen 1992; Keshavan et al. 1991; Meyerhoff et al. 1994; Parnetti et al. 1997, see also Chapter 11, this volume).

**Brain iron.** High-field-strength (1.5 tesla) MR imaging can be used to visualize brain nuclei that are rich in iron. On heavily “T2-weighted” images, brain iron produces reduced signal intensity (the paramagnetic properties of iron accelerate T2 relaxation time) that correlates with the distribution of iron staining in postmortem brains (Coffey et al. 1989; Sachdev 1993). Nuclei of the extrapyramidal system are especially rich in iron, and aging is associated with increased deposition of iron in these regions. Although these age-related changes are maximal during development and early adulthood (Pujol et al. 1992), MR imaging changes consistent with increased iron deposition have been reported in the elderly (Steffens et al. 1996; see also Appendix 9–4).

**Magnetic resonance imaging of cerebral blood flow.** Because of its sensitivity to flow-related phenomena, MR imaging can be used to image in remarkable detail the extracranial and intracranial vasculature—a form of noninvasive angiography (Caplan et al. 1995;

Ståhlberg et al. 1992). MR imaging may also permit quantitative measurements of blood flow velocity and volume, and possibly of CSF hydrodynamics as well. Measurement of brain perfusion with MR imaging is also possible, permitting noninvasive assessment of brain functional activity comparable to that obtained with PET or SPECT. Such techniques would have obvious applications to the study of normal and abnormal brain aging (see Chapters 10 and 11 in this volume).

## ■ Summary

Modern computer-based imaging technologies provide an excellent opportunity to examine *in vivo* the spectrum and extent of changes in brain morphology that occur with normal aging. Such data are essential for an understanding of pathological brain aging in the elderly. The interpretation of these imaging studies must include careful consideration of a plethora of methodological issues that can obscure, confound, or modify apparent aging effects. Although studies vary in the extent to which such factors have been controlled, general agreement is found in the literature that increasing age is associated with 1) nonlinear increases in lateral and third ventricular volume; 2) increasing sulcal CSF volume; 3) decreasing brain volume, especially of the frontal lobes and of cortical and subcortical gray matter structures; 4) increasing variability in measures of brain size; and 5) increasing frequency and severity of subcortical hyperintensity on MR imaging. The effects of age on the two hemispheres are similar for most structures. Gender differences in the effects of age on brain morphology may exist for some regions or structures (e.g., sulcal CSF volume and possibly the frontotemporal regions), and in most cases such changes are greater in men than they are in women. Further study is needed to characterize in greater detail the effects of “usual versus successful” aging on global and regional brain structure, and the relationship of such age-related changes to cognitive function in aging people.

Research is also needed that identifies strategies to preserve brain function in the face of aging, an issue of increasing interest to the public. As discussed above, we know that the effects of age upon brain structure may be mollified by optimizing general medical health, by minimizing use of alcohol and other recreational drugs, and by avoiding injury to the head (e.g., by wearing bicycle helmets, wearing seat belts, avoiding extreme contact sports). Estrogen replacement therapy may also prove beneficial in maintenance of cognitive functioning in postmenopausal women, and its effects on age-related changes in brain structure

should be studied. Finally, we need to understand the value of “brain exercise” as it relates to aging—can we preserve cognitive functioning by maintaining a vigorous intellectual life, much as physical exercise helps preserve muscle functioning in the face of age-related muscle cell loss? I for one certainly hope so, and at any rate, there doesn’t seem to be much of a down side to tackling the morning crossword puzzle over a good cup of coffee.

**APPENDIX 9-1. Imaging studies of human aging and brain cerebrospinal fluid spaces**

Study	Subjects	Imaging and measurement technique	Findings
Barron et al. 1976	135 volunteers 9 months to 90 years old Equal gender distribution in all age groups (8 M; 7 F per decade) No history of neurological disease; psychiatric history not reported Handedness not specified	CT Planimetric determination of VBR by single rater (average of three measurements) from Polaroid photograph	Age associated with increased VBR and with increased variability in VBR Interactions with gender or laterality not reported
Earnest et al. 1979	59 volunteer retirees 60–99 years old 11 M; 48 F Living independently and free of neurological disease Handedness not specified	CT Linear and planimetric measures of ventricular size at three different levels, from photographs Linear measurements of four largest sulci No additional data provided Neuropsychological test battery comprised of Trail Making Test, and the Digit Symbol and Block Design subtests of the Wechsler Memory Scale	Subjects 80 years or older ( $n = 29$ ) had larger ratio of ventricular size to intracranial size than did younger subjects ( $n = 30$ ) The sum of the widths of the four sulci was greater in older subjects than in younger subjects Adjusting for age (but not education?), ventricular size correlated only with performance on the Digit Symbol subtest Interactions with gender or laterality not reported
Jacoby et al. 1980	50 healthy elderly volunteers 62–88 years old 10 M; 40 F No history of significant psychiatric or neurological illness Handedness not specified	CT Ratings (small, normal, enlarged) of ventricular size from films by single blinded rater (rater reliability not reported) Planimetric determination of lateral ventricular/skull ratio and Evans' ratio from films by single rater (average of three measurements) with established reliabilities	8 (16%) subjects were rated as having “enlarged” lateral ventricles No correlation between age and lateral ventricular/skull ratio or Evans' ratio Interactions with gender or laterality not reported Adjusting for age, no relation between ventricular size and performance on the Hodkinson test of memory and orientation
Meese et al. 1980	160 healthy volunteers 1–71 years old 10 M and 10 F in each decade No additional data provided	CT Linear measurements of ventricular size and sulcal width from four axial slices (no additional data provided)	Apparent age-related changes in some measures of ventricular size and sulcal width, but these changes not analyzed statistically Interactions with gender or laterality not reported

Cala et al. 1981	115 volunteers 15–40 years old 62 M; 53 F No history of migraine, head trauma, or excessive alcohol intake (no additional details provided) All but 8 subjects right-handed	CT ( $n = 2$ scanners) Planimetric measurements of ventricular/ skull ratio at level of frontal horns (no additional details provided) Axial slices (13 mm thick)	No relationship between age and ventricular/skull ratio Interactions with gender or laterality not reported
Soininen et al. 1982	85 volunteers: 53 from community and 32 from nursing home 75 $\pm$ 7 years old 23 M; 62 F No neurological disease (no additional details provided)	CT Linear measurements (from films?) of ventricular and sulcal size Axial slices ( $n = 8$ –12, 8 mm thick) No additional details provided Composite neuropsychological test score comprised of personal and up-to-date knowledge, orientation, praxis of hand, receptive speech, expressive speech, memory, and general reasoning (arithmetic [Luria], similarities [WAIS], and comprehension [WAIS])	Age correlated with ratios of ventricular width to skull width (frontal horn index and cella media index) Age correlated with mean width of four largest sulci Correlations were found between the composite neuropsychological test score and the size of the lateral and third ventricles, and the left sylvian fissure, but the effects of age and education were not controlled Interactions with gender or laterality not reported
Zatz et al. 1982a	123 volunteers 10–90 years old 49 M; 74 F No history of neurological or major medical disease Handedness not specified	CT Volume measurement derived from computer-assisted pixel segmentation technique (ASI-II program) Axial slices ( $n = 9$ , 10 mm thick, 10-mm interscan gap)	Age significantly associated with increased ventricular volume ( $M = F$ ), even after controlling for IV Increased variability of ventricular size with age Age associated with increased sulcal CSF volume, even after controlling for IV During 1-year follow-up, ratio of ventricular volume to IV increased significantly by an average of 3.7%; no significant changes in linear measures of ventricular size (VBR, third ventricular ratio, frontal horn ratio) During 1-year follow-up, ratio of sulcal volume to IV increased significantly by an average of 13% Interactions with gender or laterality not reported
Gado et al. 1983	12 elderly volunteers 64–81 years old 9 M; 3 F No additional clinical data provided	CT Volume measurements derived from computer-assisted pixel segmentation technique (seven axial slices, 8 mm thick) Linear measurements from axial images Number of raters and rater reliabilities not specified	During 1-year follow-up, ratio of ventricular volume to IV increased significantly by an average of 3.7%; no significant changes in linear measures of ventricular size (VBR, third ventricular ratio, frontal horn ratio) During 1-year follow-up, ratio of sulcal volume to IV increased significantly by an average of 13% Interactions with gender or laterality not reported

(continued)

**APPENDIX 9-1. Imaging studies of human aging and brain cerebrospinal fluid spaces (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Laffey et al. 1984	212 elderly volunteers 65–89 years old 110 M; 102 F No evidence of alcoholism, dementia, or neurological illness	CT Qualitative rating (6-point scale) of ventricular enlargement and sulcal widening from films, by two experienced radiologists with established reliabilities	Age associated with increased ventricular size No association between age and ratings of sulcal widening Interactions with gender or laterality not reported
Schwartz et al. 1985	30 healthy M volunteers 21–81 years old No history of major medical, neurological, or psychiatric illness Handedness not specified	CT Volume measurements derived from computer-assisted pixel segmentation technique (ASI-II program) Axial slices ( $n = 7$ ) starting from the plane of the inferior orbitomeatal line (10 mm thick, 7-mm interscan gap)	Age correlated with areas and volumes of lateral and third ventricles, even after adjusting for height and intracranial area Age correlated with VBR Increased variability of ventricular size with age No laterality effects Age correlated with CSF volume (ventricular plus basal cisterns), even after controlling for IV Increased variability of CSF volume with age
Pfefferbaum et al. 1986	57 healthy volunteers 20–84 years old 27 M; 30 F No additional data provided	CT Volume measurements derived from computer-assisted pixel segmentation technique (modification of Gado et al. 1983) Contiguous axial slices ( $n = 5$ ) starting at the level of the superior roof of the orbits	Age associated with increased ratio of ventricular volume to IV Increased variability in ventricular volume with age Interactions with gender or laterality not reported Age associated with increased ratio of sulcal CSF volume to IV (from single axial slice [8 mm thick] approximately 48 mm from the level of the superior roof of the orbits) Age associated with increased variability of ratio of sulcal CSF volume to IV
Stafford et al. 1988	79 healthy M volunteers 31–87 years old No severe medical or psychiatric illness Handedness not specified	CT CSF volume and CT density measurements derived from computer-assisted pixel segmentation technique (ASI-II program) Axial slices ( $n = 3$ ) at mid-, high-, and supraventricular levels Cognitive test battery comprised of attention (auditory and visual continuous performance), Boston Naming Test, Wechsler Memory Scale (verbal and visuospatial memory), and Gorham Proverb Test	Age associated with increased ratio of ventricular volume to brain volume, with increased ratio of supraventricular CSF volume to brain volume, and with decreased CT density Interactions with laterality not reported Inverse correlation observed between a discriminant function of total CSF volume and a discriminant function of neuropsychological tests of naming and abstraction; no relation with a discriminant function of memory and attention No relation between CT density and any cognitive test measure

Pearlson et al. 1989b	31 healthy elderly volunteers 68.3 ± 1.2 years old 15 M; 16 F No major medical, neurological, or psychiatric illness Handedness not specified	CT Planimetric determination of VBR from films by one of two raters, each with established reliabilities	Age correlated with VBR Interactions with gender or laterality not reported No correlation ( $n = 14$ ) between VBR and scores on Boston Naming Test or Rey Auditory Verbal Learning Test (Rey 1964)
Kaye et al. 1992	107 healthy volunteers 64 M (21–90 years old); 43 F (23–88 years old) No major medical, neurological, or psychiatric illness Handedness not specified	CT Volume measurements derived from computer-assisted pixel segmentation technique (ASI-II program) Axial slices (10 mm thick, 7-mm interscan gap)	Age associated with increased ventricular volume in both M and F (about 20% per decade); precipitous increases observed beginning in the fifth decade in M and in the sixth decade in F Interactions with laterality not reported Adjusting for age, no relation between ventricular volume and sum of the scores on the WAIS verbal or performance scales
Sullivan et al. 1993	114 healthy volunteers 21–82 years old (51.2 ± 17.7 years) 84 M; 30 F No history of major medical, neurological, or psychiatric illness 90% right-handed	CT Volume measurements derived from computer-assisted pixel segmentation technique (modification of Gado et al. 1983) Axial slices ( $n = 10$ , 10 mm thick) Neuropsychological test battery comprised of MMSE, Trail Making Test A and B, WAIS-R subtests—Information, Digit Span, Vocabulary, Digit Symbol, Picture Completion, Block Design, and Object Assembly	Age correlated with total and third ventricular volume, even after adjustments for head size (M = F) No correlation between age-related changes in total or third ventricular volume and age-adjusted performance on any of the 10 neuropsychological tests Age correlated with increased CSF volume in sylvian fissure and in vertex, frontal, and parieto-occipital sulci (M = F) No correlation between age-related changes in sulcal fissure CSF volume and age-adjusted performance on any of the 10 neuropsychological tests
Shear et al. 1995	35 healthy volunteers (included in Sullivan et al. 1993) 67.4 ± 7.4 years old 23 M; 12 F No history of major medical, neurological, or psychiatric illness	CT Longitudinal within-subject follow-up, using blinded volume measurements per technique of Sullivan et al. 1993 High rater reliabilities	Over mean (± SD) follow-up of 2.6 (± 0.96) years, increases were observed in CSF volumes of frontal sulci (0.31 mL/year), sylvian fissure (0.58 mL/year), parieto-occipital sulci (0.05 mL/year), and ventricular system (0.61 mL/year) Interactions with gender not reported

(continued)

**APPENDIX 9-1. Imaging studies of human aging and brain cerebrospinal fluid spaces (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Elwan et al. 1996a	88 healthy "lower middle class" volunteers 40-76 years old (54.8 ± 9.6 years) 57 M; 31 F No major medical, neurological, or psychiatric illness All right-handed	CT Multiple distance measurements (no additional details provided)	Age correlated with maximum width of third ventricle Interactions with gender or laterality not reported
Grant et al. 1987	64 healthy volunteers 18-64 years old 25 M; 39 F No history of neurological disease; psychiatric history not reported Handedness not specified	MR imaging (0.15 tesla) Mathematically derived estimate of ventricular volume and CSF volume from signal intensity measurements made on single sagittal slice (number of raters not specified)	Age associated with increased ventricular volume in M, but not in F; however, this apparent gender difference was not tested statistically Interactions with laterality not reported Age associated with increased total (ventricular plus cisternal) cranial CSF volume (M = F) No control for size of brain or head
Condon et al. 1988	40 volunteers 20-60 years old 20 M; 20 F No additional details provided	MR imaging (0.15 tesla) Volume measurement (two raters) derived from computer-assisted pixel segmentation of contiguous sagittal slices (variable slice thickness and number)	For males but not females, age correlated with ratio of total ventricular volume to IV, total CSF volume to IV, and total sulcal CSF volume to IV
Yoshii et al. 1988	58 healthy volunteers 21-81 years old 29 M; 29 F Neurological and psychiatric histories not reported Handedness not specified	MR imaging (1.0 tesla) Blinded global ratings (4-point scale) of lateral ventricular enlargement from inversion recovery films (axial slices [ <i>n</i> unspecified], 10 mm thick, 3-mm interscan gap) Numbers of raters and rater reliabilities not specified	Age correlated with ratings of lateral ventricular enlargement (M = F) Interactions with laterality not reported
Jernigan et al. 1990	58 healthy volunteers 8-79 years old 35 M; 23 F No neurological, psychiatric, or medical (e.g., diabetes mellitus and heart disease) illness Handedness not specified	MR imaging (1.5 tesla) Volume estimates (one of two raters) derived from computer-assisted pixel classification of multiple spin-echo axial images (5 mm thick, 2.5-mm interscan gap)	Age associated with increased ratio of ventricular CSF volume to IV Age associated with increased ratio of sulcal CSF volume to IV Interactions with gender or laterality not reported

Wahlund et al. 1990	24 healthy elderly volunteers 75–85 years old (mean = 79 years) 8 M; 16 F No evidence of neurological or psychiatric illness Handedness not specified	MR imaging (0.02 tesla) Visual ratings (5-point scale) of CSF spaces on T2-weighted axial films (slice: 10 mm thick, no gap) by two raters (blind?) with established reliabilities Area measurements of lateral ventricles based on computer-assisted pixel classification technique, from single axial section at level of basal ganglia Neuropsychological test battery comprised of MMSE, WAIS-R subtests (Information, Digit Span, Similarities, Block Design, Object Assembly, Digit Substitution) and Wechsler Memory Scale (Associative Learning, Visual Reproduction)	No correlation between age and visual ratings or area measurements of sulcal CSF or lateral ventricle CSF size No relation between size of sulcal or lateral ventricular CSF and any neuropsychological test measure
Gur et al. 1991	69 healthy volunteers 18–80 years old 34 M; 35 F No neurological or psychiatric illness 66 right-handed; 3 left-handed	MR imaging (1.5 tesla) Volume measurements (any two of four raters) derived from segmentation technique based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, contiguous)	Older ( $\geq 55$ years) subjects ( $n = 26$ ) had larger total CSF volume ( $M > F$ ), larger ratio of ventricular CSF volume to IV ( $M = F$ ), and larger ratio of sulcal CSF volume to IV ( $M > F$ ) Effects of age on ratio of ventricular CSF volume to IV were asymmetric ( $L > R$ ) in M but not in F Age correlated with ratio of ventricular CSF volume to total CSF plus total brain volume Trend (nonsignificant) for age to be associated with increasing ratio of sulcal CSF volume to total CSF plus total brain volume Interactions with gender or laterality not reported Adjusting for IV, age associated with increased volumes of the third (2.8% per year) and lateral (3.2% per year) ventricles ( $M = F$ ) Age associated with increased odds (7.7% per year) of at least mild lateral ventricular enlargement, from 0.10 at age 40 to 2.22 at age 80 ( $M = F$ ) No interactions with laterality
Tanna et al. 1991	16 healthy volunteers 52–86 years old 5 M; 11 F No evidence of major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Volume measurements (one of two raters with established reliabilities) derived from segmentation techniques based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, 2.5-mm interscan gap)	
Coffey et al. 1992	76 healthy volunteers 36–91 years old 25 M; 51 F No lifetime evidence of neurological or psychiatric illness All right-handed	MR imaging (1.5 tesla) Volume measurements (one of three blinded raters with established reliabilities) using computer-assisted trace methodology of T1-weighted coronal images ( $n = 30$ – $35$ , 5 mm thick, contiguous) Blinded clinical ratings (5-point scale) of lateral ventricular enlargement from films (average score of two experienced raters)	
Lim et al. 1992	14 healthy M volunteers 8 young (21–25 years old); 6 elderly (68–76 years old) No evidence of significant medical or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements derived from semiautomated pixel segmentation of intermediate and T2-weighted axial imaging ( $n = 8$ , 5 mm thick, 2.5-mm interscan gap)	Compared with younger M, older M had higher percentage of CSF volume to IV (8% vs. 20.1%)

(continued)

**APPENDIX 9-1. Imaging studies of human aging and brain cerebrospinal fluid spaces (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Matsubayashi et al. 1992	73 healthy volunteers 59–83 years old 24 M; 49 F No history of major medical, neurological, or psychiatric illness	MR imaging (0.5 tesla) Planimetric determination of VPR No additional details provided Neuropsychological test battery comprised of MMSE, Hasegawa Dementia Scale (Hasegawa 1974), a visuospatial cognitive performance test, and a manual dexterity test	Age correlated with VPR Interactions with gender or laterality not reported Adjusting for age, no relation between VPR and any neuropsychological test measure
Murphy et al. 1992	27 healthy M 19–92 years old No major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (0.5 tesla) Blinded volume measurements derived from semiautomated pixel segmentation of proton density axial images ( $n = 36$ , 7 mm thick, contiguous) Rater reliabilities established, but number of raters not specified	Compared with younger M (< 60 years old; $n = 10$ ), older M ( $n = 17$ ) had larger ratio of lateral ventricular volume to IV, larger ratio of third ventricular volume to IV, and larger ratio of peripheral CSF volume (total CSF volume minus ventricular volumes) to IV No interactions with laterality
Raz et al. 1993c	29 healthy volunteers 18–78 years old 17 M; 12 F No major medical, neurological, or psychiatric illness Self-reported right-handers	MR imaging (0.30 tesla) Blinded volume measurements from films using digital planimetry of T1-weighted and proton density sagittal and coronal images Good rater ( $n = 2$ ) reliabilities	Controlling for head size, age associated with increased lateral ventricular volume (M = F) Interactions with laterality not reported
Christiansen et al. 1994	142 healthy volunteers 21–80 years old 78 M; 64 F No major medical or neurological illness	MR imaging (1.5 tesla) Volume measurements using manual tracing of T2-weighted axial images (4 mm thick, 4-mm interscan gap) No additional details provided	Age associated with increased lateral ventricle volume in M (134%) and F (66%), but these apparent gender differences were not statistically compared Interactions with laterality not reported
DeCarli et al. 1994	30 healthy M volunteers 18–92 years old No major medical, neurological, or psychiatric illness 29 right-handed	MR imaging (0.5 tesla) Volume measurements of T1-weighted coronal images (6 mm thick, contiguous) by single rater using computer-assisted pixel segmentation techniques Good rater reliabilities	Age associated with increased volume of sulcal CSF to IV (1.3%/decade), central CSF to IV (0.3%/decade), and third ventricle CSF to IV (0.04%/decade) For all measures, no interactions with laterality

Golomb et al. 1994	54 healthy volunteers with MMSE $\geq 28$ (overlap with Golomb et al. 1993) 55-87 years old ( $59.7 \pm 7.9$ years) 23 M; 31 F No major medical, neurologic, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements of sulcal CSF using computer-assisted trace methodology of T1-weighted coronal images (4 mm thick, 10% gap) by single rater with established reliabilities	Adjusting for head size, age associated with increased sulcal CSF volume
Pfefferbaum et al. 1994	73 healthy M volunteers (included in Pfefferbaum et al. 1993) 21-70 years old ( $44.1 \pm 13.8$ years) No major medical, neurological, or psychiatric illness Left-handers included ( <i>n</i> not specified)	MR imaging (1.5 tesla) Blinded volume measurements of T2-weighted axial slices (5 mm thick, 2.5 mm-interscan gap) by four raters using computer-assisted pixel segmentation techniques Good rater reliabilities	Age associated with increased cortical CSF volume to IV (0.6 mL/year) and with ventricular volume to IV (0.3 mL/year) Interactions with laterality not reported
Blatter et al. 1995	194 healthy volunteers 16-65 years old 89 M; 105 F No history (by questionnaire) of any neurological or psychiatric illness 95% right-handed	MR imaging (1.5 tesla) Volume measurements derived from semiautomated pixel segmentation and trace methodologies, of intermediate and T2-weighted axial images (5 mm thick, 2-mm gap) High rater reliabilities (blind)	Adjusting for IV, age associated with increased subarachnoid CSF volume, and lateral and third ventricular volumes, but not with fourth ventricular volume; correlations tended to be higher for M than for F, but these apparent differences were not analyzed Interactions with laterality not reported
Murphy et al. 1996	69 healthy volunteers 35 M (mean $\pm$ SD age = $44 \pm 23$ years); 34 F (mean $\pm$ SD age = $50 \pm 21$ years) No major medical or psychiatric illness All right-handed	MR imaging (0.5 and 1.5 tesla) Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous coronal images (5-6 mm thick) Number of raters not specified	Relative to younger subjects (age 20-35 years), older subjects (60-85 years) had larger ratios of lateral ventricular volume to IV ( $M = F$ ), third ventricular volume to IV ( $F > M$ ), and peripheral CSF volume to IV ( $M = F$ ) No interactions with laterality
Salonen et al. 1997	61 healthy volunteers 30-86 years old 30 M; 31 F No neurological symptoms or disease; psychiatric history not specified Handedness not specified	MR imaging (1.0 tesla) Qualitative ratings (5-point scale) of sulcal and lateral ventricular enlargement Linear measurement of maximum width of third ventricle T1-weighted axial slices (5 mm thick, 1-mm interscan gap) Number of raters and rater reliabilities not specified	Age associated with increased ratings of sulcal and lateral ventricular enlargement, and with width of third ventricle Interactions with gender or laterality not reported
Yue et al. 1997	1,488 healthy elderly volunteers from the Cardiovascular Health Study 65-80+ years old No major medical or neurological illness (psychiatric illness not assessed) Number of M and F not specified Handedness not specified	MR imaging (0.35 or 1.5 tesla) Blinded ratings of sulcal prominence (10-point scale) and ventricular size (10-point scale) from T1-weighted axial images Good to excellent rater reliabilities, but number of raters not specified	Age associated with increased sulcal prominence and ventricular enlargement ( $M = F$ )

(continued)

**APPENDIX 9-1. Imaging studies of human aging and brain cerebrospinal fluid spaces (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Coffey et al. 1998	330 elderly volunteers living independently in the community 66–96 years old (74.98 ± 5.09) 129 M; 201 F No lifetime history of neurological or psychiatric illness All right-handed	MR imaging (1.5 tesla, <i>n</i> = 248; 0.35 tesla, <i>n</i> = 82) Blinded volume measurements (one of two raters with established reliabilities) using computer-assisted trace methodology of T1-weighted axial images (5 mm thick, no interscan gap)	Adjusting for IV, age associated with increased peripheral (sulcal) CSF volume, lateral fissure CSF volume, lateral ventricular volume (0.95 mL/year), and third ventricular volume (0.05 mL/year) M showed greater age-related changes than did F for peripheral CSF (2.11 mL/year vs. 0.06 mL/year, respectively) and lateral fissure volumes (0.23 mL/year vs. 0.10 mL/year, respectively) No interactions with laterality
Guttman et al. 1998	72 healthy volunteers 18–81 years old 22 M; 50 F No history of psychiatric illness, epilepsy, or severe head trauma Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous axial images (3 mm thick) Good interrater reliabilities	Age associated with increased ratio of total CSF volume to IV Interactions with gender or laterality not reported
Mueller et al. 1998	46 healthy elderly volunteers 65–74 years old (6 M, 5 F), 75–84 years old (8 M, 7 F), and 85–95 years old (9 M, 11 F) All functionally independent, MMSE ≥ 24, and free of major medical and neurological illness, as well as depression Handedness not specified	MR imaging (1.5 tesla) Volume measurements (nonblind?) using computer-assisted pixel segmentation of contiguous coronal images (4 mm thick) Excellent interrater reliabilities Scanning repeated annually or biannually over 3- to 9-year follow-up	Adjusting for IV, age associated with increased temporal horn volume, but not with total CSF, sulcal CSF, or lateral ventricle volumes Interactions with gender not reported Over the follow-up period, significant increases were seen only in total CSF volume (1.5 mL/year, F > M) and in lateral ventricular volume (1.4 mL/year, M = F)
Pfefferbaum et al. 1998	28 healthy M volunteers (overlap with Pfefferbaum et al. 1994) 21–68 years old (51 ± 13.8 years) No major medical, neurological, or psychiatric illness Left-handers included ( <i>n</i> not specified)	MR imaging (1.5 tesla) Blinded volume measurements derived from semiautomated pixel segmentation of intermediate and T2-weighted axial images ( <i>n</i> = 17–20, 5 mm thick, 2.5-mm interscan gap) Scanning repeated at 5-year follow-up	Over the follow-up interval, significant increase in volume of lateral (5 mL, or 20%) and third ventricles, but not in cortical sulcal CSF volume

*Note.* CSF = cerebrospinal fluid; CT = computed tomography; F = female(s); IV = intracranial volume; M = male(s); MMSE = Mini-Mental State Exam; MR = magnetic resonance; VBR = ventricular/brain ratio; VPR = ventricular/parenchymal ratio; WAIS-R = Wechsler Adult Intelligence Scale-Revised.

## APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy

Study	Subjects	Imaging and measurement technique	Findings
Jacoby et al. 1980	50 healthy elderly volunteers 62–88 years old 10 M; 40 F No history of significant psychiatric or neurological illness Handedness not specified	CT Ratings (4-point scale) of cortical atrophy from films by single blinded rater; five regions rated (frontal, parietal, temporal, insular, and occipital) and scores summed	Age correlated with total cortical atrophy score Interactions with gender or laterality not reported Adjusting for age, no relation between cortical atrophy and performance on the Hodkinson test of memory and orientation
Cala et al. 1981	115 volunteers 15–40 years old 62 M; 53 F No history of migraine, head trauma, or excessive alcohol intake (no additional details provided) All but eight subjects right-handed	CT ( $n = 2$ scanners) Ratings (5-point scale) of cortical atrophy (no additional details provided) Axial slices (13 mm thick)	Age apparently associated with increased frequency of mild (grade 2) atrophy of frontal lobes and cerebellar vermis, but no statistical analysis reported Interactions with gender or laterality not reported
Schwartz et al. 1985	30 healthy M volunteers 21–81 years old No history of major medical, neurological, or psychiatric illness Handedness not specified	CT Volume measurements derived from computer-assisted segmentation technique (ASI-II program) Axial slices ( $n = 7$ ) starting from the plane of the inferior orbitomeatal line (10 mm thick, 7-mm interscan gap)	Adjusting for IV, age negatively correlated with volume of gray matter and with volume of gray plus white matter, but not with white matter volume Subjects > 60 years old ( $n = 11$ ) had smaller volumes of thalamus, lenticular nuclei, and total gray matter than younger subjects ( $n = 19$ ) Effects similar for both hemispheres
Golomb et al. 1993	154 healthy volunteers with MMSE score > 27 55–88 years old ( $70 \pm 8$ years) 73 M; 81 F No evidence of active medical, neurological, or psychiatric illness Handedness not specified	CT ( $n = 51$ ); MR imaging ( $n = 81$ ); both CT and MR imaging ( $n = 22$ ) Blinded ratings (4-point scale) of hippocampal atrophy as defined by dilation of transverse choroidal fissure on films, by raters ( $n = ?$ ) with established reliabilities Neuropsychological test battery comprised of WAIS Digit Span and the Guild Memory Test (Paired Associates, Paragraph Recall, and Design Recall)	Subjects with hippocampal atrophy (rating of 2 or greater in either hemisphere; $n = 50$ ) significantly older than those without atrophy More M (41%) than F (25%) with hippocampal atrophy After controlling for age, education, and WAIS vocabulary score, subjects with hippocampal atrophy performed worse on recent verbal memory portion of the Guild Memory Scale; no group differences were observed in digit span or recall of designs

(continued)

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Meyer et al. 1994	81 healthy volunteers 27–90 years old 44 M; 37 F No major neurological or psychiatric illness	CT ( $n = 2$ scanners) Blinded measure of tissue density (densitometry) and regional brain volume (trace methodology) from axial slices (8 mm thick)	Age associated with decreased tissue density in cortical gray matter (frontal, temporal, parietal, and occipital) and in white matter (frontal only), but not in subcortical gray matter (caudate, putamen, or thalamus) Age associated with decreased ratios of cortical gray matter volume to IV and subcortical gray matter volume to IV, but not with white matter volume to IV Interactions with gender or laterality not reported
Elwan et al. 1996b	88 healthy “lower middle class” volunteers 40–76 years old ( $54.8 \pm 9.6$ years) 57 M; 31 F No major medical, neurological, or psychiatric illness All right-handed	CT Multiple linear measurements (no additional details provided)	No correlation between age and maximal bifrontal distance, bifrontal index, maximal bicaudate distance, maximal septum-caudate distance, or cella media index Interactions with gender or laterality not reported
Condon et al. 1988	40 volunteers 20–60 years old 20 M; 20 F No additional details provided	MR imaging (0.15 tesla) Volume measurement (two raters) derived from computer-assisted pixel segmentation of contiguous sagittal slices (variable slice thickness and number)	For M but not F, age negatively correlated with ratio of total brain volume to IV Interactions with laterality not reported
Yoshii et al. 1988	58 volunteers 21–81 years old 29 M; 29 F Neurological and psychiatric histories not reported Handedness not specified	MR imaging (1.0 tesla) Mathematically derived estimate of brain volume from inversion recovery films, based on planimetric measurement made on single slice (10 mm thick) at level of foramen of Monro Blinded global ratings of cortical atrophy from films (axial slices, [ $n = ?$ ], 10 mm thick, 3-mm interscan gap) Number of raters and rater reliabilities not specified	No correlation between age and brain volume Age significantly correlated with ratings of cortical atrophy for both M and F

Jernigan et al. 1990, 1991	58 healthy volunteers 8–79 years old 35 M; 23 F No history of neurological, psychiatric, or medical illness (diabetes mellitus, heart disease) Handedness not specified	MR imaging (1.5 tesla) Volume estimates (one of two raters) derived from computer-assisted pixel classification of multiple spin-echo axial images (5 mm thick, 2.5-mm interscan gap)	Age negatively correlated with ratios of cerebral volume to IV and of gray matter volume to IV Among gray matter structures, age negatively correlated with ratios of cortical gray matter volume to IV, caudate volume to IV, and diencephalon volume to IV; but not with thalamus volume to IV or anterior cingulate volume to IV No correlation between age and ratio of white matter volume to IV Interactions with gender or laterality not reported
Krishnan et al. 1990	39 healthy volunteers 24–79 years old 17 M; 22 F No evidence of major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Stereological measurement (one of two raters) of axial slices (variable number, 5 mm thick, 2.5-mm interscan gap) from intermediate and T2-weighted films	Age negatively correlated with total caudate volume (M = F) Caudate volume was less in subjects older than 50 years ( $n = 22$ ) No adjustments for cranial size
Doraiswamy et al. 1991	36 healthy volunteers (overlap with subjects of Krishnan et al. 1990) 26–79 years old 16 M; 20 F No evidence of major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Area measurement of T1-weighted midsagittal image using computer-assisted trace methodology Rater reliabilities not reported	Age negatively correlated with corpus callosum area in M but not in F
Escalona et al. 1991	37 healthy volunteers (overlap with subjects of Krishnan et al. 1990) 24–79 years old 16 M; 21 F No evidence of major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Stereological measurement (one of two raters) of axial slices (variable number, 5 mm thick, 2.5-mm interscan gap) from intermediate and T2-weighted films Good rater reliabilities	No association between age and volume of cerebellar hemispheres
Gur et al. 1991	69 healthy volunteers 18–80 years old 34 M; 35 F No neurological or psychiatric illness 66 right-handed; 3 left-handed	MR imaging (1.5 tesla) Volume measurements (any two of four raters) derived from segmentation technique based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, contiguous)	Older ( $\geq 55$ years) subjects ( $n = 26$ ) had smaller whole brain volumes than younger subjects (M = F)

(continued)

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
McDonald et al. 1991	36 healthy volunteers (subjects also included in Krishnan et al. 1990) 24–79 years old 13 M; 23 F No evidence of major medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Same as Krishnan et al. 1990 (above)	Age negatively correlated with total putamen volume (M = F; left = right), but no adjustments for cranial size
Shah et al. 1991	36 healthy volunteers (overlap with subjects in Krishnan et al. 1990) 26–79 years old 16 M; 20 F No evidence of major medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Computer-assisted measurements from T1-weighted midsagittal films by single rater with established intrarater reliabilities	Increasing age associated with decreasing midbrain area (M > F?) No age effects on areas of pons, medulla, anterior cerebellar vermis, or fourth ventricle
Tanna et al. 1991	16 healthy volunteers 52–86 years old 5 M; 11 F No evidence of major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Volume measurements (one of two raters with established reliabilities) derived from segmentation techniques based on two-feature pixel classification of multiple spin-echo axial images (5 mm thick, 2.5-mm interscan gap)	Age negatively correlated with ratio of total brain volume to total CSF plus total brain volume Interactions with gender or laterality not reported
Coffey et al. 1992	76 healthy volunteers 36–91 years old 25 M; 51 F No lifetime history of neurological or psychiatric illness All right-handed	MR imaging (1.5 tesla) Volume measurements (one of three blinded raters with established reliabilities) using computer-assisted trace methodology of T1-weighted coronal images ( $n = 30-35$ , 5 mm thick, contiguous) Blinded clinical ratings (5-point scale) of “cortical atrophy” (average score of two raters)	Age associated with decreased total volumes of the cerebral hemispheres (0.23% per year), the frontal lobes (0.55% per year), the temporal lobes (0.28% per year), and the amygdala-hippocampal complex (0.30% per year); all effects similar for M and F, and for both hemispheres Increasing age associated with increasing odds (8.9% per year) of “cortical atrophy,” from 0.08 at age 40 to 2.82 at age 80
Doraiswamy et al. 1992	75 healthy volunteers (overlap with subjects in Krishnan et al. 1990) 21–82 years old (52.5 ± 18 years) 34 M; 41 F No neurological or psychiatric illness	MR imaging (1.5 tesla) Blinded measurements of midbrain size on T2-weighted axial films (no additional details provided)	Age negatively correlated with midbrain volume and anteroposterior diameter, but not with red nucleus size Effects similar for both M and F

Jack et al. 1992	22 healthy elderly volunteers 76.3 ± 11.3 years old 10 M; 12 F No major medical or neurological illness; no depression Handedness not specified	MR imaging (1.5 tesla) Volume estimates (single rater) derived from computer-assisted pixel classification of T1-weighted coronal images (4 mm thick, contiguous) Intrarater reliabilities not reported	Age associated with decreased ratio of hippocampal volume to IV and of anterior temporal lobe volume to IV Interactions with gender or laterality not reported
Lim et al. 1992	14 healthy M volunteers 8 young (21–25 years old) and 6 elderly (68–76 years old) No evidence of significant medical or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements derived from semiautomated pixel segmentation of intermediate and T2-weighted axial images ( <i>n</i> = 8, 5 mm thick, 2.5-mm interscan gap)	Compared to young M, elderly M had lower ratio of gray matter volume to IV (49.7% vs. 38.7%) No group difference in ratio of white matter volume to IV (47.2% vs. 41.2%) Interactions with laterality not reported
Murphy et al. 1992	27 healthy M volunteers 19–92 years old No major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (0.5 tesla) Blinded volume measurements using computer-assisted trace methodology of proton density axial images ( <i>n</i> = 36, 7 mm thick, contiguous) Manual tracing of subcortical nuclei from enhanced images Rater reliabilities were established, but number of raters not reported	Older M (> 60, <i>n</i> = 17) had smaller ratios of total, left, and right hemisphere volume to IV than did younger M Older M had smaller ratios of total caudate volume to IV and of total lenticular nuclei volume to IV than did younger M; no difference in ratio of total thalamus volume to IV Reductions in caudate and lenticular volumes also found when the volumes were normalized to total brain volume, suggesting a differential effect of aging on these structures Older M exhibited a R > L asymmetry in lenticular volumes; the reverse was true in younger M
Doraiswamy et al. 1993	Same as Doraiswamy et al. 1992	MR imaging (1.5 tesla) Blinded linear measurements of interuncal distance on T1-weighted axial image (no additional details provided)	Age associated with larger interuncal distance (NB: this measure was not correlated with amygdala volume in a follow-up study [Early et al. 1993]) Interactions with gender or laterality not reported

*(continued)*

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Raz et al. 1993a, 1993b, 1993c	29 healthy volunteers 18–78 years old (43.8 ± 21.5 years) 17 M; 12 F No history of medical, neurological, or psychiatric illness All right-handed	MR imaging (0.3 tesla) Volume measurements using computer-assisted trace methodology of digitized images from the films, by two blinded raters with high reliabilities T1-weighted axial slices ( $n = 9$ , 4.2 mm thick, 6.0-mm interscan gap) T2-weighted coronal slices ( $n = 17$ –21, 6.6 mm thick, 8.6-mm interscan gap) Measures of “fluid” (Cattell Culture-Fair Intelligence Test) and crystallized (Extended Vocabulary) intelligence	After controlling for head size, age associated with decreased volumes of caudate and visual cortex ( $F > M$ ) No association between age and volumes of dorsolateral prefrontal cortex, anterior cingulate gyrus, prefrontal white matter, hippocampal formation, postcentral gyrus, inferior parietal lobule, or parietal white matter Both measures of intelligence were associated with L > R asymmetry in cerebral hemisphere volume, but not with any other measure of brain size
Christiansen et al. 1994	142 healthy volunteers 21–80 years old 78 M; 64 F No major medical or neurological illness	MR imaging (1.5 tesla) Area and volume measurements using computer-assisted trace methodology of T2-weighted axial slices ( $n = 15$ , 4 mm thick, 4-mm interscan gap) Number of raters, their “blindness,” and their reliabilities not specified	Age associated with decreased volume of cerebral hemispheres Interactions with gender or laterality not reported
Cowell et al. 1994	130 healthy volunteers (overlap with subjects in Gur et al. 1991) 18–80 years old 70 M; 60 F No major medical, neurological, or psychiatric illness All right-handed	MR imaging (1.5 tesla) Volume measurements using a combination of computer-assisted trace methodology and pixel segmentation of three-dimensional images reconstructed from T2-weighted axial images (5 mm thick, contiguous) Good rater reliabilities, but “blindness” not specified	Ratio of <i>frontal lobe</i> to IV was smaller in M > 40 years old than in younger M; no such group difference in F In contrast, the R > L asymmetry of frontal lobe to IV was larger in older F than younger F; no such group difference in M Ratio of <i>temporal lobe</i> to IV was also smaller in M > 40 years old than in younger M; no such group difference in F; no interactions with laterality Ratio of the <i>remaining brain volume</i> to IV was smaller in older than in younger subjects for both sexes; no interactions with laterality

DeCarli et al. 1994	30 healthy M volunteers 19–92 years old No major medical, neurological, or psychiatric illness 29 right-handed	MR imaging (0.5 tesla) Volume measurements using computer-assisted trace methodology of T1-weighted coronal images (6 mm thick, contiguous) through temporal lobe, by single (blind?) rater	Age associated with decreased ratio of frontal lobe volume to IV but not with temporal lobe volume to IV No interactions with laterality
Golomb et al. 1994	54 healthy volunteers (overlap with Golomb et al. 1993) 55–87 years old ( $59.7 \pm 7.9$ years) 23 M; 31 F No major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted trace methodology of T1-weighted coronal images (4 mm thick, 10% gap) by single rater with established reliabilities Composite scores of primary (WAIS Digit Span) and secondary memory with immediate and delayed recall components (Guild Memory Test, list recall, facial recognition)	Adjusting for head size, age associated with decreased volumes of hippocampal formation and of superior temporal gyrus After adjusting for age, gender, WAIS vocabulary, and subarachnoid CSF volume, hippocampal volume was associated with delayed recall but not with initial recall or digit span Volume of superior temporal gyrus was unrelated to any memory measure
Pfefferbaum et al. 1994	73 healthy M volunteers (included in Pfefferbaum et al. 1993) 21–70 years old ( $44.1 \pm 13.8$ years) No major medical, neurological, or psychiatric illness Left-handers included ( $n$ not specified)	MR imaging (1.5 tesla) Blinded volume measurements derived from semiautomated pixel segmentation of intermediate and T2-weighted axial images ( $n=17-20$ , 5 mm thick, 2.5-mm interscan gap)	Adjusting for head size, age associated with decreased cortical gray matter volume (0.7 mL/year), but not with cortical white matter volume Interactions with laterality not reported
Soininen et al. 1994	32 healthy volunteers from the community, all with MMSE scores > 25 16 with AAMI ( $67.7 \pm 7$ years; 4 M, 12 F) 16 control subjects ( $70.2 \pm 4.7$ years; 6 M, 10 F) without AAMI All but 1 right-handed	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted trace methodology of T1-weighted coronal images (1 mm thick, contiguous) through temporal lobe, by single rater with established reliabilities Neuropsychological measures of verbal memory (Buschke-Fuld Selective Reminding Test) and visual memory (Benton Visual Retention Test, Heaton Visual Retention Test)	No group differences in hippocampal volumes, although control subjects (but not AAMI subjects) exhibited significant R > L asymmetry No group differences in amygdala volume or asymmetry No correlation between verbal memory and any volume measurement Visual memory (BVRT) correlated with 1) right hippocampal volume and with degree of R > L asymmetry in total sample only, and 2) with left hippocampal volume and right amygdala volume in AAMI subjects Visual memory (Heaton) correlated with volumes of right and left amygdala in total sample and in AAMI subjects

(continued)

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Blatter et al. 1995	194 healthy volunteers 16–65 years old 89 M; 105 F No history (by questionnaire) of any neurological or psychiatric illness 95% right-handed	MR imaging (1.5 tesla) Volume measurements derived from semiautomated pixel segmentation and trace methodologies of intermediate and T2-weighted axial images (5 mm thick, 2-mm gap) High rater reliabilities (blinded status?)	Adjusting for head size, age associated with decreased total brain volume and gray matter volume, but not white matter volume Correlations tended to be higher for M than for F, but these apparent differences were not analyzed. However, only F showed significant age-related reductions in gray matter. Interactions with laterality not reported
Convit et al. 1995	37 healthy adult volunteers 27 older (14 M, 13 F; 69.2 ± 8.3 years old) 10 younger (5 M, 5 F; 26.1 ± 4.1 years old) No evidence of stroke or major medical or psychiatric illness	MR imaging (1.5 tesla) Blinded volume measurements by single rater (reliabilities?) using computer-assisted trace methods of T1-weighted coronal images (4 mm thick, 10% gap)	Controlling for gender and head size, age associated with volume loss in lateral temporal lobe (especially fusiform gyrus) and medial temporal lobe (especially hippocampus and parahippocampus)
Hokama et al. 1995	15 healthy M community volunteers 20–55 years old No lifetime history of major medical, neurological, or psychiatric illness All right-handed	MR imaging (1.5 tesla) Volume measurements of basal ganglia using semiautomated computer assisted trace methodology from T1-weighted coronal and axial sections (1.5 mm thick, contiguous) by raters with established reliabilities	Age associated with decreased volumes of caudate and putamen, but not of globus pallidus No correlation between basal ganglia volumes and IQ as estimated by WAIS-R Information subscale
Parashos et al. 1995	80 healthy volunteers (overlap with subjects in Coffey et al. 1992) 30–91 years old 28 M; 52 F No lifetime history of neurological or psychiatric illness All right-handed	MR imaging (1.5 tesla) Blinded area measurements using computer-assisted trace methodology of T1-weighted midsagittal image (5 mm thick), made by single rater with established rater reliabilities	Adjusting for IV, increasing age associated with smaller total and regional callosal areas, especially of anterior regions (M = F)
Fox et al. 1996	11 adult volunteers with no evidence of memory impairment on testing 5 M, 6 F; 51.3 ± 5.9 years old No additional details provided	MR imaging (1.5 tesla) Volume measurements using computer-assisted pixel segmentation of T1-weighted coronal images (1.5 mm thick, contiguous) Scanning repeated at 12.8 ± 4.3 months and volume differences determined from subtraction images	Over the follow-up period, brain volume decreased by 0.05% (0.03 mL)

Golomb et al. 1996	44 healthy volunteers (from Golomb et al. 1994) 68.5 ± 7.7 years old 16 M; 28 F No major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted trace methodology of T1-weighted coronal images (4 mm thick, contiguous) Guild Memory Test (Paired Associates, Paragraph Recall, and Design Recall) administered at baseline and at mean of 3.8 years later	After adjusting for age, gender, and years of education, change in paragraph recall scores over the follow-up interval were significantly inversely related to baseline hippocampal volume (adjusted for intracranial volume), but not to baseline superior temporal gyrus size or subarachnoid CSF volume Baseline hippocampal volume (adjusted for intracranial volume) was significantly smaller in the 14 subjects who declined to a score of 3 (mild cognitive impairment) on the Global Deterioration Scale
Janowsky et al. 1996	60 healthy elderly volunteers 66–94 years old (mean 78.2) 15 M; 45 F No major medical, neurological, or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Area measurement of corpus callosum derived from computer-assisted trace methodology Number of raters and their “blindness” not specified	Age associated with decreased total callosal area, anterior callosal area, and middle callosal area Interactions with gender not reported
Murphy et al. 1996	69 healthy volunteers 35 M (44 ± 23 years old); 34 F (50 ± 21 years old) No major medical or psychiatric illness All right-handed	MR imaging (0.5 and 1.5 tesla) Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous coronal images (5–6 mm thick) Number of raters not specified	Relative to “young” subjects (age 20–35 years), “old” subjects (60–85 years) had smaller brain matter volume ratios of cerebellum to IV (M = F), cerebrum to IV (M > F), frontal lobe to IV (M > F), temporal lobe to IV (M > F), parietal lobe to IV (F > M), parieto-occipital lobe to IV (M = F), parahippocampal gyrus to IV (M = F), amygdala to IV (M = F), hippocampus to IV (F > M), thalamus to IV (M = F), lenticular nucleus to IV (M = F), and caudate to IV (M = F) For the frontal lobe, the right side decreased more than the left with age in M, but in F the left side decreased more than the right; for all other regions, there were no interactions with laterality
Deshmukh et al. 1997	10 healthy M volunteers 50.1 ± 13.8 years old No evidence of major medical, neurological, or psychiatric illness 9 right-handed; 1 left-handed	MR imaging (1.5 tesla) Volume measures using semiautomated computer-assisted trace methodology from three-dimensional T1-weighted sagittal sections, realigned in the axial plane, by raters with established reliabilities	Age associated with decreased volume of cerebellar lobules VI–VII

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Jack et al. 1997	126 healthy elderly volunteers 51–89 years old ( $79.15 \pm 6.73$ years) 44 M; 82 F No active neurological or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted trace methodology of T1-weighted three-dimensional volumetric images (1.6 mm thick, contiguous, $n = 124$ ) by single rater with established reliabilities	Age associated with decreased volume ratio of hippocampus to IV (45.63 mL/year), amygdala to IV (20.75 mL/year), and parahippocampal gyrus to IV (46.65 mL/year); effects similar for M and F Effects were similar for the 2 hemispheres except for the parahippocampal gyrus (L > R)
Kaye et al. 1997	30 healthy elderly volunteers from the community, with MMSE $\geq 24$ All $\geq 84$ years old; 14 M, 16 F No evidence of major medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted trace methodology of T1-weighted coronal images (4 mm thick, contiguous) by raters with established reliabilities Scanning repeated annually over a mean of 42 months	12 subjects developed cognitive decline (MMSE < 24) during follow-up (predementia group) Ratio of temporal lobe volume/IV declined at a faster rate in the predementia group (about 1.27%/year) than in the others (0%/year) No group differences in rate of decrease in hippocampal/IV (about 2%/year) or parahippocampal volume/IV (about 2.5%/year)
O'Brien et al. 1997	40 healthy community volunteers 55–96 years old 20 M, 20 F No evidence of major medical or neurological illness, nor of depression or drug abuse	MR imaging (0.3 tesla) Ratings of amygdala-hippocampal atrophy from T1-weighted coronal images (5.1 mm thick, 0.5-mm gap) by two raters with established reliabilities, blind to cognitive scores	Age associated with presence of amygdala-hippocampal atrophy Controlling for the effects of age and education, amygdala-hippocampal atrophy was associated with lower scores on CAMCOG, a relation entirely the result of lower scores on the memory subscale

N. Raz et al. 1997	<p>148 healthy volunteers  18–77 years old  66 M (47.39 ± 8.07 years old); 82 F  (45.72 ± 16.48 years old)  No major medical, neurological, or  psychiatric illness  All right-handed</p>	<p>MR imaging (1.5 tesla)  Blinded volume measurements (digital  planimetry) from scans of T1-weighted  reformatted coronal images (1.3 mm thick,  contiguous)  Good rater reliabilities among eight raters</p>	<p>Adjusted for height, age significantly related  to smaller volumes of whole brain (M = F),  prefrontal gray matter (M = F), inferior  temporal cortex (M &gt; F), fusiform gyrus  (M = F), hippocampal formation (M = F),  primary somatosensory cortex (M = F),  superior parietal cortex (M = F),  prefrontal white matter (M = F), and  superior parietal white matter (M = F)  No age effects were found for anterior  cingulate cortex, parahippocampal cortex,  primary motor cortex, inferior parietal  cortex, visual cortex, and precentral,  postcentral, or inferior parietal white matter</p>
Salat et al. 1997	<p>76 healthy elderly volunteers  65–95 years old (mean 77.7 years)  31 M; 45 F  No major medical or neurological illness, and  no depression  All right-handed, except 1 left-handed F</p>	<p>MR imaging (1.5 tesla)  Area measurements (one of three raters with  established reliabilities) of corpus callosum,  pons, and cerebellum using trace methodology  of T1-weighted midsagittal image  Neuropsychological test battery comprised of  Wechsler Memory Scale and Block Design  subtest of WAIS</p>	<p>No interactions with laterality  Age associated with decreased total, anterior,  and middle callosum areas in F but not in M  No relation of age to pons or cerebellum areas  No relation between any brain measure and  verbal memory or visual construction  Nonverbal memory correlated with  callosum area in F</p>
Coffey et al. 1998	<p>330 elderly volunteers living independently  in the community  66–96 years old (74.98 ± 5.09)  129 M; 201 F  No history of neurological or psychiatric illness  All right-handed</p>	<p>MR imaging (1.5 tesla, <math>n = 248</math>; 0.35 tesla,  <math>n = 82</math>)  Blinded volume measurements (one of two  raters with established reliabilities) using  computer-assisted trace methodology of  T1-weighted axial images (5 mm thick, no  interscan gap)</p>	<p>Adjusting for IV, age associated with decreased  cerebral hemisphere volume (2.79 mL/year)  (M = F), frontal region area (0.13 mL/year)  (M = F), temporal-parietal region area  (0.13 mL/year) (M = F), and parietal-  occipital region (M &gt; F, 0.31 vs. 0.09  mL/year, respectively)  All effects similar in both hemispheres</p>
Davatzikos and Resnik 1998	<p>114 healthy volunteers  56–85 years old  68 M (70.9 ± 7.6 years),  46 F (69.4 ± 8.0 years old)  All right-handed  No additional details provided</p>	<p>MR imaging (1.5 tesla)  Quantitative morphometry of the corpus  callosum using computer-assisted trace  methodology of T1-weighted midsagittal image  (1.5 mm thick); morphometry was quantitated  using a template and deformation function  No additional details provided</p>	<p>Age associated with decreased total and  regional callosal size (M = F), with exception  of anterior and posterior extremes</p>

(continued)

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Gunning-Dixon et al. 1998	Same as Raz et al. 1997	MR imaging (1.5 tesla) Blinded volume measurements (digital planimetry) from scans of T1-weighted reformatted coronal images (1.3 mm thick, contiguous)	Age associated with decreased caudate volume (L > R in M, R > L in F), decreased putamen volume (R > L, M = F), and decreased globus pallidus volume (M only, R = L)
Gur et al. 1998	17 healthy volunteers (overlap with subjects in Gur et al. 1991 and Cowell et al. 1994) 31.9 ± 8.9 years old 13 M; 4 F	MR imaging (1.5 tesla) Volume measurements using a combination of computer-assisted trace methodology and pixel segmentation of three-dimensional images reconstructed from T2-weighted axial images (5 mm thick, contiguous) Good rater reliabilities, but “blindness” not specified	No significant change over follow-up period in whole brain, CSF, or frontal lobe volumes Significant volume loss was observed for L (7.5%) and R (7.2%) temporal lobes
Guttmann et al. 1998	72 healthy volunteers 18–81 years old 22 M; 50 F No history of psychiatric illness, epilepsy, or severe head trauma Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted segmentation and trace methodology of contiguous axial images (3 mm thick) Good interrater reliabilities	Age associated with decreased ratio of total white matter volume to IV and decreased total gray matter volume to IV Interactions with gender or laterality not reported
Jack et al. 1998	24 elderly volunteers 70–89 years old (81.04 ± 3.78 years) 8 M; 16 F No active neurological or psychiatric illness Handedness not specified	MR imaging (1.5 tesla) Blinded volume measurements using computer-assisted trace methodology of T1-weighted three-dimensional volumetric images (1.6 mm thick, contiguous, <i>n</i> = 124) by single rater with established reliabilities	Over a 12-month interval, mean hippocampal volume decreased by 1.55%, and mean temporal horn volume increased by 6.15% (M = F, L = R)
Kohler et al. 1998	26 healthy elderly community volunteers 70.8 ± 6.3 years old 12 M; 14 F No history of neurological or psychiatric impairment, and no dementia or age-associated memory impairment on neuropsychological testing	MR imaging (1.5 tesla) Blinded volume measurements (one of two raters, reliabilities ?) using computer-assisted trace or stereological methods, from T1-weighted coronal images (1.3 mm thick, contiguous) Mattis Dementia Rating Scale and neuropsychological testing of verbal recall (California Verbal Learning Test) and visual recall (Visual Reproduction Test of WMS-R)	Controlling for age, gender, education, and head size, a trend was found for a negative association between hippocampal volume and delayed verbal recall (CVLT) No relations observed between parahippocampal volume and any memory measure

Laakso et al. 1998	42 cognitively normal healthy elderly community volunteers 64–79 (72 ± 4) years old 19 M; 23 F	MR imaging (1.5 tesla) Volume measures using computer-assisted trace methods from T1-weighted coronal images (2 mm thick, contiguous) by a single blinded rater with established reliabilities	No relation between age and hippocampal size
Mueller et al. 1998	46 healthy elderly volunteers 65–74 years old (6 M, 5 F), 75–84 years old (8 M, 7 F), and 85–95 years old (9 M, 11 F) All functionally independent, MMSE ≥ 24, and free of major medical and neurological illness, as well as depression Handedness not specified	MR imaging (1.5 tesla) Volume measurements (nonblind?) using computer-assisted pixel segmentation of contiguous coronal images (4 mm thick) Excellent interrater reliabilities Scanning repeated annually or biannually over 3- to 9-year follow-up	Adjusting for IV, age associated with decreased volumes of total brain, cerebral hemispheres, frontal lobes, temporal lobes, basilar-subcortical region, hippocampus, and hippocampal gyrus Interactions with gender not reported Over the follow-up period, significant volume decreases were seen in hippocampus (0.02 mL/year), parahippocampal gyrus (in youngest group only, 0.05 mL/year), parieto-occipital region (in middle and oldest age groups, 3 mL/year), and basilar region (in middle group only, 0.5 mL/year); no volume decreases were seen in cerebral hemispheres, frontal lobes, or temporal lobes.
Oguro et al. 1998	152 healthy adults 81 M, 71 F Age range 40s–70s No evidence of neurological disease	MR imaging (0.2 tesla) Linear and area measurements using computer-assisted trace methodology from T1-weighted midsagittal image (7 mm thick) and T2-weighted axial images (no details), by raters ( $n = ?$ ) with established reliabilities	Age associated with decreased linear measures of midbrain tegmentum (M only), midbrain pretectum (M and F), and base of pons (M only), but not with pontine tegmentum or fourth ventricle Age associated with decreased area of cerebellar vermis (M only), but not of pons Age associated with decreased ratio of cerebrum to IA (M and F) at level of third ventricle and at level of body of lateral ventricles Interactions with laterality not reported
Pfefferbaum et al. 1998	28 healthy M volunteers (overlap with Pfefferbaum et al. 1994) 21–68 years old (51 ± 13.8 years) No major medical, neurological, or psychiatric illness Left-handers included ( $n$ not specified)	MR imaging (1.5 tesla) Blinded volume measurements derived from semiautomated pixel segmentation of intermediate and T2-weighted axial images ( $n = 17–20$ , 5 mm thick, 2.5-mm interscan gap) Scanning repeated at 5-year follow-up	Over the follow-up interval, significant decrease in total gray matter volume and in regional gray matter volume (prefrontal gray 2 mL, or 7%; posterior parieto-occipital gray 1 mL, or 3.5%); no change in frontal, anterior superior temporal, posterior superior temporal, or anterior parietal region gray matter volume Interactions with laterality not reported

(continued)

**APPENDIX 9-2. Imaging studies of human aging and brain parenchymal atrophy (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Raz et al. 1998a	146 healthy volunteers (overlap with N. Raz et al. 1997) 18–77 years old 64 M (48 ± 18 years); 82 F (46 ± 17 years) No evidence of major medical, neurological, or psychiatric illness All right-handed	MR imaging (1.5 tesla) Blinded volume measurements (digital planimetry) from scans of T1-weighted reformatted coronal and sagittal images (0.8 mm thick, 1.5 mm thick) Good rater reliabilities	Age associated with volume loss in cerebellar hemispheres (2%/decade), vermis, vermian lobules VI and VII (4%/decade), and posterior vermis (lobules VIII–X; 2%/decade), but not in anterior vermis (lobules I–V) or pons
Raz et al. 1998b	95 healthy volunteers (selected from N. Raz et al. 1997) 18–77 (44.02 ± 16.35) years old 41 M (42.98 ± 17.24 years); 54 F (44.82 ± 15.76 years) No major medical, neurological, or psychiatric illness All right-handed	MR imaging (1.5 tesla) Blinded volume measurements (digital planimetry) from scans of T1-weighted reformatted coronal images (1.3 mm thick, contiguous) Good rater reliabilities among eight raters Neuropsychological test measures of executive functions and of verbal and nonverbal working memory, explicit memory, and priming	Age associated with decreased test scores and with decreased volumes of dorsolateral prefrontal cortex, orbitofrontal cortex, pericalcarine cortex, fusiform gyrus, and hippocampal formation Using path analysis, atrophy of prefrontal cortex was related to an index of perseveration (from Wisconsin Carol Sort Test) and atrophy of visual processing areas to nonverbal working memory; volume of limbic structures was unrelated to any cognitive measure
Hokama et al 1995	15 healthy M community volunteers 20–55 years old No lifetime history of major medical, neurologic or psychiatric illness All right-handed	MR imaging (1.5 tesla) Volume measurements of basal ganglia using semiautomated computer-assisted trace methodology from T1-weighted coronal and axial sections (1.5 mm thick, contiguous) by raters with established reliabilities	Age associated with decreased volumes of caudate and putamen, but not of globus pallidus No correlation between basal ganglia volumes and IQ as estimated by WAIS-R Information subscale
Carmelli et al. 1999	148 elderly male monozygotic twins (74 twin pairs) 72.7 ± 2.1 years old Medical history remarkable for hypertension (37%), coronary artery disease (25%), diabetes (13%), and cerebrovascular disease (5%)	MR imaging (1.5 tesla) Volumetric measures using computer-assisted pixel segmentation of T2-weighted axial images (5mm, contiguous) by single blinded rater with established reliability Principal component analysis used to derive a “memory” factor (from California Verbal Learning Test) and a “speed” factor (from Digit Symbol subtest of WAIS-R, Stroop Color Test, and Trail Making Test)	Within-pair differences in brain volume were associated with within-pair differences in lower memory scores, but not with “speed” scores Relations between CSF and cognitive tests not reported

Coffey et al. 1999	330 elderly volunteers living independently in the community (overlap with Coffey et al. 1998) 66–96 (74.98 ± 5.09) years old 129 M; 201 F No history of neurologic or psychiatric illness All right-handed	MR imaging (1.5 tesla, $n = 248$ ; 0.35 tesla, $n = 82$ ) Blinded volume measurements (one of two raters with established reliabilities) using computer-assisted trace methodology of T1-weighted axial images (5 mm thick, contiguous)	Education was associated with age-specific increase in sulcal CSF volume, but not with decreases in total or regional brain volumes or with increased volumes of lateral or third ventricles
Fox et al. 1999	15 healthy older adult volunteers 55.3 ± 14.0 years old Sex and handedness not specified MMSE = 29.5 ± 0.7	MR imaging (1.5 tesla) Volumetric measures using computer-assisted pixel segmentation of coronal images (1.5 mm thick, contiguous) by raters ( $n$ not specified) with established reliabilities MR imaging repeated an average (± SD) of 1.7 ± 1.2 years later (minimum interval = 5 months)	Over the follow up interval, brain volume decreased by mean (± SD) of 0.4% (± 0.7%) per year
Frisoni et al. 1999	30 healthy elderly volunteers 53–86 (68 ± 5) years old 10 M; 20 F No evidence of neurologic disease or cognitive deficits	MR imaging (1.5 tesla) Volumetric measures using computer assisted trace methodology of T1-weighted coronal images (2 mm thick, contiguous) by rater with established reliability	No relation between age and volumes of hippocampus or entorhinal cortex
Magnotta et al. 1999	148 healthy volunteers 18–82 (28 ± 9.8) years old No evidence of active psychiatric, neurologic, or general medical disorders	MR imaging (1.5 tesla) Volumetric measures using computer assisted pixel segmentation of T1-, intermediate, and T2-weighted coronal images (1.5 mm thick), by raters with established reliabilities	Age associated with changes in shape of gyri (more sharply and steeply curved) and sulci (more flattened and less curved) ( $M = F$ ), as well as with decreased cortical thickness ( $M > F$ )
Mu et al. 1999	619 healthy adult volunteers 40–90 years old 313 M; 306 F No evidence of cardiovascular, neurologic, or neuropsychologic disease	MR imaging (1.5 tesla) Volumetric measures using computer assisted trace methodology of T1-weighted coronal images (2 mm thick, contiguous) by 5 blinded raters (average used)	Age correlated with decreased ratios of hippocampal formation volume/IV and amygdala volume/IV, and with increased ratio of temporal horn volume/IV
Salat et al. 1999	28 healthy elderly community volunteers (overlap with Kaye et al. 1997) Young group: 65–76 years old; 7M, 7F Old group: 84–95 years old; 7M, 7F No significant medical disease or stroke, and MMSE ≥ 25	MR imaging (1.5 tesla) Volumetric measures using computer assisted trace methodology of T1- and T2-weighted coronal sections (4 mm thick, contiguous) from prefrontal region (8 slices per subject) by single rater with established reliabilities	Old group had smaller volumes of total prefrontal region and of prefrontal white matter, but no group differences in volume of prefrontal gray matter

*Note.* AAMI = age-associated memory impairment; BVRT = Benton Visual Retention Test; CAMCOG = Cambridge Cognitive Examination; CSF = cerebrospinal fluid; CT = computed tomography; CVLT = California Verbal Learning Test; F = female(s); IV = intracranial volume; L = left; M = male(s); MMSE = Mini-Mental State Exam; MR = magnetic resonance; R = right; WAIS = Wechsler Adult Intelligence Scale; WMS-R = Wechsler Memory Scale-Revised.

**APPENDIX 9-3. Neuropsychological correlates of subcortical encephalomalacia**

<b>Study</b>	<b>Subjects</b>	<b>Imaging and measurement technique</b>	<b>Findings</b>
Steingart et al. 1987	105 elderly volunteers 59–91 years old 56 M; 49 F No evidence of dementia or stroke	CT Determination of presence of “leukoaraiosis” by single blinded rater	Subjects with leukoaraiosis ( $n = 9$ ) had lower scores on the Extended Scale for Dementia than did subjects without the finding ( $n = 96$ ), even after controlling for age, gender, education, and presence of infarct
Skoog et al. 1996	134 volunteers without dementia Mean age = 85 years 45 M; 89 F	CT Severity rating (0–3) of white matter attenuation by two blinded radiologists with good agreement ( $\kappa = 0.75\%$ ) Neuropsychological examination by blinded psychologist comprised of MMSE, Synonym Test, Figure Classification Test, Block Design Test, Identical forms, Thurstone Picture Memory Test, Digit Span, Clock Test, Coin Test, MIR Memory Test, Prose Recall Test, and Ten-Word Memory Test	Subjects with white matter lesions ( $n = 46$ ) scored lower on MMSE and on tests of verbal ability (Synonyms), spatial ability (Block Design, Clock Test), perceptual speed (Identical Forms), secondary memory (Thurstone Picture Memory), and basic arithmetic (Coin Test)
Brant-Zawadzki et al. 1985	14 elderly volunteers 59–81 years old 6 M; 8 F No medical conditions “associated with cognitive loss”	MR imaging (0.35 tesla) Standardized severity ratings (5-point scale) of white matter hyperintensity made by two raters (interrater agreement not given) from intermediate and T2-weighted scans	No statistical analysis of neuropsychological test data (10 tests) conducted One of the 10 subjects with a hyperintensity rating of 1 or less scored in the “demented range” on the WMS (Russell revision) and WAIS-R Block Design One of the 4 subjects with a hyperintensity rating of 2 or greater had impaired performance on WAIS-R Picture Arrangement
Hendrie et al. 1989	27 elderly volunteers 63–86 years old 10 M; 17 F No evidence of medical or neurological illness	MR imaging (1.5 tesla) Standardized rating by two blinded raters of severity (4-point scale) of white matter hyperintensity from T2-weighted films Cognitive test battery comprised of MMSE, CAMCOG, and WAIS Digit Symbol	No differences (statistical analysis not described) between the 4 severity categories of white matter hyperintensity with regard to scores on the three cognitive measures

Hunt et al. 1989	46 elderly volunteers Mean $\pm$ SD age = 78.2 $\pm$ 4.6 years old 17 M; 29 F No evidence of major medical illness	MR imaging (1.5 tesla) Single blinded rater determined number (4-point scale) and size (3-point scale) of white matter hyperintensity changes from intermediate and T2-weighted scans Severity score derived from multiplying number by size, summed across five brain regions Neuropsychological test battery from which were derived composite scores for 5 cognitive “domains”—verbal ability (WAIS-R Information, Boston Naming-Revised, Word List Generation Task, and Token Test), spatial ability (WAIS-R Block Design, Rey-Osterreith Complex Figure, and Hooper Visual Organization Test), memory (Wechsler Memory Scale (logical and visual) and Rey-Osterreith Complex Figure), attention and concentration (MMSE, Blessed Dementia Scale, Jacobs Dementia Scale, and Digit Span), and executive functioning (Luria and Christensen tasks)	When controlling for age, no relation between total severity of white matter hyperintensity and composite neuropsychological performance in any of the five “domains” No apparent difference in neuropsychological performance between subjects with more or less than the median number of white matter lesions (statistical analysis not reported)
Rao et al. 1989	50 healthy middle-aged volunteers 25–60 years old 11 M; 39 F No evidence of major medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Presence of leukoaraiosis on intermediate and T2-weighted scans (no description of rating methodology provided) Neuropsychological test battery comprised of measures of verbal intelligence (from 6 subtests of the WAIS-R), recent memory (Buschke Verbal Selective Reminding Test, 7/24 Spatial Recall Test, Story Recall Test), remote memory (President’s Test), rate of forgetting (Brown-Peterson Interference Test), abstract/conceptual reasoning (Wisconsin Card Sorting Test, Booklet Category Test, Standard Raven Progressive Matrices, Stroop Color/Word Interference Test, and Hooper Visual Organization Test), attention/concentration (WAIS-R Digit Span, Sternberg High Speed Scanning Test, and the Paced Auditory Serial Addition Test), language (Boston Naming Test, Controlled Oral Word Association Test, and Category Word Generation Test), visuospatial skills (Benton Line Orientation, Benton Facial Recognition, and Benton Visual Form Discrimination), and upper extremity motor function (Wisconsin Motor Battery)	Relative to subjects without leukoaraiosis ( $n = 40$ ), subjects with the finding ( $n = 10$ ) performed significantly worse on 3 of the 45 neuropsychological tests ( $t$ -tests): Benton Facial Recognition Test, Brown-Peterson Interference Test (18-second delay), and the President’s Test
Austrom et al. 1990	27 elderly volunteers 63–86 years old 10 M; 17 F No significant medical or neurological illness	MR imaging (1.5 tesla) Consensus ratings of white matter hyperintensity (4-point scale) from T2-weighted axial slices by two raters with established reliabilities	Subjects without white matter hyperintensity at baseline ( $n = 11$ ) showed a significant improvement on the WAIS Digit Symbol test, whereas subjects with white matter hyperintensity tended to have lower scores at follow-up Neither group showed significant changes in MMSE or CAMCOG scores

(continued)

**APPENDIX 9-3. Neuropsychological correlates of subcortical encephalomalacia (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Harrell et al. 1991	25 healthy elderly volunteers Mean $\pm$ SD age = 65.6 $\pm$ 6.9 years old Gender not reported No history of significant medical, neurological, or psychiatric illness	MR imaging (0.5 or 1.5 tesla) Standardized severity ratings (6-point scale) of white matter hyperintensity by single blinded rater from T1- and T2-weighted scans	No correlation between severity of either periventricular or deep white matter hyperintensity and scores on MMSE or Mattis Dementia Rating Scale
Mirsen et al. 1991	39 elderly volunteers 73.2 $\pm$ 5.8 years old 20 M; 19 F 3 subjects with infarcts; an indeterminate number with no evaluation (medical, neurological, or psychiatric), apart from cognitive testing, which was normal	MR imaging (1.5 tesla) Blinded determination by two raters of presence of periventricular hyperintensity and severity (5-point scale) of leukoaraiosis on T1- and T2-weighted films (interrater agreement ranged from 56% to 88%)	No correlations between presence of either periventricular hyperintensity or leukoaraiosis and performance on the Extended Scale for Dementia
R. Schmidt et al. 1991	32 healthy volunteers 22-49 years old 25 M; 7 F Most receiving medication for hypertension, but otherwise no evidence of major medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Blinded determination of white matter lesions from intermediate and T2-weighted films (no description of rating methodology provided) Neuropsychological test battery comprised of a computerized test of vigilance and reaction time, a test of visual attention (d2 test), and a test of learning and memory (Lern und Gedächtnistest)	No differences between subjects with ( $n = 12$ ) and without ( $n = 20$ ) white matter lesions on any of the neuropsychological tests
Almkvist et al. 1992	23 healthy elderly volunteers All > 75 years 9 M; 14 F No major medical, neurological, or psychiatric illness	MR imaging (0.02 tesla) Computer-assisted volumetric measurements of subcortical hyperintensity by single blinded rater (no intrarater reliabilities reported) Neuropsychological test battery comprised of MMSE, 6 subtests from WAIS-R (Information, Digit Span, Similarities, Block Design, Object Assembly, and Digit Symbol), Wechsler Memory Scale (Associative Learning and Visual Reproduction), Corsi Block Tapping Test, Digit Span Test, Simple Reaction Time Test, Finger Tapping Test, Boston Naming Test, FAS Word Fluency Test, Maze Test (from WISC), Map Orientation Test, Line Bisection Test, and the Tactile Identification of Objects Test	No relationship between total or regional volumes of subcortical hyperintensity and performance on any of the 24 neuropsychological tests

Boone et al. 1992	100 healthy volunteers 45–83 years old 36 M; 64 F No major medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Computer-assisted area measurements of subcortical hyperintensity from T2-weighted axial sections by single rater (additional rater information not reported) Neuropsychological test battery comprised of measures of frontal lobe functioning (Wisconsin Card Sorting Test, Stroop 3, Auditory Consonant Trigrams), general intelligence (WAIS-R), memory (Wechsler Memory Scale-R logical and visual reproduction subtests), attention and information processing speed (WAIS-R Digit Span and Digit Symbol subtests, Stroop 1 and 2), language (Verbal Fluency), and visuospatial skills (Rey-Osterrieth Complex Figure)	Subjects ( $n = 6$ ) with lesion areas greater than 10 cm <sup>2</sup> performed less well on measures of frontal lobe ability (Auditory Consonant Trigrams, Wisconsin Card Sorting Test [Heaton 1985], and Stroop Test), attention (Digit Span), and speed of information processing (Digit Symbol, Stroop Test)
Matsubayashi et al. 1992	73 healthy elderly volunteers 59–83 years old 24 M; 49 F No history of major medical, neurological, or psychiatric illness	MR imaging (0.5 tesla) Standardized severity ratings (4-point scale) of periventricular hyperintensity by single blinded rater (intrarater agreement not reported) Neuropsychological test battery comprised of MMSE, Hasegawa Dementia Scale (Hasegawa 1974), a visuospatial cognitive performance test, and a test of manual dexterity	Subjects with periventricular hyperintensity ratings of 3 or greater ( $n = 19$ ) performed worse on all neuropsychological test measures even after controlling for age effects
Tupler et al. 1992	66 healthy volunteers (overlap with subjects in Coffey et al. 1992) 45–89 years old 24 M; 42 F No evidence of lifetime neurological or psychiatric illness	MR imaging (1.5 tesla) Consensus ratings (4-point scale) of severity of white matter hyperintensity from axial scans by two blinded raters with established reliabilities Two neuropsychological tests were selected a priori: the Benton Facial Recognition Test and the Digit Symbol	After adjustments for age and education, neither test was associated with severity of subcortical hyperintensity
Levine et al. 1993	127 healthy nonelderly volunteers 50 M (35.2 ± 11.8 years old); 77 F (43.3 ± 8.4 years old) No history of significant medical, neurological, or psychiatric illness	MR imaging (0.5 tesla) Presence of subcortical hyperintensity determined by three “experienced neuroradiologists” from intermediate and T2-weighted axial scans (no additional data provided) Neuropsychological test battery comprised of measures of general intellectual functioning (WAIS-R), frontal lobe functioning (Wisconsin Card Sorting Test), attention (Digit Span Task, binaural dichotic listening task), and visuospatial functioning (Benton Line Orientation, Benton Facial Recognition)	Among subjects with subcortical hyperintensity (5 M, 7 F), M exhibited impaired attention on a dichotic listening task, relative to subjects without subcortical hyperintensity

(continued)

**APPENDIX 9-3. Neuropsychological correlates of subcortical encephalomalacia (continued)**

Study	Subjects	Imaging and measurement technique	Findings
R. Schmidt et al. 1993	150 healthy elderly volunteers 44–82 years old (mean = 59.9) 82 M; 68 F No severe medical, neurological, or psychiatric illness	MR imaging (1.5 tesla) Area of SH as assessed by three blinded raters using trace methodology on proton-density axial images (5 mm thick) Neuropsychological test battery assessing verbal intelligence (Mehrfachwahl-wortschatetest), mood (Janke and Debus), learning capacity and intermediate memory (Lern und Gedächtnistest), conceptual reasoning (Wisconsin Card Sorting Test), attention and speed (multiple tests), and visuopractical skills (Purdue Pegboard Test)	Presence of SH associated with Purdue Pegboard Test (complex reaction time, number of errors on the complex reaction time task, the assembly procedure) and form B of the Trail Making Test No relation between the total SH area and any test score
Ylikoski et al. 1993	120 volunteers living in the community 55–85 years old 54 M; 66 F No evidence of neurological illness	MR imaging (0.02 tesla) Blinded severity ratings (4-point scale) of SH from T2-weighted axial and coronal images (10 mm thick, no gaps) by single blinded rater (no reliabilities given) Neuropsychological test battery assessing memory (Fuld Object-Memory Evaluation, WMS-R), verbal intelligence (Information and Similarities subtests of WAIS), construction (Block Design of WAIS), language (Token Test, Boston Naming Test), and speed and attention (Trail Making Test A, Stroop Test)	Controlling for the effects of age, both presence and severity of SH correlated with scores on Trail Making A and Stroop Test (correlations were similar for both hemispheres)
DeCarli et al. 1995	51 healthy community volunteers 19–91 years old 26 M; 25 F No evidence of chronic medical illness, psychiatric illness, or head trauma	MR imaging (0.5 tesla) Computer-assisted volumetric measurements of SH by blinded raters ( $n = ?$ ) with established reliabilities Neuropsychological test battery comprised of WAIS, Wechsler Memory Scale, and frontal lobe tests (Porteus Maze Test, FAS Word List Generation, Trail Making Test A and B, and WAIS Digit Symbol Test)	Controlling for the effects of age and education, SH volume was significantly associated with WAIS IQ, immediate and delayed visual memory, and Trails A and B times
O'Brien et al. 1997	39 healthy community volunteers 55–96 years old No evidence of major medical or neurological illness, or of depression or drug abuse	MR imaging (0.3 tesla) Ratings of SH (0–3) by two raters with established reliabilities, blind to cognitive scores	Age associated with presence of SH Controlling for the effects of age and education, there was no relation between SH and scores on CAMCOG

Carmelli et al. 1999	148 elderly male monozygotic twins (74 twin pairs) 72.7 ± 2.1 years old Medical history remarkable for hypertension (37%), coronary artery disease (25%), diabetes (13%), and cerebrovascular disease (5%)	MR imaging (1.5 tesla) Volumetric measures using computer-assisted pixel segmentation of T2-weighted axial images (5 mm, contiguous) by single blinded rater with established reliability Principal component analysis used to derive a “memory” factor (from California Verbal Learning Test) and a “speed” factor (from Digit Symbol subtest of WAIS-R, Stroop Color Test, and Trail Making Test)	Within-pair differences in volume of subcortical hyperintensity was associated with within pair differences in lower memory and speed scores
Schmidt et al. 1999	273 elderly community volunteers 60 ± 6.1 years old 131 M, 142 F No evidence of neuropsychiatric disease	MR imaging (1.5 tesla) Consensus global ratings of SH (0–3 scale) by three blinded raters with established reliabilities Neuropsychological test battery comprised of Baumlner’s Lern-und Gedächtnistest (learning and memory), Wisconsin Card Sort Test, Trail Making Test B, Digit Span (WAIS-R), Alters-Konzentrations-Test, and Purdue Pegboard Test	Over the 3-year follow-up interval, SH progressed in 49 subjects (17.9%), with minor progression in 27 (9.9%) and marked progression in 22 (8.1%) Neuropsychological test performance improved on the Wisconsin Card Sort Test but declined on the Trail Making Test No relation between SH lesion progression and changes on neuropsychological test performance

*Note.* Abbreviations: CAMCOG = Cambridge Cognitive Examination; CT = computed tomography; F = female(s); M = male(s); MMSE = Mini-Mental State Exam; MR = magnetic resonance; SH = subcortical hyperintensity; WAIS-R = Wechsler Adult Intelligence Scale–Revised; WMH = white matter hyperintensities; WMS-R = Wechsler Memory Scale–Revised.

## APPENDIX 9-4. Imaging studies of human aging and other brain changes

Study	Subjects	Imaging and measurement technique	Findings
<b>T1 and T2 relaxometry</b>			
N. Raz et al. 1990	26 healthy volunteers 18–76 years old (45.8 ± 21.8 years) 15 M; 11 F No history of neurological or psychiatric illness All right-handed	MR imaging (0.3 tesla) T1 relaxometry calculated from multiple images derived from a single coronal slice (6.6 mm thick, 2-mm gap) through anterotemporal lobe Number of raters and their reliabilities not reported	Age correlated positively with T1 in white matter and hippocampus and negatively with ratio of T1 gray matter to T1 white matter Scores on a test of “fluid” intelligence (the Cattell Culture-Fair Test) were associated with shorter white matter T1 (but not gray matter T1) and with higher gray matter to white matter T1 ratio Scores on a test of “crystallized” intelligence (Extended Vocabulary) were associated with shorter gray matter T1
Agartz et al. 1991	79 healthy volunteers 19–85 years old 36 M; 43 F No evidence of major medical illness	MR imaging (0.02 tesla) Multiple T1- and T2-weighted images obtained on single axial slice at level of basal ganglia T1 and T2 relaxation times calculated for regions of interest within right and left frontal white matter, caudate, thalamus, and occipital white matter	T1 relaxation times showed a “cradle-shaped” relation to age, with minimal values at ages 40–45 years; no interactions with gender or laterality No relation between age and T2 relaxation times
Breger et al. 1991	151 healthy volunteers 10–90 years old No evidence of major medical or neurological illness	MR imaging (1.5 tesla) Multiple T1- and T2-weighted images obtained on single slice (level not specified) T1 and T2 relaxation times calculated for regions of interest within right and left anterior white matter, posterior white matter, anterior gray matter, and basal ganglia	Age correlated with T1 relaxation times in white matter and caudate Age correlated with T2 relaxation times in white matter and thalamus No interactions with gender
Laakso et al. 1996	34 volunteers 18 old (74 ± 2 years old); 8 M, 10 F 16 young (26 ± 7 years old); 9 M, 7 F No evidence of neurological illness	MR imaging (1.5 tesla) T2 relaxometry calculated from multiple images derived from four oblique coronal slices (8 mm thick, 2-mm gap) through anterotemporal lobe Number of raters and their reliabilities not specified	Age correlated with T2 relaxation times in temporal and parietal white matter, but not in hippocampus

Salonen et al. 1997	61 healthy volunteers 30–86 years old 30 M; 31 F No neurological symptoms or disease; psychiatric history not specified Handedness not specified	MR imaging (1.0 tesla) T2 relaxometry calculated from axial slices (5 mm thick, 1-mm gap) through the frontal horns Number of raters and rater reliabilities not specified	Age correlated with T2 relaxation times in white matter, but not in caudate, putamen, or thalamus T2 relaxation times were greater in F than in M after age 60
<b>Spectroscopy</b>			
Christiansen et al. 1993	16 healthy volunteers 8 young (20–30 years), 8 old (60–80 years) No neurological, cardiovascular, or diabetic diseases, and no medications	MR imaging (1.5 tesla) MR spectroscopy (stimulated echoes, or STEAM) of volumes of interest (2 mL) from right basal ganglia and frontal, temporal, and occipital hemispheres	Young (but not old) group had higher concentrations of NAA in occipital region than in the other three areas. No regional variations found in either group for concentrations of Cr, PCr, or Cho Young (but not old) group had higher NAA/Cho ratio in occipital region relative to other regions No group differences in T1 or T2 relaxation times for the three metabolites
Charles et al. 1994	34 healthy volunteers 21–75 years old ( $47 \pm 17$ years) 15 M; 19 F No evidence from examination of “significant medical or psychiatric condition”	MR imaging (1.5 tesla) MR spectroscopy (STEAM) of voxel (27 mL) at level of basal ganglia	Old (> 59 years old) group had lower Cho, Cr, and NAA in voxel containing cortical and subcortical gray matter. No group differences within white matter or noncortical gray matter voxels Interactions with gender not reported
Meyerhoff et al. 1994	16 healthy volunteers 10 elderly (6 M, 4 F; $70 \pm$ years), 6 young (4 M, 2 F; $32 \pm$ years) No evidence of major medical, neurological, or psychiatric illness, and MMSE > 28	MR imaging (2.0 tesla) MR spectroscopy of 9 voxels (2.5 mL each) from angulated axial image (17 mm thick) at supraventricular level (3 voxels in mesial cortex and 3 each in right and left centrum semiovale)	No difference between young and elderly groups in distribution or signal intensities of NAA, of Cho residues representing lipid metabolites, or of Cr-containing metabolites Interactions with gender or laterality not reported
Smith et al. 1995	25 healthy volunteers 8 old ( $75 \pm 7$ years old); 5 M, 3 F 17 young ( $29 \pm 9$ years old); 9 M, 8 F No neurological illness and no psychoactive drugs for at least 2 weeks	MR (1.5 tesla) MR spectroscopy of voxel (50 mL) from anterosuperior frontal lobe	Old group had higher ratio of PCr/Pi In young group, age correlated with a decrease in Pi mole percent and an increase in PCr/ Pi ratio Interactions with gender not reported

(continued)

**APPENDIX 9-4. Imaging studies of human aging and other brain changes (continued)**

Study	Subjects	Imaging and measurement technique	Findings
Chang et al. 1996	36 healthy volunteers 19–78 years old (40.8 ± 2.9 years) No additional details provided	MR imaging (1.5 tesla) MR spectroscopy of voxels (2–4 mL) from mid-frontal gray matter or right frontal white matter	In gray matter, age associated with increased concentrations of total Cr, Cho-containing compounds, and <i>myo</i> -inositol, as well as increased percent age of CSF; no change in NAA compounds No age-related spectroscopic changes in white matter
Soher et al. 1996	16 healthy volunteers 5–74 years (39 ± 20) 11 M; 5 F All “free of any known neuropathological conditions”	MR imaging (1.5 tesla) MR spectroscopy of voxels from two oblique slices (15 mm thick, 2.5-mm gap) at levels of third ventricle and centrum semiovale	Age associated with increased concentrations of Cho in frontal white matter, thalamus, putamen, and genu of callosum, and of Cr in frontal white matter; no changes in forceps minor or major, centrum semiovale, posterior white matter, splenium of callosum, or frontoparietal gray matter
Fukuzako et al. 1997	36 healthy volunteers 24–78 years old (48.8 ± 14.6 years) 17 M; 19 F No history of psychiatric or neurological illness, no medications All right-handed	MR imaging (2.0 tesla) MR spectroscopy (STEAM) of voxels (3 mL) from left frontal lobe and left medial temporal lobe	No relation between age and ratios of NAA/Cho, NAA/Cr, and Cho/Cr (M = F)
Lim and Spielman 1997	10 healthy F volunteers 5 young (20–28 years), 5 old (65–75 years) All free of medical and psychiatric disorders	MR imaging (1.5 tesla) MR spectroscopy of two oblique axial slices (15 mm thick, 5-mm gap) at 30 mm and 50 mm above the AC-PC line	Ratio of NAA signal in gray matter to white matter was lower in the old group than in the young group
<b>Brain iron</b>			
Steffens et al. 1996	56 healthy volunteers 25–82 years old (57.4 ± 15.8 years) 27 M; 29 F No history of neurological or psychiatric illness 52 were right-handed, 3 were left-handed, 1 unknown	MR imaging (1.5 tesla) Global visual ratings of signal hypointensity in the putamen (5-point scale) made from T2-weighted axial films (slices 5 mm thick, 2.5-mm gap) by single rater (blind?)	Age associated with higher ratings of signal hypointensity in putamen consistent with increased iron deposition Interactions with gender not reported

*Note.* AC-PC line = anterior commissure–posterior commissure line; Cho = choline; Cr = creatine; CSF = cerebrospinal fluid; F = female(s); M = male(s); MR = magnetic resonance; NAA = *N*-acetylaspartate; Pi = inorganic phosphate; PCr = phosphocreatine.

### ■ Introduction

That aging is invariably associated with changes in body and mind has been known since the ancient days. The Roman philosopher Seneca wrote, “aging in fact is an incurable disease.” Although advances in health care during the last decades have improved the quality of life of older people and have softened Seneca’s statement, it remains true

that the human body and mind undergo inevitable modifications during aging, even in the absence of evident disease.

As far as the brain is concerned, many cognitive, neurochemical, histological, and morphological changes are known to accompany aging. Neuropsychological tests, for example, have shown that some cognitive features, referred to as “fluid intelligence,” including perceptual

---

We wish to thank Giampiero Giovacchini, M.D., for his comments and assistance during the preparation of this manuscript.

speed, memory span, and associative memory, usually decline with age, whereas others, referred to as “crystallized intelligence,” including verbal comprehension, general information, and arithmetic skills, remain intact (Horn 1975). This suggests that a large part of cognitive processing, related to the ability to cope with the environment, is preserved in older people (Creasey and Rapoport 1985). Long before the development of the cognitive sciences, the French essayist Montaigne (1580/1952), provided a clear description of the phenomenon: “Since I was 20 years of age, I am certain that my mind and body have deteriorated more than they have developed. It is likely that knowledge and experience increase with aging, but activity, alertness, strength and other important qualities nevertheless decline.”

Different experimental approaches have been used to examine the functional neurobiological correlates of these alterations. In the past two decades, the introduction of sophisticated imaging techniques such as positron-emission tomography (PET) has made it possible to visualize cerebral metabolism and blood flow *in vivo* and to investigate metabolic and flow correlates of brain function and structure in relation to human aging. In this chapter, we describe these and earlier related techniques and examine how functional neuroimaging has helped to elucidate aging of the human brain.

### **Historical Background: Kety-Schmidt and Xenon-133 Techniques**

Noninvasive measurements of brain function have been sought since the beginning of modern medicine. Normally, the brain produces the energy necessary for its functioning through oxidation of glucose. Although comprising only 2% of body weight in the adult, the human brain consumes about 20% of glucose used by the body as a whole (Sokoloff 1959). Neurons require energy in the form of adenosine triphosphate (ATP) to maintain their membrane potentials through activation of the  $\text{Na}^+/\text{K}^+$  membrane pumps to support their electrical activity for signal transduction (Purdon and Rapoport 1998) and for synthetic processes. Accordingly, the regional cerebral metabolic rate for glucose (rCMRglc) will represent largely the functional and baseline metabolic activity of neurons in a given region (Rogers and Friedhoff 1998). Furthermore, because regional cerebral blood flow (rCBF) normally is coupled with rCMRglc (Roy and Sherrington 1890), the earliest clinical investigations by Kety and Schmidt (1948) were designed to determine *in vivo* average cerebral blood flow (CBF) in order to examine global brain functional activity. The technique chosen was based on the Fick principle, which relates arterial delivery of a chemically inert substance, its brain

uptake, and its removal by the venous system. This method did not provide regional information, and it was invasive because it required a carotid artery injection and internal jugular sampling of nitrous oxide, a freely diffusible and nonmetabolizable substance. Initial studies with the Kety-Schmidt technique confirmed that global CBF and the cerebral metabolic rate for oxygen (CMRO<sub>2</sub>) were correlated. Both rapidly decreased from childhood to adolescence, followed by a more gradual but progressive decline throughout the adult life span (Kety 1956).

Subsequent modifications of the original method led to the clearance technique that used the  $\gamma$ -emitting isotope xenon-133 (<sup>133</sup>Xe) (Obrist et al. 1967, 1975; Risberg 1980). With this method, it was possible to quantify rCBF in regions of the cerebral cortex after inhalation or intracarotid artery injection of <sup>133</sup>Xe and, when using extracranial scintillation crystals, to record and localize radioactivity. Although the <sup>133</sup>Xe methods were an improvement over the Kety-Schmidt technique, their limited spatial resolution and inability to examine subcortical structures restricted investigations to large areas of the lateral surface of the cerebral cortex. Studies performed with <sup>133</sup>Xe consistently indicated an age-related decline in cortical blood flow.

In addition to technical limitations, methodological restrictions affected conclusions obtained with the Kety-Schmidt and <sup>133</sup>Xe clearance techniques. Most studies did not select optimally healthy subjects, blurring distinctions between effects of healthy aging and of age-related brain disease on CBF. Thus, subjects were recruited from hospitalized patients having “minor elective surgery” (Scheinberg et al. 1953) or “minor illness” (Schieve and Wilson 1953), or even from patients with a history of convulsive disorder (Kennedy, in Kety 1956). Patients with a history of psychosis, mental deterioration, or other degenerative processes often were included, and study conditions frequently were uncontrolled. With the exception of the study by Melamed et al. (1980), <sup>133</sup>Xe measurements were not performed with subjects in the “resting state,” with eyes covered and ears plugged with cotton to minimize sensory stimulation. As vision and hearing acuities on average decline with age (Lehnert and Wuensche 1966), observed age-related flow reductions in subjects not studied in the “resting state” may be in part a result of these extrinsic changes, rather than a result of reduced intrinsic brain functional activity (see below) (Rapoport 1983).

### **Positron-Emission Tomography**

During the last two decades, PET has facilitated the noninvasive investigation of brain functional activity in awake human subjects, not only in the cerebral cortex but

also in subcortical structures, with progressively better spatial and temporal resolutions. A number of positron-emitting compounds have been employed to study various aspects of brain integrity and function, including neurotransmitter metabolism. It is now possible to determine rCBF, rCMRglc, and the regional cerebral metabolic rate for oxygen (rCMRO<sub>2</sub>) in regions of the human brain smaller than 3 mm in diameter (Jagust et al. 1993). Radiolabeled transmitters (i.e., [<sup>18</sup>F]fluoro-L-dopa) and transmitter receptors (i.e., serotonin or dopamine receptors) can also be studied with PET. More recently, measuring in vivo signal transduction with PET using [<sup>11</sup>C]arachidonic acid has become feasible (Chang et al. 1997; Rapoport et al. 1997). PET scans can be repeated, thus allowing brain functional patterns to be evaluated in the same subject under different test conditions (resting state versus sensory stimulation), before and after drug administration, or in longitudinal studies of aging.

### Basic Principles of Positron-Emission Tomography Technology

PET employs unstable nuclides that have an excess of protons in their nucleus and thus emit *positrons*, antimatter electrons with the same mass as an electron but with a positive charge. Once emitted, a positron has the kinetic energy to travel a few millimeters within tissue, until it meets an unbound electron. Because the two particles have opposite charge, they annihilate each other and, following the law of conservation of energy, emit two  $\gamma$  ray photons of 511 keV energy at 180° to each other (Horwitz 1990) (Figure 10–1). The  $\gamma$  photons are detected by rings of radiation detectors that surround the subject's head and measure the number of photons originating from all the angles within the brain. Through a computer reconstruction algorithm, it is possible to identify where the annihilation event took place and from where the positron was emitted (with an approximation of a few millimeters because of the distance traveled by the positron before the event of annihilation), as well as the quantity of radiation emitted from that site.

**Regional cerebral blood flow.** By employing PET and water labeled with oxygen-15 (<sup>15</sup>O), rCBF can be assessed. Water is an excellent flow indicator because it is almost freely diffusible at physiological flow rates and can quickly equilibrate between brain and blood. Immediately after an intravenous injection of a bolus of 10–40 mCi of radiolabeled water (depending on the sensitivity of the tomograph employed), a dynamic acquisition PET scan is obtained to measure local cerebral radioactivity during the subsequent 1–4 minutes. Radioactivity concurrently is

monitored in the blood through an indwelling arterial line connected to an automatic counter. Using this method, it is possible to determine absolute rCBF values, expressed in mL/100 g tissue/minute.

In a variant of this procedure, the subject continuously inhales <sup>15</sup>O-labeled carbon dioxide, which in the lung gives rise to <sup>15</sup>O-labeled water. When a steady state is reached, and the rate of delivery of radioactive water to the brain equals its rate of removal by venous washout, measured brain radioactivity is directly proportional to the constant input function, which is a function of rCBF (Frackowiak and Lammertsma 1985).

Because the <sup>15</sup>O in water has a rapid radioactive decay (half-life = 2.02 minutes), multiple studies only 6–12 minutes apart can be performed sequentially in the same subject. This makes it possible to evaluate rCBF repeatedly in a single sitting, while the subject is in the resting state or performing any of several tasks. By subtracting baseline rCBF from task rCBF, regions that are specifically and significantly activated during the task can be identified. In such studies, global CBF frequently is corrected for arterial blood PaCO<sub>2</sub>, which should be measured.

**Cerebral glucose metabolism.** By using PET with [<sup>18</sup>F]fluoro-2-deoxy-D-glucose (FDG), an analogue of glucose labeled with <sup>18</sup>F, it is possible to visualize and measure the uptake of FDG by neural cells in different brain regions in an awake subject. FDG reaches the brain through blood flow and, like glucose, can be transported bidirectionally across cerebral capillaries by a monosaccharide transport system. Once inside brain cells, FDG is phosphorylated to FDG-6-phosphate (FDG-6-P) by the enzyme hexokinase. Unlike glucose-6-P, however, FDG-6-P cannot be transformed into fructose-6-P and is not further metabolized by glycolytic pathway enzymes. As brain phosphatase activity is low, FDG-6-P remains essentially trapped inside brain cells, virtually unchanged during the duration of the study (Sokoloff 1982) (Figure 10–2).

The quantity of FDG-6-P that has accumulated in a brain region during 45 minutes after FDG injection is measured by PET and is a function of the rate of phosphorylation of glucose to glucose-6-P by hexokinase, the first reaction in the glycolytic pathway, and the plasma integral of FDG to which the brain is exposed. At a steady state with regard to unlabeled concentrations, the net rate of any step in a pathway equals the net rate of the overall pathway; thus, the net rate of glucose phosphorylation estimated with FDG represents the net flux of glucose through the entire glycolytic pathway. Sokoloff et al. (1977) elaborated an operational equation to calculate rCMRglc from 1) the quantity of FDG-6-P within brain, 2) the ratio of the integrated

**FIGURE 10-1.** Positron-emission tomography (PET) detection. After the annihilation of a positron ( $\beta^+$ ) with an electron ( $\beta^-$ ), two  $\gamma$  rays are emitted in diametrically opposite directions. These  $\gamma$  rays are detected by the PET machine, and their local site of origin and intensity are reconstructed. KeV = kiloelectron volts.

plasma activity of FDG to cold plasma glucose concentration during 45 minutes, and 3) a “lumped constant” to correct for the use of FDG instead of the natural glucose (“isotope effect”) (Huang et al. 1980).

A detailed description of the physical principles and the technical and methodological aspects of PET goes far beyond the aims of this review; the interested reader may refer to Herscovitch (1994), Holcomb et al. (1989), and Mazziotta and Phelps (1986).

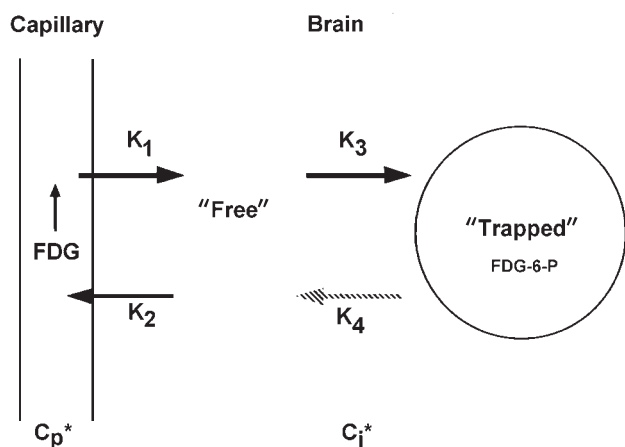

## ■ Positron-Emission Tomography Studies in Healthy Aging

### Regional Cerebral Blood Flow and Oxygen Consumption

PET has allowed researchers to overcome many of the limitations of earlier techniques and to obtain more reliable information about relations among regional cerebral metabolism, rCBF, and age. Results of human aging studies with regard to rCBF and rCMRO<sub>2</sub> are summarized in Table 10-1. The table shows that, in general, studies per-

formed in the resting state (reduced auditory and visual input) demonstrated lesser changes than those in which visual and/or auditory input was uncontrolled.

In accord with conclusions from a majority of studies performed with the <sup>133</sup>Xe technique, initial PET studies using the steady-state <sup>15</sup>O inhalation method supported a decrease of rCBF with aging. Frackowiak et al. (1983, 1984) found a 28% reduction in mean gray matter rCBF in a group of 14 older subjects compared with 18 young subjects, not studied in the resting state. The regression between rCBF and age was statistically significant and had a slope of  $-4.9$  mL/100 g/minute/decade. rCMRO<sub>2</sub> in gray matter was significantly decreased by  $-19\%$  in the older subjects, but failed to show a significant regression with age. White matter showed no rCBF group difference. The tendency of the oxygen extraction ratio (OER, the ratio of rCMRO<sub>2</sub> to rCBF) to be elevated in the elderly group (Frackowiak and Gibbs 1983), if confirmed, could be an early sign of hemodynamic decompensation increasing neuronal vulnerability and characterize subjects with cerebrovascular disease (Yao et al. 1990). An age-associated decline in rCBF in temporosylvian, medial frontal, and visual medial occipital areas also was demonstrated in 19

**FIGURE 10-2.** Fluorodeoxyglucose model.

[ $^{18}\text{F}$ ]Fluoro-2-deoxy-D-glucose (FDG) reaches the brain via blood and is transferred across brain capillaries and into cells with an influx rate constant equal to  $K_1$ . Once inside cells, FDG is phosphorylated to FDG-6-P by the enzyme hexokinase, at a rate equal to  $K_3$ . FDG-6-P remains essentially trapped intracellularly because the rate of dephosphorylation,  $K_4$ , is quite slow as a result of a low brain activity of the enzyme glucose-6-P phosphatase.  $K_2$  is the rate constant for efflux of FDG from cells to blood.  $C_p^*$  is the concentration of FDG in plasma;  $C_i^*$  is its concentration in brain.

"hospitalized patients with nonacute illness," using low-resolution PET in subjects with eyes closed but ears unobstructed (Lebrun-Grandie et al. 1983).

In a later study, the same group (Pantano et al. 1984) examined 27 "healthy hospitalized patients" ages 19–76 years and found a significant linear decline with age of gray matter rCBF (3.2 mL/100 g/minute/decade) but not of rCMRO<sub>2</sub>. When the younger (< 50 years old) and older (> 55 years old) subjects were compared, both mean rCBF and rCMRO<sub>2</sub> were decreased significantly in the older group (by –18% and –17%, respectively). Decreases were mostly in frontal, temporosylvian, and parieto-occipital cortical areas. White matter rCBF and rCMRO<sub>2</sub> did not differ between groups. Although the OER was age invariant, no correction for a possible difference in cerebral blood volume (CBV) was performed.

Takada et al. (1992) in an inadequately described study also reported a significant linear decline with age for CMRO<sub>2</sub> but not for rCBF, and only in the association neocortex of the left hemisphere. Significant age reductions of rCBF in the frontal cortex and insular gray matter and of rCMRO<sub>2</sub> and regional cerebral blood volume (rCBV) in white matter and in many cortical areas were reported in

healthy subjects between 22 and 82 years of age with eyes closed but ears unobstructed (Leenders et al. 1990). Rates of decline approximated 0.5%/year. OER significantly increased with age in some cortical regions.

In contrast to these results, no age difference in mean rCBF, OER, or CBV was noted in 22 healthy volunteers, whereas mean gray rCMRO<sub>2</sub> significantly decreased with age (Yamaguchi et al. 1986). A slight increase of PaCO<sub>2</sub> and a decrease of hematocrit observed in the older subjects could have tended to elevate rCBF in this study, masking an age-related decrease.

Structural changes, such as enlargement of the CSF spaces and cortical atrophy, have been claimed to be responsible for intrinsic (by reducing the number of neurons in the gray matter) and apparent (by increasing partial volume effects of cerebrospinal fluid or white matter) age declines in rCBF. However, despite evidence of progressive cortical atrophy by X-ray computed tomography (CT), no significant decrease in rCBF or rCMRO<sub>2</sub> was detected in healthy subjects between 50 and 85 years of age (Itoh et al. 1990). High-resolution morphometric measurements of brain structures, which can now be obtained by using magnetic resonance imaging (MRI), can be co-registered with functional PET images. As we discuss later, this methodology has begun to be applied to correct for brain atrophy rCMRglc data obtained in neurodegenerative disorders, and it could be employed also to demonstrate to what extent atrophy influences PET-rCBF measurements in the elderly.

With high-resolution PET and a sophisticated method of anatomical localization, statistical parametric mapping (Friston et al. 1990, 1995), Martin et al. (1991) recently reported a significant age-related decline in rCBF in limbic regions and in bilateral temporal, parietal, and frontal association cortices, more in the left than right hemisphere. These changes in subjects studied with eyes closed and ears unobstructed were unrelated to differences in global CBF and thus were thought to represent an age-related redistribution of rCBF (Martin et al. 1991).

As illustrated in Table 10–1, PET studies relating rCBF and rCMRO<sub>2</sub> to age have differed technically and methodologically, and it is not surprising therefore that results have been inconsistent and have not led to firm conclusions. Early PET studies employed low-resolution scanners, with limited anatomical definition of cortical and subcortical structures and significant error as a result of "partial voluming" (see below). Subjects ranged from "healthy hospitalized patients" (Pantano et al. 1984) or "hospitalized patients with nonacute illness" (Lebrun-Grandie et al. 1983) to carefully screened healthy volunteers (Eustache et al. 1995; Marchal et al. 1992), and cogni-

**TABLE 10-1. Summary of principal studies and methods and techniques used with positron-emission tomography (PET), relating regional cerebral blood flow (rCBF) and regional cerebral metabolic rate for oxygen (rCMRO<sub>2</sub>) in human subjects to age**

Study	Subjects	PET procedure	Results and comment
Lebrun-Grandie et al. 1983	14 M, 5 F (19–76 yr) Hospitalized patients with nonacute illness	Oxygen-15 Steady state ECAT (FWHM 19 mm) Eyes closed; ears open Measured attenuation	rCBF declined with age in temporosylvian, medial frontal, and medial occipitovisual regions. No age effect on CMRO <sub>2</sub> .
Frackowiak and Gibbs 1983	18 young (24–43 yr) 14 older (49–74 yr)	Oxygen-15 Steady state ECAT II (FWHM 17 mm)	Gray matter: 19% CMRO <sub>2</sub> and 28% rCBF reductions; – 0.5 mL/100 mL/min/year.
Pantano et al. 1984	19 M, 8 F (19–76 yr) Healthy hospitalized patients	Oxygen-15 Steady state ECAT II (FWHM 17 mm)	CMRO <sub>2</sub> significantly reduced in the older group; rCBF: –0.32 mL/100 mL/min/year.
Yamaguchi et al. 1986	17 M, 5 F (26–64 yr) (14 < 50 yr; 8 > 50 yr) Healthy, no medications	Oxygen-15 Steady state HEADTOME III (FWHM 8.2 mm)	Gray matter CMRO <sub>2</sub> : linear negative correlation with age. No difference in rCBF, OER, CBV.
Itoh et al. 1990	17 M, 11 F (50–85 yr) Healthy volunteers	Oxygen-15 Steady state ECAT II (FWHM 17 mm) Calculated attenuation	No change with age; CMRO <sub>2</sub> and rCBF were not related to brain atrophy as measured by CT scan.
Leenders et al. 1990	18 M; 16 F (22–82 yr) Patient relatives and hospital staff No CT or MRI scan	Oxygen-15 Steady state ECAT II (FWHM 17 mm) Eyes closed; ears open No face mask Measured attenuation	rCBF, CBV, and CMRO <sub>2</sub> decreased significantly in the frontal cortex and insular matter. OER increased in some areas.
Martin et al. 1991	15 M, 15 F (30–85 yr) Healthy, no medications	Oxygen-15 Steady state ECAT 931/8/12 Eyes closed; ears open Measured attenuation	No change in global CBF; decrease in limbic and association areas.

Takada et al. 1992	15 M, 17 F (27–67 yr) Healthy volunteers	Oxygen-15 Steady state PET scanner: ? Eyes closed; sensory stimulation or deprivation	CMRO <sub>2</sub> significantly decreased in bilateral putamen and left temporal, frontal, and parietal cortices. rCBF decreased only in the left superior temporal cortex. Methodology poorly described.
Burns and Tyrrell 1992	6 M, 8 F (51–85 yr) Patients' healthy relatives No careful medical screening	Oxygen-15 Steady state ECAT 931/8/12	CMRO <sub>2</sub> significantly decreased in the parietal lobe.
Marchal et al. 1992	14 M, 11 F (20–68 yr) Healthy volunteers Careful medical screening At least 7-year education	Oxygen-15 Steady state LETI TTV03 (FWHM 8 mm) stereotactic frame Eyes closed; ears open Measured attenuation	CMRO <sub>2</sub> decreased in 24/31 cortical gyri (–6% per decade); rCBF decreased in 10/31 gyri.
Eustache et al. 1995	14 M, 11 F (20–68 yr) Healthy volunteers Careful medical screening	Oxygen-15 Steady state LETI TTV03 (FWHM 8 mm) stereotactic frame Eyes closed; ears open Measured attenuation	CMRO <sub>2</sub> values, normalized to cerebellum, decreased significantly with age in all the neocortical regions and in left thalamus.

*Note.* CBV = cerebral blood volume; CT = computed tomography; F = female; FWHM = full width at half maximum, millimeter; M = male; MRI = magnetic resonance imaging; OER = oxygen extraction rate; yr = age in years.

<sup>a</sup>Mean ± SD. ECAT, ECAT II, HEADTOME III, LETI TTV03, and Scanditronix PC1024-7B are different PET scanners, whose properties are described in original references.

tive evaluation was rarely carried out. Dementing processes, such as Alzheimer's disease, can have an insidious onset and progress for years before becoming clinically evident. For example, in early stages of Alzheimer's disease, in subjects with only a memory deficit, abnormal rCMRglc has been demonstrated in association neocortices and precedes additional cognitive deficits that later appear (Grady et al. 1988; Haxby et al. 1990). To date, all aging studies have been cross-sectional, and the possibility cannot be ruled out that some reported age-related differences reflected sampling bias from surviving subjects (Martin et al. 1991).

Marchal et al. (1992) attempted to control for some of these variables by examining 25 optimally healthy, carefully screened volunteers between the ages of 20 and 68 years studied with eyes closed and ears unobstructed. High-resolution PET and stereotactic positioning of the head were employed. A significant decline in rCBF was detected only in two frontal gyri, perhaps because of the large coefficient of variation in the other regions (up to 32%). However, a significant age-related decrease of rCMRO<sub>2</sub> was seen throughout the cerebral cortex, except for the orbitofrontal gyrus, hippocampal, and lateral occipital regions. rCMRO<sub>2</sub> declined by 6%/decade. No significant relation was shown between whole-cortex rCMRO<sub>2</sub> and gender, cortical atrophy, or head size; subcortical structures, the cerebellum, and white matter showed no significant age-dependent change. An age-related linear decline in global brain oxygen consumption (normalized to cerebellum) also was found in a group of 25 health-screened subjects (examined with their eyes closed but ears open) who were part of a larger sample in a neuropsychological study (Eustache et al. 1995). The reduction in oxygen consumption reached statistical significance in all the neocortical areas and in the left thalamus. An age-associated decline was observed in some cognitive abilities, including working memory and verbal episodic and explicit memory; other cognitive skills remained unaffected by age.

In summary, data from numerous studies relating rCBF and rCMRO<sub>2</sub> to age are somewhat contradictory. In studies of subjects not in the resting state, age-dependent reductions are of the order of 20%–25%. The functional significance of these changes is not clear. In some studies, largest reductions were reported in cortical association regions, which subserve cognitive functions that decline even in the healthy elderly. These association areas appeared relatively recently during primate evolution, usually are the latest to myelinate, and may be selectively vulnerable to age-related degenerative processes such as Alzheimer's disease (Rapoport 1988, 1990). In subjects not studied in the resting state, age reductions could have been affected by re-

duced visual and auditory acuities (Creasey and Rapoport 1985; Grady et al. 1984), as the majority of the studies did not screen for ocular or auditory age-related pathologies, including cataract, glaucoma, or hearing loss (see earlier). A reduced rCBF in older people also might be caused by subclinical cerebrovascular disease, as atherosclerotic brain lesions are more frequent in the elderly and 50% of brains show such lesions after 50 years of age (Moosy 1971). Atherosclerotic vascular disease (Dastur et al. 1963) and hypertension (Meyer et al. 1985; Salerno et al. 1995), whose prevalence also increases with age, have been shown to be accompanied by reduced rCBF and/or rCMRglc.

### **Regional Cerebral Metabolic Rate for Glucose**

PET studies of rCMRglc and human aging also have led to conflicting results, but, in general, studies outside of the resting state have demonstrated greater declines than those within it (Table 10–2). Kuhl et al. (1982) found a gradual age decline in rCMRglc in 40 healthy subjects between 18 and 78 years old, who were studied with eyes open and ears unplugged. The rate of decline was 0.43%/year (a net of 26% in the above age range), with no hemispheric preference. The ratio of rCMRglc in the frontal cortex to rCMRglc in the parietal cortex, an index of “hyperfrontality” (Ingvar 1979), fell with age, suggesting a selective effect on the frontal lobe. Chawluk et al. (1987) reported a comparable 0.26%/year decline in rCMRglc in healthy subjects studied outside of the “resting state.” In contrast, other studies found no significant age-associated reduction in rCMRglc both in subjects studied in the resting state (eyes covered, ears plugged with cotton) (Duara et al. 1983, 1984) and in subjects with eyes closed and ears unobstructed (de Leon et al. 1983). In a relatively large sample of subjects, significantly lower absolute rCMRglc was seen in frontal, temporal, and parietal regions in the older group (≥ 50 years old) as compared with the young subjects (< 50 years old). These reductions were no longer significant when rCMRglc was corrected for brain volume and atrophy (Yoshii et al. 1988). It should be noted, however, that a global correction method was applied that did not take into account any regional variability in atrophy-related brain changes (see discussion on atrophy correction later).

In the last few years, additional sophisticated methods of analysis have been developed to explore the effects of healthy aging on the brain metabolic data obtained in relatively large samples. Moeller et al. (1996) applied a statistical model of regional covariation to two large independently studied groups of subjects between 21 and 90 years in age. The main topographic profile identified by this

**TABLE 10-2. Summary of principal studies and of methods and techniques employed with positron-emission tomography (PET), relating regional cerebral metabolic rate for glucose (rCMRglc) in human subjects to age**

Study	Subjects	PET procedure	Results and comment
Kuhl et al. 1982	17 M, 23 F; 18-78 yr	ECAT II (FWHM 17 mm) Eyes and ears open Calculated attenuation	Generalized decrease in rCMRglc (0.43%/yr); frontal cortex more affected.
de Leon et al. 1983	14 young M (26 ± 5 yr) 21 older M (67 ± 7 yr)	PETT III (FWHM 15 mm) Eyes closed; ears open No attenuation correction	No change with age.
Hawkins et al. 1983	7 M, 1 F (18-68 yr)	NeuroECAT (FWHM 12 mm) Eyes and ears open	FDG rate constants do not change with age; no rCMRglc change with age.
Duara et al. 1983, 1984	40 M (21-83 yr) Healthy volunteers Careful medical screening	ECAT II (FWHM 17 mm) Eyes and ears covered Measured attenuation	No change with age.
Horwitz et al. 1986	15 young M (20-32 yr) 15 older M (64-83 yr) (Data from Duara 1984)	ECAT II (FWHM 17 mm) Eyes and ears covered Analysis of cerebral functional intercorrelations	No change with age. Decreased number of correlations between frontal and parietal areas and within the parietal lobes bilaterally in the older subjects.
Chawluk et al. 1987	21 young (mean age 27 yr) 23 older (mean age 63 yr) Subjects with medical illness included	PETT V (FWHM 16.5 mm) Eyes and ears open Calculated attenuation	rCMRglc was reduced in frontal, parietal, and temporal regions. No difference between subjects with and without cardiovascular or minor noncardiovascular disease.
Schlageter et al. 1987	49 M (21-83) Healthy volunteers	ECAT II (FWHM 17 mm) Eyes and ears covered CT scan for cerebral atrophy correction	No change with age; cerebral atrophy negatively correlates with rCMRglc.
Hoffman et al. 1988	22 M, 14 F (21-74 yr) Healthy volunteers	NeuroECAT (FWHM 12 mm) Eyes and ears open	Significant rCMRglc reductions only in some frontal areas. No effects of handedness or gender.
Yoshii et al. 1988	39 M/37 F (21-84 yr) Healthy volunteers Careful medical screening	PETT V (FWHM 15 mm) Eyes patched; ears open "Arterialized" venous blood	Absolute rCMRglc lower in older (≥ 50 yr) than in young (< 50 yr) subjects in frontal, temporal, and parietal lobes. Age difference no longer significant after taking into account brain volume and atrophy.
Grady et al. 1990	23 M, 37 F (20-90 yr) Healthy volunteers Careful medical screening	Scanditronix PC1024-7B (FWHM 6 mm) Eyes and ears covered Measured attenuation	12% decline in global CMRglc over 60-yr age range.
Salmon et al. 1991	14 young (mean age 26 yr) 11 older (mean age 27 yr) Healthy volunteers	NeuroECAT (FWHM 12.4 mm)	No age-related reduction in absolute rCMRglc. Age-related reduction in normalized rCMRglc in frontal lobe and increase in normalized rCMRglc in cerebellum.

**TABLE 10–2. Summary of principal studies and of methods and techniques employed with positron emission tomography (PET), relating regional cerebral metabolic rate for glucose (rCMRglc) in human subjects to age (continued)**

Study	Subjects	PET procedure	Results and comment
Loessner et al. 1995	64 M, 56 F (19–79 yr) Some medical conditions in the elderly	PENN-PET (FWHM 5.5 mm) Eyes open; ears unoccluded Qualitative inspection of scans	Decreased cortical glucose metabolism particularly in the frontal lobes. Preservation of subcortical structures, cerebellum, posterior cingulate, and visual cortical areas.
DeSanti et al. 1995	40 young (mean age 28 yr) 32 older (mean age 68 yr) Partial medical screening	Siemens CTI-931 (FWHM 6.2 mm) Eyes open; ears unoccluded Measured attenuation	Reduced frontal and temporal rCMRglc, with stronger effect (24% decline in rCMRglc over 40-yr age range) in the frontal lobes.
Eberling et al. 1995	6 M, 3 F young (mean age 27 yr) 4 M, 4 F older (mean age 66 yr) Healthy volunteers Some medical screening	PET 600 (FWHM 2.6 mm) Eyes open; ears unoccluded	Reduced temporal lobe rCMRglc in older subjects (up to 27% in anterior temporal cortex).
Moeller et al. 1996	Group 1 62 M, 68 F (21–90 yr) Group 2 10 M, 10 F (24–78 yr)	Scanditronix PC 1024-7B (FWHM 6 mm) Measured attenuation Eyes patched; ears occluded Scanditronix Superpett 3000 (FWHM 8 mm) Eyes open and ears unoccluded in a dimly lit room Analysis of cerebral functional intercorrelations	12.5% decline in global CMRglc over 60-yr age range relative frontal hypometabolism associated with covariate normalized metabolic increases in parieto-occipital association areas, basal ganglia, cerebellum.
Murphy et al. 1996	55 M, 65 F (21–91 years) Healthy volunteers Careful medical screening	Scanditronix PC 1024-7B (FWHM 6 mm) Measured attenuation Eyes patched; ears occluded	Significant age-related rCMRglc decline in global CMRglc and in frontal, temporal, and parietal regions. Metabolic reductions differed between males and females.
Blesa et al. 1997	9 M, 8 F (20–74 years) Healthy volunteers Partial medical screening	Scanditronix PC 2048-15B (FWHM 6.5 mm) Measured attenuation Eyes patched; ears occluded	8% decline in global CMRglc per decade; decline more pronounced in limbic structures.
Petit-Taboué et al. 1998	15 M, 9 F (20–67 yr) Healthy volunteers Careful medical screening	LETI TTV03 (FWHM 8 mm) Eyes closed; ears partially blocked; pixel by pixel analysis (SPM)	6% decline in global CMRglc per decade; decline most pronounced in frontal, temporal, and anterior cingulate cortical areas.

*Note.* CT = computed tomography; F = female; FDG = [<sup>18</sup>F]fluorodeoxy-D-glucose; FWHM = full width at half maximum, millimeter; yr = age in years; M = male; SPM = statistical parametric mapping.

<sup>a</sup>Mean ± SD. ECAT, ECAT II, HEADTOME III, LETI TTV03, and Scanditronix PC1024-7B are different PET scanners, whose properties are described in original references.

principal component analysis was characterized by relative frontal glucose hypometabolism with covariate metabolic increases in parieto-occipital association areas, basal ganglia, midbrain, and cerebellum. A more selective effect of aging on frontal lobe glucose metabolism also was found in a study by DeSanti et al. (1995), with less pronounced reductions in the temporal lobes of the elderly subjects, whereas Eberling et al. (1995) found cerebral metabolic rates lower only in the temporal lobes in older subjects compared with rates in younger subjects.

All the previous studies discussed above employed a regions of interest approach for the metabolic analyses. Recently, a systematic voxel by voxel analysis performed by using the statistical parametric mapping software (Friston 1995) demonstrated a global CMRglc decrease of 6%/decade (Petit-Taboué et al. 1998). Decreases in rCMRglc were bilateral and symmetrical, with some areas (frontal inferior and posterior lateral areas; anterior cingulate, anterior temporal, and parietotemporal junction cortices; left caudate; anterior thalamus) affected more than others.

### Factors Influencing Positron-Emission Tomography Studies of Aging

As in the cases of rCBF and rCMRO<sub>2</sub> (see earlier), the question of whether and to what extent rCMRglc declines with age is not settled. Methodological issues and technical limitations noted above probably contributed to discrepancies in the different studies (Table 10–3). This chapter is not the place to discuss these issues in detail (for an excellent review, see Horwitz 1990), but it may be useful to discuss some of them in order to better interpret the findings in the literature.

What we measure with PET, using the FDG or <sup>15</sup>O-labeled water isotopes, are absolute values and correlated patterns of regional cerebral glucose metabolism and blood flow. Unlike morphometric measurements of dimensions of brain structures obtained with CT or MRI, which are invariant over years in adult subjects except with progressive neurodegenerative or cerebrovascular disease (Luxenberg et al. 1987), PET examines variable and often uncontrolled states of cerebral functional activity (Gur et al. 1987). Differences in sensory input during a scan can induce dramatic variations in rCMRglc or rCBF. Indeed, hemispheric CMRglc was shown to be approximately 20% higher in young subjects scanned with their eyes open and ears plugged, compared with subjects studied in the condition of eyes closed and ears plugged (resting state) (Mazziotta et al. 1982). Progressive increases in the complexity of visual stimulation resulted in parallel elevations of rCMRglc in visual association areas, with an average

**TABLE 10–3. Factors that may contribute to variability of data obtained in different PET studies measuring rCBF, rCMRO<sub>2</sub>, or rCMRglc in relation to age in human subjects**

<b>PET technique</b>	Low-resolution (17-mm) versus high-resolution (6-mm) PET scanners
	Up to 25% coefficient of variation with low-resolution PET scanners to measure a potential 15%–30% change in rCMRglc over an adult age span of 60 years.
<b>Brain atrophy</b>	“Partial volume effect” may artificially reduce rCBF and rCMRglc values.
<b>Health screening</b>	Selection of “too healthy” elderly subjects (“supernormals”).
	Inclusion of subjects with (sub)clinical vascular disorders or with subtle cognitive deterioration.
	Medications with potential effects on brain metabolism and function.
<b>Experimental procedure</b>	Sensory input: eyes covered and ears plugged (resting state) versus eyes closed and ears open versus eyes and ears open.
	Resting state versus cognitive activation (e.g., performing a neuropsychological task).
	Calculated versus individually measured radiation attenuation by head tissues and skull.
	Semiautomated regions of interest on individual brains versus automated pixel-by-pixel on stereotaxically normalized brains methods of image analysis.
<b>Anxiety and stress during PET examination</b>	High levels of stress or anxiety may affect frontal lobe metabolism.
	“Familiarity” with PET scanning: first versus repeated scan examination
<b>Gender</b>	Differences in time course and topographical distribution of the brain areas primarily affected by the aging process between men and women.
	Effect of hormone cycle in female subjects at the time of the PET scan examination.

*Note.* PET = positron-emission tomography; rCBF = regional cerebral blood flow; rCMRO<sub>2</sub> = regional cerebral metabolic rate for oxygen; rCMRglc = regional cerebral metabolic rate for glucose.

60% rCMRglc difference between subjects who were at rest and subjects who looked at a landscape of a park during the uptake period of FDG (Phelps et al. 1981).

Metabolic and flow responses to different sensory stimuli are unlikely to be age invariant, as visual and auditory acuities, and even proprioception, decline with age (Creasey and Rapoport 1985; Grady et al. 1984; Lehnert and Wuensche 1966). Thus, reported age differences in PET measures in subjects not in the sensory-deprived resting state could partially reflect reduced sensory acuity rather than only intrinsic age-related reduced activity. To date, resting state studies such as those by Duara et al. (1983, 1984) and Murphy et al. (1996) on optimally healthy subjects provide the best estimate of the actual age decline in intrinsic (sensory independent) brain functional activity.

Other factors, such as anxiety and stress during a scan or simply the novelty of the experimental setting, may affect cerebral metabolism and should be taken into consideration. Although minimally invasive, PET is stressful to some subjects because it involves arterial and venous catheterization, frequent blood sampling, a restraint to minimize head movement, resting in place for perhaps longer than 1 hour, and some sensory deprivation. Gur et al. (1987) reported an inverted U-shaped relation between rCBF and anxiety; rCBF increased with increasing anxiety up to a point and then decreased with additional anxiety. Swedo et al. (1989) also reported a direct correlation between anxiety during PET and rCMRglc in prefrontal areas. Healthy male volunteer subjects with high anxiety showed significantly greater right/left hemisphere metabolic ratios than low-anxiety people (Stapleton et al. 1997). Moreover, in the low-anxiety subjects, cerebral metabolism was lower in the second PET session compared with that in the first examination, whereas no changes occurred in the high-anxiety group, suggesting that metabolic changes may be related simply to becoming familiar with the procedure. This finding would warrant that subjects be trained before undergoing the actual PET scan examination to minimize this “novelty” effect and ensure more homogenous conditions across experimental sessions (something similar to the adaptation night used in sleep research). Training was used in our laboratory to maximize compliance in PET studies of young and older individuals with Down’s syndrome (Dani et al. 1996; Pietrini et al. 1997). Furthermore, these findings highlight the necessity that the order of presentation of different experimental conditions be counterbalanced when one wishes to examine brain functional activity associated with distinct sensory or cognitive stimulation states (Pietrini et al. 1997).

Subject selection is particularly important in studies of functional activity and human aging. In many such PET

studies, no attempt was made to exclude subjects with cardiovascular risk factors or clinical disorders that might affect the brain. Only a few studies (e.g., Duara et al. 1983, 1984; Marchal et al. 1992; Murphy et al. 1996) performed careful clinical, laboratory, and neuropsychological testing to rule out organic or mental abnormalities that might interfere with functional measurements. Although careful screening has been criticized as selecting for “super-normals” who, especially in the elderly, may not represent a “normally distributed” population, for the issue at hand we believe that such selection is appropriate. Less restrictive selection to obtain a sample more representative of the “normal population” might be adopted if many hundreds of subjects of both sexes and of different ages could be studied in the same PET facility with the same procedure. Then, one would have enough subjects to statistically partial out effects of confounding variables and risk factors (such as cardiovascular risk factors, history of psychiatric or medical disorders, mental status during examination) on the results. Additional variability may derive from gender differences and, in women, from fluctuations in plasma levels of sex hormones linked to the menstrual cycle. In a small sample of young women, Reiman et al. (1996a) showed that glucose metabolism was significantly higher in thalamic, prefrontal, temporal, and parietal areas in the mid-follicular phase (low plasma concentrations of estradiol and progesterone) and in superior temporal, anterior temporal, occipital, cerebellar, and limbic regions in the mid-luteal phase (high plasma concentrations of estradiol and progesterone). When using MRI and PET in a large population of carefully screened healthy subjects, we reported significant gender-related differences in aging of brain areas that are essential to higher cognitive functions, including temporal and parietal lobes, Broca’s area, thalamus, and hippocampus (Murphy et al. 1996). This evidence of gender-specific morphometric and metabolic profiles in brain aging may underlie some of the reported differences between men and women in age-related cognitive decline.

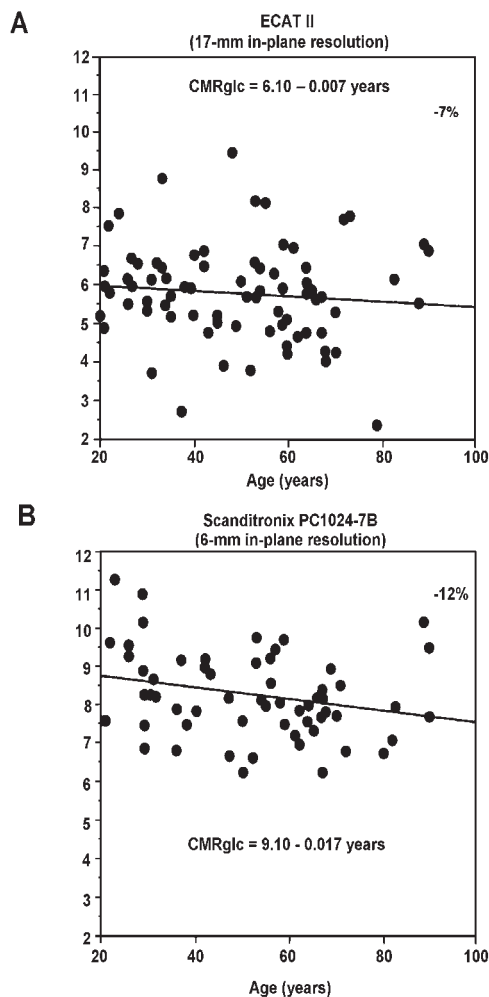

Finally, technical aspects related to PET instrumentation have contributed to variability between PET centers. Tomographs with different spatial resolutions ranging from 6 to 17 mm full width at half maximum (FWHM) have been used to measure cerebral metabolism and blood flow. The degree of recovery of radioactivity in a brain region depends on the relation between regional volume and scanner resolution, and only high-resolution PET machines are appropriate for examining small regions.

In our laboratory, initial PET studies of aging (Duara et al. 1983, 1984) used a low-resolution PET tomograph (ECAT II; FWHM = 17 mm) for subjects in the resting

state (see above). Global gray CMRglc, assessed in 77 healthy men between 20 and 70 years of age, showed a nonsignificant 7% decrease over this age range (Grady et al. 1990) (Figure 10-3, *panel A*). When we later used a Scanditronix PC 1024-7B scanner (6 mm in-plane resolution), under the same resting state conditions to study 60 healthy men, a statistically significant –12% age decline in global gray rCMRglc was evident (Figure 10-3, *panel B*). The slope of the regression lines in Figure 10-3 do not differ significantly (0.01 versus 0.02 mg glucose/100 g/minute/year), but because the slope with the high-resolution Scanditronix scanner had a much smaller coefficient of variation than with the lower resolution ECAT scanner, the former reached statistical significance. The –12% decline obtained with the high-resolution scanner likely represents a maximum rate of change because it was not corrected for partial voluming and brain atrophy.

In this regard, age-associated brain atrophy (de Leon et al. 1984; Schwartz et al. 1985; Zatz et al. 1982) is an additional complication. Resulting from partial voluming, atrophy can reduce recovery by the scanner of radioactivity from a given region. Recently, Ibanez et al. (1998) developed a segmented MRI-based method to correct rCMRglc data from patients with Alzheimer's disease and age-matched older healthy control subjects for the effects of partial voluming as a result of brain atrophy. This correction increased global CMRglc by approximately 12% in the control subjects and 20% in the patients with Alzheimer's disease, with the largest corrections being in the frontal and insular areas. Nevertheless, the initial uncorrected rCMRglc differences between the two groups remained statistically significant after correction. Thus, rCMRglc reductions obtained by PET in Alzheimer's disease reflect intrinsic metabolic reductions per gram tissue and are not artifacts of partial voluming. They represent neuronal/synaptic dysfunction in the affected regions (Pietrini et al. 1997, 1999). The Ibanez correction algorithm is now being applied to our other PET data involving age, gender, and disease group differences.

In some studies, attempts were made to correct PET data for brain atrophy by correcting with regard to dilation of lateral ventricles, measured using CT or MRI (Alavi et al. 1985; Herscovitch et al. 1986; Schlageter et al. 1987). Schlageter et al. (1987) used CT and PET to study 49 healthy men between 21 and 83 years old. When global CMRglc (which included gray and white matter and ventricular cerebrospinal fluid spaces) was corrected for age changes in lateral ventricular volume, the correlation coefficient with age changed from –0.29 to –0.04, indicating that the calculated uncorrected decline with age in resting glucose utilization largely was reflected by atrophy.

**FIGURE 10-3.** Global gray matter cerebral metabolic rate for glucose (CMRglc) as a function of age in 77 healthy men studied with a low-resolution ECAT II positron-emission tomography (PET) scanner (*panel A*) and in 60 healthy men studied with a high-resolution Scanditronix PC 1024-7B machine (*panel B*). Regression analyses demonstrated an insignificant –7% decrease in CMRglc over a 70-year range in *panel A*, but a statistically significant –12% decline in *panel B*. Data from the high-resolution scanner had a smaller coefficient of variation than data obtained with the low-resolution scanner. *Source.* Reprinted from Grady CL, Rapoport SI: “Cerebral Metabolism in Aging and Dementia,” in *Handbook of Mental Health and Aging*. Edited by Birren J, Sloane RB, Cohen G. San Diego, CA, Academic Press, 1992, pp. 201–228.

In summary, despite the many studies that have been carried out to ascertain the effects of age on rCMRglc, the exact relation is not yet known. As in the cases of rCBF and rCMRO<sub>2</sub>, most evidence suggests that an age-dependent reduction in rCMRglc, if present, is modest and of the order of –12% for a 60-year range, despite some isolated reports of much more dramatic reductions (Petit-Taboué et

al. 1998). In view of the many possible confounding factors that can affect measurements, and given that several technical advances have recently been introduced, a renewed effort to quantify age-related *in vivo* measures of brain functional activity, and to understand how these measures reflect changes in cognition and behavior, should prove fruitful.

### **Can Functional Imaging Tell Us More About Brain Function and Brain Aging?**

In the last few years, our ability to understand and characterize brain metabolism and functional activity *in vivo* has been greatly expanded by the rapid development of sophisticated experimental paradigms that combine neuroimaging techniques with cognitive, sensory, or pharmacological stimulation paradigms. Furthermore, new ways to interpret PET data, using powerful methods of analysis, have allowed us to identify specific patterns of functional interrelationship among different brain regions. Finally, new functional imaging methodologies, particularly functional magnetic resonance imaging, have become available to investigate functional activity in the living human brain with high spatial and temporal resolutions.

**Brain functional correlations.** With the exception of the study by Moeller and collaborators (1996), the PET studies that are summarized above simply reported differences in mean values for cerebral blood flow or glucose metabolism between young and older subjects or the regression of these values with age. However, another way to examine age-related differences in functional activity with PET is to use correlational or multivariate analysis to determine pattern of brain glucose metabolism and blood flow in the resting state or during activation. Indeed, despite that the subjects studied in the resting state by Duara et al. (1983, 1984) showed no age-related declines in rCMRglc, they did demonstrate clear age differences in their correlation patterns (Horwitz et al. 1986).

Correlation coefficients between pairs of rCMRglc values are thought to indicate functional associations between the two brain regions (Clark et al. 1984; Horwitz et al. 1984; Metter et al. 1984). The fundamental assumption of the correlation method is that if two brain regions (A and B) are functionally coupled, so that neuronal activity in one region depends on activity in the other, a plot of rCMRglc in region A against rCMRglc in region B across subjects, using normalized parameters such as rCMRglc/CMRglc, will demonstrate a statistically significant correlation. Conversely, if two regions show a significant correlation between their normalized rCMRglc parameters, these two

regions are assumed to be functionally coupled. Two regions may have a significant correlation in activity if they are anatomically linked and that link is functional in the resting state or during a specific task. However, the regions also could have a large correlation if they are not directly connected, but rather receive concomitant inputs from a third region, for example, a thalamic nucleus. Or, one could have a combination of both direct and indirect effects going on at the same time. Horwitz et al. (1986) compared pairwise correlations of normalized resting state metabolic rates between a group of 15 young healthy subjects (20–32 years old) and a group of 15 elderly optimally healthy subjects (64–83 years old). In the young group, many statistically significant positive correlations were demonstrated within and between the frontal and parietal lobes, a smaller number were demonstrated within and between the temporal and occipital lobes, and only a few such correlations were found between the frontal-parietal and the temporal-occipital domains. The older group, although demonstrating the same general pattern of correlations, had fewer significant correlations between frontal and parietal areas and between regions within the parietal lobes than did the younger group. This evidence of loss of functional integration among regions of the parietal lobe corresponded to measured deficits in cognitive performance subserved by parietal structures (Grady et al. 1990). Even more complex mathematical models, including discriminant function analysis and structural equation modeling (often referred to as path analysis), have been elaborated and applied successfully to identify subtle changes in brain metabolic functions indicative of disease or even in asymptomatic subjects at risk for developing brain disorders, including Alzheimer's disease (Azari and Pietrini 1995; Horwitz et al. 1995).

**Cognitive and sensory stimulation paradigms.** In addition to measuring brain metabolism and blood flow in the resting state, several experimental paradigms have been developed to examine brain activity during cognitive tasks or sensory stimulation conditions in healthy subjects at different ages. Most of these studies have been conducted using the  $^{15}\text{O}$ -labeled water PET methodology to determine rCBF in distinct conditions of brain activity. The short half-life of  $^{15}\text{O}$  makes it possible to perform a number of sequential studies during the same PET scan session. With the PET scanners of the last generation, which exhibit an excellent sensitivity and thus require the injection of very small amounts of radioactive water, more than two dozen of these short studies (called *runs*) can be performed during the same PET session while subjects alternate among different experimental paradigms. Given that neuropsychological studies and clinical obser-

variations indicate that several cognitive abilities decline with aging (Creasey and Rapoport 1985; Horn 1975), functional PET studies have been designed to investigate brain activation, as revealed by rCBF changes, during visuospatial and object recognition tasks, memory tasks, abstract reasoning, and sensory stimulation (Table 10–4).

In our laboratory, Grady et al. (1992) used  $^{15}\text{O}$ -labeled water to show that healthy elderly (9 subjects, mean age  $72 \pm 7$  (SD) years), compared with healthy young subjects (11 subjects, mean age  $27 \pm 4$  years), while performing certain visual tasks during PET with equivalent mean accuracies and reaction times, activated different network components within their brain. In the young subjects, the occipitotemporal cortex was selectively activated during an object recognition task (face matching) compared with a sensorimotor control task, whereas the occipitoparietal cortex was activated during a spatial location task (dot location) (Figure 10–4). In the elderly subjects, the same regions were activated as in the young, but, in addition, rCBF increased significantly in the occipitotemporal cortex during the spatial task and in the superior parietal cortex during the object recognition task.

Age-related differences in activation were found also when subjects were tested on encoding and recognition processes during memory tasks. Young subjects showed rCBF increases in the right hippocampus and the left prefrontal and temporal cortical areas during encoding of novel faces and in the right prefrontal and parietal cortex during recognition (Grady et al. 1995). In contrast, the older subjects failed to show significant activation in the areas activated in the young during encoding, but they did have rCBF increases in the right prefrontal cortex during recognition (Figure 10–5). The lack of activation of hippocampal and frontal cortex during encoding suggests that memory decline in the elderly is a result of a failure to encode the stimuli properly.

Other studies of memory processes provide further support to age-associated changes in brain activity (Table 10–4). Elderly people show not only reduced or absent activation in many regions activated in young subjects, but also show significant activation of different regions. Additionally, several studies indicate that young subjects have a lateralized pattern of activation, with the left frontal cortex involved during encoding and the right frontal cortex involved during recall (hemispheric encoding/retrieval asymmetry model; Tulving et al. 1994). In the older subjects, in contrast, this lateralization appears to be disrupted as they show a more bilateral activation of the frontal cortex (Cabeza et al. 1997; Madden et al. 1999). These areas of increased activity in the elderly may be recruited for alternative strategies to maintain performance (Cabeza et al. 1997).

Taken together, the resting state correlation analyses of Horwitz et al. (1986) and the results of the visual and memory activation studies (Cabeza et al. 1997; Grady et al. 1992, 1994, 1995, 1998) suggest that healthy aging is accompanied by reorganization of network integrity and network processing efficiency in the brain, and that such reorganization can be elucidated with methods of functional imaging and multivariate data analyses, during tasks related to vision, audition, memory, attention, language, and other cognitive processes.

As the cognitive paradigms described above require that subjects actively perform on a given task, interpretation of the results would be biased if subjects perform poorly or not at all. The issue of compliance with the task requirements becomes critical when one wishes to compare effects of healthy aging with effects of a neurodegenerative disorder of the elderly, such as Alzheimer's disease (see below). Patients with moderate to severe dementia (Folstein et al. 1975) may be unable to understand or follow the instructions of even simple cognitive tasks testing visual recognition or memory. To address these limitations, our laboratory developed a passive audiovisual stimulation paradigm that makes it possible to assess brain responses to widespread audiovisual stimulation that does not require active performance by subjects. Using this experimental paradigm in combination with PET, we examined brain metabolic responses in young and middle-aged subjects with Down's syndrome and in patients with Alzheimer's disease with mild to severe dementia.

Employing a "double FDG injection technique" (Brooks et al. 1987) with blood flow measurements using  $^{15}\text{O}$ -labeled water, two sequential measures of both rCBF and rCMRglc were obtained during the same PET session while a subject is in the resting state and during audiovisual stimulation (seeing and hearing a simple and colorful movie). As the two sets of studies were performed less than 1 hour apart, with the subject remaining in the tomograph, variance arising from differences in mental status, head positioning, or experimental procedure is minimized. Resting state and audiovisual stimulation were alternated randomly, and young and elderly subjects and patients and control subjects were studied alternately as well. Anxiety during PET was rated by a subjective measure (ranging from 0 = absent to 3 = severe) (Duara et al. 1983) and by administering a State Anxiety Questionnaire (Spielberger 1968) after the scan. Subjects were instructed to remain awake and were confirmed to be awake by the attending physician during the resting state measurements and were told that they would be given a questionnaire on the content of the movie at the end of the study. Subjects who had no previous experience of PET scan examination were

**TABLE 10-4. Summary of principal studies that have used positron-emission tomography (PET) in combination with sensory or cognitive stimulation paradigms to examine brain activity in human subjects at different ages**

Reference	Subjects	PET procedure	Results and comment
Grady et al. 1992	11 young M (27 ± 4 yr) 9 older M (72 ± 7 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus Scanditronix PC 1024-7B (FWHM 6 mm) Object and spatial vision task Statistical parametric mapping	Less functional separation of the dorsal and ventral visual pathways in the older subjects.
Grady et al. 1994	15 young (26 ± 4 yr) 17 older (67 ± 6 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus Scanditronix PC 1024-7B and Scanditronix PC2048-15B Faces and location visual task Statistical parametric mapping	Young and older subjects have different patterns of activation during face-matching and spatial location visual tasks, suggestive of reduced efficiency of occipital visual areas in the elderly.
Tempel and Perlmutter 1992	14 M, 12 F (20–72 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus PETT VI; low-resolution mode Vibrotactile stimulation to one hand (130 Hz) Pixel-by-pixel subtraction	rCBF responses to vibrotactile stimulation in contralateral primary sensorimotor and supplementary motor areas do not change with normal aging.
Grady et al. 1995	10 young (8 M, 2 F) (25 ± 2 yr) 10 older (7 M, 3 F) (70 ± 6 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus Scanditronix PC 2048-15B (FWHM 6.5 mm) Memory for faces task Statistical parametric mapping	Medial temporal cortex (including hippocampus) was activated in young but not in older subjects during encoding of faces.
Madden et al. 1996	10 young M (18–27 yr) 10 older M (63–75 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus GE 4096-Plus Visual word identification Statistical parametric mapping	Older subjects have, in comparison with young subjects, reduced increase of rCBF during visual word identification in ventral occipitotemporal pathway.
Schacter et al. 1996	8 young (mean age = 21 yr) 8 older (mean age = 68 yr) Healthy volunteers	Oxygen-15 steady state GE-Scanditronix PC 4096 (FWHM 6 mm) Retrieval of episodic memories Statistical parametric mapping	Young and older subjects had similar hippocampal activations during recollection of a studied word. Young subjects showed bilateral activations in anterior prefrontal cortex during retrieval attempts, whereas in older subjects activations were more posterior.
Cabeza et al. 1997	12 young (6 M, 6 F) (19–31 yr) 12 older (5 M, 7 F) (67–75 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus Scanditronix PC 2048-15B Memory task: encoding and retrieval of word pairs Statistical parametric mapping	Young and older subjects showed different patterns of activation during encoding, recognition, and recall suggestive of age-related deficits and neuroplastic compensatory mechanisms.

Nagahama et al. 1997	6 young (6 M) (21–24 yr) 6 older (4 M, 2 F) (66–71 yr) Healthy volunteers	Oxygen-15 water iv bolus PCT-3600W (FWHM 7.5 mm) Modified Card Sorting Test Statistical parametric mapping	Older subjects had, in comparison with young subjects, reduced rCBF increases during a Card Sorting Test in left dorsolateral prefrontal cortex and inferior parietal lobule, striate, and prestriate cortices.
Grady et al. 1998	13 young (10 M, 3 F) (25 ± 3 yr) 16 older (11 M, 5 F) (66 ± 4 yr) Healthy volunteers Careful medical screening	Oxygen-15 water iv bolus Scanditronix PC 2048-15B (FWHM 6.5 mm) Working memory for faces Statistical parametric mapping	Older subjects showed reduced activation in right ventrolateral prefrontal cortex and greater activation in left dorsolateral prefrontal cortex during working memory for faces as compared with that of young subjects.
Madden et al. 1999	12 young (6 M, 6 F) (20–29 yr) 12 older (5 M, 7 F) (62–79 yr) Healthy volunteers Partial medical screening	Oxygen-15 water iv bolus GE Advance (FWHM 5 mm) Verbal Recognition Memory Task	Age-related slowing of encoding and retrieval processes. During retrieval, young subjects had activation in right prefrontal cortex, whereas older subjects had bilateral prefrontal activation.

Note: F = female; FWHM = full width at half maximum; iv = intravenous; M = male; rCBF = regional cerebral blood flow; yr = age in years.

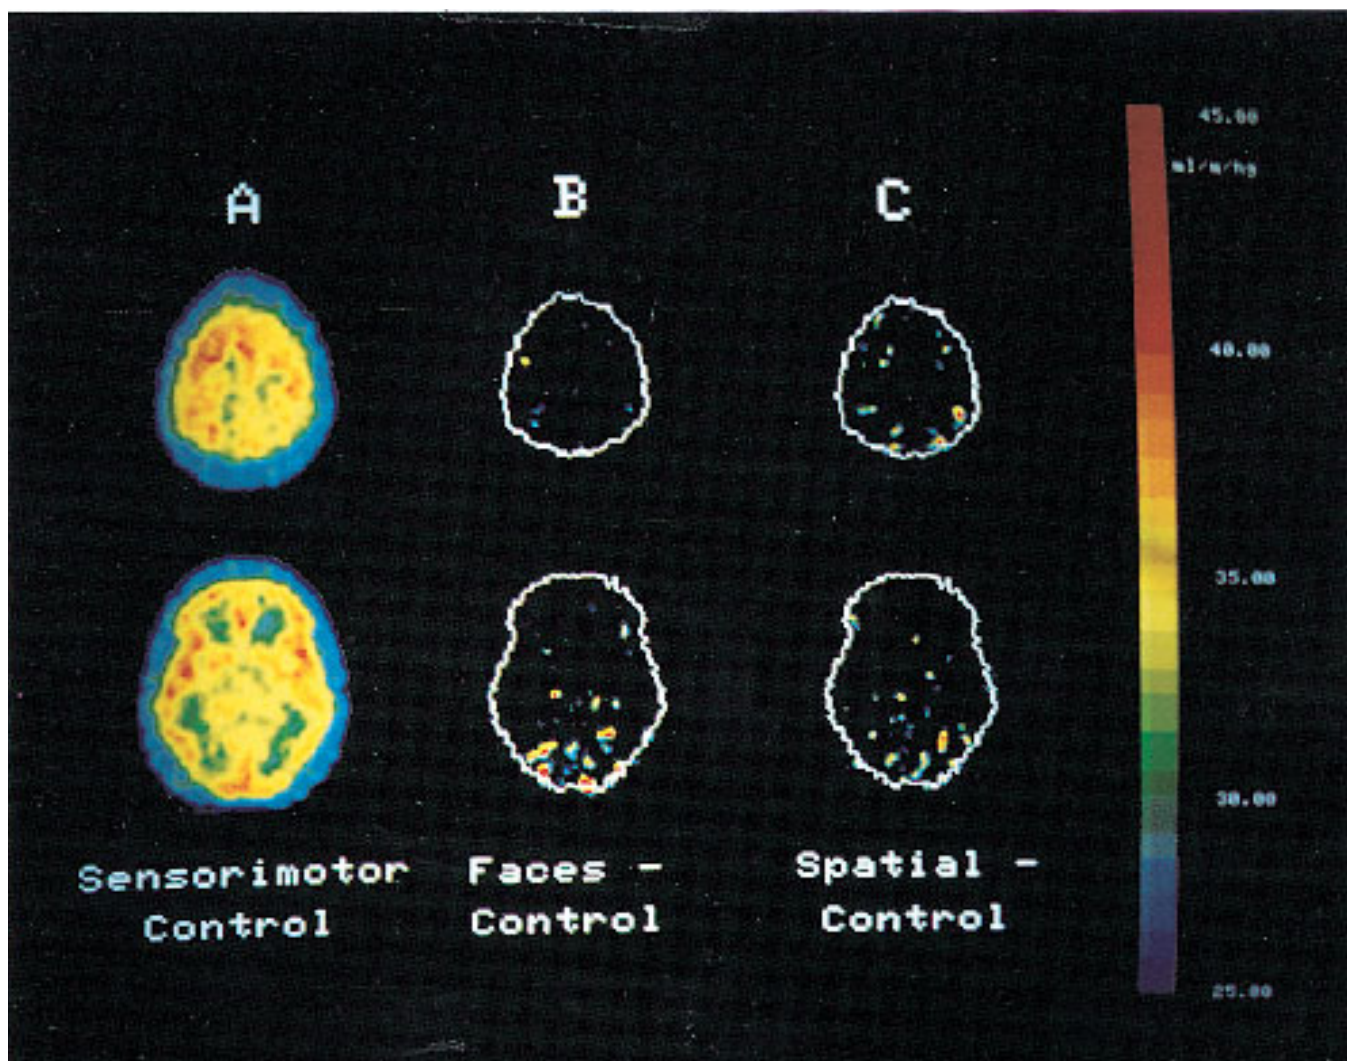

trained to increase compliance during the actual PET session and minimize the effects of novelty (Stapleton et al. 1997) on brain metabolism. The results of the first studies in patients with Alzheimer’s disease or at risk for developing Alzheimer’s disease are presented below.

## ■ Positron-Emission Tomography in Geriatric Neuropsychiatry

Although our focus in this chapter is the aging process in healthy humans, it may be useful to mention briefly some PET studies of neuropsychiatric disorders that may affect the elderly, such as Alzheimer’s disease and depression, which are discussed extensively elsewhere in this textbook.

Alzheimer’s disease, the most common cause of dementia, accounts for up to 80% of all cases of dementia, followed by vascular diseases (4%–10%) and other diseases, including Pick’s dementia (Chui 1989). Alzheimer’s disease is characterized by a progressive, global, and irreversible deterioration of cognitive functions, which initially presents with memory problems and, later in the course of the disease, with language, mathematical, visuospatial, and personality decline. Many studies have been conducted with PET to investigate cerebral glucose metabolism in the different stages of Alzheimer’s disease. In agreement with autopsy studies that demonstrated an unequal distribution of neurofibrillary tangles in the Alzheimer’s disease brain, PET with FDG in the resting state showed reduced rCMRglc values mostly in the association neocortical areas, with a relative sparing of primary neocortical and subcortical regions, at least until the latest stages of the disease (DeCarli et al. 1992; Duara et al. 1986; Grady and Rapoport 1992; Kumar et al. 1991; Pietrini et al. 1996).

As shown in Figure 10–6, the reduction in rCMRglc in patients with Alzheimer’s disease usually first appears in parietal and temporal neocortical areas and then later in the remainder of the neocortical mantle (severe stage), with only a relative preservation of the sensorimotor and primary visual cortices (Duara et al. 1986; Grady and Rapoport 1992; Kumar et al. 1991). The pattern of reduced rCMRglc may be different in individual patients, that is, some patients may show a greater involvement of the left side, whereas others may show more reductions in the right hemisphere. Interestingly, these heterogeneous reductions in neocortical rCMRglc may precede and predict later nonmemory impairments of cognitive functions thought to involve the neocortex and are correlated with heterogeneous patterns of nonmemory impairments in individual patients (Grady et al. 1988; Haxby et al. 1990). In other words, patients with predominant left hemisphere

**FIGURE 10-4.** Positron-emission tomography (PET) scan images from a young healthy subject, obtained using oxygen-15 water during different neuropsychological tasks. Pictures are taken parallel and 45 mm (*bottom*) and 90 mm (*top*) above the inferior orbitomeatal line. The pictures in *column A* show the pattern of regional cerebral blood flow (rCBF) during a sensorimotor control task. Pictures in *column B* and *column C* are obtained by subtracting the sensorimotor control task rCBF pattern from the rCBF pattern obtained during a faces-matching task and a spatial-location task, respectively. Thus only the areas selectively activated during either task are shown. During face matching, there was a selective activation of the occipitotemporal regions (*column B*), whereas during a spatial location task the occipitoparietal cortex was activated (*column C*). (See text for further explanation.) The color bar on the right side shows rCBF in mL/100 g tissue per minute. For each individual picture, the right side corresponds to the right side of the brain, and the left to the left side.

hypometabolism will have a greater language impairment compared with visuospatial function, and those with disproportionate right hemisphere hypometabolism will show a greater impairment of visuoconstructive abilities (Haxby et al. 1985).

Depression is common in older individuals, probably also because of age-related decrease in the serotonergic system (Meltzer et al. 1998). Depression in the elderly often represents a clinical dilemma because its symptoms may resemble those of a dementia process. The term “de-

pressive pseudo-dementia” was proposed to indicate cases of depression that, because of the coexistence of cognitive impairment, were mistakenly diagnosed as dementia (Kiloh 1961). Early diagnostic differentiation between the two conditions is important because some antidepressant treatments may actually worsen cognitive impairment as a result of their anticholinergic effects and because an undiagnosed depression can be life-threatening (Dolan et al. 1992). PET can help to distinguish these two conditions. Baxter et al. (1989) found that patients with depres-

**FIGURE 10-5.** Graphical representation of the cortical areas that showed regional cerebral blood flow increases during encoding and recognition (*Recog.*) in a face-memory task in young (*top*) and older (*bottom*) healthy subjects. All areas in *color* showed significant activation when the encoding and the retrieval conditions were compared with the sensorimotor control task (*green*), with a forced-choice match-to-sample task (*red*; in this condition a sample face and two choice faces were presented simultaneously), or both (*yellow*).

**FIGURE 10-6.** Positron-emission tomography (PET) images from a healthy control subject (age 69 years), a patient with mild dementia (age 53), a patient with moderate dementia (age 63), and a patient with severe dementia (age 72). All subjects were women. Scans were obtained using a Scanditronix PC 1024-7B positron tomograph (full width at half maximum [FWHM] 6 mm). For each subject, three horizontal brain slices taken parallel and above the inferior orbitomeatal line are shown: 45 mm (*left*), 70 mm (*middle*), and 90 mm (*right*). For each individual picture, the right side corresponds to the right side of the brain; the left, to the left side of the brain. In comparison to the healthy control subject, reduction of regional cerebral metabolic rate for glucose (rCMRglc) can be appreciated in the association cortical areas of the patients with dementia. In the early stages of disease, primary cortical areas and subcortical structure are not affected. With the progression of disease, the deficit becomes gradually worse, and in the patient with severe dementia of the Alzheimer type (DAT), only primary sensorimotor areas show a relative sparing. The *color scale* indicates rCMRglc in milligrams per 100 grams of tissue per minute. AC = anterior cingulate; CD = caudate nucleus; FR = frontal cortex; INS = insula; OCC = occipital cortex; PA = parietal cortex; PF = prefrontal cortex; SM = sensorimotor cortex; TH = thalamus; TP-PA = temporoparietal cortex.

*Source.* Adapted from Grady and Rapoport 1992.

sion had decreased lateral left prefrontal lobe rCMRglc compared with matched healthy control subjects. In addition, patients with bipolar depression and those with unipolar depression had significantly lower normalized caudate rCMRglc. Reduced rCMRglc values became normal values when patients returned to the euthymic state. The finding of a reduced rCMRglc in prefrontal areas and in the caudate nucleus of patients with depression is of par-

ticular interest because an independent study in patients with Parkinson's disease showed reduced inferior orbitofrontal and caudate rCMRglc only when depression was evident, whereas metabolism was normal in those with motor symptoms only (Mayberg et al. 1990). These regions usually are not affected in early Alzheimer's disease, and thus their involvement could help to differentiate the two processes.

In the last few years, as new drugs are being developed, the search for early changes in brain metabolism that could be used for a preclinical diagnosis of Alzheimer's disease has become a major focus of the researchers working in this field. This is particularly important because the early metabolic changes in Alzheimer's disease are potentially reversible, whereas the later ones are irreversible (Rapoport, in press). Using distinct PET approaches, different groups have examined populations at risk for developing Alzheimer's disease, such as individuals with family history of autosomal dominant Alzheimer's disease, those who are homozygous for the APOE $\epsilon$ 4 allele, or older subjects with Down's syndrome (Pietrini et al. 1993, 1997; Reiman et al. 1996b; Small et al. 1995). For example, we conducted neuropsychological and neuroimaging studies in young and middle-aged subjects with Down's syndrome. All subjects with Down's syndrome who are over 40 years of age show some neuropathological and neurochemical changes of Alzheimer's disease, and some 90% develop dementia after 60 years of age. Thus, subjects with Down's syndrome can be used to investigate the preclinical and clinical stages of Alzheimer's disease.

A longitudinal study in older nondemented and otherwise healthy subjects with Down's syndrome showed that cognitive measures and resting state brain metabolism remained stable until the onset of dementia, at which point the subjects began to rapidly decline. This suggested that dementia and metabolic dysfunction appear only after a threshold level of neuropathology is attained (Dani et al. 1996). On the other hand, the accumulation of Alzheimer's neuropathology in the years preceding clinical onset of dementia may impair the neuronal capability to respond to an increase in functional load or stress. To test this hypothesis, we measured rCMRglc in conjunction with the audiovisual stimulation paradigm described above, in young and older nondemented adults with Down's syndrome. Supporting our hypothesis, we found that the brain of older compared with younger nondemented subjects with Down's syndrome showed reduced metabolic increments in response to audiovisual stimulation in brain regions known to be affected by Alzheimer's disease, particularly temporal and parietal cortical regions (see above) (Figure 10-7, *panel B*). In the resting state, in contrast, glucose metabolism between the two groups did not differ in any cortical area (Figure 10-7, *panel A*). Although in need of being replicated in other at-risk groups without Down's syndrome, these results indicate that a paradigm that increases the functional demand on the brain can reveal neuronal/synaptic dysfunction that is not evident in the resting state before the onset of dementia.

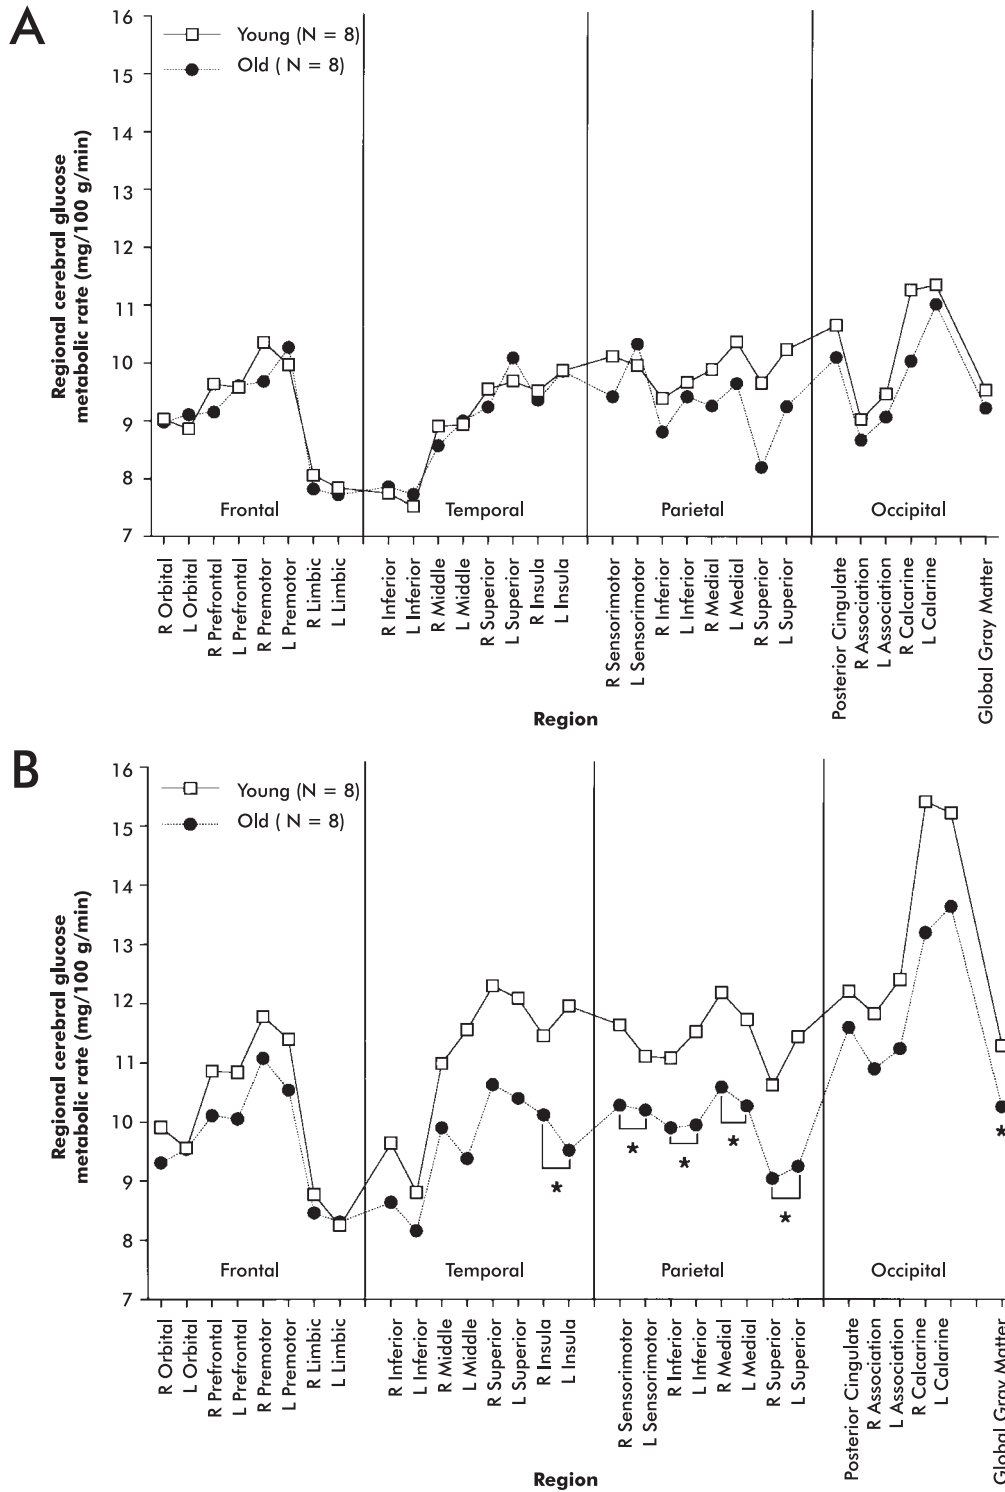

This audiovisual paradigm also has been used to inves-

tigate neuronal/synaptic efficiency as a function of dementia severity in patients with Alzheimer's disease. In 15 otherwise healthy patients with Alzheimer's disease with mild to severe dementia (Folstein et al. 1975), we demonstrated that brain responsiveness to stimulation declined with worsening of dementia, to a point where no metabolic response could be elicited by audiovisual stimulation (Pietrini et al. 1999; Pietrini et al., in press). Reduced synaptic integrity in patients with moderate to severe dementia may contribute to unsuccessful responses to pharmacological treatment to enhance synaptic transmission in such patients (Rogers and Friedhoff 1998). As most drugs act by enhancing (cholinergic) neurotransmission, these agents require that synapses be functional in order for them to exert their pharmacological effects.

## Summary

The rapid development of increasingly more sophisticated techniques for functional neuroimaging and of accompanying mathematical and statistical models to analyze multivariate imaging data have made it possible to quantify, localize, and interpret in vivo measures of brain functional activity. The majority of the studies to date indicate that absolute and normalized values of rCBF, rCMRglc, and rCMRO<sub>2</sub> are modestly affected by the aging process and that the net decline in intrinsic brain functional activity between 20 and 70 years of age for these parameters does not exceed approximately -12% in the resting state, with the largest changes affecting the frontal lobes. Furthermore, partial voluming as a result of age-related brain atrophy and morphological changes may have inflated the magnitude of the reported metabolic reductions. Larger declines reported in the literature, when obtained under uncontrolled conditions of sensory stimulation, in part may also be biased by age-related reductions in visual and auditory acuities. In the absence of systematic screening, declines could also be in part a result of age-related brain disease such as hypertension.

Age differences in cognition and behavior may be better related to demonstrable and clear differences in integration of brain functional activity, rather than to differences in absolute or normalized values of rCBF, rCMRglc, and rCMRO<sub>2</sub>. Such differences deserve to be explored in more detail by employing multivariate correlation or path analysis approaches. Horwitz et al. (1986) demonstrated clear age differences in correlated metabolic activity obtained in the resting state, which are more robust than the observed differences in absolute or normalized metabolic values. Finally, the stimulation approach initiated by

**FIGURE 10-7.** Brain glucose metabolism in young and older subjects with Down's syndrome without dementia at rest (*panel A*) and during passive audiovisual stimulation (*panel B*). Asterisks indicate significantly lower regional cerebral metabolic rate for glucose (rCMRglc) ( $P < .05$ ) in the older compared with the young subjects with Down's syndrome. Despite no differences in brain metabolism in the resting state between older and young subjects with Down's syndrome (*top*), during audiovisual stimulation (*bottom*) significant rCMRglc reductions in parietal and temporal cortical areas are observed in the older group. R = right; L = left.

Grady et al. (1992) and Pietrini et al. (1997, 1999), especially if it is used parametrically with tasks of continuously varying difficulty (Rapoport and Grady 1993), should prove useful for examining which brain networks actually are used during a given cognitive process and how network strategies may change with age.

# Functional Brain Imaging

## *Functional Magnetic Resonance Imaging and Magnetic Resonance Spectroscopy*

Mark S. George, M.D., Kathleen A. McConnell

Jeffrey P. Lorberbaum, M.D., Andrew Greenshields

Daryl E. Bohning, Ph.D., Jacobo Mintzer, M.D.

Advances in neuroimaging are transforming basic and clinical neuroscience. Technological developments first in computed tomography (CT) and then magnetic resonance imaging (MRI) have provided noninvasive methods of directly examining brain structure. For years, however, the only ways to examine brain *function* included electroencephalograms (EEGs) (with poor spatial resolution) or radiotracer-based methods such as single photon emission computed tomography (SPECT) and positron emission tomography (PET) (also with relatively poor spatial resolution and requiring the injection of radioactive tracers). Recently, researchers have devised several methods to use conventional MRI scanners to obtain images of brain function. By varying the ways in which the magnetic signal is acquired, researchers can now use MRI

to not only image brain structure and pathology in exquisite detail, but they can also image regional brain oxygen use, blood perfusion, and diffusion of water through and across membranes. Additionally, by using MR spectroscopy, they can directly image brain neurochemical activity as well.

These new applications using MRI to image brain function rather than structure are collectively referred to as *functional MRI*, or *fMRI*. These exciting developments are still in early stages and do not have many direct clinical applications yet, but they hold the enormous promise of one day having a single examination that will yield information about both brain structure and function. Such innovations directly allow for the development of MR scanning protocols that would facilitate diagnosis and monitor treatment. For example, in the diagnosis and treatment of multiple

sclerosis, structural MRI is crucial for initial diagnosis and is a sensitive evaluator of changes in disease activity, even better than a detailed physical examination (Khoury and Weiner 1998). Eventually, fMRI will likely assume a similarly important role in many other areas of geriatric neuropsychiatry. Perhaps most important for the future clinical utility and application of fMRI is that it involves only minor upgrading of conventional MRI machines (see Table 11–1).

Despite this enormous promise, MRI presents several problems specific to imaging in aging individuals. MRI involves the patient's lying relatively motionless in the bore of a scanner that is generally 3–4 feet in diameter and long enough to extend from one's thighs past the head. Many patients find this situation frightening and claustrophobic, especially those who are already agitated or who are cognitively impaired with delirium or dementia. Additionally, when the magnetic gradients inside the scanner disturb the magnetic field in the process of producing an image, they generate a loud rhythmic noise. The combination of confinement and noise can result in up to 20% of the general population being unable to remain still enough for a quality examination.

Technicians are working to circumvent this problem. Newer MRI scanners are being designed with shorter

**TABLE 11–1. Advantages of functional magnetic resonance imaging (MRI) compared with advantages of positron-emission tomography (PET) and single photon emission computed tomography (SPECT), especially in geriatrics**

#### Advantages

- Has potential for high temporal and spatial resolution
- Lacks radioactivity, and most techniques are noninvasive
- Can be repeated multiple times
- Is performed on upgraded, common MRI scanners

#### Disadvantages

- Is extremely sensitive to head movement
- Is awkward environment for complex functional imaging paradigms
- Has contraindications:
  - Irremovable magnetic devices
  - Extreme claustrophobia
- Cannot perform receptor-ligand studies as with PET and SPECT
- Is new technique with less track record than PET and SPECT

bore that are less confining, and some MRI machines are “open,” that is, they wrap around rather than encompass the patient. Other, more easily applicable, techniques for reducing anxiety include using prism glasses, goggles, and earphones to minimize the feelings of confinement. These measures do help in some cases. In an agitated patient with dementia, however, one must often resort to pharmacological sedation, which directly affects the functional image. On another front, more rapid MRI sequences are now able to image the entire brain in much shorter time (3 seconds), decreasing the amount of time that a subject must remain still. Nevertheless, problems of motion sensitivity and a relatively confining environment will likely continue to be of particular concern in using MRI in the elderly for many years to come, despite the wealth of clinical information that MR scanning can provide.

Previous chapters review the use of MRI to image brain structure in geriatrics, as well as the use of PET and SPECT. In this chapter, we briefly describe the new fMRI techniques and then highlight many of the initial geriatric applications.

## ■ Magnetic Resonance Spectroscopy

Nuclear magnetic resonance (NMR), discovered in 1946, describes the fact that certain molecules are magnetic and resonate to specific radio frequencies depending on the molecule's magnetic elements and the chemical bonding of these elements (Kato et al. 1998). Magnetic resonance spectroscopy (MRS) exploits this phenomenon to detect the presence of various molecules in millimolar concentrations. Since 1946, MRS has been used mostly in chemistry research to analyze molecular structure. In 1978, Chance et al. first used *in vivo*  $^{31}\text{P}$  MRS in mouse brain, but it was not until the much more recent development of MRI that spectroscopic analysis became applicable for use in the human brain because the two techniques require basically the same hardware (Kato et al. 1998). Some of the molecules resolvable by MRS are involved in high-energy phosphate or membrane phospholipid metabolism, so a particular advantage of MRS is that it allows the noninvasive, *in vivo* measurement of tissue metabolites and steady-state metabolic processes (see Table 11–2).

### Basic Principles of Magnetic Resonance Spectroscopy

As mentioned above and discussed in the previous chapter on structural MRI, the isotopes of certain atoms are magnetic and spin about their axes. In a uniform magnetic field

**TABLE 11–2. Some general features of magnetic resonance imaging (MRI) spectroscopy**

Noninvasively measures tissue biochemistry
Relies on flipping nonwater hydrogen atoms or other magnetic atoms
Magnetic compounds identified by spectrographic peaks
Single voxel and metabolic spatial techniques available
Common types:
<sup>1</sup> H spectroscopy
<sup>31</sup> P spectroscopy
<sup>7</sup> Li spectroscopy
<sup>19</sup> F spectroscopy (i.e., fluorinated compounds such as fluoxetine hydrochloride [Prozac] and trifluoperazine hydrochloride [Stelazine])
Restricted to the study of mobile magnetic compounds
Receptor-ligand studies not currently possible
Limited spatial and temporal resolution
Resolution may improve with introduction of stronger MRI magnets

such as that produced by an MRI scanner, each magnetic isotope aligns in the direction of the magnetic field and spins at a rate specific to its type and chemical bonding pattern. In response to a magnetic pulse of specific frequency (Larmor frequency), a nucleus spinning at its Larmor frequency resonates; that is, it absorbs the energy of the pulse, and temporarily flips out of alignment with the magnetic field. As the flipped nucleus gradually relaxes back to its aligned state, it emits absorbed energy in the form of electromagnetic waves called free induction decay (FID). The concentration of the target nucleus is related to the intensity of its observed decay. The Larmor frequency for each nucleus depends not only on the identity of the isotope itself but also on that nucleus's local molecular magnetic environment as determined by its chemical bonding. Depending on this local environment, the resonant or Larmor frequency for a particular nucleus will shift (chemical shift) and produce a slightly different signal, thus allowing one to distinguish the presence of the same nucleus in different molecules.

The results of a spectrographic assay appear as a spectrograph of several peaks, each representing a particular molecule. Figure 11–1 illustrates an idealized <sup>1</sup>H MRS spectrograph and Figure 11–2, an actual spectrograph with accompanying structural MRI. The location of each peak corresponds to a specific molecule's Larmor frequency, and the area under each peak is proportional to the concentration of the metabolites in the target tissue.

Generally the concentrations of these molecules are so

small that many samples must be acquired and averaged to obtain enough signals for quantitative analysis. To achieve this repetition, one uses a spin-echo method, in which the radiofrequency signal is pulsed a second time after a period called the echo time (TE), and a second decay signal, the echo, is observed. One repeats this process over a period called the repetition time (TR) and averages the values of observed decay times (FID), or echoes.

Spectrographic assays can be localized to certain regions of the brain. The simplest and oldest method is to use a surface coil, which roughly targets cortical regions under the area of the scalp covered by the body of the coil itself (Charles et al. 1997). At least three techniques are used for targeting more focal, single-voxel regions such as a tumor or stroke: depth-resolved surface coil spectroscopy (DRESS), stimulated-echo method (STEAM), and image selected in vivo spectroscopy (ISIS) (Kato et al. 1998). For analyzing several regions of the brain simultaneously, one uses a method of multiple voxel localization called magnetic resonance spectroscopic imaging (MRSI) or chemical shift imaging (CSI) (Charles et al. 1997; Kato et al. 1998). With this method, one can even reformat the data to

produce an image of the spatial distribution of a particular metabolite in the brain.

### Complications of Magnetic Resonance Spectroscopy Data Analysis

Several inherent features of MRS make it difficult to obtain accurate measures of absolute concentrations. For example, signal peaks sometimes overlap, making it difficult to define an area under a specific peak. Differences in hardware conditions, even within the same scanner, such as the magnetic field drifting with time, mean that any MR analyses are relative and not absolute. In an attempt to correct for these complications, most spectrographic data on molecular concentrations are normalized to an internal (usually  $H_2O$ ) or external signal and/or expressed in terms of ratios to a metabolite whose concentration remains relatively constant in the brain, such as creatine. Finally, because research in neurochemistry has tended to focus on neurotransmitters and neuroreceptors at the expense of the neurometabolites detectable by MRS, and because the technical capabilities of in vivo MRS in humans are so new, MRS is still in its infancy. Many of the techniques for both data acquisition and data analysis have yet to be standardized. All of the issues above contribute to the considerable discrepancies in the results of many MRS studies. The highest hope for MRS in geriatric medicine seems to be its development as a diagnostic tool for differentiating early stages of Alzheimer's disease (AD) from other kinds of de-

mentia such as vascular dementia or Parkinson's dementia. These diagnoses are particularly difficult for the practitioner, and in fact, to date, AD can be definitively proven only by biopsy and postmortem pathological examination. A less invasive and more reliable in vivo diagnosis would guide both the differential treatment of these dementias and the development of drugs that could combat them in their early stages. For this reason, most MRS studies in the geriatric population have focused on comparisons between AD and other forms of dementia. After a cursory description of the main spectra and the metabolites they resolve, we proceed to a discussion of these studies.

### Different Magnetic Resonance Spectra and Their Neurochemical Correlates

**$^{31}P$  magnetic resonance spectroscopy.** In a phosphorus-31 magnetic resonance spectrograph of human brain, seven peaks typically appear, representing the seven most abundant nuclei in metabolites containing phosphorus: phosphomonoester (PME), inorganic phosphate (Pi), phosphodiester (PDE), phosphocreatine (PCr), adenosine diphosphate (ADP), and adenosine triphosphate (ATP), and nucleoside triphosphate (NTP).

- **Phosphomonoester:** The PME peak includes metabolites involved in membrane phospholipid synthesis such as phosphatidylcholine or phosphoethanolamine. The concentration of PME normally de-

creases with age but is elevated in early AD (Lorberbaum et al. 1998; Pettegrew et al. 1988).

- Inorganic phosphate (Pi): The Pi peak includes both  $\text{PO}_4^-$  and  $\text{PO}_4^{-2}$  from the dynamic equilibrium reaction  $\text{H}_2\text{PO}_4^- \rightarrow \text{HPO}_4^{-2} + \text{H}^+$ . Based on this reaction, one can calculate the intracellular pH of the target voxel from the specific chemical shift of this peak. pH has been found to increase in cases of chronic infarction, possibly because of the high pH of macrophages that gravitate to the site of a lesion (Ross and Michaelis 1994; Vion-Dury et al. 1994).
- Phosphodiester (PDE): The PDE peak, alternately, represents metabolites produced in membrane phospholipid degeneration such as glycerophosphotidylcholine and glycerophosphoethanolamine. It was once thought that the PME/PDE ratio represented membrane phospholipid turnover, but because of the complexities of determining the specific source of the PDE signal, this is no longer the case (Kato et al. 1998). The concentration of PDE normally increases with age.
- Phosphocreatine (PCr): PCr is a high-energy phosphate found in both brain and muscle. PCr can donate its phosphate group to ADP, thus helping replenish a cell's ATP. This probably explains the observed decrease in PCr levels in response to increased energy demand, such as with photic stimulation.
- Adenosine triphosphate (ATP): Concentration of ATP remains relatively constant in response to stimulation, but the chemical shift of these peaks can be affected by magnesium and lithium and has allowed assays of these nuclei (Gupta et al. 1984; Iotti et al. 1996; Kato et al. 1998; Ramasamy and Mota de Freitas 1989).

**<sup>1</sup>H magnetic resonance spectroscopy.** Because  $\text{H}_2\text{O}$  is the most abundant molecule in the body, its spectrographic peak normally obliterates the signals of those molecules containing hydrogen that appear in lesser concentrations. After one suppresses the huge signal for  $\text{H}_2\text{O}$ , five peaks generally appear: *N*-acetyl-L-aspartate (NAA), creatine (Cr)/phosphocreatine (PCr), choline (Cho), inositol, and lactate.

- *N*-acetyl-L-aspartate (NAA): NAA is a component of neurons but not glial cells. It is thought to be a marker of viable or functional neurons, and its concentration has been observed to decrease in conditions of neuronal death and degeneration such as stroke and AD (Charles et al. 1997; Kato et al. 1998).
- Creatine (Cr)/phosphocreatine (PCr): The Cr peak

contains both Cr and PCr. The sum of these molecules (Cr + PCr) was thought to remain relatively constant in the brain and has been used as an internal concentration standard for expressing concentrations of other metabolites as ratios (Kato et al. 1998; Lorberbaum et al. 1998).

- Choline (Cho): The choline peak includes signals from choline containing compounds such as phosphocholine and glycerophosphocholine, which are involved in membrane synthesis and breakdown, and to a lesser degree the neurotransmitter acetylcholine and its precursor choline.
- Inositol: The inositol peak contains *myo*-inositol, which is important in phospholipid metabolism and second messenger systems (Belmaker et al. 1990).
- Others: The excitatory neurotransmitters glutamate and aspartate and the inhibitory neurotransmitter  $\gamma$ -aminobutyric acid can be resolved by <sup>1</sup>H MRS, as can lipids. Because the fat surrounding the brain contains high concentrations of lipids, however, signals from these lipids outside the brain can easily contaminate the lipid peak in a spectrum.

**Lithium-7 and fluorine-19 spectra.** Because lithium and fluorine do not naturally appear in the human body but are components of many psychotropic drugs, spectra of these isotopes can be used for pharmacokinetic studies in patients treated with such drugs (Komoroski et al. 1994). Tables 11–3 and 11–4 provide chronological lists of <sup>31</sup>P MRS and <sup>1</sup>H MRS studies relevant to the field of geriatric neuropsychiatry.

## Normal Aging

In an <sup>1</sup>H MRS study of age-related changes in NAA, Cr + PCr, and Cho, Christiansen et al. (1993) examined four different brain regions: occipital, temporal and frontal lobes, and the basal ganglia, in eight healthy volunteers between the ages of 20 and 30 and eight healthy volunteers between the ages of 60 and 80. The researchers had expected elevated levels of NAA in the basal ganglia because this region has the highest density of neurons. Between brain regions of both groups, the only significant difference in metabolite concentrations was an increase in NAA in the occipital region of the younger group.

In a 1994 <sup>1</sup>H MRS study of age- and gender-related changes, Charles et al. examined 34 healthy volunteers (15 men, 19 women) between the ages of 21 and 75. They found no differences between men and women and generally lower levels of Cho, Cr, NAA, Cho/NAA, and Cho/Cr in white matter compared to levels in gray matter in all

**TABLE 11–3. Chronological table of phosphorus  $^{31}\text{P}$  magnetic resonance spectroscopy (MRS) studies relevant to geriatric neuropsychiatry (starting in 1989)**

Study	Subjects	Purpose	Results
Brown et al. 1989	17 control 17 AD 10 MSID	To examine phosphorus metabolism in groups with different dementias	% PME and PME/PDE increased in temporoparietal area of brains of patients with AD. Pi increased in AD. PCr/Pi increased in MSID.
Bottomley et al. 1992	11 AD 14 control	To see if phosphorus metabolism is altered in AD To combine MRI and MRS to attempt to get absolute values for volumes of brain	After correcting for atrophy, study found no change in any metabolites across groups.
Sappey-Marinier et al. 1992a	30 subjects with WMSH and no other significant neurological disease	To characterize cerebral oxidative phospholipid metabolism in WMSH	No change in PCr, PME, and PDE levels or ratios. Decrease in ATP/Pi in WMSH, inconclusive if this relates to ischemia.
Brown et al. 1993	18 MSID 21 control 19 AD	To test whether $^{31}\text{P}$ MRS can distinguish among patients with AD, those with vascular dementia, and control subjects	Patients with MSID had higher high-energy phosphate levels than did either those with AD or control subjects.
Longo et al. 1993	2 case studies of AD 6 control	To attempt to find objective marker of AD	PDE/ATP and PCr/ATP were elevated for patients with AD, but these results might be the result of noise effects or even normal aging. $^1\text{H}$ MRS on one patient with AD found lower NAA levels and increased Cho.
Murphy et al. 1993	9 AD 8 control	To examine differences in phosphorus metabolism between patients with AD and control subjects To see if that difference correlates with severity of AD Using PET, to examine how glucose metabolism is related to above changes To use MRI to correct for atrophy	Glucose metabolism decreased in patients with AD, but no change in Pi ratios or concentration between those with AD and control subjects or with severity of the disease.
Cuenod et al. 1995	24 mild AD 15 control	To look for changes in PME and PDE levels in early stages of AD	Increased levels of PME/Pi found in frontal regions of AD.
Pettegrew et al. 1995	7 AD active 5 AD placebo 21 control	To see if acetyl-L-carnitine helps symptoms, membrane phospholipid, and high-energy phosphate metabolism	Active treatment showed less symptomatic decline than with placebo. Baseline PME levels were lower in both AD groups than in control subjects. PME levels for the active treatment group increased. ATP and PCr increased in group given placebo.

Study	Subjects	Purpose	Results
Smith et al. 1995	17 mild-moderate AD elderly and young control	To examine differences between patients with AD and control subjects	PCr/Pi levels elevated in patients with AD compared with both groups of control subjects. No change found in PME nor PDE except as a feature of gender. PME and PME/PDE decreased in women patients with AD. PCr/Pi levels correlated with age in patients with AD and in young control subjects. Decreased PCr/Pi found in frontal lobe of patients with AD and control subjects.
González et al. 1996	16 mild-moderate AD 8 control	To find neuronal abnormalities early in course of AD	NTP and PCr found normal. Decreased levels of PDE/NTP in patients with AD. PME/PDE increased in patients with AD because of decrease in PDE.

*Note.* AD = Alzheimer's disease; Cho = choline; MRI = magnetic resonance imaging; MSID = multiple subcortical ischemic dementia; NAA = *N*-acetyl-L-aspartate; NTP = nucleoside triphosphate; PCr = phosphocreatine; PDE = phosphodiester; PET = positron-emission tomography; Pi = inorganic phosphate; PME = phosphomonoester; WMSH = white matter signal hyperintensities.

ages. They did find that the Cho, Cr, and NAA levels in the cortical and subcortical gray matter containing the caudate and putamen decreased with age. The authors point out that the reduction in metabolite concentrations in this region corresponds with previously reported age-related morphometric changes here also. Charles et al. address here an issue that is central to MRS data analysis, that is, the need to correlate “volumetric observations in MRI with metabolic observations in MRS” or more generally, correcting for the general atrophy of our brains as we age.

**<sup>31</sup>P magnetic resonance spectroscopy studies of brains of patients with Alzheimer's disease.** As mentioned above, most MRS studies in the geriatric population have sought to find alterations in metabolite concentrations specific to the most common types of dementia with the intention of 1) *understanding* the metabolic processes in each disease, 2) *diagnosing* dementia causes, and 3) *tracking disease progression and response to treatment*. One of the more promising findings so far involves alterations in PME and PDE levels in the brains of patients with AD that might distinguish AD from normal aging (Pettegrew et al. 1988). In a series of *in vitro* studies, Pettegrew et al. found that, in normal aging, PME levels decreased while PDE levels increased (Pettegrew et al. 1987, 1990), but that, in early AD, PME levels increased.

Because PME and PDE are involved in membrane phospholipid synthesis and breakdown, alterations of these metabolites suggest increased membrane turnover.

Brown et al. in 1989 replicated Pettegrew's finding *in vivo*. They observed elevations in percentage of PME and PME/PDE in the temporoparietal region significant enough to differentiate patients with AD from control subjects and those with multi-infarct dementia (MID). But, in 1992, Bottomley et al. found no such alterations in any metabolites (PCr/NTP, PCr/Pi, PDE/NTP, PME/NTP, Pi/NTP, PDE/PME) after correcting for the atrophy of the brains of their patients with AD, as measured by MRI. Murphy et al. in 1993 also found no changes in PME and PDE levels in patients with AD as compared with control subjects after correcting for atrophy. Later, in 1993, Brown et al. again found elevated PME levels in the frontal regions of brains of patients with AD compared with brains of control subjects and subjects with MID, but no change in the temporoparietal regions of all three groups. In 1995, Cuénod found increased levels of PME in the brains of patients with early AD, in agreement with Brown et al. and in disagreement with Bottomley et al., even after correcting for brain atrophy. Cuénod suggests that differences in the techniques of acquiring spectrographic data might actually account for the different results. Smith et al. in 1995 found no significant differences in PME or PDE between pa-

Study	Subjects	Purpose	Results
Sappey-Marinier et al. 1992b	7 control 7 stroke 7 WMSH	To test hypothesis of coexistent ischemia in brain infarcts and WMSH as evidenced by increased lactate levels  To test hypothesis that brain infarct and WMSH are associated with greater loss of neurons than other cells as evidenced by decrease in NAA	In patients with stroke, increased lactate and decreased NAA.  For patients with WMSH, no changes in proton metabolites except Cho, which was increased.
Ford et al. 1992	8 cerebral infarction 5 control	To investigate the time course and distribution of biochemical changes after stroke	6 patients had decreased NAA/PCr and NAA/Cr.  Greater decreases correlated with least recovery of function. Lactate was observed in infarcted region 9 and 11 days after stroke.
Christiansen et al. 1993	Healthy volunteers 8 in 20s and 30s 8 in 60s and 70s	To observe differences in NAA, Cr + PCr, and Cho in different brain regions (occipital, basal ganglia, temporal, frontal) in two different age groups	Within younger group, NAA was higher in occipital than other areas.  No other significant regional variations.  NAA levels were higher in occipital area in younger group compared with that in older.  No significant regional or age-related variation in T1 and T2 relaxation times.
Shiino et al. 1993	9 PDD 3 NPH 21 control, age 21–72	To investigate metabolic changes associated with dementia	No age-related changes in NAA/Cr in volunteer control subjects.  NAA/Cr reduced in PDD.  No reduction in NAA/Cr in NPH.
Charles et al. 1994	34 healthy volunteers (15 men, 19 women) between the ages of 21 and 75	To assess the effect of age and gender on brain metabolites	No differences between men and women.  NAA, Cho, Cr, Cho/NAA, and Cho/Cr were lower in white matter than in gray matter.  Cho, Cr, and NAA were lower in cortical and subcortical gray matter of older individuals.
Meyerhoff et al. 1994	8 AD 10 healthy control	To survey large sections of brains of patients with AD to see if cortical loss in AD measured in vitro is also detectable in vivo  To see if alterations in NAA levels in brains of patients with AD correlate with atrophy as estimated from structural MRI	NAA was lower throughout the white matter of brains of patients with AD. NAA/Cho was lower and the Cho/Cr higher in mesial gray matter of subjects with AD compared with that of control subjects.  Posterior section of centrum semiovale of brains of patients with AD showed increased Cho/Cr and Cho/NAA ratios with NAA/Cr unchanged between patients with AD and control subjects.
Christiansen et al. 1995	12 AD 8 control	To survey absolute differences in metabolite levels using the unsaturated water signal as an internal standard; also, with varied echo times and repetition times, to estimate the T1 and T2 relaxation times of the three metabolites	NAA concentration lower in patients with AD than in control subjects.  No significant difference found for any other metabolite ratios.  The only significant difference in signal ratios was that, at TE = 92 msec and TR = 1.6 seconds, the NAA/Cho ratio was lower in patients with AD.

Study	Subjects	Purpose	Results
Bowen et al. 1995	14 Parkinson's disease 13 healthy control	To determine whether the proton spectra from patients with clinically diagnosed Parkinson's disease differ from that of control subjects with respect to major cerebral metabolite resonances as well as lactate	No significant difference in NAA/Cr or NAA/Cho between patients with Parkinson's disease and control subjects. A significant increase was found in lactate/NAA for patients with Parkinson's disease compared with that for control subjects.
Shonk et al. 1995	65 AD 39 other dementias 10 FLD 98 medical patients without dementia 32 healthy control subjects	To distinguish patients with AD from those with other dementias and from the elderly without dementia	Reduced levels of NAA and increased levels of MI characterized AD. Patients with other dementias had reduced NAA, but normal MI. Using MI/NAA, patients with AD differed from normals, with 83% sensitivity and 98% specificity. Using MI/Cr, patients with other dementias were distinguished from those with AD and FLD with negative predictive rate of 80%, sensitivity of 82%, and specificity of 64%.
Constans et al. 1995	21 elderly control 8 WMSH 11 probable AD with WMSH 8 IVD with WMSH	To investigate the association of WMSH with changes in $^1\text{H}$ metabolites	Differences in regional metabolite levels were found within supraventricular brain of elderly control subjects. In patients with AD, extensive WMSHs showed a lower percentage of NAA and a higher percentage of Cho compared with contralateral normal-appearing white matter. In patients with IVD, extensive and large WMSHs were associated with a higher percentage of Cho and a lower percentage of Cr compared with contralateral normal-appearing white matter.
MacKay et al. 1996	14 AD 8 SIVD 18 elderly control	To study differences in neuron density (NAA), membrane phospholipid metabolites (Cho), and creatine-containing metabolites (Cr + PCr) in subjects with AD (SIVD) and elderly control subjects	Lower levels of NAA/Cho and NAA/Cr and higher levels of Cho/Cr in both gray and white matter in subjects with AD. Lower levels of NAA/Cho and higher levels of Cho/Cr in posterior gray matter of subjects with AD. Subjects with SIVD had lower gray and white matter NAA/Cr levels. NAA/Cr level was lower in frontal white matter of subjects with SIVD compared with control subjects.

Study	Subjects	Purpose	Results
Parnetti et al. 1996	6 DAT 6 AAMI 6 cognitively healthy control	To examine neuroanatomical (MRI), perfusional (SPECT), and neurochemical ( $^1\text{H}$ MRS) differences among groups	Lower NAA concentration in brains of patients with DAT and AAMI compared with that in control subjects. Mean inositol concentration was higher in brains of patients with DAT than in brains of control subjects. MRI showed reduced hippocampal formation in patients with DAT and those with AAMI. SPECT showed frontal, temporoparietal, and occipital hypoperfusion only in patients with DAT.
Kattapong et al. 1996	10 DAT 8 vascular dementia	To identify biochemical differences in brain tissue between patients with DAT and those with vascular dementia	NAA/Cr and NAA/Cho were lower in regions of subcortical white matter in patients with vascular dementia compared with those with DAT.
Frederick et al. 1997	47 AD 16 control	To test the hypothesis that differences in MRS metabolite resonance ratios are more pronounced in the temporal lobe than in the parietal lobe	No significant differences in parietal lobe metabolite ratios between patients with AD and control subjects, but a decrease was found in NAA/Cr in temporal lobe of the AD group compared with control subjects.
Parnetti et al. 1997	13 AD 7 control	To evaluate the pattern of $^1\text{H}$ MRS in the gray and white matter of patients with AD compared with that of control subjects	In patients with AD, NAA levels decreased in both gray and white matter, and MI increased in gray matter. The gray matter NAA/MI ratio clearly separated the two groups.

*Note.* AAMI = age-associated memory impairment; AD = Alzheimer's disease; Cho = choline; Cr = creatine; DAT = dementia of the Alzheimer type; FLD = frontal lobe dementia; IVD = ischemic vascular dementia; MI = *myo*-inositol; MRI = magnetic resonance imaging; NAA = *N*-acetyl-L-aspartate; NPH = normal pressure hydrocephalus; PCr = phosphocreatine; PDD = primary degenerative dementia; SIVD = subcortical ischemic vascular dementia; SPECT = single photon emission computed tomography; TE = echo time; TR = repetition time; WMSH = white matter signal hyperintensities.

tients with AD and elderly control subjects but surprisingly did find decreased levels of PME and increased levels of PDE in women with AD as compared with men with AD. They found similar but not as pronounced differences in the elderly control group. In 1996, González et al. found no changes in absolute PME and PDE levels between patients with AD and control subjects but did find significantly decreased levels of PME/PDE, probably as a result of decreases in overall level of PDE. González et al. also point out that the discrepancies between their study and previous ones might be attributable to technical issues of data acquisition or analysis.

**Conclusions of magnetic resonance spectroscopy and aging.** Obviously, the field of MRS con-

tinues to evolve as researchers further develop techniques of data acquisition and interpretation. Spectroscopy offers the enormous potential of providing noninvasive information about brain neurochemistry in a host of diseases involving a geriatric population. Most MRS studies in the geriatric population have sought to find alterations in metabolite concentrations specific to the most common types of dementia with the intention of 1) *understanding* the metabolic processes in each disease, 2) *diagnosing* dementia causes, and 3) *tracking disease progression and response to treatment*. To date, no firm conclusions have been reached in any of these three areas, although progress is rapid in all. MRS cannot at this time be used to diagnose a dementia. Ongoing studies will soon reveal whether MRS has utility as a marker for disease progression, which would supple-

ment clinical ratings. The next few years should see many studies assessing the sensitivity and repeatability of spectroscopy in understanding, diagnosing, and following neuropsychiatric diseases of the elderly.

## ■ Functional Magnetic Resonance Imaging

### Blood Oxygen Level–Dependent Functional Magnetic Resonance Imaging

Blood oxygen level–dependent (BOLD)-fMRI is currently the most commonly used fMRI technique (Table 11–5). For BOLD imaging, the MRI scanner is tuned to resonate and image hydrogen atoms as in conventional MRI; however, T2\*-weighted images are performed, which take advantage of the fact that deoxygenated hemoglobin is magnetic, whereas oxygenated hemoglobin is not (Kwong et al. 1992; Turner et al. 1991). Because of the magnetic properties of the unflipped magnetic deoxyhemoglobin molecule, which causes rapid dephasing, T2\* signal is retained longer in a region when it has more oxygenated blood compared with when there is less oxygenated blood. An activated brain region has relatively more oxygenated blood compared with when it is resting. Thus, an area with more oxygenated blood will show up more intense on T2\*-weighted images compared to when there is less oxygenated blood around. With this technique, it is assumed that when a brain region is active, arterial oxygenated blood will redistribute and increase to this area (Sokoloff 1977, 1978). Importantly, there is a time lag of 2–6 seconds between when a brain region is activated and when blood flow increases (Kwong et al. 1992; Turner et al. 1991). During the initial fraction of a second after increased neuronal activity, the activated areas experience a relative decrease in oxygenated blood as oxygen is extracted by the active regional neurons. Afterward, the amount of blood flowing to the entire area far outweighs the amount of oxygen that is extracted so that the level of oxygenated blood is now higher. Some have said that the brain floods the entire garden (region) for want of one thirsty flower (a small group of active neurons). Although new MRI machines can acquire images every 100 msec with echoplanar imaging, a type of rapid acquisition, this predictable but time-varied delayed onset of the BOLD response limits the immediate temporal resolution to several seconds instead of the 100-msec potential. In the future, researchers may be able to improve the temporal resolution of fMRI by measuring the initial decrease in oxygenated blood rather than the later flood of oxygen (Menon et al. 1995). Additionally, many researchers are us-

ing BOLD fMRI to look at brain changes after a single event rather than a repeated task over several seconds. Single-event MRI may offer improved temporal resolution.

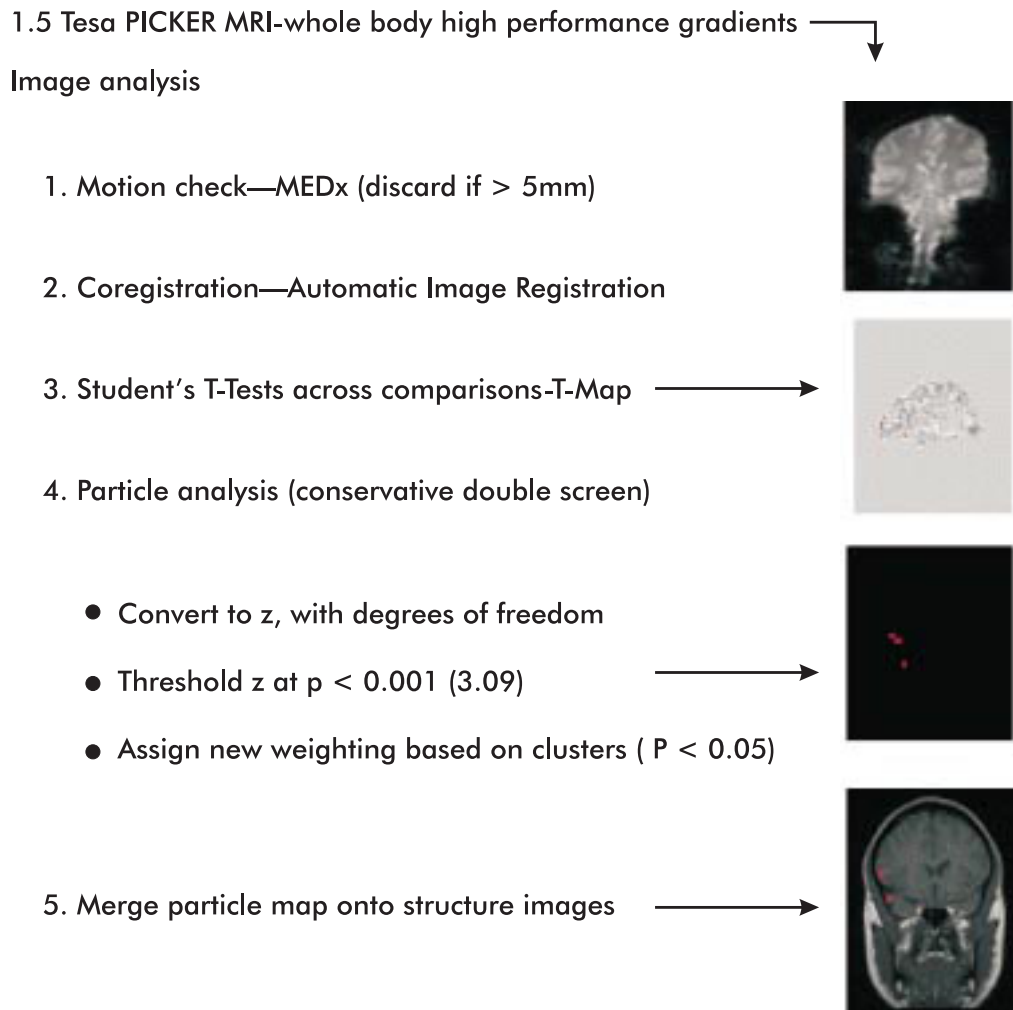

BOLD fMRI is a relative technique in that it must compare images taken during one mental state to another to create a meaningful picture. Because images are acquired very rapidly (e.g., a set of 30 coronal brain slices every 3 seconds is commonly done at the Medical University of South Carolina [MUSC]), one can acquire enough images to measure the relative differences between two states to perform a statistical analysis within a single individual. Ideally, these states would differ in only one aspect so that everything is controlled for except the behavior in question. BOLD fMRI paradigms generally have several periods of rest alternating with several periods of activation. Images are then compared over the entire activation to the rest periods. Images obtained over the first 3–6 seconds of each period are generally discarded because of the delay in hemodynamic response. Alternating paradigms are used because the signal intensity generated by the MRI scanner drifts with time. Typically, one compares activity between task and rest and then generates a statistical map of regions that are significantly changed during the task. This statistical map is then merged onto a structural MRI scan obtained in the same slices (see Figure 11–3).

With current technology, BOLD fMRI is best used for studying processes that can be rapidly turned on and off, such as language, vision, movement, hearing, and memory.

**TABLE 11–5. Blood oxygen level–dependent (BOLD) functional MRI (fMRI)**

Based on
<ul style="list-style-type: none"> <li>• Differential magnetic properties of deoxyhemoglobin and oxyhemoglobin</li> <li>• Coupling of oxygenated blood flow and neuronal activity</li> </ul>
High spatial and temporal resolution
2- to 6-second delay in blood flow response limits optimal temporal resolution
With rapid scanning, one compares images taken during active and rest states within an individual within a single session
Inferior frontal and temporal areas vulnerable to air-tissue artifacts
Very sensitive to movement and thus has not been used much so far in geriatric populations
Technique has good potential to

**FIGURE 11–3.** An outline of the image analysis steps used in blood oxygen level–dependent functional magnetic resonance imaging analysis.

The true power of BOLD fMRI for examining subtle mental processes was demonstrated in the study by Whalen and colleagues (1998). They used a backward masking procedure to present three alternating conditions to 10 subjects: 1) a baseline condition, in which subjects would see a “+” sign; 2) a “happy” (H) condition, in which subjects would see repeated presentations of 33 msec of a happy face followed by 167 msec of a neutral face; and 3) a “fear” (F) condition, in which subjects would see repeated presentations of 33 msec of a fearful face followed by 167 msec of a neutral face. Here, fearful and happy faces were presented in such a way that 8 of the 10 participants could not identify them. Despite their lack of conscious awareness of the emotive faces, subjects had relatively increased amygdala activation with fearful faces and relatively decreased amygdala activation with the happy faces, indicating that they must have processed the information at an unconscious level.

Unfortunately, BOLD fMRI is sensitive to movement so that tasks are limited to those without head movement, including speaking, which, of course, also severely limits its use in patients with dementia or those who are agitated. (With single-event fMRI, however, one cannot image during movement [speech], but because there is a 3–6 second delay in blood flow to the region, instead one must image after the task, when movement stops.) Another limitation of BOLD fMRI is that artifacts often appear on scans in brain regions that are close to air (i.e., sinuses), which cause problems in observing regions at the base of the brain such as the orbitofrontal and mediotemporal cortices. Sometimes observed areas of activation may be located more in large draining veins rather than directly at a capillary bed near the site of neuronal activation, which also complicates the interpretation of these scans (Moseley et al. 1996).

Neurologists and neurosurgeons are beginning to use

this technique clinically to noninvasively map language, motor, and memory function in patients undergoing neurosurgery (Binder 1997; Binder et al. 1996; Bookheimer 1996; Jack et al. 1994). Currently, there are no indications for BOLD fMRI in clinical psychiatry, although this technique holds considerable promise for unraveling the neuroanatomical basis of neuropsychiatric diseases. BOLD fMRI may be of potential help in sorting out diagnostic heterogeneity and treatment planning in the future.

A large literature documents that brain blood flow at rest and in response to cortical tasks declines with age. Several PET studies have reported that brain blood flow activation is reduced in elderly subjects who are shown a checkerboard or asked to move their fingers (Melamed et al. 1980). Ross and colleagues used fMRI to test this hypothesis that blood flow response to tasks declines with increasing age (Ross et al. 1997). They used echoplanar BOLD fMRI imaging of changes as a result of photic stimulation in 9 elderly subjects (average age 71) and 17 young control subjects (average age 24). The magnitude of the BOLD response was reduced in the elderly subjects (2.5% increase in the elderly compared with an average 4% increase in the younger group).

All of these activation studies employ some aspect of the peripheral nervous system to elicit brain changes. Our group at MUSC has recently been able to stimulate the brain directly and noninvasively with transcranial magnetic stimulation (TMS), thus bypassing the peripheral nervous system, while also acquiring BOLD fMRI responses. Although this work is still in progress, there does not appear to be a decline with age (Figure 11–4). An important confound is that the distance from the coil to cortex matters a great deal in TMS (the magnetic field falls off logarithmically), and this distance does increase with age. More work is necessary with this novel combination method before it can be reliably used to test the generally accepted notion that a mild decline in blood flow response to activation does occur as people age.

### Perfusion Functional Magnetic Resonance Imaging

Two fMRI methods have been developed for directly measuring cerebral blood flow. The first method, called intravenous bolus tracking, relies on the intravenous injection of a magnetic compound such as a gadolinium-containing contrast agent and measuring its T2\*-weighted signal as it perfuses through the brain over a short period of time (Belliveau et al. 1991; Rosen et al. 1991). Areas perfused with the magnetic compound show less signal intensity as the compound creates a magnetic inhomogeneity that de-

creases the T2\* signal. The magnetic compound may be injected once during the control and once during the activation task, and relative differences in blood flow between the two states may be determined to develop a perfusion image; alternatively, one can measure changes in blood flow over time after a single injection to generate a perfusion map. Belliveau et al. (1991) used the technique to create the first functional magnetic resonance maps of human task activation using a visual stimulation paradigm. They imaged the occipital lobe after injecting gadolinium–diethylenetriamine pentaacetic acid once during darkness and again during a flashing light to map the visual response. They made a statistical comparison between images obtained during visual stimulation versus those obtained during darkness to generate an image.

Although gadolinium-based contrasts are not radioactive, the number of boluses that can be given to an individual is limited by the potential for kidney toxicity with repeated tracer administration. Also, this technique generates a map of only relative cerebral blood flow, not absolute flow, as in the technique described below. Several groups have used gadolinium bolus perfusion MRI in elderly subjects, with promising initial results. González and colleagues (1995) performed fluorodeoxyglucose PET (measuring glucose metabolism) and then in the same 10 subjects assessed relative regional perfusion using fMRI. The subjects had a range of diagnoses from AD (6) to Pick's disease (1) and primary progressive aphasia (1). These researchers found that abnormal areas of metabolism also had abnormal flow as measured by the new fMRI technique.

Mattay and colleagues (1996) performed an exploratory perfusion fMRI study in 4 young control subjects, 6 psychiatrically healthy elderly control subjects (average age 71 years), and 6 matched elderly patients with senile dementia, Alzheimer type. All subjects also received perfusion SPECT. The perfusion fMRI scans were of good quality with little motion artifact (motion artifact was seen in the SPECT studies and was likely a result of a longer acquisition time). All subjects with senile dementia, Alzheimer type, showed decreased perfusion in the temporoparietal cortex. Unfortunately, the perfusion fMRI also showed decreased cortical activity in 2 elderly healthy control subjects (false-positives). In a more formal study, Harris and colleagues (1996) used bolus fMRI to study 13 patients with AD and 13 matched control subjects. Relative activity in temporoparietal cortex was decreased in the group with AD. Relative motor cortex activity did not differ. These two studies demonstrate that bolus perfusion MRI likely can be used to differentiate brain activity in patients with AD compared with that in control subjects. Larger pro-

**FIGURE 11-4.** Brain activity during transcranial magnetic stimulation (TMS)/functional magnetic resonance imaging over motor cortex from work done at the Medical University of South Carolina. Note in the graph on the *bottom* no significant decline with increased age across a small cohort. This is contrary to other studies, which have found that blood flow response to stimulation declines with increasing age. “WILL” denotes activity during volitional or willful movement.

spective studies in a more heterogeneous clinical sample are needed before making a final conclusion about the ultimate clinical utility of this form of MRI to diagnose and monitor AD.

Arterial spin labeling is a T1-weighted noninvasive technique in which intrinsic hydrogen atoms in arterial water outside of the slice of interest are magnetically tagged (“flipped”) as they course through the blood and are then imaged as they enter the slice of interest (Table 11-6) (Bohning et al. 1996a, 1996b; Warach et al. 1994). In contrast to the gadolinium bolus perfusion method described above, arterial spin labeling is noninvasive, does not involve an intravenous bolus injection, and can thus be repeatedly performed in individual subjects. Also, absolute regional blood flow can be measured, which cannot be eas-

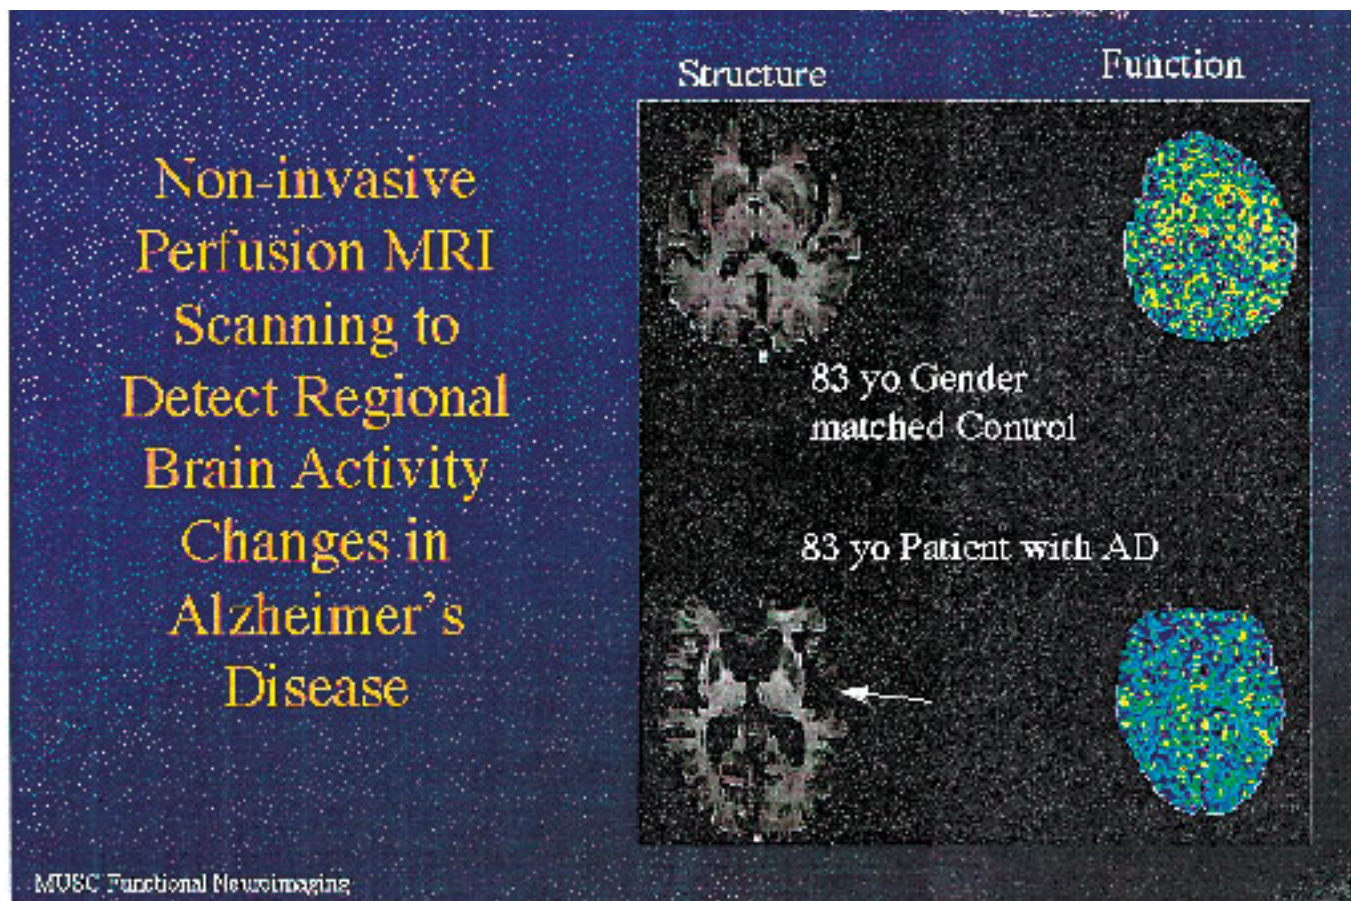

**TABLE 11-6.** Arterial spin-labeling functional magnetic resonance imaging (fMRI)

Provides for magnetic tagging of hydrogen atoms as they course through the blood and imaging them as they course through the slice of interest
Measures absolute blood flow
Directly compares data taken in different imaging sessions
Is suited to measuring state differences between groups (e.g., patients with Alzheimer’s disease versus psychiatrically healthy control subjects)

ily measured with SPECT or BOLD fMRI and which requires an arterial line with PET. Because absolute information is obtained, cerebral blood flow can be serially measured over separate imaging sessions, such as measuring blood flow in subjects with bipolar disorder as they course through different disease states (Speer et al. 1997). Absolute blood flow information may be important in imaging such processes as anxiety, which may be hard to turn on and off. For instance, in patients with AD, a medication-free cognitive task may be imaged on one day, and performing the same task following a single dose of a medication may be imaged on the next day. Comparing these separate tasks in different imaging sessions would not be possible with BOLD fMRI. Figure 11-5 shows an example of the arterial spin-labeling technique from MUSC as applied to understanding the pathological changes in advanced AD.

Our group at MUSC has had difficulty implementing

this arterial spin-labeling perfusion fMRI technique to diagnose AD as a result of the low signal-to-noise ratio of this tool, although we are hopeful that better analysis of the time curves will improve our data (Mirski et al. 1998). Sandson and colleagues recently successfully demonstrated that their version of this technique revealed differences in blood flow in 11 patients with AD compared with 8 psychiatrically healthy age-matched control subjects (Sandson et al. 1996). Further, they found that parieto-occipital hypoperfusion correlated with dementia (i.e., the more severe the dementia, the less blood flow in this region). It thus now remains for research groups to refine this technique and see if it can detect more subtle brain changes in early AD or even before symptoms manifest. This technique thus offers much promise in dementia diagnosis and follow-up because during one MRI scanning session one can accurately detect blood flow changes resulting from ischemia and measure brain volume in key structures such

**FIGURE 11-5.** A transverse structural magnetic resonance imaging (MRI) scan (*left*) and spin-labeled perfusion functional MRI (*right*) from a psychiatrically healthy control subject (*top*) and patient with Alzheimer's disease (AD) (*bottom*). Note the atrophy in the brain of the patient with AD as well as the decreased perfusion both globally and in parietal cortex. yo = year old. *Source.* From Mirski D, Greenshields AJ, Mintzer J, et al.: "Perfusion Studies of Patients with Alzheimer's Disease." Abstract presented at the Annual Meeting of the American Association of Geriatric Psychiatry, San Diego, CA, June 1998.

as the hippocampus, while at the same time detecting perfusion defects associated with classical AD, all with the elegance of 1-mm resolution. Although there is currently no clinical indication for this MRI perfusion technique, it may soon be used clinically to help characterize the different stages of acute ischemic stroke (Fisher et al. 1995).

## Summary

Functional MRI scanning is an area in its infancy. However, already it is apparent that fMRI can noninvasively provide several types of information that will undoubtedly be helpful in understanding and treating neuropsychiatric diseases in later life. MRS is still unproven but promises to serve as a noninvasive marker of disease progression in AD. An explosion of BOLD fMRI studies is mapping which brain regions are involved in performing different cognitive tasks. Most of this work is initially focusing on healthy young adults. Work in the next few years will likely begin addressing how the brain changes over time and whether the general conclusions about brain mapping drawn from young cohorts also apply to the elderly. Perfusion MRI has already been shown to distinguish subjects with AD from those with other forms of dementia. Widespread adoption of this tool in diagnosing and monitoring treatment awaits larger studies showing clinical utility and cost-effectiveness.

Although these advanced techniques have a limited role now, over the next few years these methods likely will become increasingly more a part of general clinical practice, provided that minor technical hurdles are overcome and that the early studies show that MRI can truly make a cost-effective difference in clinical care.

# Quantitative Electroencephalography

*Neurophysiological Alterations in Normal Aging and  
Geriatric Neuropsychiatric Disorders*

Daniel P. Holschneider, M.D.

Andrew F. Leuchter, M.D.

**E**lectroencephalography (EEG) is the oldest form of functional brain imaging. It has several advantages over newer forms of functional imaging, such as positron-emission tomography (PET) or single photon emission computed tomography (SPECT): EEG is noninvasive, inexpensive, and portable, and it can provide images based on less than 1 second of data. It also provides direct information about the functional integrity of fiber tracts, without the risk of exposure to ionizing radiation.

The central limitation of EEG has been the difficulty in relating potentials measured at the scalp surface to underlying brain physiology. Although most of the brain's energy metabolism is devoted to the production of electrical gradients and signals, brain electrical activity traditionally has been only a dim reflection of brain perfusion, metabolism, or structural integrity.

Over the past several years, significant advances have been made in our understanding of the relationship among

H.), research grant MH40705 and Research Scientist Development Award MH01165 from the National Institute of Mental Health (to A. F. L.), and the UCLA Alzheimer's Disease Center from the National Institute on Aging (Grant P30 AG10123-05, to A. F. L.).

brain energy metabolism, structure, and electrical signal production. Driven by widespread availability of inexpensive microcomputers, quantitative EEG (QEEG) has supplanted conventional EEG in research laboratories and many clinical settings. Studies correlating alterations in electrical activity with changes in perfusion and metabolism, or with structural disease, have significantly advanced methods for QEEG signal analysis. New algorithms have established QEEG as a reliable, noninvasive method of brain imaging with significant clinical utility. In this chapter, we review the history of EEG and QEEG and discuss their potential uses in geriatric neuropsychiatry.

## ■ History of Electroencephalography

EEG was popularized in the early 20th century by a psychiatrist, Dr. Hans Berger, who demonstrated changes in the EEG with arousal, anxiety, and other emotions and activities. Enthusiasm for EEG was supported by Berger's study of the EEGs of institutionalized patients (Berger 1937), many of whom showed distinct abnormalities (particularly diffuse slowing).

Berger's suppositions about the information contained in brain electrical activity were correct, but his technology was inadequate to decode the complex information embedded in the EEG signal. Berger used a double-coil galvanometer whose oscillations moved a mirror, thereby deflecting a beam of light, which traced the EEG signal on photographic paper (Gloor 1969). Grass and Gibbs performed the first QEEG analysis in 1938, but their mechanical Fourier transform (using a rotating drum) was too cumbersome and unreliable to process large volumes of data or multiple channels simultaneously. The development of techniques through pen-and-ink recorders, and then mechanical frequency analyzers, did not provide the tools necessary to decode the complex information contained in the EEG. As a result, researchers struggled with a central irony: although most of the brain's energy metabolism was devoted to the production of electrical potentials, researchers could not realize Berger's dream of studying brain processes, and particularly cognitive functions, using EEG. As a result, the applications for EEG in neuropsychiatry have traditionally been limited.

## ■ Conventional Electroencephalography

### Indications for Conventional Electroencephalography

Conventional EEG has several clinical applications in psychiatric practice, primarily in the evaluation of disorders at

the interface between psychiatry and neurology. First, EEG is useful for distinguishing psychiatrically healthy elderly from those with possible dementia. The EEG of a psychiatrically healthy elderly subject may differ little from that of a psychiatrically healthy young adult (Hubbard et al. 1976; Hughes and Cayaffa 1977; Katz and Horowitz 1982). Most reports, however, suggest that, beginning in the fifth or sixth decade, one observes a decrease of 0.5–1.0 Hz in the mean frequency of the posterior dominant ("alpha") rhythm (Busse 1983; Kanowski 1971; Obrist and Busse 1965; Roubicek 1977), decreased reactivity of posterior dominant rhythm to eye opening (decreased alpha blocking) (Andermann and Stoller 1961), increased theta slow-wave activity (F. A. Gibbs and Gibbs 1951; Obrist 1979), and focal slowing, primarily in the left anterotemporal region. Focal slowing has been reported in 17%–59% of psychiatrically healthy elderly subjects (Helmchen et al. 1967; Hughes and Cayaffa 1977; Katz and Horowitz 1982; Obrist and Busse 1965; Otomo and Tsubaki 1966; Soininen et al. 1982; Torres et al. 1983; Visser et al. 1987), but, if normal, it should be intermittent and never exceed 25% of the EEG recording. Similarly, although the posterior dominant rhythm may slow somewhat, it should remain above 8 Hz in the waking state (Obrist 1979; Oken and Kaye 1992). Some researchers have noted a slight increase in high frequency (beta) activity with aging (E. Gibbs et al. 1950; Matousek et al. 1967; Mundy-Castle 1951; Obrist 1954), whereas others have found a decline in beta activity in psychiatrically healthy elderly after the sixth decade (Busse and Obrist 1965; Obrist 1976; Schlagenhauff 1973; Wang and Busse 1969).

These findings contrast with those from patients with dementia. EEG abnormalities in dementia were first reported by Berger (Berger 1937), who described gross slowing of the dominant frequency. For almost 40 years after Berger's initial reports, EEG studies of dementia described decreases in the frequency, quantity (Stoller 1949), and reactivity of the alpha rhythm (Andermann and Stoller 1961; Dejaiffe et al. 1964), as well as an excess of theta and delta slow-wave activity (McAdam and Robinson 1956; Weiner and Schuster 1956). Early reports suggested that only patients with moderately advanced dementia could be distinguished from psychiatrically healthy elderly subjects because normal EEGs were the rule in patients with the early stages of dementia (Gordon and Sim 1967; Loeb 1980; Weiner and Schuster 1956). More recently, however, it has been shown that a majority of patients with dementia have abnormal EEGs, and that fully half of individuals with equivocal impairment (Mini-Mental State Exam [MMSE] scores  $\geq 24$ ) show abnormalities (Folstein et al. 1975; Leuchter et al. 1993a). The high prevalence of abnormali-

ties even in the early stages of the illness increases the diagnostic usefulness of the test.

Conventional EEG is a nonspecific indicator of the type of dementia. Focal abnormalities are reported to be more common in patients with vascular dementia (74% of patients) than in those with primary degenerative dementia (19% of patients) (Dejaiffe et al. 1964; Harrison et al. 1979; Logar et al. 1987; Roberts et al. 1978), but this finding is of limited diagnostic usefulness. Furthermore, some patients will have both illnesses, and their coexistence can be difficult to detect (Ettlin et al. 1989). Bilateral paroxysmal activity occurs in approximately 25% of patients with either vascular or primary degenerative dementia (Dejaiffe et al. 1964; Fortin 1966; Liddell 1958). Bifrontal, repetitive sharp waves or triphasic waves are seen in a majority of patients with Creutzfeldt-Jakob disease in early stages of the illness (Aguglia et al. 1997; Burger et al. 1972; Chiofalo et al. 1980; Steinhoff et al. 1996) but also are seen in a variety of toxic or metabolic dementias. The increase in focal abnormalities seen in vascular dementias, the low-amplitude background activity of Huntington's disease (Margerison and Scott 1965; Oltman and Friedman 1961; Scott et al. 1972), and the well-preserved posterior dominant background rhythm of Pick's disease (Groen and Endtz 1982; Johannesson et al. 1977; Tissot et al. 1975) are characteristic for groups of patients but have not proven sufficiently specific to allow confident diagnostic classification of individual subjects.

The abnormalities found in patients with dementia have not only diagnostic but also prognostic significance. These abnormalities identify the subgroup of patients who are at greatest risk for functional decline (Leuchter et al. 1994d, 1994e), and the degree of EEG slowing is the single best predictor of 1-year mortality in patients with dementia (Kaszniak et al. 1978).

A second illness in which EEG has a useful diagnostic role is delirium. Excessive slowing is seen almost universally in patients with delirium (G. Engel and Romano 1959), making EEG a useful physiological tool to support the diagnosis. More importantly, EEG may be used to monitor recovery because the degree of slowing is an indicator of the severity of the encephalopathy, and slowing resolves in response to effective interventions (Brenner 1991; Romano and Engel 1944). In cases in which mental status examination is equivocal, or difficult to perform (such as in a patient on a ventilator or with aphasia), such physiological testing can be useful for monitoring the resolution of the delirium. Distinguishing patients with depression or the changes of normal aging from those with delirium has been reported not to be problematic because of the severity of the abnormalities commonly seen in delirium (Brenner 1991; G. Engel and Romano 1959; Rabins and Folstein 1982).

The evaluation of late-onset seizures is not uncommon: the elderly may account for one-quarter of the cases of new-onset epilepsy (Sander et al. 1990), most commonly in association with stroke, trauma, mass lesions, and toxic metabolic disorders (Ettinger and Shinnar 1993; Luhdorf et al. 1986a, 1986b; Sung and Chu 1990). The prevalence of seizures in patients with Alzheimer's disease (AD) has been estimated at 3%–17% (Burns et al. 1991; Hauser et al. 1986; Mendez et al. 1994). The EEG may be used to confirm the presence of epileptiform discharges and to help establish the type of seizure disorder. It cannot, however, rule out a seizure disorder because a significant proportion of patients with late-onset seizure disorders have normal EEGs (estimated at 10%–47%, depending on etiology of the seizure and the time of recording on follow-up) (Ahuja and Mohanta 1982; Carney et al. 1969; da Silva et al. 1992; Luhdorf et al. 1986a, 1986b). Even when epileptiform abnormalities (i.e., spikes or spike-and-wave complexes) are detected, a diagnosis of a seizure disorder is not certain because these abnormalities generally are *interictal* in nature (i.e., not contemporaneous with an actual seizure). In some brain areas (such as occipital cortex), interictal abnormalities may have a low correlation with clinical seizures (Niedermeyer and Lopes da Silva 1987). In other cases, renal failure or degenerative brain disease can lead to the development of generalized sharp waves or spike foci that have a low association with clinical seizures. To be certain of the diagnosis, long-term observation with ambulatory or telemetered EEG with video monitoring may be necessary to capture an episode of behavioral disturbance and the attendant changes in brain electrical activity. In all cases, seizures are diagnosed on the basis of clinical presentation (Thomas 1997).

Conventional EEG has been found to be normal in a large proportion of subjects with depression (60%–76%) (Heyman et al. 1991; Leuchter et al. 1993a). Abnormalities, when they are found, are usually mild. A normal EEG may be useful in distinguishing patients with pseudodementia from those with advanced dementia. However, conventional EEG is of limited use in distinguishing among depression, early dementia, and states of depression superimposed on an underlying dementia. In fact, many patients who have cognitive complaints and a primary diagnosis of depression also have abnormal conventional EEGs (Leuchter et al. 1993a).

### Limitations of Conventional Electroencephalography

At least three factors limit the applications of conventional EEG in psychiatric practice. First, the EEG is a complex

test that is not readily subject to interpretation by most physicians. A significant degree of training is necessary to develop proficiency at identification of abnormalities and in distinguishing abnormalities from artifact. Second, even among skilled interpreters, there is an inherent problem of the limited reliability of qualitative interpretation. Different electroencephalographers (or a single electroencephalographer on different occasions) yield different interpretations of the same test a disturbingly high proportion of the time (Woody 1966, 1968). Third, for certain types of EEG activity, no consensus has been reached on the definitions of the upper and lower limits of normality. For example, excessive slow-wave activity in the EEG is a common finding in the elderly who are organically impaired and suggests the presence of either dementia or delirium. No well-established guidelines exist, however, for determining when slow-wave activity is excessive. Electroencephalographers may differ on how much slow-wave activity is acceptable at any given age. Even with general agreement, it is difficult to standardize such agreement among physicians (particularly those who do not work in the same facility) and to determine the sensitivity and specificity of the qualitative finding of “excessive slowing” in detecting brain disease. This lack of standardization also has hampered research efforts.

## Quantitative Electroencephalography

QEEG analysis minimizes or even eliminates some of the limitations of conventional EEG. After a brief discussion of the technical aspect of QEEG, the clinical applications of the technique are discussed below.

### Description of the Quantitative Electroencephalography Technique

Conventional EEG is rapidly yielding to QEEG, in which on-line digitization of the signal and recordings onto magnetic or optical media replace analogue pen-and-ink recordings. As short a time as 15 years ago, quantitation commonly was performed with a roomful of costly mini-computers. Starting in the mid-1980s, coincident with the wide availability of low-cost microcomputers, QEEG began to flourish and now is performed by academic and community-based physicians.

QEEG data are sampled at rates of at least 100 points per channel per second, and the analogue waveforms may be displayed in real time from these digital data either through a polygraph interface on paper or on a high-resolution video display terminal. Either of these display

methods allows for conventional EEG interpretation of the digital recording.

Once digital data are recorded, the data can be transformed from the domain of amplitude versus frequency, in which they are recorded, to the domain of energy (or “power”) versus frequency band (Figure 12–1). The process of this transformation is known as spectral analysis and commonly is achieved by processing the data through an algorithm known as Fourier transform. This algorithm is based upon the assumption that the complex waveform of the EEG may be modeled as the summation of a series of sinusoidal waveforms of different amplitudes and frequencies. A segment (or epoch) is decomposed into a series of simpler sine wave components, and the power at each frequency band for that epoch can be calculated from the characteristics of the sine wave at that frequency. Power (or amplitude<sup>2</sup>) can be calculated for frequencies up to half the value of the sampling rate (the so-called Nyquist frequency).

Power estimates can be calculated for a second of data or even less, although the representative nature of such a small epoch for that individual’s resting brain electrical activity is questionable. Commonly, the power in a series of frequency bands (the so-called power spectrum) is calculated for 20–30 seconds of data, either as discrete smaller

**FIGURE 12–1.** *Panel 1a:* Posterior dominant rhythm from a psychiatrically healthy subject, showing a sinusoidal 10-Hz rhythm. *Panel 1b:* Spectral analysis of this signal showing a peak of power at 10 Hz. *Panel 2a:* Posterior dominant rhythm such as that seen in a patient with dementia. Although some retained 10-Hz activity is seen, a number of intermixed slow waves are also present. *Panel 2b:* Spectral analysis of this more complex signal, showing peaks of power in the delta (0–4 Hz), theta (4–8 Hz), and alpha range.

epochs averaged together or as a single epoch.

QEEG overcomes several of the limitations of conventional EEG. Because it yields quantitative measurements of the frequency content of any segment of EEG, it provides much more reliable information regarding the amount of slow-wave activity in a record. These quantitative estimates not only minimize errors in judgment but also yield reproducible estimates that can be compared over time in a single individual.

The QEEG procedure also provides information that is not accessible from the visual inspection of the conventional recording. For example, QEEG can reliably measure the proportion of the total power that is in any given frequency band (so-called relative power, measured as a percent of total power). This measure is particularly useful because it normalizes for the wide fluctuations in total power across individuals and can detect subtle shifts in brain function in an individual over time.

Another product of the Fourier transform is *coherence*. Coherence quantifies the phase consistency of two signals, that is, the extent to which EEG signals from different brain regions have common, time-locked frequency components. Coherence is analogous to a correlation coefficient between the signals recorded at two locations and is computed from the formula:

$$C_{xy}(\lambda) = \frac{|S_{xy}(\lambda)|^2}{S_x(\lambda) * S_y(\lambda)}$$

in which the square of the cross-spectrum is divided by the product of the spectra of the individual channels (Bendat and Piersol 1986). Values vary between 0 and 1. A value near 1 indicates extensive shared activity; a value near 0 indicates little shared activity. Coherence has been used as an indirect measure of functional connectivity and intactness of neuronal fiber tracts.

## Evoked Potentials

In an attempt to standardize QEEG information, some investigators have controlled variability by recording electrical activity while the subjects are exposed to standardized visual, auditory, or other stimuli. These so-called evoked potentials (EPs), or event-related potentials (ERPs), are multicomponent waves of positive and negative potentials that result when the EEG signal from the scalp is averaged across numerous trials for a specified time interval after a stimulus. ERP components are labeled usually according to their polarities ("P" for positive, "N" for negative) and according to their latency from time of the stimulus (in milliseconds); some components are labeled according to their

presumed function (e.g., contingent negative variation).

ERPs are classified as to the type of triggering physical stimuli used. Visual evoked potentials (VEPs) commonly are generated in response to simple flashes of light or to reversal of background and foreground colors in complex patterns (such as a checkerboard). Auditory evoked potentials (AEPs) are generated in response to a series of clicks or tones that may be constant or vary unpredictably over time. Somatosensory evoked potentials (SSEPs) are generated as a result of the electrical stimulation of a peripheral nerve.

After stimulation of a sense organ, it takes approximately 20 msec for the electrical signal to reach the cortex. ERPs recorded with short latencies of 20–80 msec are termed *stimulus bound* or *exogenous*, as they are believed to represent obligate responses of the nervous system generated in spinal cord or brainstem structures. Perhaps of greater interest for geriatric neuropsychiatry are ERPs with medium to long latencies, termed *endogenous* or *cognitive* potentials, thought to represent responses of higher centers (including primary or association cortex). These potentials are more sensitive to psychological variables, such as the subject's motivation, attention, or intention, and less sensitive to characteristics of the eliciting stimulus. Certain endogenous ERPs are indicative of the subject's "cognitive set" or preparation for a motor response or cognitive task and may be recorded even in the absence of an associated physical stimulus. The main advantage of ERPs is their fine temporal resolution, which is fast enough to monitor the multiple, sequential stages of human sensory and cognitive processes.

## Quantitative electroencephalography and event-related potential changes with normal aging.

QEEG studies of normal aging reveal some differences from conventional EEG studies. It is agreed that there is a slight slowing of the posterior dominant rhythm by 0.5–1.0 Hz, although by definition it must remain above 8 Hz (Busse 1983; Duffy et al. 1984a; Oken and Kaye 1992), and decreased alpha blocking (Duffy et al. 1984a). There is disagreement, however, regarding increases in slow-wave power, with several studies finding that delta and theta power do not increase with normal aging (Duffy et al. 1984a; Katz and Horowitz 1982; Leuchter et al. 1993b; Matejcek et al. 1979; Williamson et al. 1990). Factors associated with aging such as hypertension (Visser 1991), atherosclerosis (Obrist et al. 1963), and diabetes (Mooradian et al. 1988; Pramming et al. 1988) can cause subclinical cerebrovascular insufficiency and structural and functional brain changes (Giaquinto and Nolfé 1988; Obrist et al. 1963; Visser 1991; Visser et al. 1987). The finding in some QEEG studies that slow-wave power does not increase

with aging probably reflects a superior health status of the subjects (Oken and Kaye 1992). QEEG studies further indicate that increased temporal slow-wave power with aging may reflect underlying pathology because it is inversely related to performance on memory testing (Rice et al. 1991).

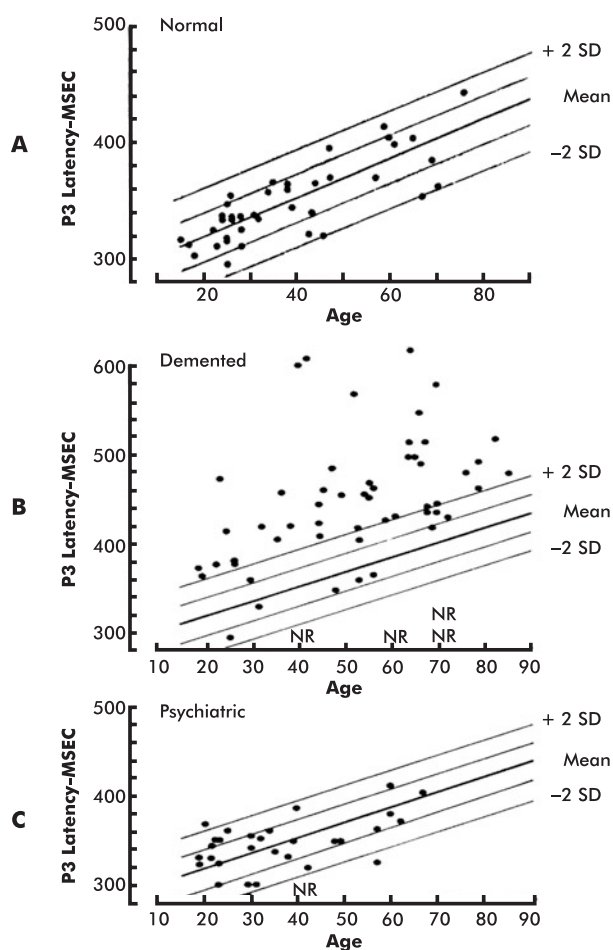

Studies of beta power suggest that it increases with aging until the seventh decade, when decreases can occur (Duffy et al. 1984a; Holschneider and Leuchter 1995; Williamson et al. 1990). The effects of health status on beta power have not been addressed, but augmented beta power has been seen during cognitive tasks including states of focused arousal (Sheer 1975, 1976, 1984) and performance on problem-solving tasks (Loring et al. 1985; Spydell and Sheer 1982). Retained beta activity may be an indicator in the elderly of preserved cognitive function.

Investigators have reported consistent changes in long-latency ERPs with aging. During development, the P300 decreases in latency until approximately the second decade. Using auditory stimuli, Goodin and colleagues (1978a) were the first to describe increased P300 latency in the elderly. Since then, similar observations have been made by others using AEPs, VEPs, and SSEPs (Beck et al. 1980; Brown et al. 1983; Pfefferbaum et al. 1984a; Picton et al. 1984, 1986; Syndulko et al. 1982). It now is widely accepted that P300 latency increases between 0.9 and 1.8 msec/year (Hillyard and Picton 1987; Polich 1991); this increase is believed to occur independently of any change in motor reaction time. Some investigators have found that the relationship between P300 latency and age is best described by a linear function (Pfefferbaum et al. 1984a; Picton et al. 1984; Polich et al. 1985; Squires et al. 1980; Syndulko et al. 1982), whereas others (Brown et al. 1983; Mullis et al. 1985) report a curvilinear relationship with greater annual latency increases for elderly subjects. Some have described increasing frontal distribution of the P300 (Pfefferbaum et al. 1984a; Smith et al. 1980). Others have been unable to replicate this finding (Maurer et al. 1988; Picton et al. 1984) with increasing age (Figure 12-2, *panel A*).

**Detection of dementia.** It is generally agreed that QEEG is useful for detecting the presence of a dementing illness (Duffy et al. 1984b; Nuwer 1997; Pritchep et al. 1994). Few studies, however, have systematically compared conventional EEG interpretation with QEEG for the detection of dementing illness. Brenner and colleagues (1998) compared 35 patients with clinically diagnosed dementia of the Alzheimer type (DAT), 23 with major depressive episodes, and 61 psychiatrically healthy control subjects. They found that QEEG offered “modest gains” in sensitivity over conventional EEG for the detection of moderate dementia (an increase from 57% to 66%), with

essentially equal specificity (95% and 93%, respectively). This improved sensitivity using QEEG methods was found despite collecting data from only four pooled QEEG channels from the parasagittal regions and relying upon mean frequency as the sole parameter studied. Furthermore, the fact that minutes of QEEG data could achieve greater sensitivity than conventional EEG, with equal specificity and using less physician time for test interpretation, suggests an advantage of QEEG over conventional EEG for routine evaluations.

Most studies use several types of QEEG measures (absolute power, relative power, spectral ratios) and linear combinations of these to discriminate subjects with de-

**FIGURE 12-2.** P300 (P3) latencies from the rare-tone evoked potential waveforms as a function of age for individual psychiatrically healthy subjects (*panel A*); individual patients with dementia (*panel B*); and individual psychiatric patients without dementia (*panel C*). Also shown are regression lines 1 and 2 SD from the mean, derived from the data for psychiatrically healthy subjects.

Source. Adapted from Squires et al. 1980.

mentia from those without dementia. These measures are complementary: they are additive in detection of abnormality and yield different regional information regarding the distribution of the abnormalities (Leuchter et al. 1993b). A number of studies have shown increased delta and theta power and decreased alpha and beta power, as well as decreased mean frequency in dementia (Brenner et al. 1986; Breslau et al. 1989; Coben et al. 1985; Giaquinto and Nolfé 1986; Pentillä et al. 1985; Stigsby et al. 1981; Visser et al. 1985; Vitiello and Prinz 1987). Such brain electrical changes are seen usually in a generalized distribution, though recent work suggests that, in DAT, increases in cortical slow-wave activity and decreases in high-frequency activity appear most prominent in the temporoparietal region (Albert et al. 1990; Buchan et al. 1997; Duffy et al. 1995; Holschneider and Leuchter 1995; Kwa et al. 1993; Pozzi et al. 1996; Saletu et al. 1991; Schreiter-Gasser et al. 1993).

In comparing patients with early- and late-onset DAT, Duffy and colleagues (1984b) found that increases in theta and/or delta activity and decreases in beta activity were maximal in temporal regions in subjects with early-onset DAT and in the frontal regions in subjects with late-onset DAT. Retrospective subject classification by discriminant function analysis using a combination of evoked response and electroencephalographic features correctly discriminated 95.8% of patients with early-onset DAT and 90% of patients with late-onset DAT from their respective control subjects. Leuchter and colleagues (1987) found large differences among subjects with DAT, those with vascular dementia (VaD), and control subjects in spectral ratios, which combine high-frequency and low-frequency power in a single measure. Using spectral ratios, as well as coherence variables, these researchers accurately classified more than 90% of subjects into their correct diagnostic group.

Most studies suggest that a positive linear relationship exists between the degree of cognitive impairment in dementia and increases in slow-wave power and decreases in high-frequency power (Brenner et al. 1986; Erkinjuntti et al. 1988; Holschneider and Leuchter 1995; Hughes et al. 1989; Johannesson et al. 1979; Rae-Grant et al. 1987; Soinen et al. 1982). It has been considerably uncertain, however, how early in the course of dementia QEEG may be useful for detecting disease. The answer to this question depends, to a great extent, on which measures are assessed. Gordon and Sim (Gordon 1968; Gordon and Sim 1967) reported that changes in alpha power preceded increased slow-wave power as a manifestation of disease, whereas others have reported that either increases in theta power or decreases in beta power were the earliest changes (Berg et al. 1984; Coben et al. 1983a; Jelic et al. 1996; Prichep et al.

1994). Sensitivities ranging from 20% to 36% and specificities ranging from 93% to 100% have been reported by others using a combination of EEG measures in varying scalp locations (Brenner et al. 1998; John et al. 1988; Prichep et al. 1994). The highest sensitivity (24%) and specificity (100%) for any single QEEG variable have been reported with percentage theta (Coben et al. 1990). Recently, Jelic and colleagues reported in subjects with AD, with average MMSE scores of 21, that when temporoparietal coherence appears as a discriminant variable together with alpha and theta relative power, sensitivity increases to 78%, while retaining a specificity of 100% (Jelic et al. 1996).

QEEG appears to be of greater use for distinguishing depression from dementia than is conventional EEG. Pollock and Schneider (1990) reviewed studies performed over the preceding decade and found that more than half found increases in both alpha and beta power in depression; these investigators themselves (Pollock and Schneider 1989) found that increased alpha activity persisted after recovery from depression. Other specific QEEG findings in depression have included right temporal slowing, increased frontal beta (Schatzberg et al. 1986), and increased left frontal alpha power (Davidson 1988). The increased delta (Brenner et al. 1986; John et al. 1988; Visser et al. 1985) and decreased beta power in dementia (Brenner et al. 1986; Visser et al. 1985) appear particularly helpful in separating those with dementia from those with depression alone. Because no single feature appears to be robust for the diagnosis of depression, several investigators have used a multivariate statistical approach to the diagnosis of depression (John et al. 1977, 1988; Shagass et al. 1984) and have reported overall accuracy in classification of 60%–90%. The stability of these multivariate methods for diagnosis remains to be verified.

An abnormal EEG may identify a subgroup of depressed patients with structural brain disease. These structural changes (as defined by hyperintensity on T2-weighted magnetic resonance imaging [MRI] scans) have been associated both with late-life depression (Leuchter et al. 1997) and EEG abnormalities (Oken and Kaye 1992). The high prevalence of these changes is of clinical significance because elderly subjects with abnormal EEGs show functional decline regardless of their diagnostic group (Leuchter et al. 1994d, 1994e). In some instances, these abnormalities may portend the development of a dementing illness (Liston 1979). Although an abnormal EEG in subjects with depression is not specific for dementia, it does identify the patients at greatest risk for functional decline and therefore is a useful part of the evaluation for dementia.

QEEG is an excellent tool for monitoring the effect of manipulations of the cholinergic system and thus may be a useful adjunct in monitoring response to cholinomimetic treatment in patients with dementia. Administration of cholinergic antagonists increases slow-wave power and decreases high-frequency power, whereas cholinergic agonists result in a reversal of this phenomenon (Vanderwolf 1992). The topography of such brain electrical changes has in animal models been shown to directly correlate with regional cortical changes of choline acetyltransferase (Holschneider et al. 1997a; Ray and Jackson 1991). Serial brain mapping studies in subjects with DAT who have been administered the cholinergic agonist bethanechol have demonstrated a dose-dependent decrease in slow-wave power (Leuchter et al. 1991). Decreases in slow-wave power and increases in high-frequency power have been shown also after the administration of the acetylcholinesterase inhibitor tetrahydroaminoacridine (tacrine) (Minthon et al. 1993; Perryman and Fitten 1991; Riekkinen et al. 1991; Shigeta et al. 1993), the acetylcholine-releasing agent DuP 996 (Saletu et al. 1989), as well as nerve growth factor (NGF), a cholinergic neurotrophin (Holschneider et al. 1997a; Olson et al. 1992). Though QEEG appears sensitive in monitoring response to cognitive enhancers, changes in brain electrical activity may not be specific for alterations of cholinergic function. Decreases in slow-wave power and increases in high-frequency power have been reported also after the use of estrogen (Ohkura et al. 1994) and ergoloid mesylates (Hydergine) (Matejcek et al. 1979; Saletu et al. 1990). A greater understanding of neurochemical correlates of individual QEEG parameters is needed.

Several investigators have attempted to use short-latency ERPs for the diagnosis of dementia (Coben et al. 1983b; Harkins 1981; Visser et al. 1976). Prolonged flash VEP latency and increased amplitude (Coben et al. 1983b; Visser et al. 1976; Wright et al. 1984), as well as some changes in brainstem AEPs (Harkins 1981) and SSEPs (Huisman et al. 1985), have been reported in patients with dementia. However, the differences in the exogenous potentials between subjects with dementia and psychiatrically healthy control subjects are too small or inconsistent to permit definitive classification.

Most of the research on the late components of ERPs in dementia has focused on the P300 peak. It has been established that the P300 latency is prolonged in dementia in excess of that seen during normal aging. Goodin and co-workers (1978b) first reported an abnormally large increase in the P300 latency in a group of patients with dementia of different etiologies; they also noted that the increase in latency correlated with severity of dementia as

assessed by the MMSE. Although these findings have been confirmed by several laboratories, prevalence of reported "abnormal" latency varies from 13% to 83%, with most studies reporting that 70%–80% of patients with dementia have prolonged P300 latency (Brown et al. 1982, 1983; Gordon et al. 1986; Patterson et al. 1988; Squires et al. 1980; Syndulko et al. 1982) (Figure 12–2, *panel B*).

The usefulness of the P300 latency alone is limited for several reasons. First, there is the wide variability in the prevalence of the abnormality. Pfefferbaum and colleagues (1984a, 1984b) used both auditory and visual ERP paradigms to compare 77 subjects with dementia of different etiologies (MMSE < 25) with 66 normal control subjects. They reported that fewer than 30% of the patients with dementia had P300 latencies that were at least 2 SDs greater than that expected for age. Although this low specificity reflects in part the particular paradigm used to elicit the P300 component, as well as the variability in normal P300 latency in the control subjects, the increases in P300 latency in mild dementia have been reported to be too small to be clinically useful (Leppler and Greenberg 1984; Polich et al. 1986; Syndulko et al. 1984).

Second, the P300 latency has been shown to be prolonged in other conditions and has been reported in up to 12% of patients with depression and 13% of patients with schizophrenia (Gordon et al. 1986; O'Donnell et al. 1995). Furthermore, an increased P300 latency is seen with dementia in a variety of conditions such as alcohol abuse, Huntington's disease, Parkinson's disease, Down's syndrome, scopolamine-induced "dementia," and geriatric depression (Calloway et al. 1985; Hansch et al. 1982; Kalayam et al. 1998; Lukas et al. 1990; Pfefferbaum et al. 1979; Rosenberg et al. 1985; St. Clair and Blackwood 1985). Patients with DAT cannot be distinguished from patients with other dementias on the basis of P300 amplitude or latency (Brown et al. 1982; Polich et al. 1986).

P300 latency measures are useful in certain clinical situations and as a component of a broader neurophysiological evaluation. Measurement of P300 latency can be useful as a component of an overall evaluation when there is a specific diagnostic question of dementia versus depression or delirium (Goodin 1990; Pfefferbaum et al. 1990), although it probably is of little use for specifying the type of dementia (Pfefferbaum et al. 1990). In combination with measures of power and/or coherence, this ERP measure can add greater sensitivity to the QEEG evaluation of dementia.

**Diagnosis and assessment of delirium.** QEEG offers substantial advantages over conventional EEG in the examination of subjects with delirium. Although Engel and

Romano (G. Engel and Romano 1959; Romano and Engel 1944) demonstrated that EEG slowing is almost invariably present in delirium, and grossly excessive slowing suggests the presence of delirium instead of, or in addition to, dementia (Brenner 1991; Rabins and Folstein 1982), it is difficult to determine the severity of slowing by visual inspection.

Examination of subjects with delirium indicates that QEEG can be used to successfully quantitate the magnitude of slow-wave power. QEEG detects significant changes in the amount of slow-wave power in the course of a delirium when the conventional EEG shows equivocal change, and decreases in slow-wave power may actually precede improvements in mental status (Leuchter and Jacobson 1991). QEEG indices are strongly correlated with not only the severity of delirium but also the length of delirium and hospitalization (Koponen 1991; Koponen et al. 1989).

Although it has been suggested that the severity of slowing may differ between subjects with delirium and those with dementia, studies indicate that it may be practical to differentiate these two groups based upon QEEG. Koponen and colleagues (1989) found that subjects with delirium with concomitant dementia had more severe slowing than those without dementia. Jacobson and colleagues (1993a) reported that several QEEG indices were useful for distinguishing delirium from dementia. Follow-up work from this group indicates that distinct QEEG measures of absolute and relative power indices are sensitive to the progression of dementia or the development of delirium, suggesting that QEEG may be particularly helpful for identifying the onset of delirium as a complication of dementia (Jacobson et al. 1993b).

ERPs also have been used in the assessment of delirium, primarily in patients with hepatic or renal encephalopathy (some of whom are elderly). Some investigators have reported abnormal latencies of brainstem auditory evoked potentials (Chu and Yang 1987; Pierelli et al. 1985; Rossini et al. 1984), whereas others have not (Trzepacz et al. 1989; Yang et al. 1986). More consistent results have been obtained with VEPs (Casellas et al. 1985; Kuba et al. 1983; Levy and Bolton 1986; Levy et al. 1990; Pierelli et al. 1985; Rossini et al. 1981; Zeneroli et al. 1984) and SSEPs, in which changes in latency correlate with severity of encephalopathy (Trzepacz et al. 1989; Yen and Liaw 1990).

In hepatic encephalopathy, changes occur in both VEP and SSEP latency during progressive stages of encephalopathy (Davies et al. 1991). In a review of the clinical usefulness of QEEG methods, including spectral analysis, EEG, SSEPs, brainstem auditory evoked potentials, VEPs, and

P300, van der Rijt and Schalm (1992) found that the highest percentage of abnormalities in patients with subclinical hepatic encephalopathy was detected by flash VEPs (25%–46%, 95% confidence interval). The auditory and pattern-reversal P300 shows an increase in latency and may be used for the detection of milder disease, although its applications are limited because it requires more patient participation than short-latency ERPs (Sandford and Saul 1988).

Little work has been done using ERP topographic mapping in hepatic encephalopathy. This area holds considerable promise for the future. Researchers led by Matos and Paiva (Matos et al. 1988; Paiva et al. 1988) have reported that 73%–75% of patients with liver disease without clinical signs of encephalopathy show abnormal VEP topographic maps.

### Limitations of Quantitative Electroencephalography

Quantitation of the power in different frequency bands has been touted as more “objective” and as minimizing variability in interpretation. It is true that QEEG yields more reliable and reproducible measurements of brain activity and is more likely to detect subtle focal or generalized alterations in brain function (Jerrett and Corsak 1988; Nuwer et al. 1987). Quantitation alone does not, however, indicate whether activity is normal or abnormal; traditionally, these determinations are made based upon statistical comparison of data from an individual to a normal base value and determination of whether the individual is beyond the “cutoff” for normality. Thus, QEEG does not eliminate the confounding problem that slowing increases both with age and emergence of organic brain disease. It does, however, allow the clinician to be more precise in measuring the amount of slowing and determining whether this appears to be excessive for the patient’s age. The most common method for establishing base values is building a *normative database* by collecting data from individuals who are in good health and not receiving any medications that might influence brain electrical activity. Stratification of normative data by age and gender may be additionally helpful in determining whether changes in an individual’s record are indicative of abnormality. Commonly, when the amount of slow-wave power at a given site is 2 SDs from the mean of a group of psychiatrically healthy subjects, this is interpreted as abnormal.

This statistical database approach can be useful for the interpretation of an individual’s data but has significant limitations. First, it is not clear how much deviation from a group of age-matched psychiatrically healthy control sub-

jects is acceptable for any given EEG measure. Some patterns of brain activity are very different from the patterns seen on most EEGs, and would be 2 SDs from a normal mean, but are a recognized *normal variant* (such as the low-voltage fast recording without any posterior dominant rhythm). Second, there are instances in which a persistent focal increase in slow-wave power is significant and indicative of abnormality but may be less than 2 SDs from the mean for that subject's age group. Such a focal increase can be especially significant if it is progressive over time. Third, a small but consistent deviation at many or all recording sites could be highly significant clinically and indicative of brain dysfunction, even if less than 2 SDs. Finally, a highly significant difference (i.e., 4 SDs) at a single recording site may need to be interpreted with caution because with multiple tests at multiple recording sites in multiple frequency bands, false-positive results can occur.

Several different approaches can be used to increase confidence in the comparisons between a patient's data and a normative database. Some researchers have proposed looking at multiple independent segments of data from within a recording session (Duffy et al. 1990, 1992). Another alternative is to examine a subject by using multiple modalities, such as resting EEG and evoked potentials. If a brain area appears abnormal in multiple independent samples of data, obtained under different recording paradigms, this could increase confidence that a finding is valid (Duffy 1998). Of course, if the abnormality is not detected on all occasions or under all conditions, this does not necessarily mean that it is not "real"; it simply may be episodic or state-dependent.

An alternative to the normative database model is to compare a given individual to his or her own baseline. When the first recording is performed in the premorbid condition, this may be the ideal method for assessment of brain electrical activity. Both the absolute intensity of power in any given frequency band, as well as the proportional distribution of power across frequency bands, may be examined and a determination made if there has been a change from the individual's baseline. This method is particularly applicable to the study of patients with delirium, in whom multiple studies over a short period of time may be indicated, or for the long-term follow-up of patients with dementia. Unfortunately, normal baseline studies rarely are available, so this method is of little help in interpreting the initial study of a patient with possible dementia or delirium. Furthermore, significant fluctuations can occur in patients' brain electrical activity with changes in state, so that it still is difficult to determine if subtle changes are indicative of abnormality or are within the normal range.

At present, QEEG is considered an adjunct to conven-

tional EEG in the study of psychiatric illnesses (American Psychiatric Association Task Force on Quantitative Electrophysiological Assessment 1991). This is understandable because, in some clinical situations, conventional EEG offers some advantages over QEEG. Very fast transient EEG activity lasting only milliseconds is not easily detected through quantitative analysis because it accounts for a very low proportion of the total power in a recording epoch. Therefore, an area of focal damage that is producing transient disturbances, such as rare epileptiform spikes, will not be detected by spectral analysis unless it also is producing a disproportionate amount of slow- or fast-wave power. Computer programs are currently available to scan QEEG data for the presence of epileptiform spikes or other specific abnormalities, but these are not yet widely accepted.

QEEG is sensitive to the proportion of energy in any given frequency band but is much less sensitive to specific wave morphology; in other words, it is less sophisticated at pattern recognition. Therefore, rhythmic triphasic waves would not be readily distinguished from frontally predominant intermittent rhythmic delta activity (FIRDA) or from continuous polymorphic delta activity in the frontal region. Although pattern recognition might lead the electroencephalographer to suspect either a particular metabolic encephalopathy or focal structural lesion with one or the other of these patterns, the frequency spectra might look remarkably similar.

The unique advantages of visual pattern interpretation indicate that there always will be a role for conventional electroencephalography, although as artificial intelligence algorithms for pattern recognition develop, conventional EEG may evolve into "computer-assisted EEG."

## ■ New Methods for Interpreting Quantitative Electroencephalography

### Neurophysiology of Electroencephalography Abnormalities

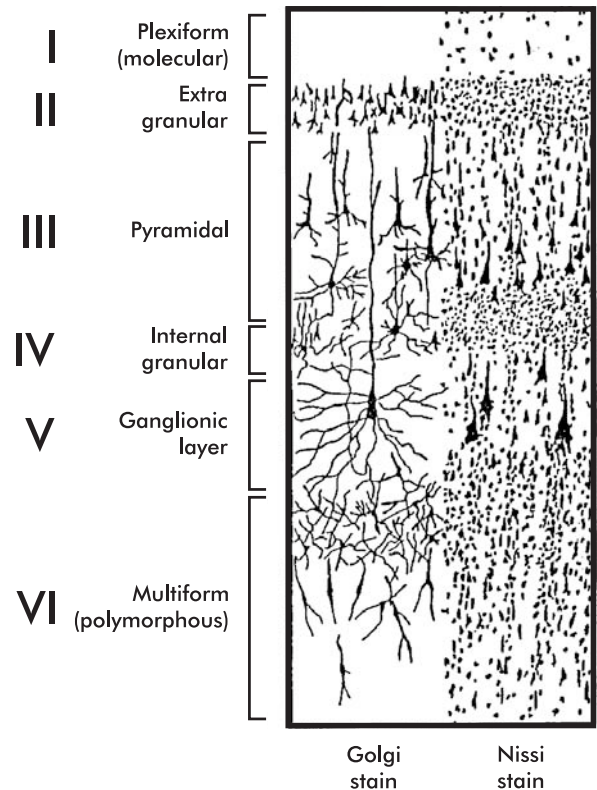

Ample evidence from studies of both animals and humans indicates that pathological slow waves in the EEG are caused by partial deafferentation of pyramidal cells of the cerebral cortex (Steriade et al. 1990). Complete destruction of cortex does not cause excessive slowing but instead leads to electrical silence; only through partial deafferentation of the cortex or nonlethal damage to cortical neurons do pathological slow waves develop (Gloor et al. 1977) (Figure 12-3). One of the strengths of QEEG is its ability to monitor the activity and integrity of afferent and effer-

ent fibers that are responsible for integrating electrical activity of different brain areas. Deafferentation can be the result of primary neuronal disease or of a brain insult (such as a stroke) secondarily affecting nerve function. Deafferentation can occur at any level: direct damage to the cortex, undercutting of the cortex by white matter lesions, and damage to the cortically projecting basal forebrain neurons all can cause an increase in cortically recorded slow waves. Research suggests that deafferentation can be structural or functional (such as through reversible toxic damage) (Steriade et al. 1990). This finding explains the similar patterns of increased slowing resulting from either DAT or administration of atropine: the former process causes loss of the origins of cortically projecting cholinergic afferents from the basal forebrain, whereas the latter inhibits firing of the cortically projecting afferent cells (Buzsaki et al. 1988; Detari and Vanderwolf 1987; Schaul et al. 1981; Steriade et al. 1990). The mechanism of slow waves that accompany metabolic derangements such as hypoxia, hypoglycemia, or other toxic states has not been established, but these also may represent dysfunction of cells projecting to the cortex or of the cortical pyramidal cells themselves.

#### Detection of deafferented cortex: the cordance method.

A specific measure of cortical deafferentation could be useful clinically. Such a measure could potentially indicate which slow waves were pathological and even in the absence of grossly excessive slowing suggest that pathology exists. Based on the knowledge that surface-recorded EEG should be sensitive to cortical deafferentation, we studied subjects with large white matter lesions that presumably undercut and partially deafferented cerebral cortex (Leuchter et al. 1994a, 1994b). These areas appeared to be hypoperfused on SPECT scanning and hypometabolic on PET, findings consistent with deafferentation. Such areas showed a characteristic QEEG pattern: although the deafferented cortex produced less slow-wave power on an absolute basis than did other cortical areas, it produced greater slow-wave power on a relative basis compared with that of other brain areas.

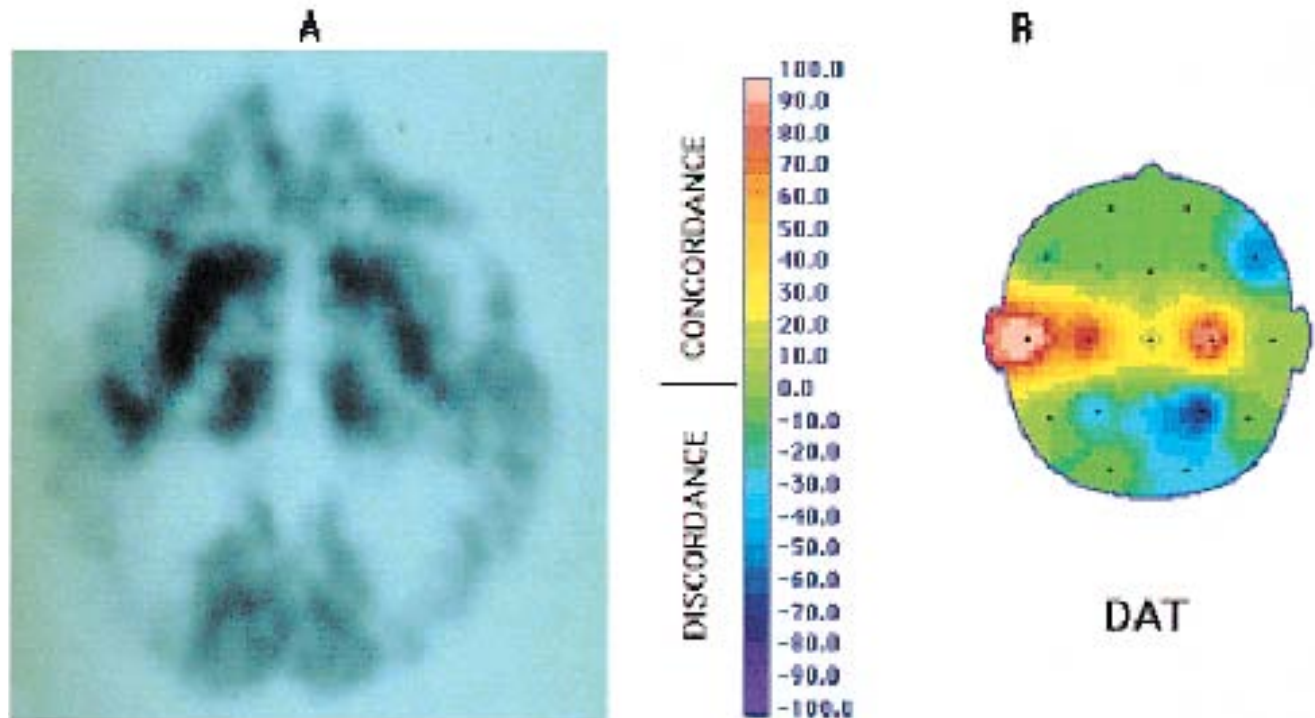

This finding of decreased absolute but increased relative slow-wave power over white matter lesions was termed *discordance*. Though not all white matter lesions were sufficient to cause discordance, the presence of discordance was associated reliably with areas that were found to be hypoperfused as a result of stroke or the presence of brain degeneration (i.e., DAT). The opposite indicator state, called *concordance*, was associated reliably with states of high perfusion and appears to be an indicator of cortex that is

**FIGURE 12-3.** Schematic representation of the layers of the cerebral cortex (showing association cortex; from Cummings and Coffey, in this volume). Partial deafferentation of the large pyramidal cells in layers II and III is the cause of pathological slow waves in the electroencephalogram. Source. functioning normally. For example, in patients with DAT, discordance is seen over the parietal regions and other areas that are hypometabolic on PET (Figure 12-4). These areas are known to be deafferented by the degenerative processes of DAT, in which the pyramidal cells of laminae II and III that project corticocortical afferents die selectively (Morrison et al. 1986). Concordance is seen over the central brain areas, particularly the area of the motor strip, which is known to be relatively spared by the neuropathological changes of DAT.

The concordance and discordance indicators (known jointly as *cordance*) show promise for detecting pathological changes, even in cognitively intact subjects. We recently examined cordance in six psychiatrically healthy subjects who underwent simultaneous  $H_2^{15}O$  PET scanning and cordance studies, both in the resting state and while they performed motor tasks. A moderately strong association was found among their levels of perfusion, and PET and

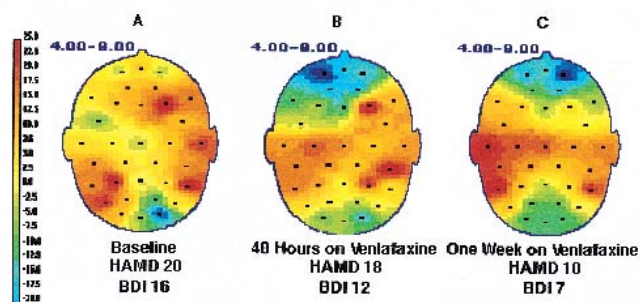

**FIGURE 12-4.** Brain scans of an 88-year-old man with progressive confusion, memory loss, social withdrawal, and agitation, who was diagnosed with dementia of the Alzheimer type (*DAT*). His positron emission tomography (PET) scan showed biparietal hypometabolism as well as focal left temporal hypometabolism (*panel A*). The concordance map shows three prominent areas of discordance, at the right and left parietal and left temporal electrodes, that have a strong spatial association with the three areas of hypometabolism (*panel B*). Significant alpha concordance is seen over the frontocentral region bilaterally, in the general area of the motor strip; this area commonly has the highest metabolism in subjects with *DAT*. PET scan shows the brain as viewed from below, whereas concordance map shows it viewed from above (i.e., right and left are reversed in the two pictures).

cordance were equally effective detecting the lateralized activation that accompanied motor tasks (Leuchter et al. 1999). This suggests that cordance is sensitive to even modest changes in perfusion and can be used to monitor brain function in subjects with relatively normal brain function.

We recently have applied cordance to the study of subjects with depression and have found that cordance is sensitive both to the brain dysfunction of depression and to the effects of antidepressant medication. Cook and colleagues (1998) studied 27 subjects with late-life depression and found that those with depression showed significantly more discordance than did psychiatrically healthy subjects. Interestingly, subjects who were undergoing treatment with antidepressant medication had *further* decreases in cordance in the prefrontal region. This finding is consistent with the work of Drevets and Raichle (1992), Sackeim (Sackeim and Prohovnik 1993; Sackeim et al. 1990), and others, showing that antidepressant treatment leads to further decreases in cerebral perfusion, particularly in the frontal regions.

We recently studied prospectively over 8 weeks 24 subjects with current unipolar major depression who were receiving fluoxetine (Cook et al. 1999; Leuchter et al. 1997). In this double-blind study, subjects demonstrating concordance prior to treatment has a more robust response to the antidepressant than did subjects with a pretreatment discordant pattern. This suggests that cordance may be useful in predicting treatment response to fluoxetine. An example of these changes is shown in Figure 12-5. This subject, who underwent treatment with venlafaxine, showed a significant, sustained bilateral reduction in frontal cordance during antidepressant treatment (Figure 12-5, *panels B* and *C*).

This decrease appears to be specific for a stable and lasting antidepressant response. A subject with depression (Figure 12-6) showed a decrease in frontal cordance in response to the first antidepressant she received, but this decrease was only mild and asymmetrical (Figure 12-6, *panel B*). Within a few months, the patient suffered a relapse of her symptoms and, despite an increase in dose, there was no remission (Figure 12-6, *panel C*). The patient was changed

**FIGURE 12-5.** A series of cordance maps from a 32-year-old woman, recorded during the first week of venlafaxine treatment. *Panel A* shows the baseline image. Subject started to show resolution of depressed cordance pattern as early as 2 days after medication was started (*panel B*), before clinical symptoms improved. The cordance continued to decrease over the next week as depression scores (*panel C*) decreased. BDI = Beck Depression Inventory (Beck 1978); HAMD = Hamilton Rating Scale for Depression (Hamilton 1960).

to a second antidepressant, but without response (Figure 12-6, *panel D*). Finally, she was changed to a third antidepressant to which she had a robust and lasting response. Only at this time did the patient show a marked, bilateral reduction in frontal cordance, which is indicative of successful antidepressant treatment (Figure 12-6, *panel E*).

Cordance may have wide applicability for the assessment and treatment of mental disorders. Additional studies of subjects undergoing treatment for depression, AD, and other conditions will help to determine if this technique could be used to guide treatment.

### Disconnection between brain areas: the role of coherence.

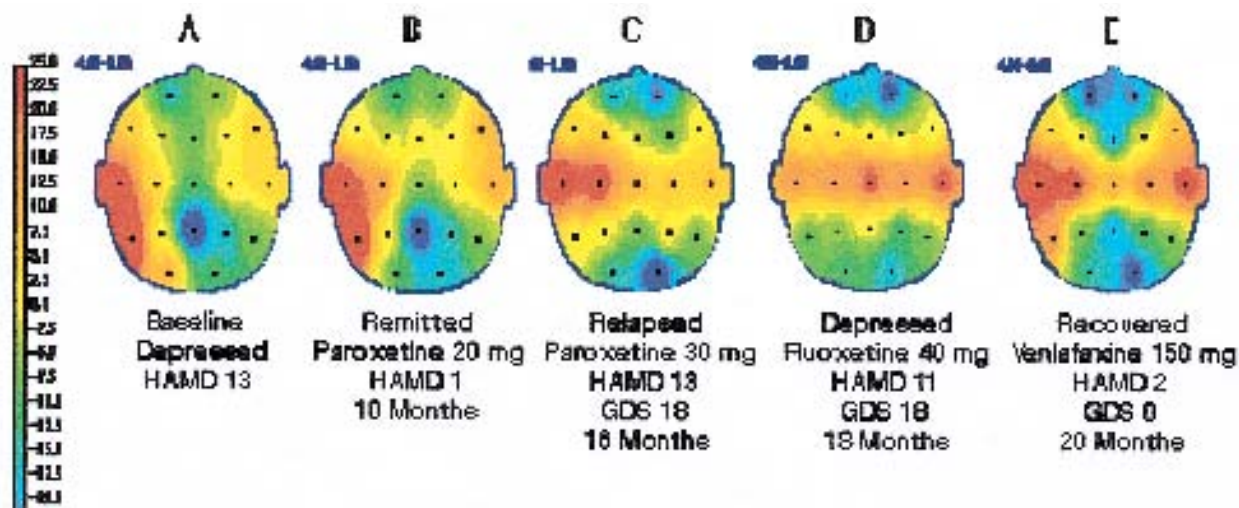

Another example of the usefulness of the deafferentation model of QEEG lies in the ability of this model to detect damage to afferent and efferent fibers linking two brain regions. As discussed above, coherence is a measure of synchronization of brain electrical activity between regions. Coherence appears to be a reliable measure of the functional connections between brain areas, monitoring interactions between cortical areas while subjects are at rest or engaged in a relevant cognitive task (Busk and Galbraith 1975; Davis and Wada 1974; O'Connor and Shaw 1978; Shaw et al. 1977, 1978; Tucker et al. 1986). In subjects with dementia, coherence measures have been shown to correlate with measures of cognitive function (Dunkin et al. 1995; Jelic et al. 1996), as well as functional outcome (Leuchter et al. 1994d, 1994e), consistent with the notion that the extent of neuronal deafferentation determines the severity of a dementia.

Deafferentation as measured through QEEG coherence has proved useful in detecting differences between subjects with DAT and those with VaD. In the past, differential diagnosis between these disorders using conventional EEG has relied upon detection of focal abnormalities, which reportedly are more common among subjects with VaD. This finding is not sufficiently prevalent, however, to be of diagnostic usefulness (Dejaiffe et al. 1964; Harrison et al. 1979; Logar et al. 1987; Roberts et al. 1978). Likewise, although measures of brain electrical power or spectral ratios have proved useful at differentiating between DAT and VaD in the research setting (Leuchter et al. 1993b; Logar et al. 1987), such measures have not been sufficiently robust to be used clinically.

Electrographic coherence has been used with greater success to distinguish patients with DAT from those with VaD. It has been helpful in understanding differences in the specific types of disconnections that characterize these neurodegenerative disorders. DAT and VaD have been hypothesized, on the basis of neuropathological data, to effect different types of brain connections: DAT causes selective disconnection of long corticocortical fibers, whereas VaD causes more diffuse disconnection of corticosubcortical white matter networks. Leuchter and colleagues (1992), as well as others (O'Connor et al. 1979), have shown that coherence detects these different types of disconnection and may be used to successfully distinguish high proportions of subjects with DAT or VaD (Figures 12-7 and 12-8).

Morrison and colleagues (Hof et al. 1990; Morrison et al. 1991) have highlighted the heterogeneity in types of disconnection among patients with DAT and have found that those with greater visuospatial difficulty (Balint's syndrome) show greater neuropathological disruption of the visual association pathways. The strong associations between performance on neuropsychological tests and coherence in relevant brain regions (particularly visuospatial function and visual system coherence) (Dunkin et al. 1995) suggest that coherence may be useful for characterizing the distribution of pathology among patients with dementia.

Given the ubiquitous nature of white matter disease in geriatric patients with depression or dementia or those without illness, the concept of disconnection may have applications for the study of other groups of elderly subjects. An area that is particularly vulnerable to white matter changes is the periventricular region (Bowen et al. 1990), where high-signal lesions may be seen in 60%–100% of asymptomatic control subjects (Leuchter et al. 1994c). These periventricular fibers are critical components of the networks that subserve higher cortical functions, containing the projections of the prefrontal cortical neurons and the visual association pathways. Leuchter and colleagues

**FIGURE 12-6.** A series of cordance maps from a subject undergoing treatment for depression. At baseline (*panel A*), the subject had low cordance over the frontal regions and the right temporal region. Although symptoms resolved after treatment with paroxetine (*panel B*), the frontal cordance did not decrease further, and the temporal cordance did not increase. The subject relapsed, and an increased dose of paroxetine did not resolve the depression (*panel C*). Fluoxetine in a dosage up to 40 mg also was ineffective (*panel D*). Finally, the subject was treated with venlafaxine, which led to a complete remission of symptoms. The cordance map showed a large bilateral decrease in frontal cordance and a bilateral increase in temporal cordance, consistent with effective treatment (*panel E*). GDS = Yesavage Geriatric Depression Scale (Yesavage 1998); HAMD = Hamilton Rating Scale for Depression (Hamilton 1960).

(1994c) have shown that there is an association between the presence of periventricular damage seen on MRI and decreased coherence in the frontal and visual networks of connections. The association between these two measures is stronger than the association between white matter disease and clinical diagnosis, suggesting that the degree and type of disconnection may be a useful model for categorizing cognitive impairment among elderly subjects, even those who do not meet all criteria for dementia.

Recent work suggests that the cholinergic system is an important determinant of the synchronization of brain electrical activity. Indirect cholinergic agonists such as physostigmine or eserine enhance the synchronization in specific frequency bands, whereas antagonists such as atropine diminish it (Dickson et al. 1994; Leung et al. 1994). Animal studies have shown that electrocortical coherence decreases after deafferentation of cholinergic fiber tracts projecting from the basal forebrain (Holschneider et al. 1998, 1999). Losses in coherence are restored, in part, by the administration of NGF, a cholinergic neurotrophin. Increases in coherence associated with NGF are largely seen for coherences within a hemisphere, but not between hemispheres. Such observations are consistent with findings that cholinergic projections from the basal forebrain to the cortex remain largely ipsilateral, whereas virtually all

fibers connecting the hemispheres through the corpus callosum or hippocampal commissures are noncholinergic, employing glutamate, aspartate, or  $\gamma$ -aminobutyric acid as their transmitters (Conti and Manzoni 1994). Studies such as these represent a first step in the elucidation of the neurochemical correlates of brain electrical coherence.

#### **Unmasking cortical deafferentation during pharmacological activation.**

As described above, generalized reductions of beta frequencies have been consistently reported in patients with dementia. Despite a high specificity, however, the low sensitivity of beta activity obtained with patients in the resting state has constrained the clinical utility of this measure in distinguishing pathological changes from those of normal aging (Coben et al. 1990). Although it has not been extensively studied in subjects with dementia, it appears that pharmacological activation of the brain may unmask the inability of diseased neurons to mount an adequate electrophysiological response. In the brain of a psychiatrically healthy human, preanesthetic dosages of barbiturates produce an abrupt onset of fast activity (20-28 Hz) (Bickford 1953; Brazier and Finesinger 1945; Kiersey et al. 1951; Pampiglione 1952). As early as 1950, Alema and Sinisi (1950) and later Pampiglione (1952) found that these barbiturate-induced rhythms were re-

**FIGURE 12-7.** Frequency spectrum of coherence mediated by long corticocortical connections (called *FASCICLE-PA measure* because it is similar to the distribution of fibers of the superior longitudinal fasciculus). Coherence is displayed for the subjects with dementia of the Alzheimer type (*DAT*) and subjects with multiinfarct dementia (*MID*) as a proportion of the mean value for the control (*CON*) group. Mean value for the control group is standardized to 1 in each frequency band and indicated by the *dotted line* across the middle of the figure. Frequency bands are displayed across the bottom of the figure, with numbers representing the center frequency of each band (e.g., 4 represents the 2- to 6-Hz band, 8 represents the 6- to 10-Hz band).

duced over areas of damage and aided in localizing lesions. Using QEEG, our laboratory has examined high-frequency power in patients with *DAT*, those with *VaD*, and psychiatrically healthy elderly control subjects after an intravenous bolus of thiopental. Compared with both control subjects and patients with *VaD*, subjects with *DAT* showed a marked loss of high-frequency power elicited across the cortex, with largest differences noted in the frontal region (Holschneider et al. 1997b) (Figure 12-9). Barbiturate challenge revealed differences in high-frequency activity not seen at baseline between subjects with *DAT* and those with *VaD*. Such an attenuation in the brain electrical response can be seen even in the early stages of *DAT* (average MMSE 26) (Holschneider and Leuchter, in press).

The etiology of a decrease in the barbiturate-induced high-frequency response is not clearly understood. Depth

**FIGURE 12-8.** Frequency spectrum of coherence mediated by networks of short corticocortical and corticosubcortical connections (called *VISUAL measure* because it is similar to the projectors of the visual pathway). Coherence is displayed for the subjects with dementia of the Alzheimer type (*DAT*) and those with multiinfarct dementia (*MID*) groups as a proportion of the mean value for the control (*CON*) group. Mean value for the control group is standardized to 1 in each frequency band and indicated by the *dotted line* across the middle of the figure. Frequency bands are displayed across the bottom of the figure, with numbers representing the center frequency of each band (i.e., 4 represents the 2- to 6-Hz band, 8 represents the 6- to 10-Hz band, etc.).

recordings of the EEG during light pentothal anesthesia suggest that the generators of fast waves are cortical in location (unlike the activity recorded at deeper anesthetic levels) (Brazier et al. 1956; J. J. Engel et al. 1982). Histopathological studies in subjects with *DAT* strongly suggest a selective loss of large pyramidal cells whose axons form corticocortical connections between higher order association areas. This deafferentation, which has been described as a neocortical disconnection syndrome (Leuchter et al. 1992; Morrison et al. 1990), may play a role in the decreased beta activity seen in *DAT*. By comparison, in subjects with *VaD*, the thiopental response is less affected, perhaps because this dementia is characterized by greater deep-white matter ischemic disease and subcortical dys-

**FIGURE 12-9.** Changes in  $\log_{10}$  (power) ( $\text{mV}^2$ , 20–28 Hz) over time in the left and right frontal regions after thiopental administration for psychiatrically healthy elderly control subjects (CON) (solid bars), subjects with dementia of the Alzheimer type (DAT) (open bars), and subjects with vascular dementia (VaD) (cross-hatched bars). function. A thiopental challenge may be well suited for the in vivo assessment of brain function in dementias characterized by prominent cortical pathology.

#### Deafferentation in ascending pathways: the role of evoked potentials.

Another type of afferent connection that can successfully be characterized with QEEG comprises the sensory input pathways. Results suggest that many of the changes observed in ERPs reflect changes in afferent fiber function and structure. Some of the most compelling evidence for ERPs changing in response to afferent damage has been seen in patients with dementia. Several researchers (Abbruzzese et al. 1984; Kato et al. 1990) have shown a delayed central conduction time for somatosensory evoked potentials in patients with VaD, but not in those with DAT. This finding is consistent with the fact that subjects with VaD have central white matter demyelination (which delays conduction of impulses), whereas subjects with DAT do not have such demyelination.

Using the deafferentation model, investigators have used ERPs to localize damage to brain structures. Manguiere and Ibanez (1990) studied a series of patients

with strokes in a variety of subcortical (either thalamus or subcortical white matter) and cortical locations, to determine if lesion location explained losses of specific somatosensory ERPs. These investigators found that damage to specific afferent pathways (confirmed by MRI) was associated with loss of specific ERP components and with the particular symptoms that patients reported. These investigators concluded that alterations in specific ERP components represented states of “hemispheric deafferentation.” This finding may have implications for studies of sensory gating using ERPs in psychiatric patients.

Of greater direct relevance to geriatric neuropsychiatry are the changes in latency and amplitude of the P300 and other long-latency ERPs that are now well established in schizophrenia (Barrett et al. 1986; Morstyn et al. 1983). These also have been reported in children with schizophrenia (Erwin et al. 1986) and relatives of subjects with schizophrenia (Blackwood et al. 1991; Saitoh et al. 1984). Some evidence suggested significant P300 asymmetry, with lower amplitude potentials specifically over the left temporal region (McCarley et al. 1993; Morstyn et al. 1983); other investigators, however, were unable to confirm this asymmetry and suggested that it might represent a

medication effect (Pfefferbaum et al. 1984b). Work by McCarley et al. (1993), however, indicates that these ERP abnormalities are associated with specific damage to the left supertemporal gyrus and that left-sided abnormalities are associated not only with reduced P300 amplitude over the left hemisphere but also with positive symptoms. McCarley and his colleagues (1991) have hypothesized that the P300 abnormalities seen in patients with schizophrenia may represent the results of neuronal excitotoxicity on the pyramidal cells of the left hippocampus. They propose that both psychotic symptoms and neuroleptic responsiveness reflect alteration in response in efferent fibers from the hippocampus, once again emphasizing the potential usefulness of the afferent fiber model of neurophysiology.

### Future of Quantitative Electroencephalography

QEEG offers a unique contribution to the armamentarium of imaging technologies. Several powerful imaging technologies, such as PET or SPECT, directly measure the metabolism or perfusion of brain tissue; these techniques provide little or no information about damage to pathways that bring information into the central nervous system or that transfer information among critical brain areas. QEEG complements these techniques by assessing fiber system function. In some situations, QEEG using the cordance method may be the preferred method for assessing perfusion and metabolism. Because it is noninvasive, does not expose the patient to ionizing radiation, and does not require costly equipment, cordance would be ideal for patients who require long-term, frequent, or even bedside monitoring.

For similar reasons, QEEG has a variety of uses in the research setting. Researchers can observe brain function to assess drug effects, monitor the course of illness, determine prognosis, or screen novel treatments in a cost-effective manner. Multivariate analysis of QEEG measures, using several sensory modalities of ERPs or cognitive activation tasks, may improve diagnostic accuracy. The correlation of anatomical and physiological measures of brain function obtained from MRI, SPECT, and PET, with QEEG measurements, holds great promise for the future.

In the next few years, conventional EEG and QEEG probably will evolve into independent and complementary diagnostic tests. The clinician interested in detecting epileptiform abnormalities, or some other transient brain electrical activity, will request a conventional EEG. Clinicians interested in assessing global brain function, detecting focal brain dysfunction, or assessing cerebral perfusion

or metabolism will request QEEG alone.

A conventional EEG in addition to a QEEG study will yield marginally more information than the quantitative study alone, at least until computer-assisted pattern recognition algorithms develop further. As pressures for medical cost containment mount, however, clinicians in all specialties likely will more heavily use diagnostic tests that are computer-based and that therefore require less physician time. Just as computers have reduced the physician time required for electrocardiogram interpretation, QEEG will eventually eliminate much of the physician time required for EEG interpretation. QEEG in many places still is a relatively costly procedure. As computer prices decline and QEEG systems become more widely available, however, QEEG will become a highly cost-effective means of imaging the brain.

### Summary

EEG is an important tool in the evaluation of cerebral function and brain disease in geriatric patients. EEG findings rarely are pathognomonic for a specific diagnosis but provide information that is consistent with (e.g., slowing in DAT or delirium), supportive of (e.g., triphasic waves in Creutzfeldt-Jakob disease), or highly suggestive of the presence of a particular illness (e.g., anterotemporal spike-and-wave foci in a seizure disorder).

In the clinical practice of geriatric neuropsychiatry, the conventional EEG is very sensitive to the presence of an encephalopathy, but it remains a nonspecific indicator of the type of dysfunction. EEG is a useful physiological tool to confirm the diagnosis and severity of delirium and for monitoring response to treatment, but it lacks specificity in differentiating between dementia and mild-to-moderate states of delirium.

QEEG overcomes many of the limitations of conventional EEG. It yields more reliable and reproducible measurements of brain activity and is more sensitive for detecting subtle focal or generalized alterations in brain function. QEEG measures such as absolute power, relative power, and spectral ratios provide information that is not accessible from visual inspection of the conventional recording. These measures yield different functional and regional information regarding abnormality and thus are complementary and additive in the detection of brain dysfunction. QEEG measures are sensitive to changes in cholinergic tone. Hence, QEEG may be a useful adjunct in monitoring response to acetylcholinesterase inhibitors and other cognitive enhancers in patients with dementia.

Another product of quantitative EEG analysis is

ERPs. These are multicomponent waves of positive and negative potentials that result when the EEG signal from the scalp is averaged for a specified time interval after a repetitive stimulus. ERPs may be useful as supportive evidence in the diagnosis of dementia, depression, or delirium, but they probably are of little use for specifying the type of dementia.

Quantitation of the power in different frequency bands is more "objective" than conventional EEG interpretation and therefore minimizes variability in test interpretation. Standard QEEG does not, however, overcome all the limitations of conventional EEG. For example, despite the greater precision of QEEG in power determinations, the nature of the power changes observed with normal aging still shares some of the features of emerging organic brain disease. Normative databases of age-matched control subjects are useful for describing the range of normality but are of limited use for determining that a clinically significant abnormality exists in patients with mild excesses of slowing. In the absence of a consensus definition of what constitutes a statistically significant excess of slowing, comparison of serial studies from a patient over time remains the most reliable method for determining if abnormalities exist.

Recent research suggests that QEEG can provide information that is specific for the detection and diagnosis of different organic mental syndromes. New algorithms appear to be sensitive and specific for the detection of cortical deafferentation through monitoring dysfunction in different types of white matter fiber tracts. Coherence, a measure of the synchronization of electrical activity between different cortical regions, has proved useful in distinguishing subjects with DAT from those with VaD and in detecting cholinergic deafferentation, as well as fiber tract dysfunction associated with periventricular white matter changes on MRI. Cordance, a measure of cortical deafferentation in a single brain region, has strong associations with direct measures of perfusion or metabolism. Cordance appears to reliably detect areas of hypoperfusion resulting from stroke or brain degeneration (i.e., AD). Unmasking the inability of diseased neurons to mount an adequate electrophysiological response during pharmacological activation holds significant promise for examination of patterns of neuronal deafferentation in different dementias. ERPs also have been useful in examining deafferentation of ascending sensory pathways. Future research elucidating the neurophysiological and neurochemical correlates of such findings may permit the use of QEEG in the direct assessment of deafferentation within specific neuronal circuits.

Currently, QEEG is considered an adjunct to conven-

tional EEG. Conventional EEG remains more sensitive for detecting very fast transient EEG activity as well as specific wave morphology and is the modality of choice for the evaluation of possible seizure disorders. As more sophisticated algorithms for interpreting neurophysiological signals are developed and validated, conventional EEG and QEEG may evolve into independent clinical tests.

# Mood Disorders

Carl Salzman, M.D.

## ■ Symptomatic Differences in the Elderly

Mood disorders, divided into depressive disorders and bipolar disorder, are relatively common in the elderly. Although diagnostic criteria for either major depressive disorder, unipolar type, or bipolar disorder are not different for the elderly than for young and middle-aged adults, symptom expression can be age-dependent. For example, some elderly patients with depression may display typical vegetative symptoms of diminished sleep, appetite, and energy, as well as persistently altered mood, motivation, and pleasure-seeking behaviors. In other elderly patients, however, symptoms of affective disorders may be atypical and quite different from symptoms in young and middle-aged adults. For example, some older patients with depression, particularly those who are frail and above the age of 80, may not appear sad or use the term “depressed” to describe their inner affective state. Rather, they are irritable and socially withdrawn. Older patients in a manic episode may also be more irritable and paranoid rather than displaying or expe-

riencing elation and euphoria. The terms *masked depression* and *depressive equivalents* are sometimes used to describe older patients who do not appear depressed but manifest physical symptoms such as chronic pain, fatigue, or hypochondriasis. Current DSM-IV (American Psychiatric Association 1994) diagnostic terminology includes these patients in the category of major depressive episode (Katz et al. 1998).

Not only may the clinical pattern of late-life depression vary from older person to older person, and from young-old to old-old, it may vary depending on prior episodes of depression in the older person's life. Studies suggest that elderly patients with early-onset depression, as compared with those who have a first episode in late life, have more first-degree relatives with depression. In contrast, those whose depression first appears in late life have more chronic physical illness. Patients with late-onset depression are also more likely to have brain imaging findings suggestive of dementia, respond less well to treatment, and have an increased mortality (Alexopoulos 1998; Baldwin and Tomenson 1995; Coffey 1996; Coffey et al. 1990; Katz et al. 1998; Nelson 1998).

I have divided this chapter on late-life affective disorders into two general diagnostic categories: depressive disorder and bipolar disorder.

## ■ Depressive Disorder

### Types of Depressive Disorder

#### **Major Depressive Disorder**

Major depressive disorder in elderly adults is diagnosed by the same DSM criteria that are used for young and middle-aged adults. However, disturbances in sleep, sexual functioning, and appetite are not always reliable indicators of depression in older people because these functions can be affected by normal aging, by medications, and by numerous physical illnesses. Subtypes of major depression include melancholia, delusional depression, and seasonal affective disorder.

#### **Nonmajor Depressive Disorders**

Older people experience a significant rate of nonmajor depression, including dysthymic disorder and subclinical depressions (characterized by depressed mood or markedly diminished interest or pleasure in activities). Depression also commonly occurs together with symptoms of personality disorder, especially in older people whose onset of depressive illness was earlier in life.

#### **Depression and Medical Illness**

A complex relationship exists between depression in late life and medical illness. Major depression has been found in as many as 20%–25% of older patients with medical illness (Katon and Sullivan 1990; Rodin and Voshart 1986), and nearly 90% of older patients with unipolar major depression had at least one medical illness (Conwell et al. 1989). Depression increases the morbidity and mortality of patients with medical illness in all ages, but the deleterious effect of depression may be greater in the elderly. For example, mortality rates of patients with depression admitted to a nursing home is higher than that for patients without depression who are admitted (Rovner et al. 1991) (see also Chapter 37 in this volume). Medical illness also may be a common precipitant for the development of a major depression in elderly people (Nelson 1998).

## Relationship of Late-Life Depression to Neuropsychiatric Disorders

### **Depression and Dementia**

Depression and dementia are commonly associated in older patients (see also Chapters 23 and 24 in this volume). Depression may occur in as many as 23% of patients with dementia, and dementia may occur in 14% of patients with depression (Alexopoulos 1998). The dementia syndrome of depression is well known in all ages but may be more severe in the elderly. Interestingly, older patients who are depressed do not complain more of cognitive impairment than do middle-aged populations (Alexopoulos 1998).

It may be helpful to divide the dementia syndrome associated with depression into two categories: dementia in the elderly patient with depression whose dementia improves upon resolution of the depression (*reversible dementia*) and dementia in those older patients with depression whose dementia does not improve (*irreversible dementia*). Many older patients with depression and an initial reversible dementia begin to develop an irreversible dementia approximately 2 years after the initial recovery from depression and dementia (Alexopoulos 1998; Alexopoulos et al. 1993).

Depression may be the manifestation of a dementia (Alexopoulos 1998). Approximately one-third of patients with Alzheimer's disease and depression have a history of previous psychiatric illness, especially depression (Agbayewa 1986; Rovner et al. 1989). The possibility that the cognitive impairment of an elderly patient with depression may be reversible with adequate treatment of the depression indicates that clinicians should treat the elderly patient with depression with cognitive impairment in an effort to improve the cognitive disturbance as well as the depressive disorder itself.

### **Depression and Alzheimer's Disease**

Depression is quite common in patients with Alzheimer's dementia, the comorbidity rate ranging from 17% to 50% (Alexopoulos 1991; Rovner et al. 1989; Sano et al. 1989; Wragg and Jeste 1989). Depressive symptoms are more likely to occur in patients with Alzheimer's disease than is the full syndrome of major depression (Alexopoulos 1998; Lazarus et al. 1987).

Imaging studies of elderly patients with depression consistently show structural changes that would also be apparent in persons with diminished cognitive function, although not necessarily with a diagnosis of true Alzheimer's

dementia (Campbell et al., in press; Coffey 1996; Coffey et al. 1990, 1993). These imaging changes are shown in Table 13–1. Some patients with Alzheimer’s disease and major depression have also been found to have brainstem lesions (Pearlson et al. 1989; Zubenko and Moossy 1988). Also, a clear relationship exists between depression and the presence of vascular (multiple-infarct) dementia as well as stroke (see below).

### **Depression and Neurological Disorders Other Than Dementia**

**Parkinson’s disease.** Depression is associated with Parkinson’s disease in at least two ways (see Chapter 26 in this volume). It is likely that some older people who develop Parkinson’s disease may experience a *secondary depression* about having the disorder. But depression can also be an integral part of the disease itself and occurs in at least half of all patients (Cummings 1992; Dooneief et al. 1992; Mayeux 1982). Clinical diagnosis of depression, however, can be difficult in some cases because the masklike, akinetic facies of patients with the disorder may look like depression, and the depressed facies of some older people may look parkinsonian. Difficulties in diagnosis also occur because of the “on-off” experiences associated with treatment of Parkinson’s disease. Characteristically, the “off” period (the period when the bradykinetic symptoms are intense) is associated with significantly increased depression, hopelessness, and suicidal thinking. Despair, lack of initiative, marked anergia, and loss of appetite are common during the off period. In contrast, during an “on” period, the

older patient with Parkinson’s disease may look, behave, and feel like a completely different person. With the patient being lively, optimistic, and engaged, it can be difficult to recall that a short time earlier the patient had all the characteristics of a patient with a severe major depressive disorder.

Depression may be more common among patients with right hemisphere parkinsonism (Starkstein et al. 1990). However, there appears to be no relationship between the degree of motor impairment and the degree of depression (Thiagarajan and Anand 1994). Disturbances in a number of neurotransmitter systems are probably related to the depressive component of Parkinson’s disease. The disturbance in dopamine function characteristic of Parkinson’s disease has been hypothesized as an etiology for the depression as well as the motor disorder (Brown and Gershon 1993; Willner 1995). Serotonin function also can be disturbed in patients with Parkinson’s disease who are depressed (Sussman 1998).

**Poststroke depression.** Although the characteristics of depression after a stroke are similar to those of a major depressive disorder without stroke, a number of its symptoms may vary depending on the location of the lesion. Left hemisphere lesions are significantly associated with major depression as compared with right hemisphere lesions (Robinson et al. 1988). Major as well as minor depressive disorders have been associated with stroke or cerebral ischemia—20% of patients develop a major depression (Robinson and Price 1982), and another 20% develop a minor depression (dysthymia) (Robinson et al. 1998). With

**TABLE 13–1. Imaging studies of depressed patients**

Scan	Study
Computed tomography	<ul style="list-style-type: none"> <li>• Enlarged lateral ventricles in depressed geriatric patients</li> <li>• Greater ventricular enlargement in late-onset than in early-onset geriatric depression</li> </ul>

Source. Reprinted from Katz IR, Miller D, Oslin D: “Diagnosis of Late-Life Depression,” in *Clinical Geriatric Psychopharmacology*, 3rd Edition. Edited by Salzman C. Baltimore, MD, Williams & Wilkins, 1998, pp. 153–183.

the exception of early morning awakening, the symptoms of poststroke major depressive disorder resemble late-life major depressive disorder that was not preceded by stroke (Robinson et al. 1998).

The relationship between impaired speech and comprehension in patients with depression is complex. Patients with Broca's aphasia (nonfluent aphasia) have more severe depressive symptoms than do patients with mild comprehension deficit and Wernicke's (fluent) aphasia or global aphasia (Robinson and Benson 1981). It appears that, although depression and language impairment tend to occur together, they are not related in a causal fashion to one another (Robinson et al. 1998). The frequency of depression among patients without aphasia is not different than the frequency of depression among those with aphasia (Starkstein and Robinson 1988), and it does not appear that depression is common in those patients with mild comprehension deficits (Robinson and Benson 1981; Robinson et al. 1998).

Understanding the relationship between the site of the lesion, the function of the brain area affected, and the appearance or lack of appearance of depression has been helpful in understanding the role of different brain centers in the regulation of mood. Lesions in left cortical and subcortical nuclei are associated with depression significantly greater than similar lesions on the right side, especially for major depression (Figure 13-1).

Patients with left hemisphere lesions have been shown to have decrements in serotonin binding in the left temporal cortex, suggesting that the left hemisphere may be more vulnerable to dysregulation of monoaminergic projections through the central cortex (Robinson et al. 1984, 1998). (For more on the neuropsychiatric aspects of stroke, see Chapter 27 in this volume.)

**Vascular depression.** Vascular depression is depression related to multiple infarcts damaging the striato-pallido-thalamo-cortical pathways in the brain (Krishnan 1993; Krishnan et al. 1997). Depression that appears late (or very late) in life is more likely to be associated with these vascular lesions than is depression with an onset earlier in life (Campbell et al., in press; Coffey 1996; Coffey et al. 1990; Krishnan et al. 1997). This depression is characterized by a lower risk of family history of mental disorder or suicide and by a higher presence of anhedonia and functional disability. As in vascular dementia, the vascular changes seen in the brain may be related to carotid atherosclerosis, hypertension, and a history of myocardial infarcts (Bots et al. 1993; Manolio et al. 1994). Patients with vascular depression have a greater cognitive impairment than do those with nonvascular depression and have more

psychomotor retardation and less agitation (Alexopoulos et al. 1997).

Although it is not yet clear whether vascular depression requires a different pharmacological or other (e.g., electroconvulsive therapy [ECT]) treatment approach than that for nonvascular depression, prevention and treatment of cerebrovascular disease may play an important role in this syndrome.

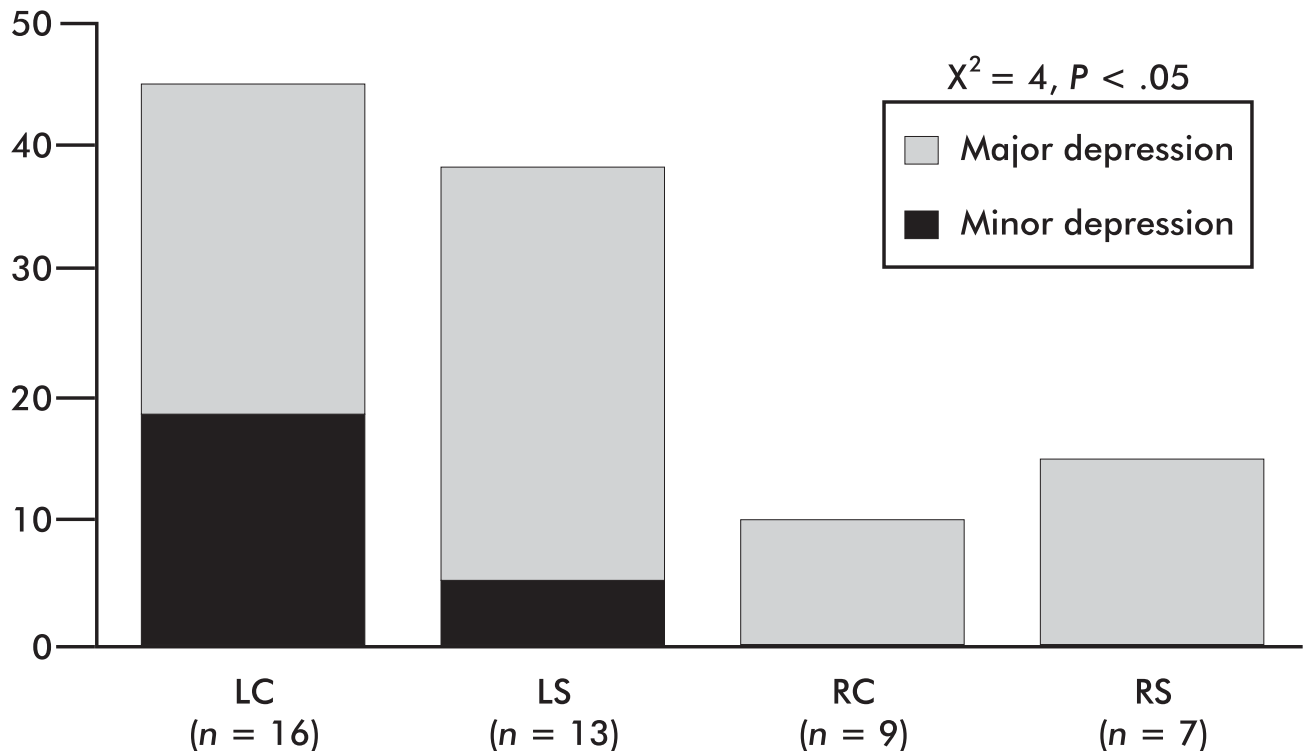

## Etiology of Late-Life Depression

There may be numerous pathways to the development of late-life depression. As discussed above, medical illness, neurological illnesses, and early-onset depression can all precede and play a role in the development of late-life depression. Additional factors include cerebral ischemia, the effects of commonly taken medications, and the numerous losses of function, friends, and health that older people must bear. No studies suggest that the neurochemical pathophysiology of depression is different in older people than in younger people when these other factors are excluded. However, virtually all markers of noradrenergic function, such as 3-methoxy-4-hydroxyphenylglycol, and  $\alpha_2$  binding tend to be diminished with age (Table 13-2), suggesting a correlation between reduced noradrenergic functioning (Sunderland 1998) and late-life depression (see Chapter 4 in this volume). Similarly, many (although not all) markers of serotonin function, such as tritiated imipramine binding, indicate a decreased function and sensitivity of serotonin receptors (Sunderland 1998) (Table 13-3) (also see Chapter 4 in this volume).

A search for biological markers that would help distinguish the elderly patient with depression as distinct from the older patient with dementia or the older patient with the normal mood variations of advanced age has been the subject of numerous studies that have not been fruitful. A summary of these studies is shown in Table 13-4. Unfortunately, none of these tests are currently useful in clinical practice.

## Treatment of Major Unipolar Depressive Disorder in the Elderly

Treatment guidelines for an older patient with depression follow those for younger and middle-aged individuals, with a few notable exceptions. As a general principle, it is reasonable to assume that most (although not all) older patients are likely to be more sensitive to both the therapeutic as well as side effects of antidepressant drugs (see Chapter 34 in this volume). Older patients with depression who also have structural and functional brain disorders such as

**FIGURE 13-1.** Percent of patients with single-stroke lesions visualized on CT scan and localized to left cerebral cortex (LC), right cerebral cortex (RC), left subcortical nuclei (LS), or right subcortical nuclei (RS) who have major or minor depression. There was a significant increase in the frequency of major depression among patients with LC or LS lesions compared with patients with RC or RS lesions.

dementia, stroke, or Parkinson's disease also may be especially sensitive to the brain toxic properties of antidepressant drugs. Older patients who are taking multiple medications are also at greater risk for side effects and drug interactions.

Regardless of the selection of antidepressant, increased vulnerability of the older person to the unwanted effects of antidepressant medication has led to the following prescribing principles for antidepressant medication (McDonald and Salzman 1994; Salzman 1995, 1997, 1998; Salzman et al. 1995).

- "Start low and go slow" (i.e., start with low doses and use only gradual dosage increments).
- Select medications with the least likelihood to produce anticholinergic and orthostatic hypotensive side effects.
- Patience is a virtue: it may take longer for the older patient to respond to an antidepressant medication, especially if they have had many previous depressions.

- Older patients may not have a complete response to antidepressant medications but may be left with significant residual symptoms.
- As with younger patients, maintenance antidepressant medication may be essential for recovered older patients who have had numerous prior depressive episodes.

And lastly, two additional guidelines are

- Special treatments may be necessary for the older patient whose depression includes delusions.
- Special caution must be taken when treating the older patient with depression who has a dementing illness.

Relatively few studies have used a double-blind placebo-controlled design to examine treatment of mood disorders (depression) in individuals with brain diseases of known pathology. Rummans et al. (in press) note that subject numbers in such controlled treatment trials are very

small for any one such group, making it difficult to endorse any one approach in treating depression in these samples. For example, only three such studies reporting significant improvement in active drug over placebo in the treatment of depression in people with neurological illness contained more than 10 subjects. These studies include one using citalopram in patients with depression occurring in Alzheimer's disease (Nyth et al. 1992), another with citalopram in patients with poststroke depression (G. Andersen et al. 1994), and a third using desipramine in patients with depression occurring in multiple sclerosis (Schiffer and Wineman 1990). Studies showing beneficial effects of nortriptyline in patients with Parkinson's disease (J. Andersen et al. 1980) were complicated by significant problems with the patients' low blood pressure; likewise, delirium and cardiovascular morbidity occurred in patients taking nortriptyline for poststroke depression (Lipsey et al. 1984).

It has become commonplace to discuss the use of antidepressant medications for older patients by grouping the medications according to their common chemical properties. For convenience, there is also a disparate category of antidepressants known as "atypical antidepressants." This antidepressant classification yields

- Tricyclic antidepressants (TCAs);
- Selective serotonin reuptake inhibitors (SSRIs);

- Monoamine oxidase (MAO) inhibitors; and
- Atypical antidepressants.

Studies demonstrate no significant therapeutic differences between compounds in these four classes (Alexopoulos and Salzman 1998; Nelson 1998). Therefore, clinicians tend to select antidepressant medications based on side-effect profile, on the patient's prior experience and response, and on their own personal prescribing preferences based on experience with other patients. Prescribing patterns of antidepressants for late-life depression also vary according to age, training, experience, and locality within the United States of the prescribing clinician, as well as with nationwide fluctuating patterns of drug-prescribing preferences. Nevertheless, at present, clinicians appear to be using antidepressants to treat late-life depression (Salzman 1998; Salzman et al. 1998) as follows:

1. SSRIs are the typical first-choice antidepressants for all except the most severely depressed elderly patients.
2. TCAs, especially nortriptyline and desipramine, appear to be used either to augment SSRI antidepressants or to replace SSRIs when they are not producing an adequate therapeutic response. Nortriptyline and desipramine also tend to be preferred

for the most severely depressed elderly patients (usually inpatients).

3. The miscellaneous group of atypical antidepressants are also widely used for the treatment of depression, and in many cases their effects are equal to or even superior to SSRIs and TCAs. The patterns of their use are difficult to discern.
4. MAO inhibitors are used significantly less frequently than the other three classes of antidepressants. They may be useful for carefully selected elderly patients (see below).

### **Selective Serotonin Antidepressants**

To date, approximately 1,500 elderly patients with a major depression have participated in studies of SSRI antidepressants. There appears to be little difference in the efficacy among SSRI antidepressants. The magnitude of therapeutic response with SSRIs is modest, interindividual variability of response is large, and significant residual symptoms are found at the end of the treatment period (Small and Salzman 1998). Although differences in pharmacokinetics exist among the four available SSRI medications, it is not clear that they significantly influence either the therapeutic response or the side-effect profile. It is likely that variations in drug response among older persons is greater than meaningful differences among the SSRIs antidepressants

(Salzman 1996). The pharmacokinetics of these drugs are also shown in Table 13-5.

Because of their relatively favorable side-effect profile, SSRIs are often the drugs of first choice, especially for the mildly to moderately ill patient with depression. The use of SSRIs for the treatment of the elderly patient with depression follows the usual geriatric guidelines of "start low and go slow." Even though side effects from these medications are less likely to interfere with the older person's function than are TCA side effects, doses that are too high may still cause unwanted side effects and treatment noncompliance. For example, traditional starting doses may produce unwanted agitation, sedation, or gastrointestinal upset. Average therapeutic daily doses are shown in Table 13-5.

SSRI antidepressants are metabolized through a number of cytochrome P450 isoenzymes and are subject to blood level fluctuation when the activity of these enzymes is altered by other medications. However, fluoxetine and paroxetine themselves significantly inhibit the 2D6 isoenzyme of this hepatic enzyme family. Because the 2D6 isoenzyme is primarily responsible for metabolizing TCAs, the combined use of tricyclic and SSRI antidepressants for therapeutic augmentation purposes may result in unsafe and unwanted high levels of TCA blood levels. Fluvoxamine is a potent inhibitor of the 1A2 isoenzyme, which metabolizes certain psychotropic drugs, such as tacrine (Cognex), that may be taken by elderly patients.

Although SSRIs may cause agitation, insomnia, or dis-

turbed gastrointestinal function, these side effects are usually mild and often transient. SSRIs do not cause cognitive impairment, although their use has been associated with confusion in some elderly patients, depending on the dose (Tourjman and Fontaine 1992).

**SSRI treatment of the neurologically impaired patient.** SSRIs have been used for the treatment of elderly patients with depression and dementia because of their relatively benign side-effect profile, in particular the low anticholinergic side effects. SSRIs may be used safely in this population of older patients, and, in some patients, reduction of depressive symptoms may be accompanied by a mild improvement in cognitive impairment (Nyth et al. 1992). Starting doses of SSRIs should be low for the dementia patient with depression because the usual

starting doses can be associated with an increased appearance of unwanted side effects, especially agitation. Paroxetine, alone among the SSRIs, has anticholinergic properties, although they tend to be mild. No data as yet, however, suggest that these anticholinergic properties interfere with the cognitive function of the older dementia patient with depression. In one study of paroxetine in nursing home residents over the age of 80, treatment with 20 mg/day for 8 weeks was not associated with impaired cognition (Burrows et al., unpublished data, July 1999).

It is likely that the efficacy of SSRIs in enhancing cognitive function in the older patient with depression and dementia will depend partly on the severity of the dementia. In early stages of dementia, in which most cognitive and behavioral function is preserved, these medications may be quite helpful for cognition as well as for mood. In the later

**TABLE 13-5. Clinical pharmacology of serotonin reuptake inhibitors**

stages of the illness, when there is more pervasive and behavioral impairment, SSRIs may have little effect on cognition.

Fluoxetine has been studied for the treatment of poststroke major and minor depression and, like the comparative drug nortriptyline, its use was associated with improved Mini-Mental State Exam scores compared with those scores with placebo (Folstein and McHugh 1978; Gonzalez-Torrecillas et al., in press).

Reports are conflicting on the usefulness of SSRIs in depressed patients with Parkinson's disease. The SSRIs may worsen motor symptoms in Parkinson's disease (Sussman 1998). However, in one case report, a patient with Parkinson's disease who was depressed responded to fluvoxamine (McCance-Katz et al. 1992). It appears that the beneficial effects of SSRIs do not necessarily outweigh the possibility of worsening motor symptoms in depressed elderly patients with Parkinson's disease. Because SSRIs may diminish central nervous system dopamine (Salzman et al. 1993), and potentially worsen motor symptoms, they probably should not be used as antidepressants of first choice for these patients.

### **Tricyclic Antidepressants**

Most geriatric clinicians tend to avoid using tertiary TCAs in elderly patients because of the relatively frequent appearance of anticholinergic and orthostatic hypotensive side effects. Side-effect profile favors the use of the secondary amines, nortriptyline or desipramine. Elderly patients treated with either of these TCAs respond to the same plasma levels as younger and middle-aged individuals. However, the response to TCAs may be influenced by a number of factors that are more common in older people

than in younger and middle-aged adults. For example, a large ventricular/brain ratio predicts poor response to nortriptyline (Young et al. 1990), and low serum albumin along with poor self-care also predicts poor response to nortriptyline in very old nursing home residents (Katz et al. 1990).

Treatment with TCAs also follows the "start low and go slow" principle. Clinicians, therefore, commonly start with doses of 10–25 mg for either drug and gradually increase into the therapeutic range, using plasma levels for monitoring, although the plasma level of nortriptyline may not correlate with the therapeutic response (Young et al. 1990, 1991). A pretreatment electrocardiogram (ECG) is essential because these TCAs can cause serious conduction difficulties. Repeat ECGs during the treatment period provide information that is also helpful to the clinician in determining the dose. There is no risk of cardiotoxicity if the QRS (or QT interval) does not widen. Using the ECG in conjunction with drug plasma levels and clinical status of the patient provides useful guidelines for treatment. Average starting and therapeutic doses are shown in Table 13-6.

Nortriptyline and desipramine produce anticholinergic side effects and orthostatic hypotension, although less severely than tertiary amine antidepressants, such as imipramine or amitriptyline. Brain anticholinergic side effects include delirium (disorientation, memory loss, confusion, and increased forgetfulness; see Chapter 19 in this volume). At low therapeutic doses, these side effects are little more than an annoyance for older patients (although for the very frail and very elderly person they may significantly interfere with daily activities). At higher doses, however, or when TCAs are given in conjunction with other medications that have anticholinergic side effects, the intensity of

**TABLE 13-6. Starting and therapeutic doses of recommended tricyclic antidepressants**

Drug	Starting dose	Average daily dose	Blood level
Nortriptyline	10 mg	25–100 mg	50–150 ng/mL
Desipramine	10 mg	25–100 mg	>115 ng/mL

brain anticholinergic toxicity may increase to the point of a delirium (see Chapter 19 in this volume). In the anticholinergic delirious state, the older person is very confused, very disoriented, and has impaired short-term memory. Symptoms are much worse in the evening, and the delirious picture may include paranoid delusions, visual hallucinations, assaultiveness, and agitation. Anticholinergic side effects are particularly disastrous for the depressed older patient who already has a dementia. At high doses, or even sometimes at the usual therapeutic doses used for young and middle-aged adults, depressed older individuals with moderately severe dementia become more cognitively impaired. Clinical experience suggests that patients with Alzheimer's disease may also become more agitated by TCAs. For these reasons, doses of TCAs need to be kept as low as possible to produce a therapeutic response, and the older person must be monitored closely.

Nortriptyline and desipramine are metabolized by several hepatic enzymes of the CP450 family. The primary metabolizing enzyme, IID6, responsible for hydroxylating TCAs into water-soluble compounds, may be inhibited by a variety of other medications, particularly fluoxetine and paroxetine. When these SSRIs are given to augment TCA response (or vice versa, see below), substantial risk of TCA toxicity occurs because of markedly elevated blood levels.

Because hydroxymetabolites are water soluble, their clearance may be impaired by age-related diminished renal function in the very elderly, or as a consequence of impaired renal clearance as a result of medications such as nonsteroidal anti-inflammatory drugs (see Chapter 34 in this volume). Hydroxymetabolites are cardiotoxic (Young et al. 1990, 1991) and, as they gradually accumulate, cardiac conduction abnormalities can develop. This toxicity is reflected in QRS widening, indicating a further need to employ follow-up ECGs during treatment.

#### **Tricyclic antidepressant treatment of the patient with neurological illness.**

A substantial body of literature demonstrates that patients with dementia who are depressed, as well as depressed patients with dementia, can be successfully treated with TCAs (Rummans et al., in press). Virtually all studies also indicate that there may be a favorable effect on cognitive performance with resolution of the depression (Reifler et al. 1989). At least four clinical trials have demonstrated response to antidepressant treatment in elderly patients with depression and cognitive impairment (Gottfried et al. 1992; Rabins 1989; Reifler et al. 1989; Reynolds et al. 1987). The subject has been well reviewed by Jones and Reifler (1994), who cite, in particular, a study showing an improvement in Mini-Mental State Exam scores of nearly 7 points in those elderly

patients with dementia whose depression responded to treatment (Folstein and McHugh 1978).

Five clinical trials have been published, each demonstrating improvement in mood in the depressed elderly patient with Parkinson's disease (J. Andersen et al. 1980; Boer et al. 1976; Indaco and Carrieri 1988; Laitinen 1969; Strang 1965). The anticholinergic properties of TCAs may also slightly help the motor impairment as well, although significant anticholinergic blockade will exacerbate some of the dementing symptoms that sometimes occur in well-advanced Parkinson's disease.

Two studies of nortriptyline in patients poststroke have demonstrated antidepressant efficacy in patients with depression (Balunov and Alemasova 1990; Lipsey et al. 1984). When stroke has resulted in cognitive impairment, treatment of a patient with poststroke depression with TCAs may result in an improvement in cognitive functioning (Lipsey et al. 1984), although anticholinergic side effects may be more prominent, resulting in disorientation, confusion, dysarthria, incoherent speech, and anxiety (Robinson et al. 1998).

#### ***Treatment of Depression With Miscellaneous "Atypical" Antidepressants***

This group of medications includes bupropion, venlafaxine, nefazodone, and mirtazapine. Each has demonstrated efficacy as an antidepressant, although the number of clinical trials data supporting their efficacy in older individuals is considerably fewer than that for the other groups of antidepressants. When clinicians follow the prescribing maxim of "start low and go slow" and use low starting doses with gradual dosage increments, the benign side-effect profiles of each of these drugs may make them useful for older patients. The starting doses, effective geriatric daily dose range, and side effects are shown in Table 13-7.

Bupropion tends to be used for its activating properties, whereas nefazodone has sedating properties. Venlafaxine is increasingly popular because it has many of the properties of TCAs but lacks significant anticholinergic side effects. Mirtazapine has not yet been assigned a specific prescribing niche for older depressed patients.

Another advantage of this group of drugs is the relative lack of significant interactions with other psychotropic drugs. Bupropion, venlafaxine, and mirtazapine appear to be relatively free of enzymatic interactions affecting the metabolism of other drugs. Nefazodone is an inhibitor of the 3A4 isoenzyme, which metabolizes numerous medications, including triazolam and alprazolam.

**TABLE 13-7. Miscellaneous antidepressants**

Drug	Starting dose (mg)	Geriatric daily dose range	Side effects
Bupropion	37.5	37.5–300	Agitation, insomnia
Venlafaxine	12.5	25–100	Nausea, vomiting, headache, hypertension
Nefazodone	50	50–300	Sedation
Mirtazapine	7.5	Insufficient information	Sedation, weight gain

### **Monoamine Oxidase Inhibitors**

MAO inhibitors are effective antidepressants and sometimes produce a remarkable reversal of depressive symptoms in some elderly patients. Their use for the general geriatric population of patients with depression, however, is limited by two factors: 1) the risk of noncompliance leading to potentially toxic combinations with other medications or tyramine-containing food substances; and 2) side effects, especially orthostatic hypotension and the potential for serious hypertensive crises.

Despite potential problems using MAO inhibitors, these medications may provide enhanced energy, optimism, and the return of zest to the lives of selected elderly patients with depression, particularly the younger depressed patients who are cognitively intact and physically healthy.

**MAO inhibitor treatment of the patient with neurological illness.** No clinical trials of MAO inhibitors have been performed in patients with neurological illness. MAO inhibitors have been reported to be effective in activating and improving the mood of elderly patients with depression (Ashford and Ford 1979), although they also have been noted to cause severe agitation and insomnia in the same sample of patients. A family member, spouse, or caregiver must be in charge of the MAO inhibitor administration, supervise the administration of the MAO inhibitor, and guard against potential drug and food interactions. This further limits the usefulness of these medications in this population.

No studies or clinical reports of the use of MAO inhibitors exist for elderly patients with poststroke depression. Because of the possibility of MAO inhibitor interactions with tyramine in foods or with blood pressure increase from medications causing a stroke, these drugs probably should not be used in this population of elderly patients with depression.

### **Treatment of Delusional Depression**

Psychotic (delusional) depression is relatively frequent in the elderly population and ranges from a prevalence of

3.6% of community residents to as much as 20%–45% of hospitalized patients (Alexopoulos and Salzman 1998). In elderly people, psychotic depression is a severe and potentially lethal illness, usually requiring inpatient treatment. Evidence suggests that elderly patients with psychotic depression respond poorly to treatment with all forms of antidepressants when used alone (Alexopoulos and Salzman 1998). When TCAs are combined with neuroleptics, however, therapeutic response has been noted (Alexopoulos and Abrams 1991; Baldwin 1988). Because of the life-threatening nature of psychotic depression, many clinicians prefer to use ECT rather than antidepressant medication (see Chapter 35 in this volume).

ECT has demonstrated efficacy for the treatment of severe depressions in elderly patients with psychotic depression (Sackeim 1998), although its use has been questioned because it induces memory impairment. The magnitude of cognitive impairment produced by ECT in the elderly differs among individuals. For some patients, the anterograde and retrograde amnesia caused by the treatment may be partially offset by the improved attention and concentration that results from reduction of depressive symptoms. For those who may be at greatest risk of memory loss (e.g., elderly patients with severe preexisting cognitive impairment), unilateral nondominant treatment carefully spaced out may mitigate the possible worsening of preexisting cognitive impairment (Sackeim 1998).

### **Treatment Resistance and Augmentation Strategies**

It appears that older patients, particularly those over 75, may have a less robust response to antidepressant treatment, even at appropriate dosages and blood levels. This lack of response is particularly true for TCAs (Agency for Health Policy and Research 1993), but is not as dramatic for the SSRIs. The elderly may take longer to respond to adequate treatment (Georgotas and McCue 1989; Nelson 1998). For these reasons, clinicians sometimes add a second antidepressant to bolster or accelerate the therapeutic response from the first drug. Although these augmentation strategies are sometimes successful in young and mid-

dle-aged patients, their efficacy in the elderly is not as convincing. Adding a second antidepressant is also likely to increase side effects.

Studies of lithium augmentation in the elderly have shown only a modest improvement in therapeutic response and a higher likelihood of neuropsychiatric side effects (Alexopoulos and Salzman 1998; Nelson 1998). Mixing antidepressants together (typically adding low dose of a TCA to an SSRI) has demonstrated efficacy in the elderly as well, although side effects are increased, and drug interactions may produce toxic TCA blood levels (Nelson et al. 1991; Seth et al. 1992). Stimulants in low doses are sometimes effective when added to other antidepressants. Methylphenidate, the most commonly used of the psychomotor stimulants, when used alone, may increase motivation, attention, and a sense of well-being, even at low doses of 2.5–20 mg/day. In conjunction with other antidepressants, methylphenidate may enhance energy and motivation. Doses must be very low to avoid unwanted agitation and insomnia. (For more information on geriatric neuropsychopharmacology, see Chapter 34 in this volume.)

## ■ Diagnosis and Treatment of Mania (Bipolar Disorder) in the Elderly

### Types of Late-Life Mania

Mania is not unusual in the elderly, although it rarely appears for the first time in late life. The clinical picture of mania differs in the elderly from patterns seen in young and middle-aged adults. Euphoria and elation are less common in the older patients with mania. More typically, features of late-life mania include confusion, paranoia, irritability, dysphoria, and distractibility. Onset of bipolar illness earlier in life, if untreated, becomes more severe and mood alterations more frequent in late life, both for the mania and the depressive component of the bipolar illness (Dhingra and Rabins 1991).

Manic symptoms can be caused also by a variety of physical disorders as well as medications. For example, vitamin B<sub>12</sub> deficiency, hypothyroidism, and infections can cause mania. The use of medications such as corticosteroids, anticholinergics, L-dopa, psychostimulants, and sympathomimetics, as well as hemodialysis, can cause late-life mania.

Mania in late life can be associated with neuropsychiatric disorders (Satlin and Liptzin 1998). Symptoms that suggest mania secondary to a medical condition as opposed to late-life onset of bipolar disorder include

- Distractibility, reduced attention span, impaired concentration, and disorientation resembling dementia or delirium;
- A first onset of affective symptoms in late life;
- A long latency period between the first episode of depression and the appearance of mania;
- A history of frequent mood cycles (rapid cycling);
- Chronic course;
- Absence of a family history of bipolar disorder; and
- Poor response to lithium or the development of neurotoxicity at low therapeutic lithium levels.

Although depression is more common after stroke than is mania, the appearance of manic symptoms after stroke is not uncommon (Robinson et al. 1998). As opposed to depression, the development of poststroke mania may be associated with right-sided lesions rather than left-sided lesions (Robinson et al. 1988; Starkstein et al. 1991). Poststroke mania may persist as poststroke bipolar depression. Patients with this disorder have greater cognitive impairment than those with just depression (Starkstein et al. 1991).

### Treatment of Late-Life Mania

The treatment of late-life mania follows general geriatric prescribing principles, using the same medications that are available for treating young and middle-aged adults. Mood-stabilizing medications, including lithium, valproate, and carbamazepine, are all useful in managing late-life mania. As for all other medications, however, older patients are more sensitive to the side effects of these medications. Starting doses, average daily doses, and side effects are shown in Table 13–8.

As with younger patients, maintenance treatment with mood stabilizers is an important part of the overall treatment program of elders with bipolar disorder. However, because older patients are more sensitive to the side effects of mood-stabilizing drugs, and may become progressively even more sensitive as they age, the maintenance doses may need to be readjusted frequently.

### **Neuropsychiatric Side Effects of Mood-Stabilizing Medication**

Neuropsychiatric and neurological side effects of mood-stabilizing medications are common in the elderly. In some cases, these side effects may appear even before other side effects, such as gastrointestinal distress, that usually appear as the first side effects in younger adults.

**Lithium.** Diminished memory loss, cognitive dulling, and apathy are common lithium side effects in the elderly.

**TABLE 13–8. Mood stabilizers**

Drug	Starting dose (mg)	Daily dose (mg)	Side effects
Lithium	75–300	300–900 (BL 0.3–0.7)	Neurological, cardiovascular, renal, thyroid, gastrointestinal disturbances
Valproic acid	125	250–1000 (BL 50–100)	Neurological disturbances, alopecia, weight gain, gastrointestinal disturbance
Carbamazepine	100	200–800 (BL 4–8)	Cardiac arrhythmia, confusion, unsteadiness

Mild confusion and forgetfulness may cause lithium non-compliance. At higher doses and blood levels, however, lithium-induced delirium characterized by confusion, forgetfulness, disorientation, and impaired consciousness is common. Other signs of lithium toxicity include tremor, lethargy, ataxia, slurred speech, and eventually coma. These toxic effects may be evident at therapeutic dosages even when lithium blood levels are within the usual therapeutic range. As many as 60% of elderly patients appear to have prolonged periods of lithium-induced neurotoxicity lasting up to 10 weeks after the discontinuation of treatment (Satlin and Liptzin 1998). Hypothesized reasons for this prolonged neurotoxicity include increased brain vulnerability as a result of late-life brain diseases such as parkinsonism, stroke, or dementia.

**Valproic acid.** Valproic acid can cause neurological symptoms in older patients. Tremor, sedation, and ataxia are not unusual. Some older patients may experience a cognitive impairment, although not as frequently as with lithium.

**Carbamazepine.** Neurotoxicity is produced by carbamazepine, resulting in confusion, sedation, disorientation, ataxia, and memory loss.

### **Treatment of Poststroke Mania**

Although no controlled studies of the treatment of poststroke mania have been undertaken, clinical experience suggests that secondary manic states after stroke are more difficult to treat than primary mania (Evans et al. 1995). A single case report found carbamazepine to be ineffective, but clonidine (600 mg/day) rapidly reversed manic symptoms (Bakchine et al. 1989). Lithium may be useful, as may other mood stabilizers, although research studies are needed for these treatments. Valproate and carbamazepine may be particularly useful in patients with poststroke mania because of the risk of seizures in this population (Robinson et al. 1998).

Other medications to treat mania, such as clonazepam and calcium channel blockers, have not been adequately

studied in the elderly. Similarly, use of new anticonvulsant mood stabilizers, such as lamotrigine and gabapentin, in the elderly has not been reported in the literature to date.

## ■ Conclusion

Affective disturbances in the elderly range in severity from mild to severe. Present clinical and research experience suggests that assertive, but careful, pharmacological treatment can bring substantial relief from the suffering of affective illness in late life. Following the prescribing principles of low starting doses, with gradual dose increments (“start low and go slow”), with frequent evaluations, many elderly people may have significant improvement in the quality of their life.

# Late-Life–Onset Psychoses

Godfrey D. Pearlson, M.D.

Late-life–onset psychosis is a fascinating but heterogeneous and insufficiently explored syndrome. To examine it objectively, one should put aside commonly held notions, such as that most cases of late-life–onset psychosis represent coarse brain disease (e.g., Alzheimer’s disease or microvascular pathology) or that early- and late-life–onset schizophrenia merely represent opposite tails of age distribution of the same syndrome.

Late-life–onset psychosis is a common condition, accounting for up to 10% of admissions to psychiatric hospitals for patients over age 60 (Bridge and Wyatt 1980a, 1980b; Kay and Roth 1961; Roth 1955; Siegel and Goodman 1987). It is feasible that all psychoses, including late-life–onset forms, represent a final common expression of diverse etiopathologies. This diversity is likely to be especially marked in late-life–onset conditions, a viewpoint argued by Holden (1987) and Post (1966). In part, this diversity may be related to a general increase in age-related biological heterogeneity (Jeste and Caligiuri 1991), as well as to the emergence in late life of several neurodegenerative disorders in which psychotic symptoms are common.

Late-life–onset psychosis is a disorder classically defined on the basis of clinical phenomenology, but clinicians also define cases, somewhat inconsistently, on the basis of pathological entities (e.g., Alzheimer’s disease) and etio-

logical descriptions (e.g., amphetamine psychosis). Two useful, but competing, approaches to defining the syndrome of late-life psychosis are 1) to cast the net broadly (i.e., include all patients with onset of delusions and hallucinations for the first time in late life) and 2) to examine a more narrowly defined group of patients who have late-life–onset delusions and hallucinations, but in the clear absence of an affective syndrome, progressive cognitive impairment, or obvious “organic” cause (i.e., as a result of a discrete brain pathology). This more restricted syndrome is closer to what has been termed *late-life–onset schizophrenia*, or *late paraphrenia*.

Depending on which of these approaches is chosen and which age at onset is used, mixtures of patients will emerge with differing etiopathologies, genetics, brain changes, and responses to treatment (Jeste et al. 1988a, 1988b, 1991). The emergence of such heterogeneous patient mixtures is precisely what has occurred in studies of such patients, resulting in a lack of clarity. As late-life–onset psychosis likely comprises a heterogeneous group of etiopathologies, even the narrowly defined subgroup referred to above, which has been assumed by many to be most similar to early-onset schizophrenia, may well exhibit significantly more heterogeneity than would be found among a comparable group of patients with early-onset schizophrenia (Rabins and Pearlson 1994). (The full range

of conditions commonly included under the broad umbrella of “late-life–onset psychosis” is discussed in the section “Diagnostic Diversity and Classification of Late-Life–Onset Psychosis” below.)

## ■ Historical Background

Use of the term *paraphrenia* (or *late paraphrenia*) is potentially problematic because of the weight of historical debates dragged in its wake. Kraepelin (1919/1971) used the former term to describe a group of chronic paranoid psychoses distinguished not by age at onset, but clinically by preservation of personality with lack of long-term deterioration and cross-sectionally by prominent elaborate delusions and hallucinations occurring in clear consciousness. Mayer (1921) followed up a large series of Kraepelin’s patients and demonstrated that deterioration occurred over the long term in most such patients. The use of the term *paraphrenia* was, therefore, deleted from the subsequent edition of Kraepelin’s textbook (Kraepelin 1926). Both Bleuler (1943) and Kraepelin (1903–1904) felt that late-life–onset cases of schizophrenia closely resembled, phenomenologically, more typical early-onset cases.

Roth revived and redefined the term in his descriptions of patients with “late paraphrenia.” He studied elderly patients with vivid and paranoid delusions and multiple hallucinations occurring in clear consciousness, with maintenance of emotional responsiveness over time (Roth 1955; Roth and Morrisey 1952). He demonstrated that the clinical course of “late paraphrenia” was different from that of both affective disorder and dementia with onset in late life in its cross-sectional symptomatic presentation, response to treatment, and outcome; in later studies (Tomlinson et al. 1968), he demonstrated that it differed neuropathologically from dementia. Patients with “senile psychoses” (mainly Alzheimer’s disease), delirious states, and arteriosclerotic psychoses (presumably multi-infarct dementia) showed a 30%–50% death rate at 6-month follow-up. Patients with late paraphrenia, who constituted approximately 10% of Roth’s total group of elderly, hospitalized psychotic patients, showed a 6-month follow-up death rate of less than 5%.

Confusingly, though some authors have remained faithful to Roth’s (1955) definition of *late paraphrenia*, others have retained the term but significantly broadened the concept to include patients with earlier onset (e.g., after age 45) or all late-life–onset psychoses. Some have also removed the qualifier “late,” further confounding the issue.

## ■ Epidemiology and Prevalence

In a review of the literature, Harris and Jeste (1988) estimated that 13% of hospitalized patients with schizophrenia have onset of the syndrome in their 50s, 7% in their 60s, and 3% in their 70s or later. Prevalence rates of late-life–onset schizophrenia in previous studies are frequently complicated by the unselected nature of the patient samples (see Harris and Jeste 1988). Social isolation and suspiciousness associated with the syndrome may also tend to minimize the true prevalence of the disorder. Reviews by Almeida et al. (1994) and Naguib and Levy (1991) show that prior epidemiological surveys of schizophrenia in the elderly have mainly surveyed hospital samples. For example, the studies of Roth and Morrisey (1952), Kay and Roth (1961), and Blessed and Wilson (1982) showed that approximately 10% of elderly patients admitted to psychiatric hospitals have a later-life–onset schizophrenic syndrome. A small number of community-based studies in the United States and United Kingdom have depicted late-life–onset schizophrenia rates varying from 1% to 4% in elderly individuals. Holden’s study (1987) of a community case register in the United Kingdom showed rates of 17–25 per 100,000 surveyed. Obviously, prevalence rates vary depending on the inclusion or exclusion criteria, perhaps most significantly the issue of possible organic etiology.

## ■ Clinical Picture and Phenomenology: Old Versus Young Patients With Schizophrenia

The best documented clinical descriptions of patients with late-life–onset schizophrenia remain the classic summaries of Kay and Roth (1961). The phenomenology of late-life–onset psychosis and its relationship to “classic” early-onset cases have engendered debates for nearly a century. As mentioned above, Kraepelin stated in the 7th edition of his textbook (Kraepelin 1903–1904) that late-life–onset schizophrenia “cannot be at all separated from juvenile forms of schizophrenia” (p. 213). However, some contrasts in phenomenological features and course between early- and late-life–onset cases have also frequently been commented on (e.g., Harris and Jeste 1988; Harris et al. 1988; Kolle 1931; Mayer-Gross 1932; Pearlson et al. 1989). Some of these differences are summarized in Table 14–1.

Phenomenologically, in cases of “late paraphrenia” (i.e., more narrowly defined late-life–onset schizophrenia), persecutory delusions are the most common, but delu-

**TABLE 14–1.** Comparison of symptoms among young patients with early-onset, patients with late-life-onset, and elderly patients with early-onset schizophrenia

Symptoms	Young patients with early-onset schizophrenia	Patients with late-life-onset schizophrenia	Elderly patients with early-onset schizophrenia
Hallucinations	80% (Pearlson et al. 1989)	Present in 94%; more vivid in multiple modalities (Kay and Roth 1961; Pearlson et al. 1989)	100% (Pearlson et al. 1989)
Delusions	69% (Pearlson et al. 1989)	98% (Pearlson et al. 1989), especially persecutory (also Kay and Roth 1961)	100% (Pearlson et al. 1989)
Schneiderian first-rank symptoms	50% (Pearlson et al. 1989)	35% (Pearlson et al. 1989); thought insertion and withdrawal rarer than that in early-onset schizophrenia (Grahame 1984; Holden 1987)	41% (Pearlson et al. 1989)
Formal thought disorder	52% (Pearlson et al. 1989)	Rare (5.6%) (Pearlson et al. 1989); similar (Bleuler 1943; Gabriel 1978; Huber et al. 1975)	55% (Pearlson et al. 1989)
Negative symptoms	22% (Pearlson et al. 1989)	Rarer (e.g., Bleuler 1943; Castle and Howard 1992; Pearlson et al. 1989)	23% (Pearlson et al. 1989)

sions of multiple types are often seen. Auditory hallucinations are most commonly seen, but hallucinations in multiple modalities are frequently reported, as are Schneiderian first-rank symptoms (Marneros and Deister 1984; Pearlson et al. 1989). Thought disorder and negative symptoms are relatively rare (Bleuler 1943; Castle and Howard 1992; Pearlson and Rabins 1988; Pearlson et al. 1989).

Pathoplastic age-associated features can mold the symptomatic expression. For example, “partition” delusions (i.e., delusions that people, gas, electricity, or some other force enters the patient’s home through the walls [partitions] from a neighbor’s apartment), which are said to be common in late-life-onset schizophrenia, can be influenced in content rather than form by the isolation and homeboundness commonly seen in elderly people. Castle and Murray (1991) argued that the schizophrenia-like illness occurring for the first time in elderly people, predominantly women, represents a variant of affective disorder. Although interesting (and further discussed in Chapter 13 in this volume), this assertion remains essentially unproven. However, few studies have contrasted patients with late-life-onset schizophrenia with groups of patients with affective disorder or with other relevant comparison samples, such as patients with early-onset schizophrenia who have grown old and young patients with early-onset schizophrenia (some exceptions being Pearlson et al. 1989; Rabins et al. 1984).

Until recently, clinical phenomenology has been the major classificatory tool for schizophrenia researchers. This limitation has put psychiatrists at a disadvantage

(comparable to that of cardiologists before electrocardiograms, chest X rays, nuclear medicine cardiac scans, and enzyme studies). Interpreting reasons behind the phenomenological differences between early- and late-life-onset schizophrenia, especially the differences in thought disorder and negative symptoms, is difficult. Is this, for example, a completely different illness, the same illness occurring in an older person, or only a case of similar clinical abnormalities occurring in an older brain assailed by neurodegenerative changes and mimicking what is most usually a neurodevelopmental disorder? (After reviewing further evidence, we attempt to address such questions in the “Conclusions” section below.)

## ■ Diagnostic Diversity and Classification of Late-Life-Onset Psychosis

### Scope of the Disorder

If, as noted at the beginning of this chapter, one uses a broad definition of patients with late-life-onset psychosis, the following mixture of patient groups is likely to be included (Table 14–2):

1. **Elderly patients with early-onset schizophrenia.** Such patients are frequently encountered, as schizophrenia is not a fatal illness. Because it is unresolved whether early- and late-life-onset cases represent the same disorder, verification of age at onset must

**TABLE 14–2. Groups included in a broad classification of patients with late-life-onset psychosis**

---

Elderly patients with early-onset schizophrenia
Patients with late-life-onset schizophrenia (“late paraphrenia”)
Patients with paranoid psychoses without hallucinations
Patients with psychotic affective disorder
Patients with cerebrovascular disease:
Classic multi-infarct dementia with psychotic symptoms
“Multi-infarct disease”
Patients with Alzheimer’s disease with psychotic symptoms
Patients with psychoses of miscellaneous causes with and without defined neuropathology
Patients in delirious and toxic states
Patients with extremes of paranoid or schizoid personality types

---

be carefully sought from available relatives or other informants and by examination of prior medical records.

2. **Patients with late-life-onset schizophrenia (“late paraphrenia”).** As discussed at the beginning of this chapter, nomenclature for this group has been especially confusing. In general, the term *late paraphrenia* (Roth 1955) has been applied to a more circumscribed group consisting of patients who have the onset in late life (i.e., over age 60) of a syndrome that clinically closely resembles early-onset schizophrenia. There is a long debate in the British literature (e.g., Almeida et al. 1992) between those psychiatrists who view these patients as having late-life-onset classic schizophrenia (e.g., Grahame 1984) and those who have emphasized its heterogeneity (e.g., Holden 1987). DSM-IV (American Psychiatric Association 1994) omits age criteria for schizophrenia onset.
3. **Patients with paranoid psychoses without hallucinations.** Unlike those with late-life-onset schizophrenia, in which hallucinations are vivid and often in multiple modalities, these patients correspond to those with “persistent delusional disorders” with late onset, as described by DSM-IV, and to earlier descriptions in the literature by researchers such as Kay and Roth (1961) and Holden (1987). Anecdotally, such patients do not later develop hallucinations, and they tend to respond poorly to neuroleptic medications. If such is the case, this disorder seems rather remote from late-life-onset schizophrenia.
4. **Patients with psychotic affective symptoms.** El-

derly patients with both affective symptoms and mood-incongruent delusions and hallucinations are often encountered (Kay et al. 1976). They correspond to individuals with the late-life onset of psychosis described as the “affective group” by Holden (1987), and, as discussed in Chapter 12 in this volume, family history and phenomenology of prior episodes may aid differential diagnosis.

5. **Patients with cerebrovascular disease.** *Classic multi-infarct dementia* is not infrequently accompanied by psychotic symptoms. Cummings (1985) reported that approximately 50% of patients with multi-infarct dementia have delusions. We propose below that the number of patients with “*multi-infarct disease*” (see below) is significantly larger than previously estimated, with the larger prevalence now revealed through the increasing clinical application of magnetic resonance imaging (MRI) and single photon emission computed tomography (SPECT). It is becoming clear that an unknown, but significant, percentage of patients with late-life-onset psychosis manifests imaging changes consistent with cerebrovascular disease, not necessarily accompanied by cognitive deficits and hence not meeting criteria for multi-infarct dementia. This finding accounts for our use of the more inclusive term *multi-infarct disease*. Case series have been described by Miller et al. (1991, 1992) and Lesser et al. (1992).
6. **Patients with Alzheimer’s disease and psychotic symptoms.** Patients with Alzheimer’s disease often manifest secondary delusions and hallucinations (e.g., Rubin 1992). The patient described in Alzheimer’s original case report had delusional beliefs. The characteristics of hallucinating and delusional patients with Alzheimer’s disease have been described in review articles by Wragg and Jeste (1989) and Burns et al. (1990a, 1990b). Delusions in Alzheimer’s disease tend to be rather fragmentary and impersistent. Careful follow-up of all patients with late-life-onset psychosis is therefore necessary to identify those with emerging dementia syndromes.
7. **Patients with psychoses of miscellaneous causes with and without defined neuropathology.** Cerebral infections (Chapter 30), tumors (Chapter 30), Parkinson’s disease (Chapter 26), stroke (Chapter 27), head injury (Chapter 28, all in this volume), and other causes can all be associated with late-life emergence of hallucinations and delusions in clear consciousness (e.g., Signer 1992). *Delirious and toxic states* (e.g., anticholinergic delirium, alcohol withdrawal, hypothyroidism, and amphetamine psycho-

sis) can manifest with similar symptomatology. Finally, *extremes of paranoid or schizoid personality types* (Chapter 20 in this volume) (e.g., those described by Post [1966] and Holden [1987]) can be mistaken for cases of late-life-onset psychosis if only cross-sectional information is available.

### A Classificatory and Investigational Scheme

With so many possible syndromes encompassing diverse etiopathologies, yet sharing common clinical features, it is clear that prior studies have often been alluding to diverse patient groups. We (Rabins and Pearlson 1994) have used a multiaxial approach to classification using genetics, epidemiology, risk factors, phenomenology, course, treatment response, neuropathology, and biological markers. To evaluate patients thoroughly, to proceed from a common reference point, and to rule out other diagnoses, for a particular patient the information in Table 14-3 should ideally be gathered.

**TABLE 14-3. Information (both clinical and laboratory) to be gathered in cases of late-life-onset psychosis**

---

Family history (e.g., of early- or late-onset schizophrenia, affective disorder, and Alzheimer’s disease)
Complete psychiatric history (especially prior affective episodes)
Medical history, including history of stroke and transient ischemic attacks, and an assessment of vascular risk factors, using standardized instruments
Premorbid level of functioning and intelligence
Premorbid personality
Current medications
Current detailed cognitive functioning
Current social supports
Sensory screening examination
History of present illness, especially age at onset of psychosis, relative to other known comorbid states (e.g., Alzheimer’s disease)
Complete physical and neurological examination
Routine laboratory tests for reversible causes of dementia (e.g., B <sub>12</sub> and folate levels and syphilis serology)
Standardized neuroimaging studies, especially magnetic resonance imaging (MRI) and single photon emission computed tomography (SPECT), both to rule out coarse brain disease (e.g., obvious strokes and tumors) and to assess extent of nonspecific changes (e.g., subcortical white matter hyperintensities)

---

## Risk Factors for Late-Life-Onset Schizophrenia

As shown in many review articles (Almeida et al. 1994; Harris and Jeste 1988; Pearlson and Rabins 1988; Pearlson et al. 1989), multiple risk factors associated with more narrowly defined late-life-onset schizophrenia have been enumerated (Table 14-4).

### Genetic Factors

As regards family history of schizophrenia, Kay (1972) showed that the percentage of affected first-degree relatives for patients with late-life-onset schizophrenia (3.4%) was intermediate between that of patients with early-onset schizophrenia (5.8%) and that of the known risk (1%) in the general population. As reviewed by Castle and Howard (1992) and by us (Pearlson and Rabins 1988), the assessment of family history rates presents problems, however. Prior studies have often not used standardized instruments such as family history, research diagnostic criteria, or strategies such as an adoption study design. Informants for late-life-onset diseases are often dead or unavailable and potential cases who are relatives may have died before the age of clinical risk, if the illness “breeds true” as has been suggested by some authors. The evidence overall is consistent with the notion that late-life-onset psychosis may be partly genetically determined; however, much remains to be clarified. This issue will be settled only when risk genes for schizophrenia are discovered.

### Gender

Female gender appears to be a very robust risk factor, even when the relative excess of older women is corrected for. The excess of women patients in late-life-onset cases has variously been reported as 6- to 20-fold (Herbert and Jacobson 1967; Kay and Roth 1961). Although some authors

**TABLE 14-4. Risk factors associated with late-life-onset schizophrenia**

---

Family history of schizophrenia
Female gender
Sensory deficits (primarily auditory and visual)
Social isolation
Abnormal premorbid personality
Never married/no children
Human leukocyte antigen (HLA) subtypes
Lower social class

---

(e.g., Pearlson and Rabins 1988) believe that this gender effect represents a shift in the female incidence of schizophrenia to late life (Lewine 1981, 1985), others (e.g., Castle and Murray 1991) have argued otherwise. Similar changes in gender preponderance are not seen with early versus late-life affective disorder (e.g., Weisman 1987).

Wong et al. (1984), using positron-emission tomography (PET) to measure dopamine, subtype 2 ( $D_2$ ), receptors, showed age-related decreases in the estimated number of  $D_2$  receptors, in agreement with postmortem studies (e.g., Seeman et al. 1987) (also see Chapter 10 in this volume). These PET data suggested that physically and mentally healthy men possess more  $D_2$  receptors but lose them at an accelerated rate with normal aging, compared with that of women. Hence, older women are left with a relative excess of  $D_2$  receptors compared with that of men of the same age. If, as some (e.g., Pearlson and Coyle 1983) have suggested, schizophrenia is indeed related to an excess of  $D_2$  receptors, the relative excess of  $D_2$  receptors in young men and in elderly women may explain the classic age-related gender expression differences for schizophrenia (i.e., that schizophrenia is usually expressed by men at a significantly earlier age than it is by women). Seeman (1981, 1986) has speculated that estrogens have “neuroleptic-like” or neuroprotective effects on  $D_2$  receptors, which would be lost after menopause. A PET study (Pearlson et al. 1993) offered preliminary support for  $D_2$  receptor increases in late-life-onset schizophrenia.

### Sensory Deficits

Sensory deficits, especially auditory and visual declines, which are more common in late life, have been reported in many studies to be a relative risk factor for late-life-onset schizophrenia. Cataracts and conductive deafness are the most common causes. Findings related to sensory deficits have been reported by multiple authors (e.g., Cooper and Porter 1976; Cooper et al. 1974; Naguib and Levy 1987; Pearlson et al. 1989; Post 1966). Conductive deafness seems to be a risk factor rather specific to late-life-onset schizophrenia, with prevalence being significantly higher than that in patients with late-life-onset affective disorder (e.g., Cooper et al. 1974). Some authors (e.g., Eastwood et al. 1981) have stated that, among the hearing impaired, psychotic symptoms respond favorably to treatment of the deafness. As reviewed by us (Pearlson and Rabins 1988), sensory impairment can be associated with reduced social contact and lead plausibly, therefore, to social isolation, suspiciousness, and liability to misinterpret environmental events. In an individual who is already predisposed to develop late-life-onset schizophrenia, sensory impairment

may therefore encourage symptom formation. Sensory deficits may thus in part account for the higher rates of social isolation reported in patients with late-life-onset schizophrenia. Kay and Roth (1961) reported sensory impairment rates three times higher among patients with late-life-onset schizophrenia than rates among elderly patients with affective disorder.

### Premorbid Personality

Another factor undoubtedly contributing to social isolation is the abnormal premorbid personality (mainly paranoid or schizoid) identified by multiple researchers as preceding late-life-onset psychosis (Herbert and Jacobson 1967; Kay 1972; Kay and Roth 1961; Pearlson et al. 1989; Post 1966). Kay and Roth (1961) and Post (1966), but not our group (Pearlson et al. 1989), found that women with late-life-onset schizophrenia were significantly more likely to have never married or had children. This observation has been reported less often in United States studies. If the finding is valid, low marriage rates may be related to the abnormal premorbid personalities seen in such patients.

It remains to be determined whether the abnormal premorbid personality traits described in late-life-onset schizophrenia represent a forme fruste of a schizophrenic disorder of a long-standing nature, significantly predating emergence of overt clinical symptoms, or a “risk factor” as classically understood. Other, miscellaneous factors have been explored, such as association with human leukocyte antigens (Naguib et al. 1987). Post (1966) showed that many patients with late-life-onset schizophrenia tended to have lower socioeconomic status premorbidly.

### ■ Brain Changes in Late-Life-Onset Psychosis

Compared with their respectively age-matched healthy control groups, individuals with late-life-onset psychosis have a significantly higher prevalence of identifiable brain abnormalities than do young individuals with similar symptoms (Miller et al. 1991). This observation is a rather general one, however. Many patients with late-life-onset psychosis do not have a specific lesion or an etiology for their brain change, and lesions reported in many studies do not share common localization or represent a single well-defined pathology. The reported prevalence of such brain changes varies, as might be expected for such a heterogeneous syndrome as late-life-onset psychosis. Some studies have carefully excluded all patients with probable organic pathology (e.g., Krull et al. 1991; Naguib and Levy

1987). Such series of screened patients have generally reported a smaller number of nonspecific brain changes (e.g., white matter hyperintensities) on MRI scans. Others (Lesser et al. 1989, 1992; Miller et al. 1992) included cases of probable vascular dementia. Nevertheless, given the above caveat, new and potentially important information has emerged from structural and functional brain imaging study of patients with late-life-onset psychosis (Table 14–5). It is clear that demonstrably altered brain structure or function is a predisposing factor in a proportion of such cases and that this proportion is higher than was suspected before modern neuroimaging methods became available. Reported changes fall into three broad categories: global structural changes, white matter hyperintensities on MRI, and cerebral blood flow changes documented on SPECT scans.

### Structural Changes

Several studies have demonstrated increased ventricular-to-brain ratio (VBR) in patients with late-life-onset

schizophrenia compared with that in age-matched psychiatrically healthy control subjects. For computed tomography (CT), such studies include Burns et al. (1989), Naguib and Levy (1987), Rabins et al. (1987), and ourselves (Pearlson et al. 1987). Howard et al. (1992a, 1992b) found lateral VBR (as well as third ventricular changes) to be no different from that for control subjects. Rabins et al. (1987) found patients with late-life-onset schizophrenia to have VBRs greater than those of control subjects, but smaller than those of patients with Alzheimer's disease with psychotic symptoms. Similarly, Krull et al. (1991), assessing VBRs on MRI scans, found values in late-life-onset schizophrenia to be intermediate between those of control subjects and patients with Alzheimer's disease. Howard et al. (1992a; see also Almeida et al. 1992) found patients with late-life-onset schizophrenia without Schneiderian first-rank symptoms to have ventricular and sulcal enlargement more comparable to that seen in patients with Alzheimer's disease; in contrast,

**TABLE 14–5. Structural and functional abnormalities reported in early-onset and late-life-onset psychosis patients**

Abnormality	Patients with early-onset schizophrenia	Patients with late-life-onset schizophrenia	Patients with late-life-onset depression
Increased ventricular/brain ratio on CT or MRI	Johnstone et al. 1976; Pearlson et al. 1987; Weinberger et al. 1979	Howard et al. 1992a, 1992b, 1994; Naguib and Levy 1987; Rabins et al. 1987	Pearlson et al. 1987; Rabins et al. 1991
Third ventricular enlargement	Boronow et al. 1985	Howard et al. 1994; Pearlson et al. 1989	
White matter abnormalities on MRI		Breitner et al. 1990; Flint et al. 1991; Kohlmeyer 1988; Miller et al. 1986, 1989 (not Howard et al. 1995b; Krull et al. 1991; or Symonds et al. 1997)	Coffey et al. 1989, 1990; Krishnan et al. 1988; Zubenko et al. 1990
Cortical atrophy on CT or MRI	Gur et al. 1991; Pfefferbaum et al. 1988	Howard et al. 1992a, 1992b (not Burns et al. 1989; Pearlson et al. 1993 [as CSF %])	Pearlson et al. 1987
Smaller superior temporal gyrus	Barta et al. 1990; Shenton et al. 1992	Barta et al. 1997 (not Howard et al. 1995a)	
Blood flow abnormalities on SPECT	Gur et al. 1985; Matthew et al. 1988	Miller et al. 1992	
Increased dopamine, subtype 2, receptor B <sub>max</sub> on PET	Wong et al. 1986a, 1986b, 1986c	Pearlson et al. 1993	
rCBF abnormalities during provocative tasks	Weinberger et al. 1988		

*Note.* B<sub>max</sub> = measure of receptor density; CSF = cerebrospinal fluid; CT = computed tomography; MRI = magnetic resonance imaging; PET = positron-emission tomography; rCBF = regional cerebral blood flow; SPECT = single photon emission computed tomography.

**FIGURE 14-1.** T2-weighted 5-mm axial magnetic resonance images of a 71-year-old woman with first onset of schizophrenic syndrome at age 69 (*panel A*: widest portion of lateral ventricles; *panel B*: centrum semiovale). Periventricular, subcortical, and cortical hyperintensities are visible. Ventricular enlargement is also evident (in *panel A*).

patients with late-life-onset schizophrenia with first-rank symptoms were more comparable to elderly control subjects.

MRI studies in general have been less convincing than those of CT in showing ventricular enlargement in subjects with late-life-onset psychosis. For example, Miller et al. (1991) found no differences between patients and control subjects; we reported a similar finding (Pearlson et al. 1991). We (Pearlson et al. 1993) also reported significant third ventricular enlargement in late-life-onset psychosis in an MRI study, whereas Burns et al. (1989) found no cortical atrophy compared with that in control subjects using CT. Table 14-5 lists other abnormalities noted in early- and late-life-onset schizophrenia. Overall, there is some evidence for moderate cortical and subcortical changes in late-life-onset psychosis, but less so for patients with “late paraphrenia” and in MRI studies. These latter emphasize the heterogeneity of late-life psychoses (e.g., see Howard et al. 1995a).

Several studies report an excess of white matter abnormalities or *unidentified bright objects* (UBOs) in patients with late-life-onset schizophrenia compared with that found in psychiatrically healthy control subjects (Figure 14-1). Such studies include Miller et al. (1986), Miller and Lesser (1988), Breitner et al. (1990), Lesser et al. (1991, 1992), and Miller et al. (1991), but not other workers (Table 14-5). Although some suggestions of localized patterns have been reported in such studies, a general review of the changes reported (including periventricular white matter hyper-

intensities, probable subcortical vascular lesions, and white matter hyperintensities) does not convince one that they are either uniform in nature or clearly localized to particular brain regions.

For example, Breitner et al. (1990) reported on 8 patients with late-life-onset paranoia, all of whom had significant white matter hyperintensities and 7 of whom had vascular lesions in pons or basal ganglia. Lesser et al. (1992) reported that 6 of 12 geriatric patients with DSM-III-R psychotic disorder not otherwise specified (American Psychiatric Association 1987) had large confluent white matter lesions. Miller et al. (1991) examined 24 patients with late-life-onset psychosis. Temporal lobe white matter hyperintensities occurred six times more frequently among these patients than in control subjects, whereas frontal and occipital hyperintensities were found four times more frequently. Significant excess of basal ganglia and cortical abnormalities was also reported in these subjects. Flint et al. (1991) examined 16 patients with late-life-onset paranoia or paraphrenia. Five of the 16 subjects had “silent cerebral infarction,” especially those with paranoia (i.e., delusional patients without hallucinations). Krull et al. (1991) carefully screened their population of 11 patients with late-life-onset psychosis to attempt to eliminate those most likely to have a diagnosis of organic cerebral disorder. In 9 remaining patients, they found no increase in white matter disease compared with patients with Alzheimer’s disease or psychiatrically healthy control subjects.

Howard et al. (1995b) pursued a similar screening strategy and also found no excess of white matter hyperintensities.

## Functional Changes

**Single photon emission computed tomography cerebral blood flow studies.** Several SPECT studies now agree in showing a relative excess of multiple areas of reduced cerebral blood flow in patients with late-life-onset psychosis. For example, in a diagnostically mixed group of such patients, Lesser et al. (1993) showed that approximately 75% had SPECT scan abnormalities of this type. Miller et al. (1992) also demonstrated cerebral blood flow abnormalities suggestive of cerebrovascular disease in a proportion of patients with late-life-onset psychosis. Further, 83% of the patients with late-life-onset psychosis versus 27% of the control subjects had one or more small temporal or frontal areas of hypoperfusion.

**Positron-emission tomography neuroreceptor studies.** We (Pearlson et al. 1993) compared 13 neuroleptic-naïve patients with late-life-onset schizophrenia (clinical onset after age 55) to 17 control subjects. Two PET scans were obtained in each subject to estimate caudate  $D_2$  receptor density using the method previously described by Wong et al. (1986a, 1986b, 1986c). The second scan was preceded by the administration of unlabeled haloperidol to demonstrate binding under conditions of  $D_2$  receptor blockade (Figure 14-2), and  $D_2$  receptor  $B_{\max}$  (receptor density) values were calculated using a four-compartment model.

To account for variation in  $B_{\max}$  values with age and gender (the control subjects were younger), a regression equation was calculated in the control subjects, and a predicted  $B_{\max}$  based on the control regression equation was then computed for each subject with schizophrenia. Residual values were then determined by subtraction of the observed  $B_{\max}$  minus the predicted  $B_{\max}$ . Standardized residual  $B_{\max}$  values for subjects with schizophrenia showed significant increases from zero, suggesting that  $B_{\max}$  values were elevated in this group of subjects with schizophrenia, even when age and gender were taken into account. This finding is similar to reports of elevated  $B_{\max}$  values for  $D_2$  receptors in drug-naïve patients with early-onset schizophrenia reported by the same group using the same method (Wong et al. 1986a), although not by others using a different method (Farde et al. 1987).

Caveats come with many of the above neuroimaging studies. First, a proportion of patients in many of the reports had clinical evidence of cerebrovascular disease and

would unequivocally be diagnosed as having organic psychiatric syndromes. The Flint et al. (1991) and Miller et al. (1986) studies in fact identified a proportion of patients whose stroke was first diagnosed by the neuroimaging studies. Many of the changes described in the structural and blood flow studies above are nonspecific—in the sense of being unlocalized in the brain and occurring in association with other late-life disorders, such as late-life-onset depression (e.g., Coffey et al. 1990)—and are not clearly associated with a particular neuropathology. Most of the reported series are small, and usually there was no follow-up to determine whether or not these patients later clinically expressed dementia syndromes. Neuropathological confirmation was lacking for most of the cases scanned. Patients with late-life-onset psychosis in the studies reviewed generally represent an unselected series, possibly representing a referral bias in which more cases are likely to have organic factors. Most of the imaging carried out has been semiquantitative or non-quantitative. Samples have generally been diagnostically heterogeneous, including not only patients with late-life-onset schizophrenia but also those with late-life-onset delusional disorder and late-life-onset psychosis not otherwise specified, and control subjects have not always been appropriately screened or matched to patients on age, gender, race, IQ, or community of origin. Nevertheless, much useful information is emerging, and study designs are gradually improving.

## Neuropathology

Tomlinson et al. (1968) found no excess of plaques and tangles at autopsy in patients with late-life-onset schizophrenia compared with age-matched control subjects. Kay and Roth (1961) found limited cerebral lesions (mainly consisting of small strokes) in a percentage of patients with late-life-onset schizophrenia. These researchers interpreted these lesions as having often been present years before the onset of psychotic symptoms. This interpretation contrasts with the studies of Bleuler (1943) who found cerebral lesions in a proportion of patients with late-life-onset schizophrenia, lesions that he believed had appeared years after the onset of the psychotic symptoms. This vascular neuropathology, however, is in accord with several neuroimaging studies (Flint et al. 1991; Holden 1987; Miller et al. 1986) that have reported on association between stroke and the onset of psychotic symptoms in elderly patients. Such cases appear to be associated with mild cognitive loss, a greater propensity to manifesting visual hallucinations, fewer overall hallucinations, and fewer schneiderian first-rank symptoms and are thus less typi-

**FIGURE 14-2.** Transaxial positron-emission tomography (PET) images through basal ganglia in a never-medicated patient with late-life-onset schizophrenia (paraphrenia). *Panel A:* Uptake before blockade with oral neuroleptic, with high basal ganglia uptake relative to cortex. *Panel B:* A second scan in same subject, taken 4 hours after pretreatment with unlabeled oral haloperidol. Dopamine, subtype 2 ( $D_2$ ), receptors are blocked by the cold ligand, revealing consequently lower basal ganglia activity. C-11 NMSP = carbon-11 labeled *N*-methyl spiperone, a PET receptor ligand.

cally “schizophrenic.” Overall, neuropathological studies are few, and clear conclusions are hard to draw. Imaging studies and neuropathology suggest a role for cerebrovascular disease in some patients—a theme expanded in the “Conclusions” section below.

## ■ Neuropsychological Testing in Late-Life-Onset Psychosis

Miller et al. (1991) compared 21 patients with late-life-onset psychosis (over age 45) with an equal number of individually matched (on education, age, and gender) psychiatrically healthy control subjects. The patients showed an overall decrement in cognitive functioning. After correction for multiple comparisons, several frontal measures and a verbal memory task showed significant impairment of the patients. The authors felt that this pattern was similar to that identified by previous researchers in early-onset

schizophrenia. Naguib and Levy (1987) tested 43 subjects with late-onset paraphrenia and found cognitive differences from psychiatrically healthy control subjects. These patients were later followed by Hymas et al. (1989), who tested 42 patients with “late paraphrenia” and attempted to exclude those with obvious early dementias. Mild neuropsychological deficits were present at the onset of illness and tended to progress somewhat with time, but not to frank dementia.

Overall, patients seen in our own clinic tend to be poorly educated and from rural backgrounds, with low average estimated premorbid IQ. It is especially hard in such cases to document deterioration from an uncertain but low premorbid level of functioning. Our review of the literature suggests that patients with late-life-onset psychosis tend to perform worse on standardized tests than do matched control subjects, but if patients with obvious organic factors are excluded, the remaining patients do not have obvious dementia and most do not develop diagnosable dementing illnesses at follow-up.

## ■ Diagnosis, Treatment, and Treatment Response

### Diagnosis

Differential diagnosis needs first to be reviewed. Our own experience is similar to that of Webster and Grossberg (1998). Those authors retrospectively evaluated the etiology and clinical findings of patients with first manifestations of psychotic symptoms (mostly delusions and hallucinations), arising after the age of 65 in more than 1,700 consecutive admissions to an inpatient psychogeriatric unit. Nearly 10% had late-life–onset psychotic symptoms, of which Alzheimer's disease was the most common cause, followed by major depression, medical or toxic causes or delirium, bipolar disorder, delusional disorder, schizophrenia, and schizoaffective disorder.

The differential diagnosis of psychotic symptoms occurring in late life begins with history and current symptomatology. When was the first onset of psychotic symptoms? Have they been present for many years or emerged only recently? Age at onset may have to be verified from old records and informants other than the patient. This information will, for example, help distinguish between late-life–onset and persisting early-life–onset schizophrenia. Next, determine what additional symptoms are occurring with the hallucinations and delusions. As schizophrenia at any age is always a diagnosis of exclusion, dementia, delirium, and affective disorder are the most important common primary neuropsychiatric entities to consider. Structural brain imaging is helpful to rule out coarse brain disease (e.g., stroke, tumors, bleeds, multiple sclerosis).

A useful rule is to consider the overall symptomatic context in which the psychotic symptoms occur. For example, are the psychotic symptoms present as the accompaniment to a dementing illness (see Gormley and Rizwan 1998)? Assessing current cognitive function and an estimate of premorbid ability (for the latter, using an instrument such as the National Adult Reading Test [NART, Blaine and Spreen 1989]) are helpful. It is also profitable to see whether cognitive impairment, if it exists, fits a typical pattern, for example, that of a cortical dementia. If clear cognitive decline has taken place, then an appropriate diagnostic work-up must be pursued (see Chapters 23 and 24 in this volume). Blood tests (e.g., Venereal Disease Research Laboratory [VDRL] test) are taken to rule out treatable causes of dementia, and other procedures (e.g., SPECT, apolipoprotein E subtyping) may be useful to help confirm a particular diagnosis. The presence of concomitant affective

disorder symptoms must be assessed (refer to Chapter 13 in this volume). Are there clear-cut primary changes in mood, self-attitude, vital sense, or vegetative symptoms?

Is there a change in the patient's level of consciousness? A typical waxing and waning course with an abnormal, variable level of consciousness (refer to Chapter 19 in this volume) may be seen. If so, typical electroencephalogram disturbances may be detectable. Does the patient have marked extrapyramidal symptoms in the absence of current or prior treatment with neuroleptic drugs? If so, this may represent psychotic symptoms either occurring spontaneously in untreated Lewy body dementia or Parkinson's disease or secondary to L-dopa or carbidopa treatment in Parkinson's disease.

### Treatment

Recent reviews of treatment of late-life–onset psychosis are to be found in Zayas and Grossberg (1998) and Mazure et al. (1998). Elderly cases of early-onset schizophrenia should be treated as for the late-life–onset disorder, that is, with a typical or atypical neuroleptic. Psychosis occurring in the context of a dementing illness involves both the treatment of the primary dementia (see Chapter 24 in this volume), for example, an acetylcholinesterase inhibitor for Alzheimer's disease (see Raskind 1997), which may help ameliorate the psychotic as well as the cognitive symptoms. The physician should generally avoid prescribing neuroleptics with marked anticholinergic side effects, for example, chlorpromazine, as these may exacerbate cognitive symptoms and increase risk for delirium. "Classic" high-potency neuroleptics such as haloperidol or fluphenazine are more likely to be associated with extrapyramidal side effects (EPS) and tardive dyskinesia in individuals with dementia. EPS in turn may lead to the need for treatment with undesirable anticholinergic compounds. There is thus an argument for atypical neuroleptic drugs as the compounds of choice for psychosis occurring in a dementing illness. Risperidone is the best documented of the atypical neuroleptics for this use (e.g., see Citrome 1997; Lavretsky and Sultzer 1998).

If the patient is suffering from a primary depressive illness, selective serotonin reuptake inhibitors are equally effective as classic tricyclic antidepressants (see Chapter 13 in this volume), with the advantage of fewer cardiac side effects and more safety in the case of overdose, both of which are important considerations in older patients. Psychotic affective symptoms may in some cases need to be treated with a neuroleptic drug in addition to the antidepressant. If so, atypical neuroleptic compounds may be preferable, for reasons cited above. Electroconvulsive therapy is also use-

ful in patients with psychotic depressive symptoms (see Chapter 35 in this volume).

When a patient suffers from psychotic symptoms in the context of a delirious state, then the primary cause of the delirium must be addressed (see Chapter 19 in this volume). If neuroleptics need to be added for short-term behavioral control, then use the principles outlined for Alzheimer's disease above.

Psychotic symptoms in idiopathic Parkinson's disease that are a result of secondary effects of treatment of the Parkinson's disease are most often seen with L-dopa/carbidopa combinations and less likely to be seen with dopamine agonist treatments. Treatment with classic neuroleptic compounds will likely exacerbate parkinsonian symptoms. Some authors have advised treatment with ondansetron hydrochloride (Zofran), to avoid worsening EPS (Eichlorn et al. 1996; Zoldan et al. 1995); however, this medication is very expensive. Others (e.g., Friedman 1999) suggest treatment with clozapine; but clozapine is anticholinergic and entails weekly monitoring of white blood cell counts. Treatment with clozapine in the context of Parkinson's disease can still lead to exacerbations of parkinsonian symptoms (e.g., Wolters et al. 1990), as noted in the only placebo-controlled trial. Olanzapine may also be helpful (Wolters et al. 1996), as may risperidone (Workman et al. 1997), but both of these drugs, especially the latter, can still exacerbate the Parkinson's disease (although the risk is less than for high-potency dopamine D<sub>2</sub> receptor-blocking compounds). Note that remarkably few double-blind treatment trials of neuroleptics for psychotic symptoms appear in the above conditions (Rummans et al., in press).

Treatment of classic late-life-onset schizophrenia with "classic" neuroleptics such as haloperidol offers the advantage that these compounds are much cheaper. Disadvantages are the relatively greater frequency of EPS and a likely greater long-term risk of tardive dyskinesia. The usual caveats also apply to the older, high-potency D<sub>2</sub> receptor-blocking drugs, as well as to those with anticholinergic side effects; that is, in the elderly they are likely to exacerbate glaucoma and benign prostatic hypertrophy and have secondary effects on blood pressure that may increase the risk of falls. Double-blind placebo-controlled trials to demonstrate efficacy of atypical neuroleptics in late-life-onset schizophrenia are needed. Potential (if unproven) advantages of these drugs include likely fewer EPS and less ultimate risk of tardive dyskinesia, although EPS can certainly still occur with these medicines. Disadvantages include expense, although patient assistance programs from most pharmaceutical manufacturers are now available for indigent patients. The usual adage of "start low, go slow, but continue" in older people applies to all treatment groups.

The mainstay of treatment of late-life-onset psychosis has been neuroleptic medication, but the patient's lack of insight into illness and patient suspiciousness can result in variable medication compliance. Patients with late-life-onset psychosis tend not to seek treatment. The psychiatrist is often involved late in the illness, offering treatment to an uncooperative patient (e.g., see Almeida et al. 1994; Post 1984). As might be expected, medication compliance, depot medication, and use of a community psychiatric nurse for outpatients all favorably affect treatment response (Howard and Levy 1992).

Although well-organized, double-blind crossover treatment trials are scarce, several open trials of neuroleptics have shown substantial improvement in a subgroup of patients with well-characterized, late-life-onset psychosis. Four studies over a 25-year period are summarized in Table 14-6.

Clinical improvement overall seems most likely to occur in patients with late-life-onset psychosis whose phenomenology most resembles that of early-onset schizophrenia. We (Pearlson et al. 1989) found that patients with poor medication response tend to be characterized by schizoid premorbid traits; we also found no effect on response of presence of first-rank symptoms, positive family history of schizophrenia, or gender. Holden (1987) found that patients with poor clinical response were characterized by an absence of auditory hallucinations or affective features. This finding is similar to the situation in younger people with schizophrenia in which florid hallucinations, prominent affective features, and an acute onset (especially if associated with some precipitating event) are all associated with a good prognosis. Flint et al. (1991) similarly found patients with paranoid delusions alone to respond poorly to neuroleptic agents.

Although both early- and late-life-onset schizophrenia tend to respond to neuroleptics with amelioration of positive symptoms, factors affecting interpretation of studies in patients with late-life-onset illness include differential

**TABLE 14-6. Results of neuroleptic treatment in late-life-onset psychosis**

Study	Complete remission	Partial remission	No improvement	N patients
Post 1966	60.5%	31%	8.5%	71
Rabins et al. 1984	57%	28.5%	14.5%	34
Pearlson et al. 1989	48%	28%	24%	54
Howard and Levy 1992	27%	31%	42%	64

symptom patterns in late-onset versus early-onset forms of schizophrenia and different pharmacodynamics in young versus old patients. Treatment with neuroleptic medications in elderly patients must be tempered by knowledge of differential responsiveness, which depends in part on age-related changes in body size and composition (e.g., increased proportion of adipose tissue and decreased renal function) (for a review, see Tran-Johnson et al. 1992; also see Chapter 34 in this volume). There are also pharmacokinetic changes (e.g., trend for higher plasma neuroleptic levels at same doses compared with that for younger patients) and pharmacodynamic changes, including increased sensitivity to therapeutic and toxic effects (possibly as a result of altered density and affinity of relevant cerebral receptors) (see Branchey et al. 1978). Overall, many patients with late-onset psychosis are adequately treated with very low drug doses. The differential side-effect profile of older patients includes higher risk of tardive dyskinesia, falls, anticholinergic side effects with low-potency neuroleptics (including delirium, worsening of glaucoma, cardiac abnormalities, and urinary outflow obstructions), and worsening of preexisting parkinsonian syndromes. Knowledge of individual patients' existing medical illness and other medications is therefore necessary (Table 14–2). Treatment with newer atypical agents (risperidone, olanzapine, quetiapine) may be preferable.

## ■ Course and Prognosis

Although more long-term follow-up studies are still needed, investigators agree that the course of late-life–onset schizophrenia is a chronic one (Herbert and Jacobson 1967; Kay and Roth 1961). Fish (1960) emphasized the poor prognosis of the condition, but Roth (1955) offered more optimism, stating that mortality was much less than that in patients of comparable ages who had dementia or depression. It is clear, however, that some patients with late-life–onset psychosis do develop dementia. This outcome is to be expected in any elderly population; the key fact is whether the proportion exceeds that predicted. Again, because heterogeneous samples have been followed in many studies, the relative proportions of subjects with clear-cut dementing illnesses initially presenting with psychotic symptoms are unknown.

Based on chart review only, Kay and Roth (1961) found that 12% of their patients with late-life–onset paraphrenia had developed dementing illnesses at 10-year follow-up. Holden (1987) found that 35% of his patient group had dementia at 3-year follow-up. Craig and Bregman (1988) followed a select group of patients with treatment-resistant,

late-life–onset psychosis and found that 10 of 15 had dementia. Lesser et al. (1989) and Miller et al. (1991) found that, as a group, their 24 patients with late-life–onset psychosis had mild cognitive abnormalities when initially evaluated; on follow-up, many of these patients had developed classic dementia syndromes such as Alzheimer's or Pick's disease. Finally, Hymas et al. (1989) found that nearly half of their 42 patients with late-life–onset psychosis showed evidence of cognitive decline at 4-year follow-up, especially those with low cognitive scores at entry. Only 2 of the patients, however, met diagnostic criteria for dementia.

The inconsistency of results obtained in different studies is difficult to explain but probably relates to ascertainment bias. The key point is that all studies report a significantly higher incidence of dementia in patients found to have late-life–onset psychosis than would be found in a comparable population of elderly individuals. Overall, predicting the long-term outcome of late-life–onset psychosis depends on a clearer division of these patients into diagnostic subgroups as suggested above.

## ■ Multi-Infarct Disease and Its Relationship to Late-Life–Onset Psychosis

Our hypothesis concerning multi-infarct disease and its relationship to late-life–onset psychosis is a straightforward one: that microvascular disease in elderly patients can be associated with new onset of major psychiatric disorders, including schizophrenia, in the absence of dementia. Thus we draw a distinction between multi-infarct *disease* and multi-infarct *dementia*.

Evidence for this conjecture derives from several sources. The observed excess of UBOs in both late-life–onset depression (most convincing) and late-life–onset schizophrenia (less convincing) on MRI and the patchy areas of reduced cerebral blood flow on SPECT suggest vascular pathology in patients with these syndromes. It appears from several studies (e.g., Breitner et al. 1990; Miller and Lesser 1988; Miller et al. 1986) that patients with white matter lesions on MRI tend to have higher numbers of vascular risk factors. However, several studies found no excess of white matter lesions in late-onset psychosis (Table 14–5). Various hypotheses can be generated from these observations. The most nonspecific is that any form of “brain damage” in late life renders an individual more likely to express major psychiatric syndromes and such “damage” subsumes a collection of common etiologies for several

late-life-onset major psychiatric illnesses. Alternatively, and far more specifically, the observed white matter abnormalities on MRI and SPECT may represent a single pathophysiological outcome (i.e., cerebral microvascular disease) that is a highly specific risk factor for late-life-onset schizophrenia. This hypothesis seems unlikely, however, as similar changes are reported for late-life-onset depressive syndromes (Coffey et al. 1988). In addition, confirmation of the vascular etiology and/or pathology of the changes seen on cerebral imaging studies is still lacking.

From a consideration of the same observations, Guze and Szuba (1992) offered an alternative interpretation. They suggested that these neuroimaging findings are a function of normal age-related brain changes, but “beyond a critical threshold, they may increase vulnerability” to late-life-onset major psychiatric illnesses, in combination with other risk factors. Such additional risk factors could include family history of a particular disorder and the anatomic site of the brain findings (e.g., Rabins et al. 1991). These combined vulnerabilities determine the final form of the illness (e.g., late-life-onset schizophrenia, late-life-onset depression, multi-infarct dementia, or a senile-onset movement disorder). If UBOs and white matter lesions are of vascular origin, the above suggestions taken to their logical conclusion would place at least some cases of late-life-onset psychosis and depression in a continuum of pathology with multi-infarct dementia.

## ■ Conclusions

Late-life-onset psychosis is clearly a heterogeneous and understudied syndrome. Much that is vital to comprehend is still unknown, for example, how best to subdivide the condition meaningfully and, for each resulting separate syndrome, how to determine its precise prevalence and find its important pathophysiological underpinnings. Also remaining obscure are the syndrome’s precise relationship to early-onset schizophrenia, response to treatment, and long-term outcome.

Although neuroimaging has the potential to provide important insights into the underlying pathophysiology, the numbers of subjects studied in most recent studies have been small, and a great need exists for large-scale longitudinal studies with suitable comparison patients (e.g., patients with late-life-onset affective disorders or elderly patients with early-onset schizophrenia). Finally, neuropathological examination is ultimately needed to clarify the nature of the underlying brain processes.

More narrowly defined cases of late-life-onset schizophrenia (or late paraphrenia) appear both more clinically

homogeneous and most phenomenologically similar to early-onset schizophrenia. Even when more narrowly defined, late-life-onset psychosis appears to be a more diverse syndrome than early-onset schizophrenia, and neurodegenerative changes probably play a larger etiological role than formerly envisioned. Evidence suggests that neurodegenerative and neurodevelopmental changes likely contribute to late-life-onset psychosis, but because the relative importance of each is unknown in most cases, it is too soon to settle the question of whether early- and late-life-onset schizophrenia are essentially the same condition (a theme discussed by both Almeida et al. [1994] and us [Rabins and Pearlson 1994]). Perhaps the clearest parallel is with late-life-onset depressive illness (see Chapter 12 in this volume). There, too, one finds a genetic risk for the appropriate illness (albeit a diminished one compared with early-onset forms of the disease), evidence in some subjects of nonspecific brain changes (identified by neuroimaging techniques), and a likely heterogeneous mixture of delayed “true” cases and “organic phenocopies.” Neuroimaging clearly has the potential to help “biotype” the syndrome and to clarify the question of diversity. However, documenting the choice of index and comparison patients, as well as of control subjects, is critical in this endeavor, as some neuroimaging studies have cast their recruitment net broadly, whereas others have excluded cases with likely “organic” associations.

Returning to the theme of affective illness, we believe that Castle and Murray’s viewpoint (1991) that late-life-onset cases of schizophrenia in fact represent affective disorder is unlikely. Our opinion is based on observations that comparison patients with late-life-onset schizophrenia and affective disorder have different patterns of atrophy on the CERAD (Consortium to Establish a Registry for Alzheimer’s Disease) (Morris et al. 1989) MRI rating scale (Aylward et al. 1993; Rabins et al., in press) and differ phenomenologically (Rabins et al. 1984). Also the types of abnormal premorbid personality reported in late-life-onset schizophrenia and affective disorder differ; the risks of family members being affected with affective disorder versus schizophrenia appear to be different in the two groups, and the syndromes respond to different types of treatment.

So far, interactions between the various risk factors reported for late-life-onset schizophrenia, as well as the ability to separate necessary from sufficient associations, lack the development of an encompassing theory. As we have stated (Pearlson et al. 1993), the etiology and timing of the structural changes in late-life-onset schizophrenia are unknown. They could be primarily initiated in late life or, alternatively, depend on age-related brain changes unmasking a preexisting (perhaps genetic) vulnerability. If a

developmental origin, similar to that proposed for early-onset cases (Weinberger 1987), is also applicable to some cases of late-life-onset schizophrenia (e.g., as we have suggested [Pearlson and Rabins 1988]), a vital point to address is why symptomatic onset has been delayed to the senium. In this chapter, we review evidence that such possible precipitants for late-life-onset psychosis could include neuronal loss as a result of usual aging and vascular or age-related functional changes, especially those affecting women, such as postmenopausal estrogen loss and thus alterations in the relative balance of dopamine D<sub>2</sub> receptors in basal ganglia. The role of late-life brain abnormalities and the relative contributions of neurodegenerative processes versus brain damage secondary to stroke or microvascular disease remain to be elucidated. Cerebrovascular pathology is likely to prove an important etiological factor for at least some proportion of late-life-onset major psychiatric illnesses, including psychosis. The etiological evidence for late life-onset psychosis is less compelling than that for late-life depression, however.

# Anxiety Disorders

Javaid I. Sheikh, M.D.

Anxiety in the elderly, as in the young, is a normal human emotion with adaptive value that helps one anticipate and prepare for noxious events. This normal emotion, however, can be considered pathological when it becomes unjustifiably excessive and maladaptive, as in morbid anxiety in clinical situations. This morbid anxiety usually manifests itself in the form of a multitude of cognitive, behavioral, and physiological symptoms, whereas the mental content of such anxiety can range from excessive worrying about everyday concerns regarding job and relationships to episodes of intense anxiety and fear (panic attacks). The term *anxiety* is used in this chapter to refer to such clinically significant or morbid anxiety, unless specified otherwise. Anxiety disorders are diagnostic entities comprising various constellations of signs and symptoms of anxiety combined with criteria regarding their intensity and duration, as described in DSM-IV (American Psychiatric Association 1994). Table 15–1 lists some examples of multidimensional symptoms that might be experienced by patients with various anxiety disorders.

As in younger adults, in elderly patients anxiety disorders are among the most frequent psychiatric illnesses (Blazer et al. 1991). However, unlike in younger populations, in whom these disorders have attracted considerable attention from investigators over the last two decades, anx-

iety disorders remain among the least studied of psychiatric illnesses in the elderly. In this chapter, I begin with classification of anxiety disorders based on DSM-IV, summarize findings of phenomenology of anxiety disorders in the elderly from the literature, discuss manifestations of anxiety in certain medical and neuropsychiatric illnesses, present a systematic way of assessing anxiety in the elderly and differentiating it from depression, and summarize treatment methods particularly suited to geriatric anxiety.

## ■ Classification of Anxiety Disorders

DSM-IV describes operationally defined, phenomenologically oriented diagnostic criteria for various anxiety disorders. A list of anxiety disorders based on DSM-IV classification appears in Table 15–2. A detailed description of the diagnostic characteristics of each disorder can be found in DSM-IV.

## ■ Epidemiological Studies

Epidemiological studies of anxiety disorders in the elderly are scant and data somewhat conflicting depending on the methodology used. Data from the Epidemiologic Catch-

**TABLE 15-1. Multidimensional symptoms of anxiety**

Cognitive	Behavioral	Physiological
Nervousness	Hyperkinesis	Tachycardia
Apprehension	Repetitive	Palpitations
Racing thoughts	motor acts	Chest tightness
Worry	Stiffness	Dry mouth
Fearfulness	Phobias	Hyperventilation
Irritability	Pressured speech	Paresthesias
Distractibility	Startle response	Lightheadedness
		Sweating
		Urinary frequency

ment Area (ECA) study (Myers et al. 1984) suggest that phobias are the most common psychiatric disorder in elderly women and the second most common in elderly men, ages 65 and above. In an age comparison of the Duke community sample of the ECA data between age groups of 45–64 (middle-aged) and 65 or older (older-aged), Blazer et al. (1991) show that prevalence of all anxiety disorders declines somewhat from the middle-aged to the older-aged group, although a formidable combined prevalence of 19.7% was found for the 6-month period when persons were not excluded as a result of a comorbid psychiatric disorder. Some other studies have reported lower point prevalence rates. For example, using a computerized program, AGE-CAT, which is an algorithm for assembling information at interview, Kay (1988) found a rate of anxiety disorders of around 2% in the United Kingdom. It appears, however, that 50%–75% of elderly cases with clinical levels of anxiety were diagnosed as depression. Kay (1988) suggests that, if diagnosed independently, the prevalence of anxiety disorders would be doubled. Similarly, lower prevalence rates of diagnosis of anxiety disorders were found in community samples in which depression was diagnosed first in samples presenting with a mixed picture of anxiety-depression (Copeland et al. 1987). Blazer et al. (1991) also suggest the possibility of underreporting as a result of a higher threshold for reporting generalized anxiety symptoms in the older-aged group and a tendency to seek assistance when that threshold is reached.

Earlier epidemiological studies investigating symptomatology of anxiety as opposed to distinct disorders have also suggested high prevalence of clinically significant symptomatology. For example, Himmelfarb and Murrell (1984) found clinically significant symptomatology of anx-

ity among 22% of women and 7% of men among a sample of more than 2,000 community persons in Kentucky, ages 55 and older. Evidence also shows that patients with chronic medical disorders are especially prone to developing anxiety. In a community survey based on data from the National Institute of Mental Health (NIMH) ECA Program, more than 11% of people with a chronic medical illness were found to have had a recent anxiety disorder (Wells et al. 1988). Because more than 80% of people in the United States older than 65 report at least one chronic medical condition (National Center for Health Statistics 1987), geriatric patients are at increased risk for developing anxiety.

In conclusion, it appears that anxiety symptoms and disorders are among the most common psychiatric ailments experienced by older adults, particularly when a mixed-symptom picture of anxiety-depression is also considered.

## ■ Phenomenology of Anxiety Disorders in the Elderly

As noted above, empirical studies of the phenomenology of late-life anxiety disorders are scant. However, recent data shed some light on panic disorder (Sheikh and Swales 1998), phobias (Lindesay 1991), and posttraumatic stress disorder (PTSD) (Goenjian et al. 1994) in late life. Panic disorder is usually a chronic syndrome with frequent recurrences and remissions. Preliminary investigations suggest that many older patients with onset of panic attacks in early life seem to continue with their symptomatology in later life, with many of them receiving inadequate or no treatment over the years (Sheikh et al. 1991). It is less common

for panic disorder to appear *de novo* in old age (Luchins and Rose 1989; Sheikh et al. 1988).

We have previously reported data from ongoing research in our program suggesting phenomenological differences in patients with early-onset panic disorder (EOPD) with onset before the age of 55 versus patients with late-onset panic disorder (LOPD) (at or after the age of 55). Specifically, preliminary analysis of our data indicated that patients with LOPD commonly report less severe symptomatology during panic attacks, experience less severe catastrophic cognitions related to attacks, and have less avoidance behavior (Sheikh et al. 1991). In a more recent attempt to replicate our initial findings, we analyzed data from 171 self-referred patients with panic disorder (Sheikh and Swales 1998). Of this sample, 99 belonged to the EOPD group (mean age = 62.07); 26, to the LOPD group (mean age = 64.81); and 45, to the younger panic disorder (YPD) group (mean age = 38.82). After informed consent was obtained, participants were administered the Structured Clinical Interview for DSM-III-R (Spitzer et al. 1987), and a psychiatric and medical history was taken. Additional measures that assessed panic-associated domains included: cognitions, physiological symptoms, behaviors, and global functioning. Data from this larger sample replicate and confirm our earlier findings that patients with LOPD tend to have a less severe form of panic disorder and report less cognitive distress, fewer avoidance behaviors, less overall physiological arousal, and higher overall (global) functioning compared with that of either the EOPD or YPD group. This group difference may imply different causative mechanisms, risk factors, clinical course, and prognosis for patients with LOPD. Our group is investigating these issues by identifying possible risk factors (e.g., family history, life stressors, medical and psychiatric comorbidity) as well as studying the clinical course and any differential treatment response of these groups.

Epidemiological data (Blazer et al. 1991) indicate that phobic disorders are in general chronic and persisting in old age. Clinical experience suggests that public speaking may seem less frightening and eating in public more bothersome to the elderly compared with those tasks for younger people. Fear of crime seems to be particularly prevalent in the elderly population, especially in an urban setting. In a survey of elderly people in an English urban setting, Clarke and Lewis (1982) reported that 66% of their sample stated that they did not go out after dark for fear of victimization and 15% reported that this fear was a primary concern. There is also a suggestion of nocturnal neurosis in the elderly as a result of fear of crime (Cohen 1976). The elderly thus appear to be the group most anxious about crime, though they are apparently the least likely to be victimized

(Clarke and Lewis 1982). Another study (Lindesay 1991) indicates that phobic disorders in the elderly are associated with considerably higher psychiatric and medical morbidity compared with that in case controls. Further, 17 of the 28 agoraphobics described the onset of their symptomatology after the age of 65, and despite increased rates of contact with primary care services, none was receiving any specific treatment for his or her phobic disorders.

Reports of PTSD in elderly Holocaust survivors (Kuch and Cox 1992) and among elders who were prisoners of war during World War II (Speed et al. 1989) indicate that PTSD can be a chronic disorder continuing into old age. A report also documents development of PTSD for the first time in old age among survivors of the 1988 Armenian earthquake (Goenjian et al. 1994). It appears that although the overall severity of PTSD seemed similar among both young and elderly survivors of the earthquake, the elderly reported less reexperiencing but more symptoms of hyperarousal compared with that reported by the younger people. It may be premature to assign any significance to these differences before further replication of these findings.

In summary, from the limited available data, it appears that panic disorder starting earlier in life typically tends to run a chronic course with continuation into old age. New onset of panic disorder in late life is rare and when it does occur, it tends to be of milder severity. Data on phobias and PTSD are too scant and preliminary to draw any conclusions, whereas empirical data on phenomenological manifestations of other anxiety disorders in late life are nonexistent.

## ■ Neurobiology of Anxiety in the Elderly

Most recent work investigating neurobiology of anxiety has been performed in younger populations, and its relevance to the elderly remains unknown at present. In this section, I summarize literature on the neurobiology of anxiety and discuss the relevance of age-related changes in various neurotransmitter systems to phenomena of anxiety and fear in the elderly.

Attempts to discern neurobiology of anxiety date back to empirical work by Cannon (1929) in cats and suggested that central discharges, possibly thalamic in origin, are the harbinger of fear and anxiety. Increasing evidence accumulated during the last several years points to the locus ceruleus in the midbrain, containing approximately half of central norepinephrine neurons, as the harbinger of states of fear and panic. For example, Redmond and Huang (1979) document central noradrenergic activation in anxi-

ety and fear states and suggest that the locus ceruleus is implicated in such emotions. Charney et al. (1985) report a greater number of yohimbine-induced anxiety symptoms in patients with panic disorder compared with that in control subjects as well as a blunting of yohimbine response after treatment with alprazolam, supporting the hypothesis of noradrenergic activation as a result of locus ceruleus discharge of norepinephrine in panic attacks. Simson and Weiss (1988) also suggest that locus ceruleus plays a key role in the “fight or flight” response mediated via activation of the central noradrenergic system. As for the normal age-related changes in noradrenergic functioning in older populations, Sunderland et al. (1991) summarize findings from several studies suggesting that such function in old age declines and includes a decrease in the number of locus ceruleus neurons, a decrease in norepinephrine content in many brain areas, and an increase in monoamine oxidase (type B) levels (also see Chapter 3 in this volume). These findings support the phenomenological research documenting a milder symptomatology in late-onset panic disorder (Sheikh et al. 1991). Unlike studies of the noradrenergic system, those of the serotonergic system in younger patients with anxiety disorder as well as in nonanxious elderly have yielded mixed and nonconclusive results (Sunderland et al. 1991).

Since the report by Pitts and McClure (1967) that an infusion of 10 mg/kg of 0.5 M racemic sodium lactate produced panic symptoms in 13 of 14 patients who were neurotically anxious (that is, had panic disorder by present criteria) and in only 2 of 16 psychiatrically healthy control subjects, various investigators have reproduced this finding (Kelly et al. 1971; Liebowitz et al. 1984). It is now well accepted that lactate infusion produces panic attacks in approximately 70% of patients with panic disorder. The underlying mechanism for induction of panic attacks with sodium lactate remains unclear, though various postulates include sodium lactate being a nonspecific stimulant producing uncomfortable somatic sensations or a conversion of lactate to bicarbonate and CO<sub>2</sub>, with CO<sub>2</sub> crossing the blood-brain barrier and producing a transient intracerebral hypercapnia leading to stimulation of brainstem chemoreceptors. Other techniques for successful induction of panic include administration of caffeine, which may block adenosine receptors (Boulenger et al. 1984); administration of yohimbine, which may challenge locus ceruleus activation as a result of its  $\alpha_2$ -adrenergic antagonism (Charney et al. 1982); and inhalation of 5% CO<sub>2</sub> (Gorman et al. 1989). No reports of panic induction in the elderly are described in the literature, and it is not clear whether such

methods will be safe to use in this population. Availability of neuroimaging techniques has provided an impetus for carrying out more specific studies to delineate neurobiological basis of anxiety disorders. For example, Reiman et al. (1989) have documented increased parahippocampal activity during panic attacks provoked by lactic acid as well as significant blood flow increases bilaterally in the temporal poles.

Of the various theoretical models of anxiety based on neurobiological findings, three seem to be the most popular at present. The first, espoused by Gray (1982), is a complex schema of the central role of a “Behavioral Inhibition System” in the manifestations of anxiety, which involves neuroanatomical structures of the septohippocampal system and the noradrenergic, serotonergic, and GABAergic<sup>1</sup> neurotransmitter systems in a rather complicated relationship. The second model is that of Gorman et al. (1989), who have proposed a neuroanatomical hypothesis for panic disorder locating the acute panic attack in the brainstem, anticipatory anxiety in the limbic system, and phobic avoidance in the prefrontal cortex. The third and most recent model of an integrated neurobiology of panic has been espoused by Goddard and Charney (1997). In this model, the amygdala is at the center of fear and anxiety responses, with extensive afferent and efferent connections to many other fear-related neuronal structures including hippocampus, locus ceruleus, hypothalamus, and orbitofrontal cortex. This more complex model has explanatory potential for several features of panic disorder including spontaneous panic attacks, anticipatory anxiety, and avoidance behavior, among others.

In summary, whereas the relevance of the above-mentioned theoretical models of anxiety to the elderly is unknown at present, a decline in central noradrenergic activity with aging may explain the milder symptomatology of LOPD.

## ■ Anxiety and Medical Illness

Anxiety is commonly associated with medical illness for several reasons. First, being the most common psychiatric conditions, anxiety symptoms and syndromes can present as coincidental comorbid conditions. In such cases, a long-standing history of an anxiety disorder is typically forthcoming. Second, anxiety could manifest as an expected response to a physical stressor, and a temporal association with the onset of a particular medical disorder is usually present. Third, anxiety can be a manifestation of

<sup>1</sup>  $\gamma$ -aminobutyric acid.

physiological changes occurring as a result of a medical illness (e.g., Parkinson's disease) or a medication (e.g., theophylline). Finally, sudden onset of anxiety can also signal a rapidly deteriorating medical condition in patients with or without a chronic medical illness (Wise and Griffies 1995). Common medical conditions associated with anxiety are briefly described below.

### **Cardiovascular Illness**

Panic attack symptoms, consisting of palpitations, dyspnea, chest tightness, sweating, and tingling sensations in the arms, can simulate both angina pectoris and myocardial infarction. For example, between 30% and 50% of patients presenting with recurrent chest pain and no evidence of cardiovascular disease may have panic disorder (Beitman et al. 1990; Carter et al. 1997). Such episodes in older age group patients should, however, always prompt a thorough investigation of the cardiac status of the patient, except perhaps in patients in whom a diagnosis of panic disorder is well established. The relationship of panic disorder and mitral valve prolapse remains unclear, with some of the studies suggesting a higher rate of association than that in control subjects (Gorman et al. 1988; Kantor et al. 1980) and others questioning such evidence (Margraf et al. 1988; Mazza et al. 1986). Such studies have focused on generally younger patients, and data on such association or lack thereof in older patients are lacking.

### **Pulmonary Causes**

Elderly patients at bed rest remain at risk for pulmonary embolism, which might be the most common pulmonary cause of sudden anxiety in such patients. A ventilation-perfusion scan and a phlebogram can be diagnostic. Some reports also suggest an unusually high number of panic disorder cases among patients with chronic obstructive pulmonary disease (Karajgi et al. 1990; Yellowlees et al. 1987). More recently, in another study, 40% of mostly geriatric patients with chronic obstructive pulmonary disease reported significant anxiety (White et al. 1997).

### **Dietary Causes**

Caffeine intake in the form of coffee, tea, and soda can produce anxiety-like symptoms in doses as little as 200 mg (one cup = 150 mg) (Victor et al. 1981). Caffeine has also been implicated in precipitating full-blown panic attacks (Charney et al. 1985; Lee 1985; Uhde et al. 1984). A history of caffeine use should be obtained in patients with symptoms of anxiety to rule out any temporal relationship. A decrease in daily caffeine consumption in some cases can be a simple and effective intervention.

### **Drugs**

For common cold and allergic conditions, the elderly commonly use over-the-counter preparations, which can produce anxiety-like symptoms as a result of their content of adrenergic agents such as ephedrine or pseudoephedrine. Prescription drugs that can produce anxiety include amphetamines, bronchodilators such as isoproterenol and theophylline, and some calcium channel blockers such as verapamil, nifedipine, and diltiazem. A careful history of drug intake should thus be a part of the clinical assessment of anxiety in the elderly. Akathisia, a common side effect of neuroleptics, is a subjective sense of restlessness often indistinguishable from anxiety. Akathisia can also closely resemble agitation because of a tendency in patients with both conditions to pace around. Inquiring about drug history can give a clue into its temporal relationship with drug intake. Alcohol withdrawal is a well-recognized cause of anxiety and agitation among hospitalized patients (Lerner and Fallen 1985). Sedative-hypnotic withdrawal, however, might be somewhat underestimated as a cause of anxiety syndromes in older populations, in whom hypnotic use is frequent (Schweizer et al. 1989). At the beginning of the hospitalization, clinicians should inquire about any such drug use and treat with appropriate medications.

### **Endocrine Causes**

Unlike younger populations, in whom two-thirds or more of patients with hyperthyroidism may meet DSM-III criteria for an anxiety disorder (American Psychiatric Association 1980; Kathol et al. 1986), patients over 60 have hyperthyroidism more insidious in presentation, sometimes labeled as "apathetic" as opposed to "anxious or agitated" hyperthyroidism of younger people (Hurley 1983). Hypoparathyroidism and hyperparathyroidism, hypopituitarism and hyperpituitarism, hypoglycemia, diabetes mellitus, and Cushing's syndrome can also be associated with anxiety-like symptoms (Popkin and Mackenzie 1980).

In summary, older patients with medical illnesses commonly experience concomitant anxiety. Such comorbidity may confound the clinical picture for both the primary care physician and the neuropsychiatrist, and thus a systematic approach to proper evaluation of anxiety in such patients is needed and described below in the section on evaluation.

### **Neurological Disorders Associated With Anxiety**

Many neurological disorders are associated with symptoms of anxiety or a diagnosable anxiety disorder. In a comprehensive review of psychiatric presentations of medical ill-

nesses, Hall (1980) suggests that neurological disorders are among major contributors to medical causes of anxiety and contends that cerebral vascular insufficiency may be the most common neurological cause of anxiety. Below, I briefly review the literature describing association of anxiety with various neurological disorders, with particular focus on Parkinson's disease, dementia, and stroke.

Although association of depression with Parkinson's disease is now considered a generally accepted fact, presence of anxiety in this illness has received attention from researchers only relatively recently (see also Chapter 26 in this volume). In one study, 9 (38%) of 24 subjects (mean age = 58) with idiopathic Parkinson's disease had a clinically significant anxiety disorder (Stein et al. 1990). Another report describes 12 of 16 patients with Parkinson's disease meeting the criteria of a present or past diagnosis of either panic disorder or generalized anxiety disorder (Schiffer et al. 1988). Another study (Henderson et al. 1992) documents a picture of mixed anxiety-depression in 38% of 164 patients with Parkinson's disease (mean age = 67) compared with 8% in 150 age-matched psychiatrically healthy spouse control subjects. It also appears that left-sided Parkinson's disease may be associated with a greater degree of anxiety and depression (Fleminger 1991). There is some suggestion that high prevalence of anxiety disorders in patients with Parkinson's disease may be a result of a loss of normally existing dopaminergic inhibition of locus ceruleus (Iruela et al. 1992). It is speculated further that early ceruleal or nigroceruleal dopaminergic pathway degeneration leading to disinhibition of locus ceruleus may be responsible for high rates of panic disorder preceding the onset of motor signs in patients with familial parkinsonism (Lauterbach 1993). Finally, one has to be mindful that the drug treatment of Parkinson's disease itself may produce symptoms of anxiety (Cummings 1991).

In the Perth Community Stroke Study (Burvill et al. 1995), in a sample of 294 patients at 4 months poststroke, prevalence of anxiety disorders was 12% in men and 28% in women. After subtracting those who had evidence of anxiety disorder before stroke, the latter prevalence was 9% in men and 20% in women. Similarly, in 80 patients with acute stroke (0–3 months), prevalence of generalized anxiety disorder (GAD) was found to be 28% (Astrom 1996). Of concern, only 23% of these patients had remission of their GAD symptoms at 12-month follow-up. Although both depression and anxiety can be common consequences of a stroke, Robinson and Starkstein (1990) reported that comorbid major depression and GAD are associated with cortical lesions, whereas depression alone is associated with subcortical lesions (see also Chapter 27 in this volume). There is also some suggestion that women and youn-

ger patients may be more prone to developing anxiety after stroke (Schultz et al. 1997).

Anxiety-like symptoms and agitated behaviors are also common in dementing disorders (Teri et al. 1988). In fact, as many as 85% of patients with dementia develop disruptive agitated behavior (Jeste and Krull 1991) (see also Chapters 23 and 24 in this volume). Wands and colleagues (1990) reported that 38% of patients with early dementia were found to have anxiety. It is also speculated that agitation at times may be a possible expression of GAD in patients with dementia (Mintzer and Brawman-Mintzer 1996). Neurobiological underpinnings of agitation in patients with dementia remain controversial at best, although noradrenergic, serotonergic, and dopaminergic deficits are implicated (Kirby and Lawlor 1995).

In summary, anxiety can be frequently associated with Parkinson's disease, dementias, and stroke. Neurotransmitter mechanisms underlying such symptomatology are rather complex and probably depend on a functional balance between dopaminergic, cholinergic, GABAergic, glutamatergic, and peptidergic neurotransmission (Hartmann et al. 1993).

Other neurological disorders described in the literature as sometimes associated with anxiety include multiple sclerosis, peripheral neuropathy, myasthenia gravis, Huntington's disease, Wilson's disease, closed head injury, and tumors of the brain (Hall 1980). Further, anxiety remains one of the most disturbing symptoms in a small percentage of patients with postconcussion syndrome (Leigh 1979) (also see Chapter 28 in this volume), and temporal lobe epilepsy can mimic panic disorder (Edlund et al. 1987).

## ■ Evaluation of Anxiety in the Elderly

Several factors can make proper assessment of anxiety potentially difficult. These include a confounding of symptom picture by high medical comorbidity, frequent use of multiple prescribed and over-the-counter medications, substance use, difficulty of differentiating anxiety from depression, and a tendency to resist psychiatric evaluation in older cohorts. With these caveats in mind, evaluation of anxiety in the elderly is usually accomplished in three major ways: clinical evaluation, assessment with rating scales, and laboratory investigations.

### Clinical Evaluation

The clinical evaluation should include a history of presenting symptomatology, past illness (e.g., panic disorder can be characterized by remissions and relapses), a detailed his-

tory of current prescribed and over-the-counter medications (including analgesics, cold medications, anticholinergic medications, herbal and vitamin supplements), a history of alcohol or substance use, and a family history (may be helpful in panic disorder). A mental status examination can reveal many of the cognitive and behavioral signs and symptoms of anxiety including apprehension, fearfulness, distractibility, hyperkinesia, and startle response. Physiological signs and symptoms including increased pulse rate, rapid breathing, sweating, and trembling should be assessed during the physical examination.

### Assessment With Rating Scales

Anxiety rating scales are useful adjuncts to the clinical evaluation of anxiety. These measures can serve as initial screening devices, can be helpful in assessing severity of symptoms, and can be used as instruments to document effectiveness of various psychological and pharmacological therapeutic interventions. These scales are primarily of two kinds: observer-rated and self-rated. The most commonly used observer-rated scale is the Hamilton Anxiety Rating Scale (HARS) (Hamilton 1959). HARS is a 14-item scale with each item rated on severity from none (0) to very severe (4). A rating of 18 or above is generally considered to be suggestive of clinically significant anxiety. Though HARS is presently the standard in the field as a measure of change in clinical situations and in pharmacological research, older published studies in geriatrics seemed to indicate limited sensitivity to change with active drug treatment (Kochansky 1979; Salzman 1977). A more recent study, however, seems to suggest that HARS can differentiate between older patients with GAD and control subjects (Beck et al. 1996). The most frequently used self-rated scales are the State-Trait Anxiety Inventory (STAI) (Spielberger et al. 1970), the Symptom Checklist-90-Revised (SCL-90-R; Derogatis 1975), and the Beck Anxiety Inventory (BAI) (Beck et al. 1988). Several recent studies have suggested that BAI can be useful in differentiating anxious elderly subjects from nonanxious control subjects and also useful as an instrument sensitive to measure change with treatment (Stanley et al. 1996; Steer et al. 1994; Wetherell and Arean 1997). BAI is a 21-item inventory with a rating on a severity scale of none (0) to severe (3). A rating of 21 or above on BAI is suggestive of clinically significant anxiety.

### Laboratory Investigations

Laboratory tests can aid in diagnosing underlying medical conditions producing signs and symptoms of anxiety. A

complete blood count, vitamin B<sub>12</sub> and folate levels, electrocardiogram, thyroid function tests, blood sugar, blood gases, and drug and alcohol screening can be helpful when used appropriately to rule out more common medical conditions associated with anxiety as described earlier.

## ■ Anxiety and Depression

Debate about the complex relationship of anxiety and depression has raged in the psychiatric literature since the days of Sir Aubrey Lewis (1934) and continues to be a recurrent theme in the psychiatric literature (see also Chapter 13 in this volume). Traditionally, three major positions have been adhered to by various investigators: 1) anxiety and depression lie on the same continuum; 2) they are distinct conditions that are frequently comorbid as a result of their high prevalence; and 3) they are different expressions of the same biological diathesis. Despite recent advances in our knowledge about the phenomenology and biology of these conditions, we do not seem any closer to resolving this controversy. Comorbid depression and anxiety appear to be extremely common in older adults (Flint 1994). In a small sample of geriatric psychiatry outpatients, Alexopoulos (1991) reported that 38% of patients with depression also met criteria for an anxiety disorder according to DSM-III. The Guy's/Age Concern Survey reported that 39% of subjects with phobia had comorbid depression compared with only 11% of subjects without phobia (Lindsay et al. 1989). The presence and severity levels of GAO and depression were especially associated. Studying geriatric adults in South Africa who had been diagnosed with depression, Ben-Arie and colleagues found that 26% also had generalized anxiety and 5% had panic attacks (Ben-Arie et al. 1987). Comorbid anxiety and depression are also common in geriatric medical patients. For example, in a study of geriatric patients with cancer, Derogatis and colleagues reported that 13% evidenced mixed anxiety-depressive syndrome, whereas 8% evidenced an anxiety disorder exclusively (Derogatis et al. 1983).

Making a distinction between anxiety and depression clinically was considered to have pragmatic value previously because older antidepressants such as the tricyclics had many undesirable side effects for the elderly, whereas anxiolytics such as benzodiazepines and buspirone were relatively well tolerated. However, since the introduction of the serotonin selective reuptake inhibitors (SSRIs) and increasing evidence of their efficacy in the mixed-symptom picture of both anxiety and depression, this debate seems to have lost some of its intensity. Thus, a recent philosophical shift has led to acceptance of a mixed-symptom picture as

reflected in the inclusion of mixed anxiety-depression syndrome as a special category in the DSM-IV. Though mixed anxiety-depression is included as a research category, clinically it is one of the most frequently encountered presentations in geriatric neuropsychiatric practice. A mixed picture of depression and anxiety in older patients may signify the presence of an anxiety disorder coexisting with a distinct depressive disorder, the presence of one disorder associated with symptoms of another, or, more commonly, a mixed anxiety-depressive disorder in which symptoms of neither anxiety nor depression reach diagnostic threshold for an established disorder. Although symptoms of mixed anxiety-depression syndrome may not reach criteria for an established disorder, some patients experience significant functional impairment and marked subjective distress. If symptoms progress and persist for more than a month at this level of functional impairment, treatment is indicated.

In summary, a mixed picture of anxiety and depression is common among older patients in both medical and psychiatric settings. Recent studies suggesting efficacy of antidepressants for both depression and anxiety may make the older (at times painstaking) attempts to separate anxiety and depression somewhat less relevant from a clinician's perspective.

## ■ Complications of Anxiety Disorders

### Physical Illness

The issue of short- and long-term effects of anxiety on physical health remains unresolved. This question may be of particular relevance to the elderly population because of their relative increased susceptibility to developing physical illness and the possibility that they may accumulate adverse effects of anxiety over many years. A strong association of anxiety states with many medical conditions has been discussed in the literature in the past two decades. For example, researchers have documented association of anxiety with asthma (Alexander 1972), hypertension (Whitehead et al. 1977), and duodenal ulcer (Sandberg and Bliding 1976). Some authors have also contended that anxiety can give rise to potentially lethal arrhythmias (Jenkins 1971) and have suggested the use of diazepam in such cases. Also, evidence suggests that anxiety might act as a predictor of future morbidity in patients with cancer. For example, Carey and Burish (1985) found that in patients with cancer who were receiving chemotherapy, greater treatment gains were found in patients with lower pretreatment anxiety. Such associations cannot be considered causal, however, because the relationship between anxiety and physical

functioning is complicated. For example, anxiety seems to contribute to heart disease, whereas heart disease itself increases anxiety (Jenike 1985). Though knowledge about the specific mechanism by which anxiety and autonomic arousal can cause tissue damage is lacking, it is possible that the elderly accumulate deleterious effects of anxiety on the cardiovascular system over many years. Of relevance, Nowlin et al. (1973) reported in a prospective study that elevated levels of anxiety predicted the future occurrence of myocardial infarction in older men. Though this study can be considered only preliminary because of the small sample, it is of sufficient importance to warrant attempts at replication. In another survey of older adults, Himmelfarb and Murrell (1984) found a significant association of anxiety with the presence of some medical conditions including high blood pressure, kidney and bladder disease, cardiac disease, stomach ulcers, arteriosclerosis, stroke, and diabetes. It appears that patients with chronic medical disorders are especially prone to developing anxiety. For example, in a community survey based on data from the NIMH ECA Program, more than 11% of people with a chronic medical illness were found to have had a recent anxiety disorder (Wells et al. 1988). Because more than 80% of Americans older than 65 report at least one chronic medical condition (National Center for Health Statistics 1987), geriatric patients are at increased risk for developing anxiety.

### Alcohol Abuse

Several reports have documented unusually high rates of comorbidity between anxiety disorders and alcohol abuse (Chambless et al. 1987; Hasselbrock et al. 1985; Kushner et al. 1990; Ross et al. 1988; Weissman 1988) (also see Chapter 16 in this volume). Boyd et al. (1984) have estimated that the risk of alcohol problems in patients with phobia is about two and a half times that of the general population, and the risk in patients with panic disorder is more than four times. Some evidence from family studies suggests that alcoholism and anxiety are on the same spectrum of disorders. For example, Munjack and Moss (1981) found alcohol abuse among 26.5% of the first-degree relatives of people with agoraphobia, 20% of the relatives of those with social phobia, and 8.6% of the relatives of those with mixed simple phobia. Harris et al. (1983) found that approximately 10% of the relatives of patients with panic disorder and 17.6% of the relatives of those with agoraphobia had alcoholism, as opposed to only 5.4% in the control group. Though a relationship as to the cause and effect between alcoholism and anxiety disorders is not clear at present, sufficient evidence from the literature (Kushner et al. 1990) suggests that, at least in cases of agoraphobia and social phobia, alcohol

problems seem to be related to attempts at self-medication. It also appears that comorbidity is not uniform for all anxiety disorders; therefore, generalizations regarding alcoholism in anxiety states as a homogeneous group should be avoided.

Even though none of these studies have looked at this issue with particular reference to the elderly, one should keep in mind that similar comorbidity with alcoholism can exist in that population also. Considering that older people may be particularly vulnerable to effects of alcohol as a result of changes in hepatic metabolism and increased sensitivity of the central nervous system (Atkinson 1989; Liptzin 1991), clinicians need to be alert to inquire about such history in patients with anxiety. Finally, alcohol withdrawal can itself present as severe anxiety, as noted above.

## Insomnia

Sleep disturbances are common in patients with anxiety (also see Chapter 17 in this volume). In a study assessing vegetative signs and symptoms of anxiety, Mathew and colleagues (1982) found that restless sleep was the only vegetative symptom consistently related to anxiety. On the other hand, anxiety appears to be a common finding in patients with chronic insomnia. Some investigators have looked at differential effects on sleep of various anxiety syndromes. For example, in a study conducted by Reynolds et al. (1983), patients with GAD were found to have difficulty similar to that of patients with depression in both initiating and maintaining sleep. However, these investigators also found that the shortened rapid eye movement (REM) latency and increased percentage of REM sleep found in patients with depression are missing in patients with anxiety. Other researchers (Insel et al. 1982) suggest similarities between the sleep of patients with obsessive-compulsive disorder (OCD) and that of patients with depression in that both groups seem to have short REM latency compared with subjects without OCD or depression. Like patients with GAD, those with panic disorder frequently complain of difficulty in initiating and maintaining sleep (Sheehan et al. 1980). However, it appears that their REM latencies, though shorter than those of control subjects as a group, still fall within the lower limit of normal, unlike that of patients with depression (Uhde et al. 1984). Finally, it appears that patients with PTSD show a reduced efficiency of sleep, with recurrent nightmares and a lower percentage of REM sleep.

It thus appears from the foregoing studies that anxiety disorders can create problems in initiating and maintaining sleep as well as significantly affect the quality of sleep. The implications of these findings are significant for about

5 million elders in the United States who have severe sleep problems (Moran et al. 1988). Inquiry into the duration and quality of sleep should be an integral component of any management plans for geriatric anxiety. Such inquiry should take into account the common clinical observation that older people tend to go to bed early and may nap during the day; a seemingly early wake-up time may not be so in reality, and the total amount of sleep, including nap time, may be sufficient for many. Taken together, anxiety and insomnia are among the most frequently encountered problems in geriatric patients (Folks and Fuller 1997). In cases where both anxiety and insomnia overlap, it would be prudent to consider treatments beneficial for both, be they nonpharmacological aids to sleep or sedative-hypnotics.

## Increased Mortality of Cardiovascular Origin

In a series of long-term (30–50 years) follow-up studies, Coryell et al. (1982, 1986) have documented increased mortality as a result of cardiovascular disease among male but not female patients with panic disorder. Specifically, it appears that males with a panic disorder diagnosis were twice as likely to die compared with expected deaths based on age and gender matching. After a review of causes of death in his sample of men, Coryell (1988) attributed the excess mortality to chronic hyperarousal and exercise intolerance of patients with panic disorder and possibly to additional deleterious effects of associated smoking or alcohol abuse. Such findings suggest the need for proper control of panic attacks and associated chronic hyperarousal, as well as the management of the associated smoking or alcohol abuse if present.

In summary, chronic untreated anxiety can be associated with myriad complications including long-standing sleep problems, alcohol abuse, high blood pressure, stroke, and possibly increased mortality of cardiovascular origin.

## Management of Geriatric Anxiety

Effective management of geriatric anxiety can be accomplished by using pharmacological or psychological treatments, sometimes as monotherapies and at other times in conjunction with each other.

### Pharmacological Treatments

Several factors can complicate psychopharmacological management of the older patient with anxiety. These factors include physiological changes associated with aging

that affect pharmacokinetics and pharmacodynamics of drugs, presence of comorbid medical conditions, and polypharmacy (see Chapter 34 in this volume).

Age-related changes in pharmacokinetics put older patients at higher risk of adverse reactions from drugs. The most important of these changes are: 1) decreased absorption (with decreased gastric acidity, motility, blood flow, and gastrointestinal surface area); 2) decreased protein binding (with decreased albumin); 3) increased volume of distribution of lipophilic drugs; 4) decreased hepatic function (with decreased hepatic metabolism, first-pass effect, demethylation, and hydroxylation); and 5) decreased renal excretion (with decreased renal blood flow, glomerular filtration rate, and tubular excretory capacity). The overall effect of these changes is that many medications are absorbed and metabolized less efficiently and eliminated more slowly in older patients than in younger ones (von Moltke et al. 1995). Thus, the period of risk of side effects is prolonged in older patients because these drugs stay in the body longer. Even average dose ranges for the general population may be toxic for the elderly. In addition, pharmacodynamic changes in the aging nervous system make older patients more sensitive to the side effects of psychotropic medications (Salzman et al. 1995).

Older patients are more likely than younger people to have concurrent medical illnesses that may be exacerbated by the side effects of medications. In addition, the presence of chronic kidney, liver, or heart disease can further delay clearance of drugs, thus making adverse reactions more likely. Although the elderly constitute 12% of the population, they are prescribed 25% of all medications and as a group consume the majority of over-the-counter drugs (Kane et al. 1994). Not surprisingly, the average older person typically takes six to eight different medications per day. The risk of adverse drug interactions also increases substantially with such polypharmacy. Further, many of the commonly prescribed nonpsychotropic agents (e.g., digoxin, theophylline, prednisolone, cimetidine) have detectable anticholinergic levels when measured with radioreceptor assay, though these agents are not commonly viewed as anticholinergic (Tune et al. 1992). However, when taken in combination, such medications can adversely affect cognition in the elderly while increasing the risk of anticholinergic syndrome when taken in combination with commonly used anticholinergic psychotropics.

Several additional factors should be considered when selecting a medication for an older patient with an anxiety disorder. For example, prior treatment response, the nature of the targeted symptoms, concurrent medications, and the most tolerable side-effect profile should all be taken into account. To reach the optimal dose for an older

patient without causing intolerable side effects, the old adage “Start low and go slow” is well worth remembering. Drugs may be given in divided doses throughout the day to minimize possible adverse side effects. However, with divided doses, noncompliance may be an issue of concern especially in medically ill older patients taking multiple medications. Liquid medications may be easier for some patients to take. Given the prevalence of polypharmacy in this age group, only one change at a time during medication adjustments is preferable. Finally, with any change in dose or medication, close monitoring is essential.

Over the years, numerous compounds have been used as anxiolytics, including alcohol, barbiturates, antihistamines, antidepressants, neuroleptics,  $\beta$ -blockers, and benzodiazepines. Though empirical studies of the efficacy of different anxiolytics have primarily been conducted in younger populations, such efficacy is inferred in clinical practice for older patients and modifications in dosing made accordingly. A brief description of different classes of compounds currently used as anxiolytics follows.

**Benzodiazepines.** Benzodiazepines have been the most frequently prescribed anxiolytics for the last three decades. The elderly are prescribed benzodiazepines at a rate disproportionately high to their percentage in the population (Moran et al. 1988). Table 15–3 lists the more commonly used benzodiazepines along with relevant information about their half-lives and the daily doses recommended for the elderly. Lower doses of benzodiazepines are recommended for older patients because the elderly are more sensitive to both the therapeutic and toxic effects of the drugs. Thus, doses that are therapeutic in younger patients may actually be toxic in geriatric patients (Meyer 1982).

Short half-life benzodiazepines such as lorazepam, oxazepam, and temazepam appear preferable in that they are metabolized by direct conjugation in the liver (phase II metabolism), a mechanism that does not seem to be affected by aging (Moran et al. 1988). In addition, these drugs are relatively less lipophilic and are thus less prone to accumulate in fatty tissues of the elderly compared with a more lipophilic drug such as diazepam. Most other benzodiazepines tend to be metabolized via oxidative pathways (phase I metabolism) into active metabolites that tend to linger on in the elderly for long periods of time. Several studies have documented in the elderly undesirable side effects of long-acting benzodiazepines (e.g., diazepam, clorazepate, chlordiazepoxide) including drowsiness, fatigue, psychomotor impairment, and cognitive impairment (Boston Collaborative Drug Surveillance Program 1973; Curran et al. 1987; Larson et al. 1987; Pomara et al. 1984, 1991). For example, Rosenbaum (1979) documents that the half-life

**TABLE 15-3.** Commonly used anxiolytic benzodiazepines: a summary of pharmacokinetics

Drug	Half-life (hr)	Active metabolites	Daily dose (mg)	
			Adult	Elderly
Alprazolam	12–15	Yes	0.25–2.0	0.125–1
Chlordiazepoxide	7–28	Yes	25–100	5–50
Clonazepam	18–56	Yes	1–8	0.5–4
Clorazepate	30–200	Yes	15–60	7.5–30
Diazepam	20–60	Yes	5–30	2–15
Lorazepam	10–20	None	1–6	0.5–3
Halazepam	15–50	Yes	20–160	20–80
Oxazepam	5–15	None	15–90	10–45
Prazepam	25–200	Yes	20–60	10–20

of diazepam's metabolites increases from 20 hours in a 20-year-old to 90 hours in an 80-year-old. Alprazolam, a commonly used, intermediate half-life, antipanic medication, has also been shown to have a half-life of more than 21 hours in the elderly compared with 11 hours in young people (Kroboth et al. 1990).

In summary, this review suggests that short-acting benzodiazepines such as oxazepam, lorazepam, and temazepam are preferable in the elderly, whereas long-acting benzodiazepines such as diazepam, clorazepate, and flurazepam appear less desirable in general. Given the probability that, if taken for long periods of time, even short-acting benzodiazepines will tend to accumulate in older people, any use of benzodiazepines in the elderly should be for specific indications and time-limited, preferably to less than 6 months. Table 15-4 documents potential complications of long-term use of benzodiazepines in the elderly.

**Buspirone.** Buspirone, an anxiolytic medication with partial serotonin-agonist properties, has demonstrated in double-blind studies efficacy comparable to that of diazepam in patients with GAO (Rickels and Schweizer 1987; Rickels et al. 1982). Its nonaddictive profile, absence of withdrawal symptoms when discontinued (Rickels et al. 1988), and lack of psychomotor impairment even with long-term usage (Smiley and Moskowitz 1986) seem to be an advantage over benzodiazepines in chronic anxiety conditions. Studies in geriatric samples indicate that buspirone is well tolerated, does not cause adverse interactions when co-prescribed with a variety of other medications (including antihypertensives, cardiac glycosides, and bronchodilators), and is effective for remediation of chronic anxiety symptoms in this population (Napoliello 1986). It also appears that in both acute and chronic dosing the pharmacokinetics of buspirone in the elderly are very similar to the pharmacokinetics in younger people (Gamman

et al. 1989). Unlike the benzodiazepines, which can cause respiratory depression, buspirone does not seem to affect respiration adversely and has been shown in animal studies to stimulate respiratory drive (Garner et al. 1989). Such a profile seems to suggest that buspirone may be a particularly desirable anxiolytic for chronic anxiety conditions of the elderly in cases in which long-term use might be indicated. However, in contrast to research data, clinical experience with this medication suggests that a therapeutic response is somewhat inconsistent. It is important to remember that buspirone can require up to 4 weeks before manifesting its therapeutic effects. It might be desirable to combine buspirone initially with a short-acting benzodiazepine that will provide rapid relief of symptoms but that can then be withdrawn after 2–4 weeks, once the therapeutic effects of buspirone have been established.

**Antidepressants.** Several researchers have documented the efficacy of antidepressants for panic disorder,

OCD, GAD, and PTSD in younger patients. For example, the tricyclic imipramine and the monoamine oxidase inhibitor phenelzine have proven to be efficacious in younger patients with panic disorder (Mavissakalian and Michelson 1986; Sheehan et al. 1980; Zitrin et al. 1983). More recently the SSRIs have been shown in several randomized and controlled clinical trials to demonstrate superior efficacy to placebo and at least equal efficacy to tricyclic antidepressants for panic disorder and OCD in generally younger patients (Boyer 1995; Coplan et al. 1996; Oehrberg et al. 1995). Emerging evidence indicates that newer "atypical" antidepressants such as venlafaxine (Geraciotti 1995) and nefazodone may also be efficacious in panic disorder (Fawcett et al. 1995).

Given these studies documenting their efficacy in younger patients and their generally favorable side-effect profile, the SSRIs should now be considered the first drugs of choice for panic disorder in older patients. These medications can be given in a single daily dose to maximize compliance. Two potential problems can decrease compliance with antidepressants: delayed onset of action and a feeling of jitters in the first 2 weeks of treatment. These problems can be minimized by patient education, addition of benzodiazepines in the first few weeks, and use of very small doses (e.g., sertraline 12.5 mg/day) at the beginning of treatment, which can then be increased gradually upward.

Similar to the findings in studies of SSRIs for panic disorder, fluoxetine, sertraline, it has been found that fluvoxamine, and paroxetine are all superior to placebo control groups for OCD patients (Greist et al. 1992; Gunasekara et al. 1998; McDougale et al. 1993). Comparisons also found fluvoxamine, sertraline, and paroxetine to be equal in efficacy to clomipramine (Koran et al. 1996), a well-established anti-OCD compound that is undesirable for use in older patients as a result of its strong anticholinergic profile. In addition, phenelzine was found to be equal in efficacy to clomipramine (Vallejo et al. 1992), but side effects and dietary restrictions that go along with the monoamine oxidase inhibitor make the use of this medication more problematic in older patients. As is the case of SSRIs with panic disorder, SSRIs are increasingly being recognized as the treatment of choice for the treatment of OCD because they are better tolerated than clomipramine (Stokes and Holtz 1997). This is even more the case when treating older patients because of their sensitivity to anticholinergic side effects of psychotropics and the potential for cumulative anticholinergic delirium when combined with commonly used medications for chronic medical illnesses (Tune et al. 1992).

Over the last decade, the role of antidepressants in the treatment of GAD has become more prominent. At least

one study has shown superior efficacy of a tricyclic antidepressant compared with that of a benzodiazepine for GAD (Hoehn-Saric et al. 1988). More recently, a double-blind, placebo-controlled study of 377 patients with GAD demonstrated superior efficacy of venlafaxine compared with that of placebo (Aguilar et al. 1998). Clomipramine, the SSRIs, and nefazodone are being studied currently and may also prove efficacious in GAD.

Randomized controlled trials of PTSD have been few and infrequent (Solomon and Gerrity 1992). Though mixed results were seen in earlier studies of tricyclic antidepressants (Davidson et al. 1990), SSRIs (Nagy et al. 1993), and benzodiazepines (Feldman 1987) for PTSD, recent open-label studies show promise with nefazodone and SSRIs (Davidson 1998; Hertzberg et al. 1998). Randomized controlled trials of sertraline and nefazodone are presently under way. As is the case with studies of other anxiety disorders, these studies have been conducted in generally younger patients. Treatment of PTSD in older patients in clinical practice is thus guided by results from studies in younger patients.

In summary, it appears that SSRIs can be efficacious in most anxiety disorders, whereas evidence is also emerging that newer antidepressants may also be efficacious in PTSD and panic disorder (nefazodone) and in GAD (venlafaxine).

### **Antihistamines, $\beta$ -blockers, and neuroleptics.**

Antihistamines such as hydroxyzine and diphenhydramine are used with varying degrees of success to sometimes manage mild anxiety, though empirical data are generally lacking regarding their efficacy. Some older reports have suggested that  $\beta$ -blockers such as propranolol and oxprenolol may be suitable for some geriatric patients with anxiety and agitation (Petrie 1983; Petrie and Ban 1981), particularly for agitation of individuals with dementia who are refractory to antipsychotic or benzodiazepine therapy (also see Chapters 22 and 24 in this volume). However, as a result of the hypotensive effects of  $\beta$ -blockers as well as the possible risk for developing congestive cardiac failure while taking these agents, they are rarely used in clinical situations. A meta-analysis of controlled trials of neuroleptics shows evidence of a moderate effect of traditional neuroleptics for management of agitation associated with dementia (Schneider et al. 1990). Some recent evidence from a randomized controlled trial supports superior efficacy of the atypical neuroleptic risperidone compared with placebo in the management of agitation associated with dementia (Katz et al. 1997). Because long-term use of neuroleptics increases the risk for developing tardive dyskinesia, any long-term use of these agents should probably be restricted

to agitated patients with clear evidence of, or strong clinical impression of, underlying psychosis.

In conclusion, a variety of compounds including benzodiazepines, buspirone, and antidepressants seem to show effectiveness for various anxiety disorders of the elderly, whereas atypical neuroleptics can be useful in the management of agitation associated with dementia.

## Psychological Treatments

Although medications are frequently the first-line treatment for late-life anxiety disorders, cognitive-behavior treatment (CBT), that is, therapies that integrate both cognitive and behavioral approaches, should be considered as an alternative in cases in which the possibility of side effects and drug interactions is high as a result of intercurrent medical problems and polypharmacy or in which compliance with a medication regimen is an issue (also see Chapter 36 in this volume). Further, current treatment strategies for panic disorder with agoraphobia and OCD usually involve the use of CBT as an adjunct to pharmacotherapy (Baer 1993; Ballenger 1993; Telch and Lucas 1993).

Substantial empirical research documents efficacy of CBT in anxiety disorders among younger populations. For example, several reports document efficacy of CBT in panic disorder (Barlow and Cerny 1988; Clark 1986; Clark et al. 1985), phobias (Marks 1981, 1987), and OCD (Marks 1981; Rachman and Hodgson 1980; Van Noppen et al. 1997) in the general population. Typically, such empirically supported therapies for anxiety disorders have applied relaxation, exposure therapy, and cognitive therapy as their components, either singly or in combination (DeRubeis and Crits-Christoph 1998).

Despite the substantial number of systematic studies documenting efficacious CBT treatments for younger patients, such studies are generally lacking for older patients. The efficacy of numerous therapies for older adults is often extrapolated from evidence with younger populations (Sheikh and Salzman 1995). Sometimes modifications are made to treatment protocols in an effort to make them more suitable for a geriatric population, yet these modifications have not been systematically investigated (Beck and Stanley 1997).

A few recent research studies and case reports support the efficacy of using CBT with older patients. For panic disorder, case studies support the use of CBT among older adults specifically (Rathus and Sanderson 1996). A recent study from our group (Swales et al. 1996) reported significant improvement among older adults with panic disorder using CBT and applied relaxation, and these gains were maintained at the 3-month follow-up. One controlled study has compared CBT and nondirective supportive psychotherapy in a group format for older adults with GAD (Stanley et al. 1996). Participants in both conditions manifested significantly lower worry, anxiety, and depression scores posttreatment and at 6-month follow-up. Table 15-5 summarizes strategies for effective management of anxiety disorders in the elderly, and Table 15-6 summarizes recommendations for treatment of anxiety associated with neurological disorders in late life.

## Conclusions and Future Directions

Despite increasing research interest in the area of anxiety in younger age groups, few systematic studies of the phe-

**TABLE 15-5. Treatment strategies for anxiety disorders in late life**

Disorder	First-line treatment(s)	Second-line treatment(s)
Panic disorder with or without agoraphobia	SSRIs and/or CBT	TCAs, MAOIs, and newer antidepressants
Generalized anxiety disorder	Benzodiazepines, buspirone, and/or CBT	SSRIs or nefazodone
Obsessive-compulsive disorder	SSRIs plus CBT	Clomipramine, combination pharmacotherapy
Social phobia		
Generalized	Phenelzine, SSRIs plus CBT	Benzodiazepines
Specific	$\beta$ blockers plus CBT	Buspirone
Simple (specific) phobia	CBT or benzodiazepines	$\beta$ blockers
Posttraumatic stress disorder	SSRIs or nefazodone	CBT
Mixed anxiety depression	SSRIs or nefazodone	CBT

*Note.* CBT = cognitive-behavior treatment; MAOIs = monoamine oxidase inhibitors; SSRIs = selective serotonin reuptake inhibitors; TCAs = tricyclic antidepressants.

**TABLE 15–6. Recommendations for treatment of anxiety associated with neurological disorders common in late life**

Disorder	Predominant manifestations of anxiety	Recommendation(s) for treatment
Parkinson's disease	Mixed anxiety and depression	Serotonergic drugs (e.g., buspirone, nefazodone, SSRIs)
Alzheimer's disease	Agitation	Atypical neuroleptics
	Mixed anxiety and depression Agitation	Serotonergic drugs Atypical neuroleptics, anticonvulsants, serotonergic drugs
Stroke	Mixed anxiety and depression	Serotonergic drugs
	Posttraumatic stress disorder	SSRIs, nefazodone

*Note.* SSRIs = selective serotonin reuptake inhibitors.

nomenclology and treatment of anxiety disorders in the elderly have been performed. Data from ECA studies suggest that anxiety disorders remain among the most prevalent of all psychiatric disorders in the elderly. Geriatric anxiety thus remains woefully underaddressed, with large gaps of knowledge and a relevant information base predictably inadequate. The following is a list of some of the knowledge gaps and suggested directions for future research.

1. More information is needed about the phenomenology and clinical course of anxiety disorders in late life, both in healthy and physically ill populations. This goal can be achieved by designing both cross-sectional and longitudinal surveys of the elderly in various settings, including community, outpatient clinics in general medical settings, outpatient mental health clinics, hospitals, and nursing homes. DSM-IV criteria should be used as the guiding principle, but not the limiting factor, in such surveys because the elderly may exhibit differences in phenomenology from that of the general population.
2. Conducting clinical trials is a priority in the field of late-life anxiety. Such studies need to include both pharmacological and psychological treatments. Lacking such investigations, both clinicians and researchers will continue to rely on assumptions based on investigations in younger patients.
3. We need to establish safe guidelines for anxiolytic drugs for older patients. As mentioned above, the standard practice is to use the antianxiety medications proven efficacious in younger patients. Though most clinicians tend to be cautious with dosing and mindful of the possibility of causing adverse reactions when working with the elderly, in the absence of research data, such caution may lead to underdosing at times. Thus, empirically derived guidelines are needed for dosing, safety, efficacy, and specificity of these drugs in the elderly.
4. As for younger patients, studies are needed to establish the unique efficacy of the combination of pharmacological and psychological treatments for several anxiety disorders in older adults. This need is particularly true for panic disorder and OCD, in which cases clinicians frequently consider combination treatment based on symptomatology. However, empirical validation of such practice is needed.
5. Studies are needed to examine the differential phenomenology, clinical course, and treatment responses of late-onset anxiety disorders compared with anxiety disorders with onset in earlier life.
6. We need to design anxiety rating instruments specific for the elderly. Data from even well-designed treatment studies may not accurately reflect the extent of patients' anxiety unless reliable and valid measuring tools are available. The existing rating scales for anxiety have in general not been validated in the elderly. Validation studies of the existing measures of anxiety in the elderly using structured diagnostic interviews as the external validation criteria are needed. Such studies may lead to the development of better instruments specifically geared to measure anxiety in the elderly, both to carry out assessments as well as to measure progress in treatment.
7. We need to conduct studies in patients who are medically ill. Medical comorbidity is common in older patients and can complicate both assessment and treatment of anxiety. Most older patients are on several medications concurrently, which can lead to unwanted or unexpected interactions. Such interactions can exaggerate or reduce the therapeutic effi-

cacy of pharmacological treatments. Treatment investigations in this subgroup of older patients are clearly needed. Such investigations can guide the field in creating algorithms for treating such patients.

# Substance Abuse

Roland M. Atkinson, M.D.

## ■ Introduction

Significant substance abuse occurs in older persons, although for various reasons the scope of the problem has been appreciated only recently. The view, espoused in several influential papers in the 1960s, that substance abuse was seldom seen after middle age was not challenged for several decades (Atkinson et al. 1992). People with lifelong addictions to alcohol and drugs were presumed to have died prematurely or to have recovered spontaneously, and late-onset addiction was said to be rare. Trained to this view, clinicians often overlook these disorders in elderly persons. In addition, symptoms of substance abuse in older individuals may mimic symptoms of other medical and behavioral disorders, leading to misdiagnosis. Elderly persons, in particular, tend to underreport drinking problems, and clinicians also are less likely to record these problems and to make appropriate referrals in this population (Booth et al. 1992; Curtis et al. 1989; McInness and Powell 1994; Moos et al. 1993). In this chapter, I address substance abuse in elderly individuals. I begin with an overview of the terms and concepts used in the field, as well as risk factors in-

involved in substance abuse in late life. General principles of assessment and management are then discussed. Finally, special sections are presented on alcohol, benzodiazepines, tobacco, and other substance use and dependence.

## General Terms and Concepts in the Field of Substance Abuse

Table 16–1 lists the definitions of substance abuse terms used in this chapter. Two currently used sets of criteria for the diagnosis of substance dependence, the fundamental behavior disorder underlying most substance-related problems, are listed in Table 16–2. Although similar, these criteria sets differ sufficiently that agreement between them on case classification is less than optimal (Caetano and Tam 1995). (For further general information on substance abuse, see Begleiter and Kissin 1996; Lowinson et al. 1997; and Schuckit 1995.)

## Importance of Substance Abuse in the Elderly

Alcohol use disorders and subsyndromal drinking problems are common in aging persons until well into the

---

Linda Ganzini helped prepare an earlier version of this chapter.

**TABLE 16–1. Definitions of some terms used in the substance abuse field**

**Psychoactive:** Any chemical—alcohol, tobacco, therapeutic agent, industrial compound, or illicit drug—with important effects on the central nervous system.

**Substance:** A psychoactive that typically is associated with a substance use disorder. The term includes alcohol; opioids; sedative-hypnotics; antianxiety agents of the barbiturate and benzodiazepine types; psychomotor stimulants, especially amphetamines and cocaine; tobacco products; and certain over-the-counter psychoactives. The terms *chemical* and *drug* in this context are synonymous with *substance* (e.g., “chemical dependence,” “drug abuse”).

**Drink:** A standard drink of beverage alcohol is equivalent to a 12-ounce domestic beer (alcohol content approximately 4%), a 4-ounce glass of table wine (approximately 12% alcohol), or a mixed drink containing 1–1½ ounces of hard liquor (about 40% alcohol).

**Use:** Appropriate medical or social consumption of a psychoactive in a manner that minimizes the potential for dependence or abuse.

**Heavy use:** Use of a substance in greater quantity than the usual norms, but without obvious negative social, behavioral, or health consequences. Heavy alcohol or tobacco users may be dependent upon the substance. *At-risk* or *risky* drinkers refer to heavy consumers of alcohol, usually at rates of more than 15–21 drinks per week for men, 10–14 for women, or binges in which more than 4–6 drinks are consumed on a single drinking occasion. Safe drinking levels for healthy elderly persons are recommended by the National Institute on Alcohol Abuse and Alcoholism and are not to exceed 7 drinks per week or 2 drinks on a single drinking occasion.

**Misuse:** Use of a prescribed drug in a manner other than as directed. The term can mean overuse, underuse, improper dose sequencing, and lending or borrowing another’s medication, with or without harmful consequences.

**Problem use:** Use of a substance in a manner that induces negative social, behavioral, or health consequences.

A “problem” user may or may not meet criteria for substance dependence or abuse, although many do. Alcohol “problems” or drug “problems” are categories that often have been used by epidemiologists in community prevalence surveys.

**Abuse:** Abuse of a substance is defined in DSM-IV (American Psychiatric Association 1994) as a maladaptive pattern of substance use leading to clinically significant impairment or distress, as manifested by one or more of the following, occurring within a 12-month period: 1) recurrent substance use resulting in failure to fulfill major role obligations at work or home; 2) recurrent substance use in physically hazardous situations; 3) recurrent substance-related legal problems; 4) continued substance use despite having persistent or recurrent social or interpersonal problems caused or exacerbated by the effects of a substance (pp. 182–183). *Harmful use* (ICD-10; World Health Organization 1992) approximates abuse in definition. Both imply milder severity of substance involvement than that in substance dependence.

**Dependence:** Dependence upon a substance is defined by explicit diagnostic criteria, such as those listed in DSM-IV or ICD-10 (Table 16–2). Serious and persistent involvement in the heavy use of the substance is the rule. These approaches set aside the older distinction between *physical dependence* and *psychological dependence*, which are now viewed as differing manifestations of similar disorders. The terms *alcoholism* and *addiction* are usually used as synonyms for dependence on alcohol and other drugs, respectively.

**Substance use disorder:** A clinical condition in which substance abuse or substance dependence can be diagnosed.

**Substance abuse, chemical dependence, and addictions:** These terms are often used to refer to the entire professional or scientific field.

eighth decade of life, especially in men. In addition to the negative behavioral and social consequences of these disorders that are seen at any age, alcoholism in older persons confers special hazards by aggravating a number of physical and mental disorders and altering the metabolism of many prescribed medications. Older persons as a group respond favorably to treatment for problem drinking.

The elderly are the most likely age group to receive long-term prescribed benzodiazepines. In addition to inducing physical dependence in a substantial proportion of these patients, long-term benzodiazepine administration often impairs cognitive status and general functioning of elderly persons.

Tobacco dependence is the most common addictive problem in the older population and doubles the mortality rate from all diseases. When smoking cessation strategies are suitably tailored to the older smoker, quit rates are favorable, and within 1–2 years of quitting, measurable reduction in mortality is evident.

### **Risk Factors for Substance Use Disorders in Later Life**

Biomedical manifestations of substance abuse are as important in older patients as the psychosocial manifestations that form the more familiar clinical picture of these disor-

**TABLE 16–2. DSM-IV versus ICD-10 criteria for substance dependence**

DSM-IV criteria	ICD-10 criteria
<ol style="list-style-type: none"> <li>1. Tolerance, as defined by either of the following:               <ol style="list-style-type: none"> <li>a. A need for markedly increased amounts of the substance to achieve intoxication or desired effect; or</li> <li>b. Markedly diminished effect with continued use of the same amount of the substance.</li> </ol> </li> <li>2. Withdrawal, as manifested by either of the following:               <ol style="list-style-type: none"> <li>a. The characteristic withdrawal syndrome for the substance; or</li> <li>b. The same (or a closely related) substance is taken to relieve or avoid withdrawal symptoms.</li> </ol> </li> <li>3. The substance is often taken in larger amounts or over a longer period than was intended.</li> <li>4. There is a persistent desire or unsuccessful efforts to cut down or control substance use.</li> <li>5. A great deal of time is spent in activities necessary to obtain the substance (e.g., visiting multiple doctors or driving long distances), use the substance (e.g., chain smoking), or recover from its effects.</li> <li>6. Important social, occupational, or recreational activities are given up or reduced because of substance use.</li> <li>7. Substance use is continued despite knowledge of having a persistent or recurrent physical or psychological problem that is likely to have been caused or exacerbated by the substance (e.g., current cocaine use despite recognition of cocaine-induced depression; continued drinking despite a peptic ulcer made worse by alcohol consumption).</li> </ol>	<ol style="list-style-type: none"> <li>1. Strong desire or sense of compulsion to take the substance.</li> <li>2. Difficulties in controlling substance-taking behavior in terms of its onset, termination, or levels of use.</li> <li>3. A physiological withdrawal state when substance use has ceased or been reduced, as evidenced by: the characteristic withdrawal syndrome for the substance; or use of the same (or a closely related) substance with the intention of relieving or avoiding withdrawal symptoms.</li> <li>4. Evidence of tolerance, such that increased doses of the psychoactive substance are required to achieve effects originally produced by lower doses (clear examples of this are found in alcohol- and opiate-dependent individuals who may take daily doses sufficient to incapacitate or kill nontolerant users).</li> <li>5. Progressive neglect of alternative pleasures or interests because of psychoactive substance use, increased amount of time necessary to obtain or take the substance, or to recover from its effects.</li> <li>6. Persisting with substance use despite clear evidence of overtly harmful consequences, such as harm to the liver through excessive drinking, depressive mood states consequent to periods of heavy substance use, or drug-related impairment of cognitive functioning; efforts should be made to determine that the user was actually, or could be expected to be, aware of the nature and extent of the harm.</li> </ol>

*Note.* For either system, at least three of the listed criteria must be met in the same 12-month period in order to make the diagnosis of dependence on a substance.

*Source.* Adapted from American Psychiatric Association: *Diagnostic and Statistical Manual of Mental Disorders*, 4th Edition. Washington, DC, American Psychiatric Association, 1994, p. 181; World Health Organization: *International Classification of Diseases*, 10th Edition. Geneva, Switzerland, World Health Organization, 1992, pp. 75–76.

ders in younger patients. The risk factors listed in Table 16–3 reflect this perspective. Predisposing factors are similar at all ages. Factors that may increase substance exposure and consumption level and thus set the stage for abuse or dependence in some individuals include demographics, for example, gender and ethnicity (Helzer et al. 1991); chronic illnesses for which controlled substances are often prescribed on a regular basis (American Psychiatric Association 1990; Finlayson and Davis 1994); institutionalization in long-term care settings (Beardsley et al. 1989; Beers et al. 1988; Buck 1988); and several psychological and social factors, especially negative affects associated with loss and loneliness (Dupree and Schonfeld 1998). Factors that increase or prolong the effects of substances with age (e.g., pharmacokinetic and pharmacodynamic factors; see Chap-

ter 34 in this volume) may increase their dependence liability, although studies proving such an effect with regard to alcohol, benzodiazepines, or opioid analgesics are lacking (Ozdemir et al. 1996). Regular alcohol or psychoactive drug use can also increase functional impairment caused by a variety of illnesses that are more common in old age, for example, cognitive, cardiovascular, pulmonary, gastrointestinal, and metabolic disorders. Clinical complications can arise from adverse drug-drug interactions between psychoactive substances and other prescribed medications (W. L. Adams 1995; Korrapati and Vestal 1995). These alterations in biological sensitivity to drugs, comorbid medical illness, and medication interactions can lead to biomedical problems in the elderly at substance consumption rates that would have caused little or no difficulty earlier in life.

**TABLE 16–3. Risk factors for substance abuse in the elderly****Predisposing factors**

- Family history (alcohol)
- Previous substance abuse
- Previous pattern of substance consumption (individual and cohort effects)
- Personality traits (sedative-hypnotics and anxiolytics)

**Factors that can increase substance exposure and consumption level**

- Gender (men: alcohol and illicit drugs; women: sedative-hypnotics and anxiolytics)
- Chronic illness associated with pain (opioid analgesics), insomnia (hypnotic drugs), or anxiety (anxiolytics)
- Long-term prescribing (sedative-hypnotics and anxiolytics)
- Caregiver overuse of as-needed medication (institutionalized elderly)
- Life stress, loss, social isolation
- Negative affects (depression, grief, demoralization, and anger) (alcohol)
- Family collusion and drinking partners (alcohol)
- Discretionary time, money (alcohol)

**Factors that can increase the effects and abuse potential of substances**

- Age-associated drug sensitivity (pharmacokinetic and pharmacodynamic factors)
- Chronic medical illnesses
- Other medications (alcohol-drug and drug-drug interactions)

## ■ Principles of Assessment and Management

### Assessment of Geriatric Substance Use Disorders

**General approach.** Use of alcohol, tobacco products, prescription and over-the-counter psychoactive agents, and illicit substances should routinely be surveyed during the initial evaluation of all older adults. Standardized screening measures are available for problem drinking in geriatric patients, although accuracy of self-reports varies. Denial of substance abuse is common in affected persons of all ages and may be exaggerated in elderly patients because of memory problems, pessimism about recovery,

and shame based on a belief that substance abuse is immoral. For these reasons, careful rapport building through repeated contacts; inquiry with relatives, caregivers, and others in the social network; reviews of medical and pharmacy records; and home visitation are especially useful case assessment methods. DSM-IV (American Psychiatric Association 1994) and ICD-10 (World Health Organization 1992) dependence criteria offer a reasonable framework for acquiring information to establish a clinical diagnosis (Table 16–2).

**Special examinations.** Physical and laboratory findings can help to establish a diagnosis of alcohol dependence. Toxicological examinations of urine and blood for other suspected substances can be useful to corroborate the history. Neuropsychological evaluation and brain imaging (computed tomography, magnetic resonance imaging [MRI]) may help identify complicating brain disorders. Primary dementias and dementias secondary to alcohol or drugs may produce similar initial cognitive or imaging deficits. Because substance-induced deficits either remain static or actually improve with abstinence (Brandt et al. 1983; I. Grant et al. 1984; Larson et al. 1984a; Muuronen et al. 1989; Pfefferbaum et al. 1995; Schroth et al. 1988), serial psychometric and brain imaging studies may be useful in differential diagnosis (Oslin et al. 1998).

### Clinical Features

In old age, the signs and symptoms of substance use disorders can be subtle, be atypical, or mimic symptoms of other geriatric illness. In mild or circumscribed cases among community-dwelling elderly, episodic alcohol abuse or benzodiazepine dependence may not produce obvious physical signs or complaints and may be easily concealed from others. Some heavy drinkers may have a circumscribed clinical presentation of increasingly uncontrolled hypertension or diabetes mellitus, whereas moderate benzodiazepine or alcohol dependence may present with the complaint of forgetfulness. In more severe cases, substance abuse can produce or aggravate delirium or dementia (American Psychiatric Association 1990; Freund 1987; Ron 1983), which the clinician may erroneously attribute to other causes. Other serious but nonspecific presenting signs and symptoms (e.g., poor grooming, squalid living quarters, depression, erratic changes of mood or behavior, malnutrition, bladder and bowel incontinence, muscle weakness or frank myopathy, gait disorders, recurring falls, burns, or head trauma) may be caused by unsuspected alcohol or drug abuse. Other features that may be associated with alcohol or prescription drug dependence include

heavy tobacco use, chronic pain syndromes or insomnia, persistent family discord, a course of inexplicable ups and downs in mood, a pattern of doing well in hospital but poorly at home, and patient or caregiver defensiveness when queried about substance use. When such features are noted, the clinician needs to be especially alert to the possibility of underlying substance dependence.

## Case Management and Treatment

Brief interventions (e.g., physician advice to cease or cut down alcohol use, adjustment of prescribed medications, smoking cessation measures) can prevent or resolve some substance-related problems. More severe substance use disorders require further treatment. The goals of substance abuse treatment in the elderly are threefold: 1) stabilization, reduction, or cessation of substance consumption; 2) treatment of coexisting medical and psychiatric problems; and 3) arrangement of appropriate educational and social interventions to reduce the risk of relapse. Reducing consumption can be complicated and hazardous, requiring initial hospital care and a protracted outpatient course in cases of long-standing or high-dose dependence. Treatment of coexisting problems can be a crucial step in curbing substance consumption, especially when chronic pain, chronic insomnia, or a mood disorder has been a major factor sustaining the substance dependence or when serious medical complications of substance abuse are present. Cognitive-behavioral techniques teach patients to cope more effectively with circumstances that typically have triggered substance use (Dupree and Schonfeld 1998). Social interventions range from informal plans (e.g., arranging for increased visitation by loved ones or enrollment in a senior activity program or day center) to admission to a senior substance abuse program (Atkinson 1995).

## Alcohol Use Disorders and Alcohol-Associated Organic Mental Disorders

### Epidemiology

Alcohol use and alcohol problems decline with age but still constitute a significant public health problem. Recent community surveys show that alcohol use in the United States is most prevalent in the age group 25–45 years and declines stepwise in older age cohorts to 12-month prevalence levels, among persons age 55 and older, of 46% who report any alcohol use (Ruchlin 1997) and 30% who report having consumed at least 12 drinks in the past 12 months

(B. F. Grant 1997). Rates of any recent alcohol use continue to decline after age 55 to 25% of persons age 85 and older (Ruchlin 1997). Rates of heavy alcohol use, problem use, and alcohol dependence also decline with age from peaks in middle life (B. F. Grant 1997). Community prevalence rates for heavy and problem use of alcohol by older persons vary widely depending upon the population sampled and definitions of use (Atkinson 1990). Because of associated health problems, older alcoholic patients are much more commonly encountered in clinical settings. Illustrative reports on the prevalence of active alcohol problems in elderly clinical cohorts are summarized in Table 16–4. For comparison, this table also notes the prevalence of at-risk drinkers (persons identified in clinical settings who report heavy alcohol consumption without current alcohol-related problems) and community prevalence of alcohol dependence from two large national surveys.

Older men are twice as likely to use alcohol as are older women (B. F. Grant 1997), and older men are two to six times more likely than women to be problem drinkers (Atkinson 1990; Callahan and Tierney 1995; B. F. Grant 1997). These patterns hold true across diverse ethnic and racial groups (Barker and Kramer 1996; Callahan and Tierney 1995; B. F. Grant 1997; Lowe et al. 1997). Once alcohol dependence develops, it is more likely to persist in older men—especially black and Hispanic men—than in women (Callahan and Tierney 1995; Gomberg and Nelson 1995; B. F. Grant 1997). Negative health and social consequences of drinking are more severe in older black men with alcoholism than in older white men (Gomberg and Nelson 1995). Older homeless persons are more likely than younger homeless to be men and to meet criteria for lifetime alcohol use disorders (DeMallie et al. 1997). Indeed, prevalence data support the conclusion that alcoholism constitutes a public health problem of moderate proportion in men in their 60s and 70s.

As noted above, cross-sectional studies show a decline in the prevalence of alcohol dependence with age (B. F. Grant 1997). Some decline is accounted for by premature deaths of those with early-onset alcoholism and by moderation or cessation of drinking over time by those surviving alcoholism (Liberto et al. 1992) and by social drinkers (W. L. Adams et al. 1990). But longitudinal studies show that many drinkers maintain steady consumption levels into later life (Glynn et al. 1985; Gordon and Kannel 1983). Because younger birth cohorts have demonstrated increasingly higher rates of alcohol consumption and alcoholism, especially after the end of Prohibition and World War II (Atkinson et al. 1992; B. F. Grant 1997; Heath et al. 1997), the prevalence of alcohol problems in old age may increase, especially among women, for birth cohorts entering their

**TABLE 16–4. Prevalence of active alcohol problems (current or in past year) among older patients in selected clinical settings**

Setting (source)	Age cutoff	Sample size	Gender	Frequency of active alcoholism	Frequency of at-risk drinking
General medical outpatient clinic, Omaha, NE (Jones et al. 1993)	≥ 65	154	Both	4%	NA

<sup>c</sup>Men > 14 drinks per week; women > 7 drinks per week.

<sup>d</sup>Men ≥ 20 drinks per week; women ≥ 10 drinks per week.

60s in the years ahead. Even if prevalence rates remain stable, the anticipated aging of the general population over the next several decades will increase the absolute numbers of older problem drinkers substantially (American Medical Association 1996).

## Patterns of Alcohol Use and Abuse

**Heavy versus problem drinking.** For the minority of aging persons who consume more than modest amounts of alcohol, the pathophysiological effects of alcohol in many instances may have more serious clinical consequences because of increasing biological sensitivity to alcohol and because alcohol aggravates preexisting diseases that are more common in later life. When older people continue to drink despite feeling unwell or advice to stop, this meets the definition of abusive drinking, even though such drinking may not be associated with socially deviant

behavior or the desire to feel intoxicated. Put another way, the distinction between heavy drinking and problem drinking narrows with age (Chermack et al. 1996b).

**Reactive drinking.** Some older alcoholic patients (people with late-onset alcoholism, those who have a late relapse in early-onset alcoholism after years of sobriety, or those who have had a recent increase in lifelong heavy drinking) report major losses and chronic strains and hassles as precipitants of increased drinking. On the other hand, the relationship among alcohol use, alcohol problems, and life stress in older adults is enigmatic and complex, and findings vary from study to study (Finney and Moos 1984; Welte and Mirand 1995). Community studies of older drinkers show that good health, cohabitation, and financial well-being, rather than adversity, tend to correlate with increased alcohol consumption (Barnes 1979; Busby et al. 1988; C. M. Nakamura et al. 1990; Ruchlin 1997), whereas financial strain and poor health can be asso-

ciated with resolution of drinking problems or achievement of abstinence (Moos et al. 1991). Once a pattern of excessive alcohol use has been established, evanescent negative affect states (e.g., depression, sadness, boredom, anger, tension) and, far less often, positive affects (e.g., calmness, cheerfulness, friendliness) can trigger repeated drinking episodes (Dupree and Schonfeld 1998). Social reinforcement for heavy drinking is evident in some, but not all, congregate retirement settings (W. L. Adams and Cox 1995; Alexander and Duff 1988; Paganini-Hill et al. 1986).

**Early- versus late-onset alcohol problems.** Although onset of alcoholism after age 45 was long thought to be rare, findings from community (Eaton et al. 1989) and clinical samples (Atkinson 1994; Atkinson et al. 1990) offer evidence that late-onset alcoholism (i.e., onset after age 55, 60, or 65) is not uncommon. The notion that late-onset alcohol dependence usually occurs secondary to a mood or organic mental disorder also has not been upheld by recent systematic studies (Atkinson 1994). Cases in which persons with early-onset alcoholism achieved prolonged abstinence in middle life, but relapsed later, can be mistaken for late-onset alcoholism. Others with late-onset problems were social drinkers (Neve et al. 1997) or heavy or reactive drinkers (Schutte et al. 1998) in the past. Late-onset alcohol problems are typically milder and more circumscribed than those beginning earlier in life. Compared with those with early-onset problem drinking, those with late-onset problem drinking tend to have less alcoholism among relatives, less psychopathology, and higher socioeconomic status, and a larger proportion are women (Atkinson 1994; Liberto and Oslin 1995). Although clinical evidence supports the view that late-onset drinking problems often begin in reaction to life stress (e.g., Finlayson et al. 1988), it is not true that those with late-onset drinking problems exhibit more reactive drinking than those with early-onset drinking problems. Compared with alcoholism of long duration, late-onset drinking problems tend to resolve more often without formal treatment (Moos et al. 1991) and may be more amenable to treatment (Atkinson 1994, 1995; Atkinson et al. 1993; Schonfeld and Dupree 1991).

### **Therapeutic Use and Health Maintenance Value of Alcohol**

**Use for socialization and appetite.** The use of small amounts of beverage alcohol has been advocated as a social adjuvant in elder residential care facilities (reviewed in Atkinson and Kofoed 1984). Similarly, alcohol is often touted as an appetite stimulant: in healthy elderly persons

caloric intake and blood levels of some micronutrients may increase with alcohol intake, though other micronutrient levels decrease (Jacques et al. 1989). Clinicians who advise outpatients to use alcohol should beware that in the residential studies mentioned above the quantity of alcohol consumed was regulated and its use within a social context was ensured. Iatrogenic alcohol use disorders do occur. Alcohol as an “aid” for sleep is discussed below.

**Protective value of alcohol against coronary heart disease.** Consumption of regular but moderate amounts of alcohol (up to two drinks per day) tends to be associated with lower morbidity and mortality from coronary artery disease (CAD), especially in men, compared with that in heavy alcohol users and abstainers. This “U”- or “J”-shaped relationship appears to be quite robust. Explanations for a protective effect of alcohol in CAD include that alcohol elevates plasma levels of high-density lipoprotein cholesterol, reduces blood platelet aggregation, and has other anticoagulant effects, although under some circumstances alcohol also increases selected hemostatic processes (Davidson 1989; Srivastava et al. 1994). The antioxidant effects of beverage alcohol might also play a role (Artaud-Wild et al. 1993; Soleas et al. 1997). The heterogeneous abstainer group might be expected to include subgroups at high risk for CAD, for example, former drinkers and others with poor health, which might also explain why abstainers fare worse than moderate drinkers. Unfortunately, a number of reported studies did not characterize their abstainer cohorts. These include two studies reporting a protective effect that focused exclusively on the elderly (Colditz et al. 1985; Scherr et al. 1992).

**Protective value against other health problems.** A more general apparent protective effect of moderate drinking on mortality from all causes has been demonstrated in several studies (e.g., Colditz et al. 1985; Mertens et al. 1996; Thun et al. 1997), even taking into account those diseases for which increasing alcohol consumption is clearly associated with higher mortality. In one study of 490,000 persons age 35–70, moderate drinking reduced overall mortality by about 20%, although much of this general effect on mortality may be related to cardiovascular disease (Thun et al. 1997). Recent reports that moderate alcohol intake (especially red table wine) may have a beneficial effect on cognitive status (Christian et al. 1995; Dufouil et al. 1997; Letenneur et al. 1993; Orgogozo et al. 1997) and a possible protective effect against development of age-related retinal macular degeneration (Obisesan et al. 1998) require further study. An unexpected finding in several studies of alcohol and mortality that focused on

older persons is that, in contrast to findings in studies of younger and mixed-age cohorts, no significant increase in mortality risk was found among heavier-drinking older adults with regard to CAD (Klatsky et al. 1981, 1992), cardiovascular disease in general (Thun et al. 1997), or mortality from all causes (Mertens et al. 1996). Possible explanations for this finding have included a selective survival effect, that is, that only healthier heavy drinkers survive to older ages, or moderation or cessation of drinking with age, so that former heavy drinkers now appear in the abstainer and moderate-drinking categories (Mertens et al. 1996).

**Safe drinking levels in old age.** Although evidence is accumulating that modest regular drinking has protective effects on health, not all recent large surveys confirm this finding (Hanna et al. 1997). Clinicians advising patients whether to drink obviously must weigh the possible protective effects of alcohol in light of the health status of the individual patient. Patients who already have cardiovascular, hepatic, neoplastic, or organic mental diseases should not drink, nor should patients receiving complex medication regimens. Deaths from disorders made worse by alcohol clearly increase with an increase in alcohol consumption level (Thun et al. 1997). The National Institute on Alcohol Abuse and Alcoholism currently recommends that physically fit older adults drink an average of no more than one standard drink daily, or seven drinks per week, and no more than two drinks per drinking occasion (National Institute on Alcohol Abuse and Alcoholism 1995).

## **Clinical Features, Complications, and Course of Alcohol Use Disorders**

**Primary and associated features; screening and diagnosis.** Little evidence suggests that the elderly population differs greatly from other age groups in the primary manifestations of alcohol dependence (Table 16-2), even though several of the criteria for alcohol dependence (i.e., those related to social consequences) have questionable relevance for some elderly persons (Atkinson 1990). However, differences have been found between older and younger alcoholic patients. Biomedical consequences and complications become more evident with age, as previously discussed. Older people with alcoholism, especially women, more often drink alone at home than do younger people with alcoholism, and they are more likely to drink in response to negative affects, such as depression or loneliness, whereas younger people with alcoholism drink in response to a wider variety of personal and social

circumstances (Schonfeld et al. 1995). People with late-onset alcoholism may show fairly mild impairment, evidence for abuse but not dependence, and little evidence of either physical or psychiatric comorbidity (Atkinson 1994; Atkinson et al. 1990; Liberto and Oslin 1995). The CAGE test is an effective screening device for alcoholism in the elderly (Buchsbbaum et al. 1992; T. V. Jones et al. 1993; Joseph et al. 1995; Morton et al. 1996), as is the MAST-G, a version of the Michigan Alcoholism Screening Test designed for the elderly (Blow et al. 1992b; Joseph et al. 1995; Morton et al. 1996). Not all studies agree that these screening questionnaires are sufficiently sensitive and specific in the elderly (Luttrell et al. 1997), and the CAGE was shown in one large study to be inadequate to identify at-risk drinkers or binge drinkers (W. L. Adams et al. 1996). It is also necessary to inquire about quantity and frequency of drinking because alcohol consumption is not surveyed by either the CAGE, the MAST-G, or DSM-IV alcohol use disorder criteria. Several characteristic laboratory abnormalities accompanying many cases of alcohol dependence are listed in Table 16-5.

**Medical complications.** Older patients with alcoholism are at high risk for development of multiple medical problems (Piette et al. 1998); these have been reviewed extensively elsewhere (Gambert and Katsoyannis 1995; J. W. Smith 1995). Alcohol-related liver disease, when present, carries a poor prognosis if drinking continues (Woodhouse and James 1985). A number of cancers (mouth, esophagus, pharynx, larynx, liver, colorectal), hypoglycemia, hyperuricemia, hypertriglyceridemia, osteoporosis, anemias, congestive heart failure, aspiration pneumonia, and accidental injuries can also be caused or aggravated by alcohol dependence. Breast cancer in one large recent survey was 1.3 times more common in women who currently drink than in nondrinkers (Thun et al. 1997). Control of hypertension and diabetes mellitus is compromised by excessive drinking. Alcohol-associated mental disorders and psychiatric comorbidities are considered separately below.

**Adverse drug reactions.** Several varieties of problematic alcohol-drug interactions can occur. Acute doses of alcohol compete with many medications for hepatic drug-metabolizing enzymes in the cytochrome P450 system, which can produce higher than desired drug blood levels (Lieber 1991; see also Chapter 34 in this volume). Long-term alcohol dosing, on the other hand, induces the cytochrome P450 system and can lead to more rapid metabolism of the same medications, with resulting lower than desired drug blood levels. Drugs commonly prescribed for the elderly that may be affected include warfa-

**TABLE 16–5.** Frequency of laboratory abnormalities in elderly and younger inpatients with alcoholism

	Results			
	Patients ≥ 65 years <sup>a</sup>		Younger patients <sup>b</sup>	
Blood tests	Number	Percent	Number	Percent
MCH increased	213	71	123	57*
AST increased	214	56	123	42**
GGT increased	123	55	101	48
MCV increased	213	44	124	17*
Glucose increased	206	32	124	36
Uric acid increased	201	21	123	< 1*
Albumin decreased	186	17	115	3*
Alkaline phosphatase increased	213	11	123	15
Triglycerides increased	191	16	122	19
Phosphorus increased	198	9	124	11

*Note.* Number refers to the number of patients tested in each age group; percent is the percent of patients tested in the age group who had an abnormal value. AST = aspartate aminotransferase; GGT =  $\gamma$ -glutamyltransferase; MCH = mean corpuscular hemoglobin; MCV = mean corpuscular volume.

<sup>a</sup>Older patients:  $N = 216$ ; mean age 69.6 years; age range 65–83 years.

<sup>b</sup>Younger patients:  $N = 125$ ; mean age 44.3 years; age range 19–64 years.

\* $P < .01$  using Wilcoxon two-sample rank sum test to compare age groups for proportion having an abnormal value.

\*\* $P < .05$ ; for others,  $P > .3$ .

rin, phenytoin, most benzodiazepines, and propranolol. Inhibition of hepatic alcohol dehydrogenase by such drugs as chlorpromazine and isoniazid or inhibition of gastric alcohol dehydrogenase by histamine receptor antagonists (e.g., cimetidine, ranitidine, nizatidine) can reduce alcohol metabolism and lead to higher blood alcohol levels (W. L. Adams 1995). Alcohol acts in the brain to intensify the depressant effects of opioids and sedative-hypnotic agents (Korrapati and Vestal 1995). When regular heavy drinking accompanies use of nonsteroidal anti-inflammatory drugs, bleeding times may be increased and the risk of gastrointestinal hemorrhage is higher (W. L. Adams 1995). Details of these and other clinically hazardous alcohol-medication interactions have recently been reviewed elsewhere (W. L. Adams 1995; Korrapati and Vestal 1995).

**Course.** The span from onset of the first alcohol problem to date of entry into current treatment can be as long as 50 years, and over this course, drinking may have been steady, progressive, or fluctuating. In some cases, sober periods of 10 years or more occur between problem drinking episodes. People with late-onset problem drinking often resolve their problems without formal treatment (Moos et al. 1991), and many with early-onset alcoholism can and do achieve long-term abstinence or controlled, problem-free drinking, with or without treatment (Chermack et al. 1996a; Vaillant 1995). Older alcoholic patients who com-

plete treatment have variable outcomes: younger age, unmarried status, and psychiatric comorbidity predicted 4-year readmission for drinking relapse in one nationwide study (Moos et al. 1994). Although cross-sectional surveys that are further stratified for age after 60 indicate that as many as 25% of persons age 85 and older continue to use alcohol in modest amounts (Ruchlin 1997), rates of *problem* drinking after age 85 are negligible.

### Alcohol-Associated Mental Disorders

Alcohol-associated mental disorders are listed in Table 16–6 and described in standard texts on neuropsychiatry (Lishman 1997; Yudofsky and Hales 1997). Selected features of these disorders are highlighted that have special relevance to geriatric alcoholism and geriatric neuropsychiatry.

**Aging and alcohol neurotoxicity.** Although one strongly supported perspective is that all alcohol-related brain damage is a consequence primarily of thiamine deficiency and thus related to the Wernicke-Korsakoff syndrome (“continuity theory”) (Langlais 1995; Victor et al. 1989), alcohol itself is a potent neurotoxin that may cause central nervous system (CNS) pathology, especially cortical damage. Evidence for an age-associated increase in CNS sensitivity to alcohol has been demonstrated

**TABLE 16–6. Alcohol-associated mental disorders****Disorders manifested primarily by altered mental status**

- Alcohol intoxication
  - Simple intoxication
  - Idiosyncratic intoxication
  - Alcohol blackout
- Alcohol withdrawal syndromes
  - Uncomplicated alcohol withdrawal (tremulous syndrome)
  - Alcohol hallucinosis
  - Alcohol withdrawal seizures (“rum fits”)
  - Alcohol withdrawal delirium (delirium tremens, or “DTs”)
- Wernicke-Korsakoff syndrome
  - Wernicke’s encephalopathy
  - Alcohol amnesic disorder (Korsakoff’s psychosis)
- Other cognitive disorders related to alcohol neurotoxicity
  - Alcoholic dementia
  - Focal alcoholic cognitive deficits
- Alcohol-associated insomnia
- Alcohol-associated mood disorder

**Disorders manifested primarily by focal neurological findings**

- Alcoholic peripheral polyneuropathy
- Alcoholic cerebellar degeneration
- Alcohol-related movement disorder (Parkinson’s type)

**Rare neurological disorders associated with chronic alcoholism**

- Marchiafava-Bignami disease
- Nutritional amblyopia
- Central pontine myelinosis

**Disorders associated with chronic alcoholism, but not with alcohol neurotoxicity**

- Hepatic encephalopathy
- Acquired hepatocerebral degeneration
- Trauma-induced acute and chronic subdural hematoma

in studies of animals (York 1983) and in nonalcoholic human subjects on measures of subjective intoxication experience (Beresford and Lucey 1995; A. W. Jones and Neri 1985), memory (M. K. Jones and Jones 1980), performance on divided attention tasks (Collins and Mertens 1988), and body sway and hand dexterity (Vogel-Sprott and Barrett 1984) after single alcohol doses. Not all human studies demonstrate an increased pharmacodynamic effect of alcohol with age (Tupler et al. 1995); differences can depend on whether subjects ingest alcohol in a fasted (effect observed) or fed (little or no effect) state (Beresford and Lucey 1995; Lucey et al. 1999; Tupler et al. 1995). A molecular basis for altered pharmacodynamic effects of alcohol with age has

not been determined (Wood 1995). Cognitive performance also tends to be impaired in older social drinkers tested in the sober state, but only at relatively high consumption levels (i.e., more than 21 drinks per week) (Parsons and Nixon 1998). Regional cerebral blood flow is reduced proportionally to reported alcohol consumption level in otherwise healthy elderly volunteers (Meyer et al. 1984).

In mixed-age groups of patients with alcoholism but without an amnesic disorder, alcohol neurotoxicity is suggested by a number of deficits in neuropsychological performance (Parsons 1994; Parsons and Nixon 1993; Ryan and Butters 1986) and by evidence from brain imaging studies of atrophy of the cerebral cortex (Jernigan et al. 1991; Pfefferbaum et al. 1992), corpus callosum (Pfefferbaum et al. 1996), anterior hippocampus (E. V. Sullivan et al. 1995), diencephalon, caudate nucleus, and parts of the limbic system, including the mesial temporal lobe (Jernigan et al. 1991) and thalamus (Krill et al. 1997). Age, rather than duration of alcoholism, tends to be a critical factor in the manifestation of both the psychological and imaging findings. Cortical changes reflect loss of both gray and white matter, occur in older alcoholic individuals beginning about the fifth decade, and are in addition to the changes associated with normal aging (Jernigan et al. 1991; Pfefferbaum et al. 1992, 1997). These losses are especially evident in frontal areas (Krill et al. 1997; Pfefferbaum et al. 1997). Frontal cortical deficits have also been demonstrated in positron-emission tomographic studies in older alcoholic individuals (K. M. Adams et al. 1993; Gilman et al. 1990), as well as in studies of regional cerebral blood flow (Berglund and Ingvar 1976; Krill et al. 1997) and event-related potentials (Biggins et al. 1995).

Studies of mixed-age persons with chronic alcoholism suggest that these frontal cortical deficits are related to impairment in neuropsychological performance: indeed, the pattern of test performance deficits in patients with chronic alcoholism has in recent years prompted the “frontal lobe hypothesis” (Oscar-Berman and Hutner 1993). According to this view, the vulnerability of the frontal lobes to alcohol accounts for many of the neuropsychological deficits in patients with chronic alcoholism, including problem solving, abstraction, organization, judgment, and working memory (studies reviewed in Krill et al. 1997; Pfefferbaum et al. 1997). On the other hand, recent research also indicates widespread damage throughout the brain, and other models besides the frontal lobe hypothesis can explain a number of performance deficits in persons with chronic alcoholism who do not have an amnesic disorder (Evert and Oscar-Berman 1995). For example, deficits in visual-spatial-motor skills may instead be associated with tis-

sue loss in the anterior parietal cortex (Pfefferbaum et al. 1997) or with ventricular dilation rather than cortical atrophy (DiSclafani et al. 1995). Furthermore, ample evidence indicates tissue loss in deeper diencephalic and limbic structures in nonamnesic patients (Jernigan et al. 1991), which might be the primary basis for cerebral dysfunction and even cortical tissue loss (in accord with the “continuity theory”) (Langlais 1995).

Histopathological findings in older persons with alcoholism include neuron loss and damage (Samorajski et al. 1984) and reduced dendritic connections (Ryan and Butters 1986). Several studies point in particular to changes in the frontal cortex (e.g., neuron loss, shrinkage of the neuronal soma, and loss or shrinkage of large pyramidal cells from the superior frontal cortex) in people with chronic alcoholism (Harper and Kril 1989, 1990; Kril and Harper 1989). Such changes also occur with normal aging (Flood 1993; Terry et al. 1987), suggesting that age-related decline in brain structural integrity, especially in the frontal lobes, reduces the margin of safety and leaves the brains of old, relative to young, persons more susceptible to alcohol neurotoxicity (Pfefferbaum et al. 1997).

**Alcohol intoxication and withdrawal.** Elderly people show increased intoxication after a standard alcohol load compared with younger persons. One factor accounting for this phenomenon is age-associated increase in peak blood alcohol level, related to reduced volume of distribution (Beresford and Lucey 1995; Lucey et al. 1999; Vestal et al. 1977; Vogel-Sprott and Barrett 1984). Peak blood alcohol level in older men and women is about 20%–25% higher than that in younger subjects (Beresford and Lucey 1995; Vestal et al. 1977). Evidence also suggests age-associated increases in brain sensitivity to alcohol (see discussion above). Other factors that can cause greater intoxication in older patients include possible age-associated reduction in gastric (but not hepatic) metabolism of alcohol (Hahn and Burch 1983; Pedrosa et al. 1996), potentiation of alcohol effects on the brain by concurrently used medications, comorbid cognitive disorders, and comorbid medical disorders (e.g., those that influence circulation and hepatic function).

In a large series of patients 65 or older who were admitted to an inpatient alcohol treatment unit (Finlayson et al. 1988), major alcohol withdrawal disorders were equally common compared with those in younger cohorts reported elsewhere (Atkinson 1988). In two studies comparing older with younger alcoholic patients undergoing detoxification in a hospital setting, older patients demonstrated more severe and protracted withdrawal signs and symptoms (Brower et al. 1994; Liskow et al. 1989), even though recent alcohol intake was similar in

older and younger patients. Rather than age, a longer duration of alcoholism might have explained these group differences in withdrawal severity, but age itself also can play a role. Animal studies have demonstrated age-associated increases in both dependence liability (Ritzmann and Melchior 1984) and alcohol withdrawal severity (Samorajski et al. 1984; Wood 1995), although evidence for increasing dependence liability with age in humans is lacking (Ozdemir et al. 1996).

**Slowly resolving cognitive deficits after alcohol withdrawal.** Cognition is often impaired in recently detoxified alcoholic individuals of all ages, but deficits are greater and more long-lasting in older patients (Brandt et al. 1983; I. Grant et al. 1984). Impairment immediately after prolonged drinking bouts is probably multifactorial, representing the effects of chronic alcohol neurotoxicity; residual alcohol intoxication; depressed mood; hepatic and metabolic dysfunction (Schafer et al. 1991); alcohol withdrawal itself, especially in older patients (Brower et al. 1994); and effects of sedative medication used to treat withdrawal (Liskow et al. 1989). The often dramatic improvement in cognitive functioning of individuals with chronic alcoholism that typically occurs during the first few weeks of sobriety is attributable to amelioration of all these factors. Improvements in depression and liver dysfunction may be especially important (Schafer et al. 1991). Age, however, is an important predictor of the extent of residual neuropsychological performance deficits after 3–4 weeks of sobriety (Schafer et al. 1991).

These lingering deficits can be focal or patchy (i.e., may affect only one or a few specific cognitive functions) or can be sufficiently widespread to fulfill diagnostic criteria for dementia (Ryan and Butters 1986). DSM-IV offers no diagnostic category for focal abnormalities (apart from the characteristic amnesic disorder of Korsakoff’s syndrome). Because focal and even widespread dysfunction may be partially or completely reversible over years of sobriety (Brandt et al. 1983), workers uneasy about the use of the term “dementia” for such conditions have suggested terms such as “reversible alcoholic cognitive deterioration” (Lishman 1997).

Lingering deficits resulting in psychosocial dysfunction occur in younger sober alcoholic individuals, but they are more common in older patients tested beyond 1 month. In one series of 50 male alcoholic outpatients (age 60 and older) who were assessed clinically and neuropsychologically 1–6 months after their last drink, 16% showed focal cognitive deficits whereas another 6% met criteria for dementia (Atkinson and Tolson 1992). In another series, older patients (50–69 years old), who were tested between

1 and 59 months after their last drink, performed less well on several measures of memory and visuospatial tasks than did younger patients and age-matched control subjects (Brandt et al. 1983). Resolution of some deficits (e.g., psychomotor skills and short-term memory) can be demonstrated 5 years or more after initiation of abstinence (Brandt et al. 1983). On the other hand, long-term memory tended to remain impaired even after 7 years of abstinence. These differences suggest different mediating mechanisms for reversible and nonreversible functions (Butters 1985; Ryan and Butters 1986). Corresponding improvement in cortical atrophy has been demonstrated by serial MRI in abstinent older alcoholic patients (Carlen et al. 1986; Ishikawa et al. 1986; Muuronen et al. 1989; Pfefferbaum et al. 1995; Schroth et al. 1988). Regional cerebral blood flow (Ishikawa et al. 1986) also improves with abstinence.

**Alcohol-associated dementia and Alzheimer's disease.** Whether the dementia associated with chronic alcoholism is distinct from the Wernicke-Korsakoff syndrome or is a part of it is not debated here; this subject is well addressed in other sources (Heindel et al. 1991; Lishman 1997; Ryan and Butters 1986; Victor et al. 1989; Willenbring 1988). However, a clinical dilemma concerning the differential diagnosis of dementia in patients with heavy drinking histories merits discussion. This issue has practical significance for the clinician because the prognosis for alcohol-related dementia is different from that for Alzheimer's disease, provided abstinence can be maintained. For the researcher, paying greater attention in systematic dementia studies to the drinking history and clinical findings typically associated with alcoholism may also clarify the role of alcohol as a risk factor for dementing disorders more generally (Atkinson 1997; Oslin et al. 1998).

Confounding of precise dementia diagnosis by alcoholism and heavy drinking may be a more substantial problem than previously acknowledged. In a British community survey of psychiatric disorders in older adults (Saunders et al. 1991), men with heavy drinking histories were 4.6 times more likely to have a dementia diagnosis than other men. An association between past heavy alcohol consumption and current cognitive disorder was also found in the Epidemiologic Catchment Area study (George et al. 1991). In clinical case series, alcohol-related dementias have typically been reported in 4%–10% of dementias from all causes (e.g., Larson et al. 1984b; Renvoize et al. 1985; Wells 1979). However, in more recently established dementia registries, if patients with heavy drinking histories are included with those having histories of alcohol use disorders, the proportion of cases at least partially attributable to alcohol is considerably higher, having been reported in 14 of

65 patients (21.5%) in one series (King 1986) and in 26 of 120 patients (21.7%) in another (Atkinson and Ganzini 1994; D. M. Smith and Atkinson 1995). And in a study of patients with dementia in long-term care facilities, alcohol was linked to dementia in 31 of 130 patients (24%) (Carlen et al. 1994). Commonly used criteria for primary degenerative dementia of the Alzheimer type prohibit this diagnosis when alcoholism or a history of heavy alcohol consumption is present. On the other hand, nothing in DSM-IV criteria for alcohol-associated dementia, beyond the physician's judgment, distinguishes it from dementias of other etiologies: it is in fact a diagnosis of exclusion. Is alcoholism merely coincident to Alzheimer's dementia (Ryan and Butters 1986; Victor et al. 1989)? Does alcoholism act in a permissive sense to increase the vulnerability of the brain to the development of Alzheimer's dementia, as do such phenomena as repeated head trauma or stroke? Is there a true alcohol-induced dementia, or can alcohol act indirectly but specifically to cause a dementia, for example, by affecting vascular supply to particular brain structures (Fisman et al. 1996)? The answers to these questions are not reliably known (Atkinson 1997; Oslin et al. 1998; D. M. Smith and Atkinson 1995). Imaging of the cerebral cortex may not be helpful because changes of early Alzheimer's disease can be similar to those seen in chronic alcoholism. Short of post-mortem brain study, no effective way to clarify the diagnosis has been determined.

Currently efforts are under way to improve differential diagnosis by specifying additional provisional features that appear to be regularly associated with alcoholic dementia (Oslin et al. 1998; Osuntokun et al. 1994; J. Saxton, personal communication, November 1996). Features favoring alcohol-related dementia include 1) history of prolonged heavy alcohol use; 2) presence of peripheral polyneuropathy and/or gait ataxia; 3) sparing of naming (i.e., absence of dysnomia or anomia); 4) presence of other alcohol-related disorders, for example, hepatic cirrhosis; 5) evidence on MRI of *cerebellar* atrophy, especially of the vermis; 6) normal (rather than elevated) cerebrospinal fluid tau protein level; and 7) evidence, after a period of abstinence, of stabilization or improvement in cognitive functioning or reversal of cerebral atrophy seen on MRI (Atkinson 1997; Atkinson and Ganzini 1994; Morikawa et al. 1999; Oslin et al. 1998; Osuntokun et al. 1994; D. M. Smith and Atkinson 1995). This approach to differential diagnosis, if affirmed by prospective studies, may help distinguish more precisely among alcohol-associated dementia, dementia of the Alzheimer type, and mixed cases.

**Alcohol-associated insomnia.** Insomnia is emphasized because aging and chronic alcohol consumption

affect sleep architecture in similar ways: both elderly subjects and recently abstinent alcoholic subjects tend to show frequent awakenings, especially from deep slow-wave sleep, and reduced rapid-eye-movement (REM) sleep (Dustman 1984; see also Chapter 17 in this volume). Put another way, sleep of 40-year-old alcoholic subjects in one study (Dustman 1984) more closely resembled the sleep of healthy elderly individuals than did the sleep of age-matched healthy control subjects. Sleep in recovering alcoholic individuals improves with abstinence, but slow-wave sleep may not reach normal values even after 4 years of abstinence. Advising an older patient to take a drink near bedtime to aid sleep is not warranted; although sleep latency might be reduced by this practice, if continued over time, late-night drinking is likely to exaggerate age-associated alterations of sleep pattern.

**Alcohol-associated mood disorder.** Depressive symptoms are widespread in newly admitted alcoholic patients of all ages, including the elderly. For example, at entry to a treatment program for alcoholic male veterans 55 years or older, 54% of 135 patients scored 70 or higher (T score) on the Depression Scale of the Minnesota Multiphasic Personality Inventory (MMPI) (R. M. Atkinson, unpublished data, January 1990). Subsyndromal depressive symptoms are much more common than diagnosable depressive disorders, which occurred in 12% of a large series of hospitalized elderly alcoholic patients (Finlayson et al. 1988). These symptoms resolve without specific antidepressant therapy in a majority of alcoholic patients over the first 3–4 weeks of abstinence (Brown and Schuckit 1988). Residual depression after 3 weeks suggests a comorbid mood disorder (Brown et al. 1995). Some workers hypothesize that subclinical chronic depression or a potential depressive diathesis may be manifested by evanescent depressive symptoms in early sobriety or even by alcoholic drinking itself. This suggestion is the rationale for trials of antidepressant drug maintenance of alcoholic patients who do not have a diagnosable comorbid depressive disorder. However, no trial of antidepressant agents in alcoholic patients without clinical depression has demonstrated any effects on subsequent drinking behavior. The high prevalence of depressive symptoms in recently drinking alcoholic patients, evidence that the level and recency of prior alcohol consumption is correlated with depressive symptoms in early abstinence (M. M. Nakamura et al. 1983), and the spontaneous resolution of depressive symptoms with abstention all support the inference that evanescent depression after a drinking bout represents a secondary mood disorder, that is, depression induced by alcohol or alcohol withdrawal (Schuckit et al. 1997). Alcohol

neurotoxicity may itself be the sole cause, although associated alterations in nutrition, sleep, and other organ functions can act together with alcohol to induce depressed mood.

**Alcohol-associated movement disorder (Parkinson type).** A single report (Carlen et al. 1981) described seven older alcoholic patients (age 53–70) who developed transient parkinsonian symptoms and signs either during alcohol withdrawal or during chronic severe intoxication. Parkinsonism disappeared or improved significantly with reduced alcohol consumption alone. This association is plausible in the light of evidence that alcohol can disrupt striatal dopamine activity (reviewed in Wilcox 1984).

### Neuropsychiatric and Substance Comorbidity in Alcohol Use Disorders

Active tobacco dependence is highly prevalent in elderly alcoholic subjects (approximately 60%–70%) (Atkinson and Tolson 1992; Finlayson et al. 1988); active dependence on prescribed sedatives, anxiolytics, and opioid analgesics varies (from 2% to 14%) depending on the cohort studied (Atkinson and Tolson 1992; Blow et al. 1992a; Finlayson and Davis 1994); and recent illicit drug abuse is uncommon. Nonsubstance-related neuropsychiatric comorbidities in clinical data sets vary even more, depending upon the cohort and clinical setting where studied. Data from five recent reports are summarized in Table 16–7. Mood and cognitive disorders are the most common comorbid psychiatric conditions in older patients. Determining in a particular case whether depression or cognitive deficits are secondary to recent alcohol use or represent a true comorbid disorder can be difficult within the usual time constraints of inpatient care or consultation (Atkinson 1998b; in press). A strong association between major depressive disorder and alcohol dependence exists at all ages (B. F. Grant and Harford 1995), and a history of heavy drinking can be a risk factor for the occurrence (Saunders et al. 1991) and severity (B. L. Cook et al. 1991) of subsequent depressive disorders in the elderly. Alcohol problems are found in a significant number of cases of older people who commit suicide (Blazer 1982; Conwell et al. 1990; Grabbe et al. 1997; Martin and Streissguth 1982), although the association of alcoholism with suicide may be stronger in late-middle-aged men than in women or elderly men (Conwell et al. 1990). Functional impairment caused by heavy drinking ranges from mild to very severe, presenting in extreme cases as “senile squalor” or “Diogenes syndrome” (Cooney and Hamid 1995; Kafetz and Cox 1982; MacMillan and Shaw 1966; Wrigley and Cooney 1992).

**TABLE 16-7. Studies of psychiatric comorbidity in older patients with alcoholism**

	Study: authors, year, setting, <sup>a</sup> age group, basis of diagnoses, N

<sup>a</sup>Setting: A = alcohol treatment program; IP = inpatient; MH = mental health or psychiatric treatment program; OP = outpatient. All studies were from a single setting except for Blow et al., which was pooled data from 172 Veterans Administration facilities. <sup>b</sup>Not reported in paper; personal communication from senior author, R.E. Finlayson, 1994. <sup>c</sup>Cases reported as "depression" without distinguishing among major depression, dysthymia, and other types.

## Management of Alcohol-Related Disorders in the Elderly

In mild cases (heavy drinking with only mild alcohol-related problems or none), success can often be achieved simply by offering advice to cut down or abstain, accompanied by informal social interventions as needed. The use of a *brief intervention* strategy (i.e., brief sessions of structured patient education, physician advice, and contracting to reduce alcohol intake) has been found to be effective in reducing alcohol consumption by 35% at 1-year follow-up (from 15.5 to 10 drinks per week versus no change in control subjects) in one study of elderly heavier drinkers in primary care settings (M. F. Fleming, K. L. Barry, W. Adams, L. B. Manwell, and M. L. Krecker, unpublished data, June 1997). Brief intervention for older risky drinkers is currently under further study (W. Adams, personal communication, June 1998; Blow 1998).

The person with more severe alcoholism should enter an outpatient geriatric alcoholism treatment program if possible. Successful programs have been set up within geriatric centers and general substance abuse programs (reviewed in Atkinson 1995). Group social treatment (Atkinson et al. 1998; Kofoed et al. 1987) and cognitive-behavioral treatment (Dupree and Schonfeld 1996, 1998) are the predominant models for psychosocial treatment. When a geriatric alcoholism treatment program is not available, individual case management can be effective. Family involvement in treatment improves compliance and outcome (Atkinson et al. 1993). Use of drinking-deterrent drugs must be carefully considered: disulfiram can be hazardous, whereas naltrexone was well tolerated in one study of older patients (Oslin et al. 1997a, 1997b). Acamprosate appears to have a low toxicity profile, but most studies reported to date have excluded patients older than 60 or 65 (e.g., Paille et al. 1995; Sass et al. 1996). Treatment of comorbid disorders (e.g., tobacco dependence; major depression; cardiovascular, hepatic, and musculoskeletal disorders) is essential. Other specific treatment principles have been discussed in detail elsewhere (Atkinson et al. 1998; Center for Substance Abuse Treatment 1998). It is helpful to reassure the patient and family that older alcoholic patients fare as well as, or better than, younger persons in a variety of alcohol treatment settings (Atkinson 1995, 1998a).

In the most complex cases, the patient should be referred to an alcoholism inpatient treatment unit, which is also indicated when outpatient efforts fail. If severe medical or psychiatric complications are present or major withdrawal is anticipated or is already occurring, initial treatment on an acute medical or general psychiatric inpatient

unit is warranted. Patients with dementia or chronic psychosis are best managed in a psychiatric day treatment center or home visitation program. Patients with personality disorders and major mental illness can best be managed individually in a psychiatric outpatient clinic, preferably in conjunction with an alcoholism group. Intractable heavy drinking in the face of dementia or other coexisting major mental disorder may force placement in residential care, where, unfortunately, alcoholic patients are not always welcomed (see Chapter 37 in this volume). In a few locales, alcohol-free foster homes and other residential facilities have been established and are staffed by personnel trained to care for recovering alcoholic patients in an accepting manner.

## ■ Benzodiazepine Dependence

Among young polysubstance abusers, benzodiazepine abuse includes such behaviors as consumption of the drug outside of medical supervision, use for euphoriant effects, escalation of the dosage over time, and continued use despite adverse social, economic, or legal consequences. This pattern of abuse is distinctly rare among older people (Busto et al. 1986a; Pinsker and Suljaga-Petchel 1984). However, among elderly patients, long-term therapeutic prescribing of benzodiazepines can lead to physical dependence with characteristic symptoms when the drug is discontinued. Three forms of discontinuance phenomena are recognized: 1) *recurrence* symptoms that include reemergence and persistence of the anxiety symptoms for which the drug was originally prescribed; 2) *rebound* anxiety, that is, recurrence symptoms that are temporarily worse than before treatment; and 3) a true *withdrawal* syndrome, that is, signs and symptoms that are time-limited and unlike symptoms of the disorder for which the drug was originally prescribed (American Psychiatric Association 1990). Although discontinuance symptoms occur after stopping a variety of psychotropic agents, the recurrence, rebound, and withdrawal symptoms that follow benzodiazepine cessation are so unpleasant as to promote relapse to drug use in a significant proportion of patients (Roy-Byrne and Hommer 1988).

## Epidemiology

**Use of benzodiazepines by community-dwelling elderly persons.** Benzodiazepines are commonly prescribed for elderly patients, and community-dwelling older persons receive a disproportionate share of

benzodiazepine prescriptions. In 1991, persons 65 or older represented 13% of the United States population but received 27% of all benzodiazepine prescriptions and 38% of prescriptions for benzodiazepine hypnotic agents (Woods and Winger 1995). A survey of all prescriptions for the entire elderly population of British Columbia in 1990 showed that 24% had received at least one benzodiazepine prescription (Thomson and Smith 1995). Moreover, epidemiological studies indicate that courses of therapy are considerably longer in elderly than in younger patients. A large United States survey reported that 44% of older patients, compared with 20% of younger patients, who were prescribed these drugs used them for 4 months or longer (Mellinger et al. 1984). A large community-based study from Great Britain found that nearly 95% of elderly benzodiazepine users, compared with only 43% of young and middle-aged benzodiazepine users, were treated for 4 months or more (Dunbar et al. 1989). Long-term use is more common in older patients whether the drugs are prescribed as anxiolytics or hypnotics (K. Morgan et al. 1988; Smart and Adlaf 1988). A prospective study confirmed that once a benzodiazepine was prescribed, old age, especially if associated with low educational level, was significantly associated with continued prescriptions (Mant et al. 1988).

A 1979 United States national survey found that 1.6% of the population had used benzodiazepines for longer than 1 year (Mellinger et al. 1984); 71% of these long-term users were more than 50 years old. They were more likely than nonusers to report physical health problems, and despite use of these psychotropic drugs they reported considerable residual anxiety and depression. A British study (Rodrigo et al. 1988) found that 41% of long-term users were over age 70 and had used benzodiazepines daily for a mean of 5 years. Most had poor physical health, and a third had depressive disorders. More recent reports (e.g., Isacson et al. 1992; Simon et al. 1996; Thomson and Smith 1995) suggest that this pattern of more frequent long-term prescribing of benzodiazepines for community-dwelling elderly patients has persisted, even in the health maintenance organization (HMO) setting (Simon et al. 1996). Despite many years of continued benzodiazepine prescription, elderly long-term users rarely exceed recommended dosages or escalate their dosage over time (Busto et al. 1986a; Pinsker and Suljaga-Petchel 1984; Salzman 1991). One United States study found that the average daily dose for elderly outpatients rarely exceeded 4 mg in diazepam equivalents (Pinsker and Suljaga-Petchel 1984). Compared with elderly men, elderly women are more likely to receive benzodiazepine prescriptions and are more likely to take these drugs long-term (Ancill and Carlyle 1993; Simon et

al. 1996; C. F. Sullivan et al. 1988). In the Liverpool Longitudinal Study of continuing health of community elderly, the female/male ratio of the entire study sample of persons 65 and older was 1.6:1, whereas the gender ratio for benzodiazepine users was significantly higher, 2.5:1 and 4.1:1 in separate years (C. F. Sullivan et al. 1988).

**Use of benzodiazepines by institutionalized elderly persons.** Among institutionalized elderly persons, physician prescription of benzodiazepines is widespread (see Chapter 37 in this volume). A survey of one state's Medicaid recipients found that 24% of elderly nursing home residents were prescribed a benzodiazepine and that flurazepam, a long half-life hypnotic, was one of the most frequently prescribed psychotropic drugs (Buck 1988). Another survey reported that 28% of 850 residents of intermediate care facilities received a regularly scheduled sedative-hypnotic (Beers et al. 1988). Of those patients prescribed a benzodiazepine, 30% received a drug with a long half-life. These and other studies in nursing homes have documented poorly advised prescribing practices such as benzodiazepine prescription in the absence of a mental disorder for which these agents are indicated, use of benzodiazepines with a long half-life (which are more likely to cause toxicity in the elderly), and use of standing orders for hypnotics as opposed to as-needed prescribing (Beardsley et al. 1989; Beers et al. 1988).

Problematic psychoactive drug-prescribing practices were the target of federal regulations in the late 1980s intended to improve prescribing in nursing homes, but these regulations have produced mixed results with regard to benzodiazepine use. Use of hypnotics has tended to decrease (e.g., Borson and Doane 1997; Lantz et al. 1996), and in some settings benzodiazepine anxiolytic use and use in general have declined as well (e.g., Lantz et al. 1996; Siegler et al. 1997). Studies have demonstrated that strategies to rationalize prescribing can and do reduce benzodiazepine use (e.g., Avorn et al. 1992; Gilbert et al. 1993; Schmidt et al. 1998). However, in a number of recent reports it appears that although inappropriate use of antipsychotic and other psychoactive drug classes may have been curbed by federal regulations, the use of benzodiazepines, especially for anxiety (Borson and Doane 1997), is increasing in many settings—to levels of 30%–40% of nursing home residents regularly receiving these agents (Lasser and Sunderland 1998). Whether this increase indicates improved recognition of anxiety as a result of more rigorous psychiatric assessment also mandated by federal regulation, substitution of benzodiazepines for antipsychotic and other agents controlled by regulation, or other reasons, is uncertain.

### **Prevalence of benzodiazepine dependence.**

The prevalence of late-life drug dependence of all types in persons 65 and older reported in community epidemiological surveys is very low (well under 1%), but such data almost certainly do not reflect therapeutic-dose benzodiazepine dependence, which is typically not recognized as such by the patient and poorly measured by the usual criteria for drug dependence. Inferring prevalence of therapeutic-dose dependence from the frequency of discontinuance symptoms is difficult because only true withdrawal symptoms (not recurrence or rebound symptoms) suggest frank physical dependence. True withdrawal signs and symptoms have been reported to occur in 20%–50% of chronic users after discontinuation (Roy-Byrne and Hommer 1988; Schweizer et al. 1990). Clinical reports of sizable samples of prescription drug-dependent older adults are rare, and the few studies available describe cohorts that are not representative of typical older medical outpatients who make up a majority of users (American Psychiatric Association 1990). Two such surveys have shown that, among elderly patients dependent on prescription drugs, benzodiazepines are involved far more often than are opioid analgesics, the next most common class of prescribed agents associated with dependence in this age group (Finlayson and Davis 1994; Holroyd and Duryee 1997).

### **Adverse Effects of Benzodiazepine Use**

#### **Age-associated increase in the neurotoxicity of benzodiazepines.**

The most important adverse effects of benzodiazepines in the elderly include excess daytime sedation, ataxia, and cognitive impairment. Studies have demonstrated that elderly patients have more adverse effects than do young patients at similar doses of these medications (Greenblatt et al. 1991a, 1991b). After single and multiple doses of benzodiazepines, elderly patients experience substantial impairment in attention, memory, arousal, and psychomotor abilities (Pomara et al. 1991). Among healthy elderly patients, single doses of diazepam as low as 2.5 mg can impair immediate and long-term memory and psychomotor performance (Pomara et al. 1985). Cognitive impairment is also more prolonged in older compared with younger patients after single doses of a benzodiazepine (Nikaido et al. 1990). The major effect on memory of acute doses of benzodiazepines is dose-dependent impairment in the acquisition of newly learned information into long-term storage (reviewed in Barbee 1993). Decrements in recall produced by benzodiazepines in elderly persons may be no greater

proportionally than those produced in younger persons (Greenblatt et al. 1991c; Hinrichs and Ghoneim 1987; Pomara et al. 1989). However, because of baseline deficits in recall in the elderly, the additional impairment produced by benzodiazepines can represent a more severe compromise (Woods and Winger 1995). Elderly medical and surgical inpatients show deterioration in daytime performance after several nightly doses of even short half-life benzodiazepines such as temazepam (P. J. Cook et al. 1983), and daytime hangover from hypnotics can be especially prominent in frail elderly patients with dementia, hypoalbuminemia, or chronic renal insufficiency (P. J. Cook 1986).

Compared with young patients, elderly patients have more daytime balance impairment after nightly hypnotic treatment (Bonnet and Kramer 1981). Most, but not all, studies of the relationship of benzodiazepine use to risk of falls and hip fractures have shown an association (reviewed in Woods and Winger 1995). Other factors (e.g., concurrent use of other psychoactive and nonpsychoactive medications and alcohol [Neutel et al. 1996]; comorbid neurological and other medical disorders) are important additional risk factors. A large HMO study of persons over 65 demonstrated that any benzodiazepine use was associated significantly with impairment of functional status, independent of comorbid medical disorders (Ried et al. 1998). Benzodiazepines impair the driving skills of many older drivers (American Psychiatric Association 1990; Ray et al. 1992; Salzman 1991). Whether, and to what extent, tolerance develops in older persons to these various adverse brain effects of benzodiazepines are issues that have not been studied adequately (Woods and Winger 1995).

### **Cognitive impairment and long-term use.**

Clinical evidence suggests excess cognitive disability and morbidity associated with chronic benzodiazepine use. Continual use of benzodiazepines can result in a dementia-like syndrome in mixed-age (Golombok et al. 1988) and elderly (Larson et al. 1987) patients. Among 35 patients with drug-induced major cognitive disorders, benzodiazepines were the offending agents in 22 (Larson et al. 1987). Memory and other cognitive functions improve after discontinuation of long-term benzodiazepine treatment in younger (Tonne et al. 1995) and older persons (Golombok et al. 1988; Salzman et al. 1992).

**Mechanisms underlying age-associated changes in response to benzodiazepines.** As a person's age increases, alterations occur in the volume of distribution,

elimination half-life, and clearance of metabolized benzodiazepines, producing higher steady-state plasma drug concentrations (Greenblatt et al. 1991a, 1991b; Ozdemir et al. 1996; see also Chapter 34 in this volume).

However, even when old and young patients have comparable plasma drug concentrations, the elderly develop more sedation, psychomotor impairment, and memory problems (Bertz et al. 1997; Castleden et al. 1977; P. J. Cook et al. 1984; Greenblatt et al. 1991a, 1991b; Swift et al. 1985), suggesting an increased pharmacodynamic effect with age. Basic mechanisms accounting for age-associated increased sensitivity to benzodiazepines have not been determined but may involve postreceptor mechanisms in GABAergic<sup>1</sup> neurons and second messenger systems (Ozdemir et al. 1996).

## **Discontinuation Phenomena**

**Types and frequency of symptoms.** The reported incidence of benzodiazepine discontinuation symptoms in long-term users (persons who have taken benzodiazepines daily for more than 1 year) varies widely from none to 100%, reflecting heterogeneous characteristics of the patient populations and differing measurement and definition of discontinuance syndromes (Bowden and Fisher 1980; Golombok et al. 1987; Laughren et al. 1982; Noyes et al. 1988; Petursson and Lader 1981). Discontinuance symptoms increase substantially after 8–12 months of daily benzodiazepine use (Rickels et al. 1983) but have been reported in patients taking high-potency, short half-life agents whose duration of daily use was only 4–6 weeks (Higgitt et al. 1985; Murphy et al. 1984; Rickels et al. 1983). Rebound insomnia can occur after 1 week of therapy with a hypnotic (Kales et al. 1979).

Major discontinuance symptoms are listed in Table 16–8. Symptoms that frequently occur after cessation of long-term benzodiazepines are, for the most part, recurrence and rebound phenomena. In a series of studies of mixed-age patients, 90% undergoing gradual discontinuation and 100% undergoing abrupt discontinuation experienced at least mild discontinuance symptoms (Rickels et al. 1990; Schweizer et al. 1990). Milder true withdrawal signs and symptoms (e.g., nausea, anorexia, tinnitus, perceptual distortions, hyperacusis, depersonalization, and derealization) are less common than are recurrence or rebound symptoms, but they may develop in 20%–50% of long-term users after discontinuation (Roy-Byrne and Hommer 1988; Schweizer et al. 1990). Severe withdrawal symptoms

<sup>1</sup>  $\gamma$ -aminobutyric acid.

**TABLE 16–8. Benzodiazepine discontinuance symptoms by frequency**

Frequent	Common	Uncommon <sup>a</sup>
Anxiety	Flulike symptoms (nausea, coryza, lethargy, diaphoresis)	Delirium
Insomnia	Sensitivity to sound, touch, or light	Seizures
Restlessness	Aches and pains	Persistent tinnitus
Agitation	Blurred vision	Depersonalization
Irritability	Depression	Derealization
Muscle tension	Nightmares	Paranoid delusions
	Hyperreflexia	Hallucinations
	Ataxia	Psychosis
	Autonomic hyperactivity	

<sup>a</sup>Typically, when present these represent true withdrawal symptoms.

Source. Adapted from American Psychiatric Association 1990.

(e.g., delirium, psychosis, and seizures) occur far less often than do milder symptoms. Seizures are more common in patients taking higher than therapeutic doses of benzodiazepines, especially high-potency agents (American Psychiatric Association 1990; Noyes et al. 1988). Both rebound and withdrawal symptoms generally abate within 2–4 weeks of drug cessation, although persistence for months of isolated symptoms such as tinnitus and perceptual distortions has been reported (Busto et al. 1986b; Higgitt et al. 1990; Schweizer et al. 1990).

**Presentation of benzodiazepine withdrawal in the elderly.** Benzodiazepine dependence and withdrawal may be overlooked initially in elderly patients who, for example, do not or cannot disclose their daily use of these agents when entering the hospital, and a deteriorating course may be misdiagnosed as myocardial infarction, hypertensive crisis, or infection (Whitcup and Miller 1987). Delirium can be a more common presentation of withdrawal in older patients and be misattributed to other causes (see Chapter 19 in this volume). Withdrawal delirium occurred in 13% (7 of 52) of elderly long-term benzodiazepine users withdrawing abruptly from a mean of 7.75 mg/day of diazepam in one study (Foy et al. 1986). In a study of 45 medical inpatients age 60 and older who developed delirium in the hospital, benzodiazepine use was implicated in 29% of the cases (Foy et al. 1995). In an analysis of 48 case reports of benzodiazepine withdrawal seizures, only nine patients were over age 60, suggesting that elderly patients are not disproportionately represented among patients suffering this adverse event (Fialip et al. 1987).

**Age and other factors affecting severity of discontinuance symptoms.** Two studies (Cantopher et al. 1990; Schweizer et al. 1989) found that older pa-

tients reported significantly less severe discontinuance symptoms than did younger patients. Withdrawal and other discontinuance symptoms in the elderly may be attenuated because of lowered prevalence of panic disorders, decreased rate of decline of benzodiazepine plasma levels, altered functional capacity, or age-associated changes in neurotransmitter systems (Schweizer et al. 1989). Other studies have failed to show age-related differences in withdrawal severity, but most excluded patients over age 70 as well as patients with medical problems (Roy-Byrne and Hommer 1988). Several studies have reported on the correlates of withdrawal severity among long-term users, though none has focused on the elderly. The following variables were correlated with increased severity of withdrawal in some but not all studies of mixed-age patients: presence of panic disorder, abrupt drug withdrawal, high-dose dependence, short half-life agents, comorbid alcohol problems, and personality pathology (American Psychiatric Association 1990; Busto et al. 1986b; Noyes et al. 1988; Rickels et al. 1990; Roy-Byrne and Hommer 1988; Schweizer et al. 1990; Tyrer 1989).

## Outcome and Management of Benzodiazepine Dependence

**Outcome of benzodiazepine withdrawal in elderly patients.** Despite evidence that old age is not associated with more severe withdrawal, the elderly have a poorer outcome after therapeutic attempts to discontinue benzodiazepines. Studies indicate that approximately half of mixed-age patients who participate in a withdrawal protocol successfully complete the program (Busto et al. 1986b; Golombok et al. 1987; Schweizer et al. 1990). Of patients who complete a withdrawal protocol, 50%–70% remain benzodiazepine-free at follow-up ranging from 10

months to 5 years (Ashton 1987; Golombok et al. 1987; Rickels et al. 1991). However, investigators in one study (Holton et al. 1992)—in which abstinence was defined as complete nonuse of benzodiazepines throughout a 5-year period—independently validated the subject's claims of abstinence and reported that only 15% were completely benzodiazepine free during this time period. Older age was associated with both difficulty completing withdrawal protocols and increased likelihood of relapse to benzodiazepine use despite completion of a cessation program (Ashton 1987; Golombok et al. 1987; Holton et al. 1992; Rickels et al. 1991). The mean age of subjects in these follow-up studies was 40–50 years, and numbers of elderly persons were small. Besides older age, risk factors for relapse in studies of mixed-aged patients include casual efforts to discontinue (as opposed to participation in a formal protocol), personality pathology, dependence on agents with short half-lives, higher drug doses, higher caffeine intake, and continued psychiatric symptomatology (American Psychiatric Association 1990; Golombok et al. 1987; Holton et al. 1992; Rickels et al. 1991).

For long-term benzodiazepine users who do succeed in discontinuing use of these drugs, several studies indicate the possibility of at least some improvement in cognitive functioning (Golombok et al. 1988; Salzman et al. 1992; Tonne et al. 1995) and, in addition, improvement, or at least no deterioration, in symptoms of anxiety, depression, and insomnia (e.g., Rickels et al. 1990; Salzman et al. 1992; Schweizer et al. 1990). A study of 76 patients (mean age 62) who were successfully withdrawn from chronic benzodiazepine use found that medical and mental health visits fell from 25.4 per year before detoxification to 4.4 per year afterward (Burke et al. 1995). But other studies suggest that the majority of patients who successfully withdraw from benzodiazepines will continue to experience significant anxiety, depression, and insomnia and thus remain at risk for return to use of these agents (Ashton 1987; Golombok et al. 1987; Holton et al. 1992).

### **Management of benzodiazepine dependence.**

Several interventions may decrease the severity of benzodiazepine discontinuation and improve the ability to maintain abstinence. However, few studies have been performed to measure the effectiveness of these interventions in the elderly. Withdrawal severity may be lessened, though rarely completely avoided, by a taper schedule (Busto et al. 1986b). The rate of dose reduction should be based on what can be tolerated by the patient. Considerable slowing of the rate of decrease is often required for the second half of the taper (Higgitt et al. 1985). Several authors have suggested that taper schedules should last at

least 4 weeks, with many patients requiring 2–4 months to tolerate complete withdrawal (Higgitt et al. 1985; Noyes et al. 1988; Schweizer et al. 1990). Patients who are dependent on short half-life agents may be more comfortable when tapered using a long half-life agent (Rickels et al. 1990). Adjuvant pharmacological drugs to attenuate discontinuance symptoms are of limited success (Roy-Byrne and Ballenger 1993). Carbamazepine may improve outcome but has not been studied in elderly patients (Schweizer et al. 1991). Some patients will be able to reduce or discontinue benzodiazepines requiring only encouragement and support from the prescribing physician (Cormack et al. 1989; Hopkins et al. 1982). Pharmacological treatment of the comorbid depression found in many benzodiazepine-dependent elderly is recommended. Antidepressants are also an alternative therapy for panic disorder (see Chapter 15 in this volume).

The effectiveness of alternative (nondrug) anxiety reduction techniques is uncertain. Several reports found that psychological approaches are no more likely to improve outcome of benzodiazepine withdrawal than a physician's advice to reduce drug consumption (Fraser et al. 1990; Hopkins et al. 1982; Onyett and Turpin 1988). But psychological therapies (Gilbert et al. 1993; Golombok and Higgitt 1993) and self-help groups (Tattersall 1993) have been shown to be useful adjuncts for some persons withdrawing from these agents. Treatment in an inpatient substance abuse program may be required when benzodiazepine dependence has persisted for many years or is associated with comorbid alcohol or opioid analgesic dependence (Finlayson and Davis 1994). Patients requiring hospital treatment have higher rates of comorbid psychiatric disorders (including somatoform and personality disorders) compared with the rates in elderly primary alcoholic inpatients (Finlayson and Davis 1994).

### **Benefits of Long-Term Benzodiazepine Use**

The benefit of long-term benzodiazepine treatment has generated considerable debate. The long-term use of benzodiazepines as hypnotics has little support because hypnotic efficacy diminishes substantially after several weeks of treatment (American Psychiatric Association 1990; Grad 1995; see also Chapter 17 in this volume). Rebound insomnia after discontinuation of benzodiazepines is a significant clinical problem, especially with agents that have short half-lives (Kales et al. 1979). Patients most likely to receive continued benzodiazepine prescriptions are older people with chronic somatic illness and substantial psychological distress. However, no rigorously designed

studies of the efficacy of long-term benzodiazepine prescribing in elderly patients have been published. Some prospective studies of younger patients with anxiety disorders demonstrate no difference in outcome between those treated with anxiolytic drugs and psychotherapy (Catalan et al. 1984). Low-dose dependence is apt to occur with long-term use of any agent in this class (Martinez-Cano et al. 1996). More research is needed on the appropriate indications for benzodiazepine treatment in the elderly.

Most patients do not develop tolerance to the anxiolytic effects of benzodiazepines (American Psychiatric Association 1990). Several authors have proposed that if these patients receive continued benefit from benzodiazepine treatment, ongoing prescription is appropriate (Uhlenhuth et al. 1988; Woods and Winger 1995). Deciding when to prescribe long-term can be difficult, requiring consideration of the patient's relief from morbid anxiety balanced against the hazards of chronic toxicity and physical dependence (Ancill and Carlyle 1993). Long-term, low-dose therapy may be justified especially in patients whose anxiety responds better to a benzodiazepine than to alternative therapies, and who are reliable, have no history of alcoholism or drug addiction, and can be well supervised medically (American Psychiatric Association 1990). In these circumstances, however, the physician should anticipate the likelihood of inducing physical dependence and seek the informed consent of patient and family in deciding how to proceed. Moreover, as in the case of the patient with epilepsy or diabetes mellitus, steps should be taken to protect the patient from inadvertent abrupt drug withdrawal, for example, by clearly documenting in the medical record the status of the patient as a long-term user of benzodiazepines and by educating patient and family never to stop the drug abruptly.

## ■ Tobacco (Nicotine) Dependence

Although older adults are less likely to smoke cigarettes than are younger adults, tobacco dependence is the most common of all substance use disorders in the elderly population; is entirely obvious, thus taking no special effort to establish a diagnosis; and arguably accounts for far more medical disability and mortality among elderly persons than dependence on all other substances combined. Because of its low behavioral toxicity, however, tobacco dependence has held little interest for neuropsychiatrists. Compulsive tobacco use is rooted, nonetheless, in an abnormal behavior pattern that is determined by powerful nicotine effects on brain processes.

## Epidemiology

The prevalence of smoking declines with age and also has declined among older smokers in recent years. In 1994 national surveys among persons 65 and older, 13% of men and 11% of women reported regular daily cigarette smoking (Husten et al. 1997; National Center for Health Statistics 1996). These rates are considerably lower than those reported for middle-aged adults: in the age group 45–64, 28% of men and 23% of women were current smokers in 1994 (National Center for Health Statistics 1996). A survey of four large, geographically diverse areas in the United States reported the prevalence of current smoking among people over age 84 as ranging from 4.6% to 10.8% in men and from 1.1% to 4.0% in women (Colsher et al. 1990). Although prevalence in older adults has declined substantially over the years 1965–1994, the rate of decline has been slower among this older age group than among others and slower among women than men (Husten et al. 1997; National Center for Health Statistics 1996). In one large elderly cohort followed for 6 years, prevalence of smokers declined from 15% to 9%, reflecting an annual cessation rate of 10% and relapse rate of less than 1% (Salive et al. 1992). In another study, the rate of smoking cessation among older adults rose with increasing educational attainment and was consistently higher for men than for women and higher for whites than for blacks (Husten et al. 1997). A study of 339 current smokers age 50–102 found that they were more likely to be heavily addicted smokers, compared with former smokers (Rimer et al. 1990).

## Nicotine-Dependence Disorder

**Diagnosis and clinical features.** Nicotine is the addictive substance in tobacco, and regular use of tobacco in any form produces a nicotine-dependence disorder. Similar to heroin or cocaine addiction, nicotine dependence is characterized by pursuit of pleasurable effects from nicotine use, a compulsive pattern of use despite knowledge of harmful effects, withdrawal symptoms, tolerance, craving, and relapse after abstinence (Department of Health and Human Services 1988; Hughes et al. 1987; Jarvik and Schneider 1992). Some of the usual criteria for substance dependence (Table 16–2) are not satisfactory because low behavioral toxicity and easy access to relatively cheap tobacco products make several of these criteria irrelevant. Nicotine has euphorogenic properties; smokers claim, and some objective evidence supports, that nicotine improves motor performance and mood and decreases anxiety (Jarvik and Schneider 1992). How the psychotropic effects of nicotine are modified by age has been little re-

searched. When tobacco is discontinued, smokers experience a variety of unpleasant mood and physical symptoms that begin within hours of abstinence. Psychological symptoms include irritability, anxiety, depression, and craving. Physiological symptoms include low energy, concentration difficulties, headache, increase appetite, and nonspecific somatic complaints (American Psychiatric Association 1994; Hughes et al. 1986; Jarvik and Schneider 1992). Investigation into age-related changes in the prevalence or severity of these withdrawal symptoms has been minimal.

### **Neuropharmacology of tobacco dependence.**

Nicotine has many effects on the CNS, mediated via widely distributed nicotinic receptors on cholinergic neurons innervating various structures. These effects include increases in cerebral glucose uptake, epinephrine, norepinephrine, arginine, vasopressin, adrenocorticotrophic hormone, cortisol, growth hormone, and prolactin; increase in the bioavailability of dopamine; and release of endogenous opioids (reviewed in Brautbar 1995). Of greatest importance from the standpoint of tobacco dependence are the well-established effects of nicotine on midbrain dopamine systems (reviewed in Jarvik and Schneider 1992; Nisell et al. 1995). Like a number of other drugs of abuse such as cocaine, nicotine stimulates these systems: the main effects include increased burst firing in mesolimbic dopamine neurons of the ventral tegmental (VT) area, release of dopamine from the nucleus accumbens, and, in chronic dosing, increased dopamine metabolism in the prefrontal cortex (Nisell et al. 1995). Such actions are known to be associated with reward and reinforcement of learning and cognitive behavior.

These effects not only afford an explanation for tobacco dependence but also may help to explain the high prevalence of cigarette smoking (about 90%) observed in patients with schizophrenia (reviewed in Nisell et al. 1995). Reduced functional activity in the prefrontal cortex (“hypofrontality”) has been demonstrated in patients with chronic schizophrenia and is correlated with negative symptoms. The prefrontal cortex provides direct input to dopamine cells in the VT area, and impaired functional activity of the prefrontal cortex in the rat decreases burst firing in dopamine neurons of the VT area (Nisell et al. 1995). Thus high consumption of cigarettes by patients with chronic schizophrenia could be a form of attempted self-medication (Svensson et al. 1990). Cigarette smoking does help to normalize impaired auditory sensory gating in patients with schizophrenia (Adler et al. 1993). Hypofrontality in aging patients with chronic alcoholism is also strongly suggested by the neuropsychological, neuro-

imaging, metabolic, and histopathological data reviewed earlier in this chapter. Thus a compensatory or self-medication hypothesis may also help to explain the high prevalence of smoking (60%–70%) in older patients with alcoholism.

### **Complications and Comorbidities**

Tobacco use is the leading preventable cause of death in adults. Smoking doubles the risk of death from combined causes in persons age 35–70 (Thun et al. 1997), and longevity is inversely associated with cigarette consumption (Goldberg et al. 1996). Smoking increases the risk of a variety of cancers, atherosclerosis, chronic obstructive lung disease, peptic ulcer disease, and osteoporosis (Agner 1985; Hollenbach et al. 1993; Mellstrom et al. 1982; Rundgren and Mellstrom 1984; Tresch and Aronow 1996). Smoking in late life is associated with loss of mobility and poorer physical function (LaCroix and Omenn 1992) and may contribute to malnutrition in frail elderly by promoting weight loss and impairing sense of taste and smell (Rimer 1988). The metabolism of many prescribed drugs is altered by smoking (Dawson and Vestal 1984). Elderly smokers are more likely to consume alcohol (Colsher et al. 1990), and most older alcoholic patients in treatment are current smokers (Atkinson and Tolson 1992; Finlayson et al. 1988). Concomitant smoking cessation should be strongly considered in patients undergoing treatment for alcoholism (Gulliver et al. 1995; Hurt et al. 1995, 1996). Elderly smokers also report higher levels of depressive symptoms than former or never smokers (Colsher et al. 1990). Compared with older current smokers, older smokers who quit have a reduced risk of death that becomes evident within 1–2 years after quitting, and their overall risk of death approaches that of never smokers after 15–20 years of abstinence (LaCroix and Omenn 1992). Risks of coronary events, cardiac death, and death from smoking-related cancer and chronic obstructive lung disease are reduced in smokers who quit, and improvement occurs in pulmonary function and hip bone mineral density after smoking cessation (Hollenbach et al. 1993; LaCroix and Omenn 1992).

### **Smoking Cessation**

**Readiness to quit.** Ninety percent of all adult smokers who quit do so without a specialized treatment program, typically by stopping abruptly (Fiore et al. 1990). Evidence shows that many older persons who continue smoking want to quit (Rimer et al. 1990), but it is unclear whether they are more (Fiore et al. 1990) or less (Yudkin et

al. 1996) successful in quitting when compared with younger smokers. Only a minority report being advised to quit by their physicians (Cox 1993; Rimer et al. 1990). One population-based study found that, among smokers 50 and older, those with adverse health consequences of smoking and those who perceived smoking as an addiction were more likely to be ready to quit (Clark et al. 1997). In a longitudinal epidemiological study of elderly persons in three communities, intercurrent development of myocardial infarction, stroke, or cancer increased subsequent smoking cessation but not relapse (Salive et al. 1992), and among elderly women, but not men, smokers in one community, those reporting clinically significant levels of depressive symptoms were nearly four times more likely to quit smoking than nondepressed women (Salive and Blazer 1993). Among healthy older adults, on the other hand, current smokers may be less likely than younger smokers to believe in the health hazards of smoking and more likely to view smoking as a positive habit to enhance coping, reduce stress, and control weight (Orleans et al. 1994a).

**Cessation methods and outcomes in older persons.** Some smoking cessation methods (e.g., rapid smoking aversion therapy or medicinal nicotine substitutes such as polacrilex gum or transdermal patches) may be contraindicated in older patients with coronary artery disease, cardiac arrhythmias, hypertension, or diabetes mellitus. Brief intervention in primary care medical settings and self-help guides can, when appropriately tailored to elderly individuals, produce 6-month or 1-year quit rates as high as 20% compared with spontaneous quit rates of 5%–10% (G. D. Morgan et al. 1996; Rimer and Orleans 1994). Transdermal nicotine patch therapy yielded a 6-month quit rate of 29% in one naturalistic study of elderly smokers (Orleans et al. 1994b). Quit rates by any method seem to be influenced favorably by more frequent contact with supervising personnel, although elderly patients voice a preference for minimal contact approaches, which, for economic reasons, should in most cases be tried first. Success in quitting as a result of participation in a smoking cessation program has been found to be associated with previous attempts to quit, desire to quit, confidence in quitting, perceived health benefits, lower nicotine consumption, being married to a nonsmoking spouse, and achieving abstinence from smoking during the first week of treatment (Dale et al. 1997; G. D. Morgan et al. 1996; Yudkin et al. 1996). Older smokers who relapse report the same reasons as younger smokers for their return to smoking: irritability, weight gain, fear of weight gain, friction with family members, and inability to concentrate (Orleans et al. 1994a).

## ■ Other Substance Problems in Older Adults

### Prescription Narcotic (Opioid) Analgesic Dependence

Old age is associated with the development of a variety of nonmalignant but painful chronic conditions (e.g., arthritis, neuropathies) for which narcotics are frequently, though controversially, prescribed (see Chapter 18 in this volume). Few studies have been published on the prevalence and characteristics of elderly abusers of prescription narcotic analgesics. In one community survey, the 2-week prevalence of prescribed narcotic use was 2.1% in elderly women and 2.3% in elderly men (Chrischilles et al. 1990). Abuse of prescribed narcotics by the elderly appears to be rare (Portenoy and Payne 1992; Porter and Jick 1980) unless the patient was an opioid abuser when young (Jinks and Raschko 1990). Tolerance and physical dependence can occur even in the absence of abuse (Portenoy and Payne 1992). Case series of elderly patients hospitalized for prescription drug dependence indicate that opioid analgesic dependence was less common than dependence on anxiolytic and hypnotic agents (Finlayson and Davis 1994; Jinks and Raschko 1990; Whitcup and Miller 1987), although in one study 49 of 100 inpatients age 65 and older were dependent on opioids (Finlayson and Davis 1994). In a survey of 140 outpatients in a geriatric psychiatry clinic, 1.4% were dependent on prescribed opioids (Holroyd and Duryee 1997). These reports (Finlayson and Davis 1994; Holroyd and Duryee 1997) point to an association of high levels of psychopathology with vulnerability to dependence in older persons taking prescribed opioids.

The degree to which chronic narcotic use causes cognitive impairment remains unknown. One study of middle-aged persons found no evidence of cognitive impairment associated with long-term prescribed narcotics (Hendler et al. 1980). Whether dependence liability changes with age is uncertain (Ozdemir et al. 1996). Codeine and dihydrocodeine are agents frequently used in the elderly; their analgesic effect appears to be mediated by the metabolite morphine. After a single standard morphine dose, elderly subjects, when compared with younger subjects, show higher plasma concentrations and impaired drug clearance (Baillie et al. 1989). Further studies of the pharmacokinetics, CNS pharmacodynamics, and dependence liability of opioid analgesics in the elderly are needed.

### Illicit Drug Use and Dependence

Use of illicit drugs is uncommon among the current aging population, and illicit drug use disorders in this age group

are rare (Anthony and Helzer 1991; Atkinson et al. 1992). Rates of use and abuse are higher in particular elderly subgroups, for example, aging criminals, long-term heroin addicts, and alcoholic individuals (Atkinson et al. 1992; Miller et al. 1991; Myers et al. 1984).

**Illicit opioid dependence.** Opioid addicts are the best studied of elderly illicit drug abusers, but elderly individuals constitute a very small proportion of heroin addicts. For example, in 1985 only 2% of all methadone maintenance clients in New York City were older than 60 (Pascarelli 1985). Data from the Drug Abuse Warning Network (DAWN) in 1991 indicated that 1.8% of all reports of heroin/morphine abuse in United States urban emergency departments are in persons older than 55 (National Institute on Drug Abuse 1992a). Development of addiction after young adulthood is rare, and mortality over the course of addiction is high (Atkinson et al. 1992). One United States study that followed heroin addicts for 24 years reported that 27.7% died during this period (Hser et al. 1993). Medical examiner data from the DAWN in 1991 showed that 5.6% of deaths from heroin or morphine occurred in persons older than 55 (National Institute on Drug Abuse 1992b). Older addicts often have comorbid addictions, especially tobacco and alcohol, contributing to disability and early mortality. Besides premature death, another explanation proposed to account for the decrease in elderly opioid addicts was that over time they “matured out,” that is, gradually became abstinent (Winick 1962). More recent studies do not support this theory that increasing proportions of addicts become abstinent over time, especially once addiction exceeds 5–10 years (Haastrop and Jepson 1988; Hser et al. 1993). Studies from the 1970s characterized elderly addicts as socially aloof, secretive about their addiction, not otherwise criminally involved, and likely to support their drug habit with part-time licit employment (reviewed in Atkinson et al. 1992), although a more recent study suggests greater involvement in criminal activities by addicts entering their 50s (Hser et al. 1993).

Psychiatric and medical illnesses cause considerable morbidity in elderly addicts. As in younger addicts, elderly addicts experience the medical effects of contaminated needles and impure drugs, which increase their risk of a variety of systemic infections including endocarditis, sepsis, skin and CNS abscesses, and hepatitis B (Novick 1992). Of all elderly individuals with acquired immunodeficiency syndrome, 3% contracted the human immunodeficiency virus through intravenous drug use (Moss and Miles 1987). To some degree, the risk of medical complications is mitigated by the tendency of elderly addicts to practice scrupu-

lous hygiene regarding needles and syringes (Capel et al. 1972; Des Jarlais et al. 1985; Pascarelli and Fischer 1974). Long-term heroin addicts develop neuropsychological and neuroimaging abnormalities (caused by cerebral damage from infections or injected foreign substances) that are likely to further impair their functioning (Schuckit 1977; Strang and Gurling 1989). Aging opioid-dependent people frequently die from the consequences of alcohol and tobacco dependence (Des Jarlais et al. 1985). Lifelong heroin addicts appear to be better managed on methadone maintenance than by drug-free strategies (reviewed in Atkinson et al. 1992).

**Other illicit drugs.** Little information is available regarding the use of other illicit drugs by the elderly. Combined results of three national representative household surveys, conducted during 1991–1993 ( $N = 87,915$ ), showed 1-year prevalence rates in persons age 50 and older of 0.6% for marijuana use (0.8% in men, 0.5% in women) and 0.1% for cocaine use (0.2% in men, 0.1% in women) (Kandel et al. 1997). Both recreational and medical marijuana users are represented among the older population (Sussman 1997). Recent use of marijuana and cocaine is reported sporadically by older patients (Abrams and Alexopoulos 1988), especially by patients who are alcohol dependent (Miller et al. 1991). Older persons tend to acquire these drugs from their adult children or from younger sexual partners (Atkinson et al. 1998). Virtually nothing is known about age-associated changes in drug-induced psychiatric syndromes or altered treatment needs of elderly illicit drug abusers.

## **Nonprescription (Over-the-Counter) Drug Use and Dependence**

Elderly people commonly use over-the-counter preparations, including vitamins and herbal medicines, such as ginkgo biloba; their use of these substances has been reviewed recently (Ganzini and Atkinson 1996). A potential exists for medical and behavioral problems from habitual overuse of many available nostrums, especially those with sedative, anticholinergic, sympathomimetic, and anti-inflammatory effects, and these effects may be additive to prescribed medications and, in some instances, to the effects of alcohol. Anticholinergics may affect cognition (Ganzini and Atkinson 1996). Chronic salicylate toxicity increases with age and may produce a dementia-like syndrome associated with tinnitus and irritability (Bailey and Jones 1989; Grigor et al. 1987). No data exist about the true extent of dependence on nonprescription drugs in old age.

## Summary

In this chapter, the leading substance abuse problems affecting the elderly population are discussed, with special emphasis on neuropsychiatric features of these disorders. Tobacco, alcohol, and controlled prescription drugs, especially the benzodiazepines, present the greatest substance abuse hazards in old age.

Several aspects of substance abuse in old age can be highlighted. Tobacco, the substance most widely abused by elderly people, does not have prominent deleterious neurotoxic effects, though morbid effects on other organ systems such as the vascular system may result in cognitive impairment. Elderly people are more sensitive than younger people are to neurotoxic effects of substances such as alcohol and benzodiazepines. These effects are manifested both as decrements in performance on cognitive testing and as functional decline common to frail elderly such as impairment in activities of daily living or falls.

Illicit drug use by elderly persons is uncommon, but poorly investigated. The recent decade has produced little new information on the demography, characteristics, and treatment of elderly persons who abuse illicit drugs. The increasing prevalence of illicit drug abuse in current middle-aged persons (Glantz and Sloboda 1995; Sussman 1997) suggests that illicit substance abuse among elderly people looms as a possible future public health problem. Information is especially scarce on the neuropsychiatric effects of both licit and illicit opiates.

Fatalism on the part of health care providers regarding substance abuse in old age is misplaced. Studies of alcohol, tobacco, and illicit opiate dependence suggest that if abstinence could not be achieved at a younger age, it may still be achieved at an older age. Significant health benefits occur. Substance abuse may account for the largest portion of treatable dementias, and treatment of substance abuse may result in either arresting or reversing neuropsychiatric dysfunction. Further research is needed on specialized age-appropriate treatment for the substance-abusing elderly person.

# Sleep Disorders

Peter D. Nowell, M.D.

Carolyn C. Hoch, Ph.D.

Charles F. Reynolds III, M.D.

The primary challenge posed by the increasing proportion of elderly people in the United States is to increase active life expectancy and compress functional morbidity. Otherwise, increase in longevity is likely to be associated primarily with prolongation of dependency (Rosenwaike 1985). Changes in sleep, sleep quality, and daytime alertness in late life have enormous impact on quality of life, level of functioning, and ability to remain independent (Morin and Gramling 1989; Prinz et al. 1990; Wauquier et al. 1992). The prevalence of sleep disorders among the elderly ranges depending on the specific disorder, as discussed below, but approximately one in three community-dwelling older adults will report difficulties with poor sleep quality or daytime sleepiness (Ganguli et al. 1996; Newman et al. 1997). Hence, preserving the integrity of sleep for as long as possible is a major public health priority, as emphasized by the National Institutes of Health Consensus Development Conference on Sleep Disorders in Late Life (Consensus Development Conference 1990). Any understanding of how to attenuate the sleep changes and disturbances of usual and pathological aging that would reduce psychiatric morbidity, burden to families, and the

rate of institutionalization, even by a single percentage point, would pay for itself many times over. Therefore, the benefits that would accrue from an understanding of how the successful functioning of the aging sleep/wake and circadian system can be preserved in the face of medical and psychosocial challenges would have an impact not only on elderly patients themselves but on society as a whole.

To facilitate understanding of this chapter, a brief review of important concepts from normal sleep physiology is useful. Two operating states of the central nervous system characterize sleep: rapid-eye-movement (REM) sleep and nonrapid-eye-movement (NREM) sleep. The deepest level of NREM sleep, slow-wave sleep, decreases greatly with age, whereas REM sleep tends to remain more stable. The continuity of sleep also tends to diminish with age, resulting in decreased “sleep efficiency” (the ratio of time spent asleep to total recording period). Sometimes, as noted below, decreased sleep efficiency with age may be the result of intrinsic sleep pathologies (e.g., sleep-disordered breathing), whereas at other times it may reflect psychopathological processes such as depression. The regular alteration of these operating states constitutes the

essential ultradian rhythm of sleep, which in turn occurs within a circadian rhythm of sleep and wakefulness.

Self-reported symptoms of sleep cluster into domains of quantity, quality, and timing (including circadian aspects) of sleep and wakefulness. Symptoms of quantity and quality concern duration of sleep periods, time to sleep onset, number of awakenings, duration of wakefulness after sleep onset, perceived depth and satisfaction with sleep, and fatigue and sleepiness during the daytime. Symptoms related to the timing of sleep concern advances and delays in sleep-wake cycles, as well as symptoms related to shift work and jet lag. In addition to self-reported symptoms, signs and laboratory measures of sleep and wakefulness span sleep-specific measures such as polysomnography, multiple sleep latency tests (MSLTs), and circadian measures such as isolation studies under constant routines. Such procedures provide information on the “architecture” of sleep including the NREM-REM cycles, sleep stages, the quantification of levels of alertness-sleepiness, and rhythms of physiological activity such as body temperature and hormones. Supplementing these sleep-specific procedures is the full range of neuropsychological, neuroendocrine, neuroimaging, and other physiological test procedures.

In this chapter, we focus on sleep and aging and the symptoms and signs of sleep disorders in the elderly, particularly emphasizing empirical studies described since the first edition of this textbook. Generally, sleep disorders medicine is concerned with specific disorders of sleep and wakefulness as described in the *International Classification of Sleep Disorders* (Diagnostic Classification Steering Committee 1990) and more generally in DSM-IV (American Psychiatric Association 1994). As is discussed below, most disorders are not thought to be specific disorders of the elderly, though the epidemiology, expression of symptoms, comorbidity, treatment selection, and treatment outcome are modified for aging populations. This age effect has resulted in generalities such as an added emphasis on differential diagnosis in the elderly to identify general medical or medication-related etiologies of sleep complaints (Ancoli-Israel 1997; Folks and Burke 1998).

Likewise, treatment recommendations for the elderly typically caution about the potential for altered pharmacokinetics that may require dosage adjustments to reduce side effects or caution about interactions with other medications (see Chapter 34 in this volume). Specific relationships between sleep and aging would suggest strategies for prevention and intervention of sleep disorders in the elderly, thereby reducing morbidity and mortality and improving medical-related quality of life. (For general reviews of sleep and sleep disorders in the elderly, see

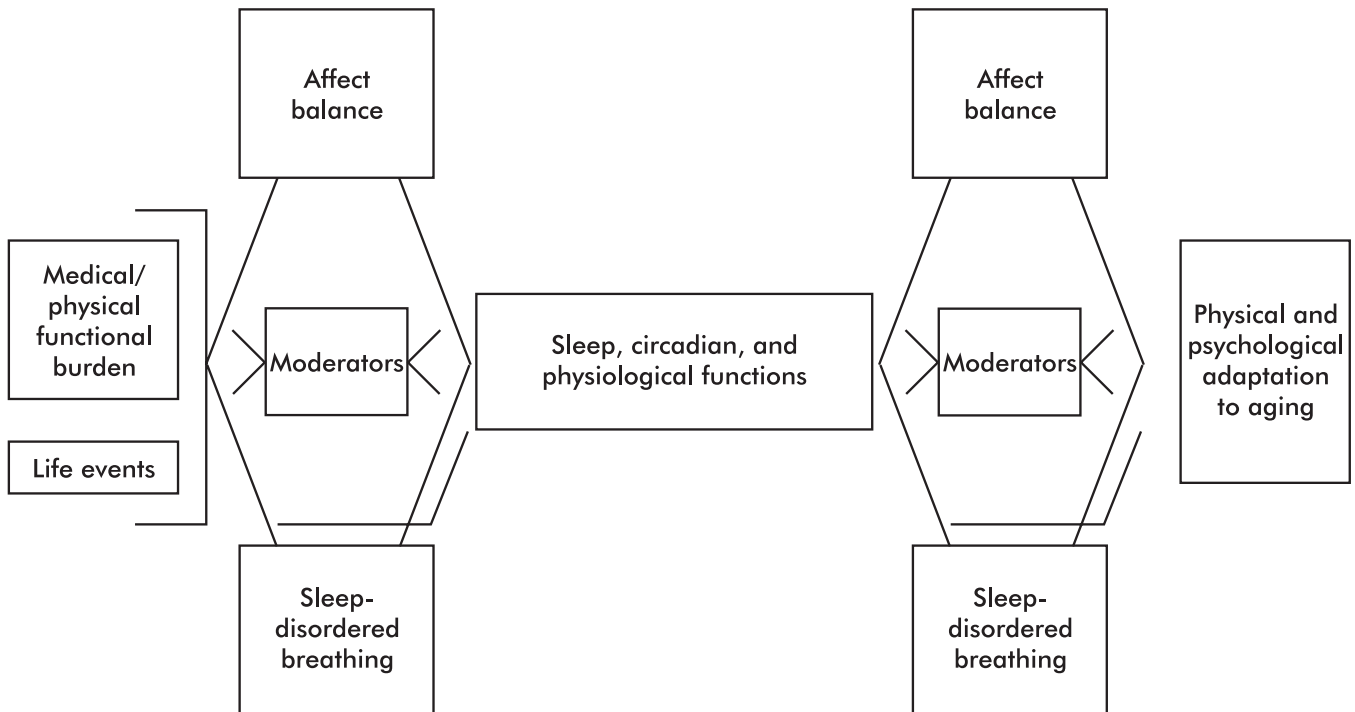

Ancoli-Israel 1997; Bachman 1992; Becker and Jamieson 1992; Gottlieb 1990; Moran et al. 1988; and Wooten 1992.)

## ■ A Conceptual Framework for Understanding Challenges to Sleep and Circadian Timekeeping in Late Life

We have formalized a model of the multiple factors that challenge successful circadian timekeeping (including sleep in elderly individuals). The model is based on the results of our own work, as well as other data in the literature, and is shown in Figure 17–1. The model explicitly shows important predictors of, as well as outcomes resulting from, the development of sleep and circadian function in very late life. Thus, changes in health and cognitive status and negative life events (particularly those associated with bereavement) are hypothesized to lead to “decay” in sleep and sleep quality. The model posits that the effect of these changes is mediated by two factors: changes in mood (negative shifts in affect balance) and worsening of sleep-disordered breathing. We also hypothesize that characteristics such as gender, stability of social rhythms, social support, nutrition, and physical fitness serve as important moderators, helping to buffer the subject from the effects of medical burden, negative life events, and their mediators. It is noteworthy that the model explicitly recognizes that sleep changes are also likely to influence subsequent adaptation to aging along physical and psychological dimensions. Thus, what appear as major predictors in the model can, over time, ultimately be influenced by the very outcomes that they have helped to produce.

## ■ Sleep Changes in Aging

Considerable data support the face validity and clinical utility of conceptualizing sleep, particularly sleep continuity, delta sleep, and REM sleep, as psychobiological markers or correlates of successful aging and adaptation in very late life (Reynolds et al. 1993). Pronounced alterations in sleep in aging consist primarily of reductions in subjective sleep quality, slow-wave and REM sleep, and a marked increase in the number and duration of awakenings interrupting sleep. Alterations in slow-wave sleep occur in young adulthood (30–40 years of age), whereas disturbances in amounts of REM and wake appear more later in life (Vancauter et al. 1998). In comparing the nocturnal

**FIGURE 17-1.** Model depicting relationships between potential factors linking the effects on sleep.

sleep of healthy subjects 80 years old or older with that of healthy 60- to 70-year-old subjects (i.e., “old old” versus “young old”), Reynolds et al. (1991) and Hoch et al. (1997) have reported the relative stability of sleep efficiency and REM sleep in the young old, but a decline of slow-wave sleep and sleep continuity in the old old. In a study using sleep deprivation as an experimental manipulation in 80- and 20-year-old subjects, Brendel et al. (1990) found that sleep continuity and delta sleep were enhanced in both groups on the first recovery night, indicating that sleep changes in very old subjects are at least partially reversible by this procedure. Surprisingly, mood and performance were disturbed by sleep loss to a significantly greater extent among the young subjects, suggesting that acute total sleep loss is a more disruptive procedure for the young than for the elderly.

Evidence is conflicting regarding changes in daytime alertness with aging. In some studies, the elderly are seen as physiologically more aroused or alert than are younger subjects (Hoch et al. 1992). In others studies, discrepancies are found between subjective and objective measures of alertness. For example, 19 elderly (mean age 65 years) and 19 young (mean age 21 years) subjects were tested by MSLTs and questionnaire. Elderly subjects were subjectively more alert than younger subjects were by question-

naire and rating scales, but MSLT results were equivalent (Kramer et al. 1998). Thus, despite changes in nighttime sleep consolidation and distribution of sleep stages in the elderly, the implications of these changes for daytime restedness and alertness remain unclear.

Successful adaptation in very late life may be associated with stable preservation of, or only modest changes in, REM sleep and sleep continuity. Failed adaptation, as discussed below, tends to be associated with decrements of sleep continuity and delta sleep and by either a relative increase of REM sleep (e.g., mood disorders) or decrease in REM sleep (e.g., neurodegenerative disorders). The latter, decreased REM sleep generation, has also been shown to be correlated with decreased survival time (Hoch et al. 1989). In contrast to healthy elderly patients, older patients with major depression comorbid with probable dementia of the Alzheimer type show less of the expected physiological hallmarks of recovery sleep after a night of total sleep deprivation (slow-wave sleep rebound and REM sleep rebound), attesting to diminished physiological resilience and plasticity (Reynolds et al. 1987). In the broader context provided by studies of sleep in aging, we concluded that the stability of REM sleep in aging suggests the utility and validity of REM sleep as a marker or correlate of successful adaptation in late life (Reynolds et al. 1993). The revers-

ibility of age-dependent sleep changes needs to be further addressed by identifying factors that support or enhance successful aging.

## ■ Sleep in Aging: The Impact of Spousal Bereavement on Sleep in Late Life

Given the theoretical interest in negative life events and their potential to disrupt sleep via changes in mood, our own work, as well as that of others (e.g., N. G. Bliwise et al. 1985; Roehrs et al. 1982), provides evidence linking negative affect balance (i.e., depression) and sleep outcomes in late life. Sleep is frequently disturbed among recently bereaved elderly people who have a full depressive syndrome. Sleep efficiency is diminished, REM latency is short, and early slow-wave sleep generation is also reduced compared with those of nondepressed, recently bereaved subjects and compared with elderly control subjects (Reynolds et al. 1992). These findings are similar to those of Cartwright (1983) in depressed divorcing women. Depressed widows and widowers in our study carried a heavier burden of chronic medical illness than did the control subjects (Reynolds et al. 1992). Similar findings linking stress, depression, and electroencephalographic (EEG) sleep disturbances (including decreased delta sleep and shortened REM latency) were reported by Cartwright and Wood (1991) in a study of middle-aged divorcing spouses. Divorce, like the loss of a spouse through death, can be an occasion for grief. We were able to find one negative report, from Vitiello et al. (1990), who observed that sleep was undisturbed in elderly depressed individuals who have *not* sought health care.

We reported an investigation of EEG sleep measures in elderly, recently bereaved volunteers stratified by the presence or absence of syndromal major depression (Reynolds et al. 1992). As hypothesized, depressed bereaved subjects had significantly lower sleep efficiency and worse sleep quality, more early morning awakening, shorter REM latency, greater REM percent, and lower rates of delta wave generation in the first NREM sleep period (i.e., lower delta sleep ratio) compared with those characteristics in nondepressed, bereaved volunteers. Sleep in the latter group was similar to that of healthy control subjects. The relevance of these data to the proposed model of challenges to successful aging is that depression (or depressive symptoms) can be an important mediating variable that links negative life events with sleep-circadian outcomes, as well as with changes in perceived sleep qual-

ity. With respect to the role of hypothesized moderators (i.e., social support and stability of social rhythms), our data suggested greater stability of psychosocial rhythms and higher levels of perceived social support among nondepressed widows and widowers compared with their depressed counterparts. Testing of the proposed model would help elucidate antecedent-consequent relationships.

Similarly, the primary protective factor examined in previous research is social support, including the dimensions of social network, tangible support, and perceived social support. George (1989) concluded that “high levels of social support are associated with decreased risk of psychiatric morbidity and that perceived support is the dimension most strongly related to mental health outcomes” (p. 215). However, we do not know whether support exerts its effects directly on such outcomes or whether it serves primarily to buffer the impact of other stressors (see also Cohen and Wills 1985; George 1989; Kessler and McLeod 1985).

We have investigated the role of psychosocial factors in buffering the impact of major life events on depressive symptoms in our sample of elderly widows and widowers (Prigerson et al. 1993). Our results suggested the importance of subjects’ sense of mastery—their feeling of competence in the face of stress—as a predictor of mood response after life stressors. Similar findings have been reported elsewhere in nonelderly samples (e.g., Dew et al. 1990), further supporting the selection of mastery as a potential buffer against the onset of disturbed mood and sleep.

## ■ General Medical Burden

Medical burden and increasing physical functional limitations represent chronic stressors in the presented model and are among the vulnerability factors most frequently addressed in previous research on the precursors of psychiatric symptoms and disorders (for a review, see George 1989). The specific chronic stressors that have received the most empirical scrutiny in mixed-age samples are job stress, chronic financial strain, and chronic physical illness, with all three being related to increased risk of psychiatric morbidity (George 1989). As reviewed by D. L. Bliwise (1993), considerable evidence now underscores the general effects (either direct or indirect) of medical illness in the poor sleep of old age (e.g., Ford and Kamerow 1989; Gislason and Almqvist 1987; Morgan et al. 1989). Specific clinical symptoms or disorders that have been shown to have negative effects on sleep quality in late life include nocturia (e.g., Zepelin and Morgan 1981), headache (Cook

et al. 1989), gastrointestinal illness (Karacan et al. 1976; Mant and Eyland 1988), bronchitis and asthma (Mant and Eyland 1988), cardiovascular symptoms, and non-insulin-dependent diabetes mellitus (Hyyppa and Kronholm 1989). Chronic pain from conditions such as osteoarthritis also disrupts sleep in elderly individuals (Wittig et al. 1982). In addition, elevated autonomic activity (Prinz et al. 1979; Zepelin and McDonald 1987) and a greater susceptibility to external arousal (Roth et al. 1972; Zepelin et al. 1984) may be important predisposing factors to disturbed sleep in very late life. In general, the effects of these general medical conditions on sleep become issues in the elderly because they are more common conditions in older individuals. However, it is also possible that increased wakefulness at night or greater susceptibility to arousal may enhance the impact of these conditions on sleep in older individuals.

Among specific brain diseases in the elderly in which sleep and sleep disorders may play a role are Parkinson's disease and stroke. Patients with Parkinson's disease report decrements in sleep quality and demonstrate progressive deterioration in sleep continuity (Kostic et al. 1991; M. C. Smith et al. 1997). Some of the deterioration in sleep continuity and quality is attributed to muscle stiffness, dystonias, and nocturnal akinesia (Stocchi et al. 1998) separate from comorbid depression and anxiety (Kostic et al. 1991; Menza and Rosen 1995). Dopaminergic agonists have been demonstrated to improve sleep continuity disturbances in Parkinson's disease in some studies (Stocchi et al. 1998). However, dopaminergic agonists have also been shown to increase motor activity at night in some patients with Parkinson's disease (van Hilten et al. 1994). It may be that REM behavior disorder (see section below on Sleep Disorders) is an early feature in some patients who develop Parkinson's disease (Tan et al. 1996).

The issue of sleep and stroke has been studied primarily from the aspect of the possible increased risk of stroke that may be associated with sleep apnea. However, research has also been directed at the effects of specific stroke locations and their effects on sleep and breathing (Giubilei et al. 1992; Mohsenin and Valor 1995) and at the potential influence that circadian factors may have in the timing of stroke within the early morning. Whether obstructive sleep apnea increases the risk of cardiovascular morbidity, including myocardial infarct and stroke, when other risk factors common in sleep apnea such as hypertension and obesity are controlled has been much debated (Bassetti et al. 1996; Dyken et al. 1996). After a stroke, patients with sleep-disordered breathing may have a worse functional outcome than those who do not have sleep-disordered breathing (Good et al. 1996).

## ■ Sleep Disorders, Sleep Quality, and Aging

For a broad overview, see Monane (1992). Generally, subjective sleep quality deteriorates in later life. Such deterioration can be seen in the increasing sleep-related complaints and insomnia symptoms in the elderly. However, the extent to which subjective sleep quality deteriorates as a part of physiological aging as opposed to pathological conditions associated with aging remains unclear. For example, a prospective United States regional epidemiological study of an age-stratified, random, community sample of 1,050 seniors (mean age 74 years, 57% women) found that sleep complaints were common and persistent over a 2-year interval. The symptoms reported were difficulty falling asleep (37%), difficulty staying asleep (29%), and early morning awakening (19%) (Ganguli et al. 1996).

When associated medical symptoms and history are examined, the prevalence of sleep complaints varies with a number of other factors. For example, in a study of more than 9,000 seniors over the age of 65 years, more than half reported sleep difficulties most of the time (Foley et al. 1995). Twenty-four percent reported insomnia and 15% reported that they never felt rested. Multivariate analyses associated sleep complaints with respiratory symptoms, physical disabilities, nonprescription medication use, depressive symptoms, and poorer self-perceived health status. The authors concluded that sleep symptoms in older persons may often be secondary to coexisting diseases. They also drew attention to the difficulty in determining the prevalence of specific sleep disorders, independent of health status, and note that the development of more sophisticated and objective measures of sleep disturbance will be necessary to meet this objective (Foley et al. 1995).

In addition to general medical conditions, gender also plays a role in the reporting of sleep complaints in aging. In the Cardiovascular Health Study (Newman et al. 1997), 5,201 adults over the age of 65 years were identified in a random community sample. Women were found twice as likely as men to report difficulty falling asleep (30% versus 14%). Both difficulty falling asleep and frequently awakenings were found to increase in prevalence with age and were associated with poor health, depression, angina, limitations in activities of daily living, and the use of benzodiazepines. Female gender, depression, and regular use of hypnotics were also found to be associated with sleep complaints in the elderly in another community study (Maggi et al. 1998). In this study, depression symptoms were more strongly associated with nighttime complaints, and physical disability was more associated with feeling poorly rested upon awakening.

These studies are in contrast to a nonrandom survey-based study of 1,485 elderly patients over the age of 50 years (Middelkoop et al. 1996). In this study, the number of nighttime awakenings increased significantly only in males. No significant correlations were found between health status and gender, age, or subjective sleep quality. The most frequently reported causes of disturbed sleep onset and sleep maintenance were worries and nocturia, respectively. Subjective sleep quality was mostly associated with self-estimated sleep latency. Lastly, in a sample of patients between the ages of 50 and 65 who were carefully assessed for physical health status, the prevalence of difficulty falling asleep was only 1% in men and 2.6% in women, and difficulty maintaining sleep was only 4.4% in men and 3.3% in women (D. L. Bliwise et al. 1992). The authors concluded that when overall physical health factors are taken into account, a decline in sleep quality is not necessarily an inevitable component of aging specifically, but rather a result of processes that accompany aging. One methodological difference among these studies is the range of ages in each. Hoch et al. (1997) examined subjective and polysomnography-defined sleep quality over 3 years in 50 subjects between the ages of 60 and 87 years old who were carefully screened for medical and psychiatric status. Subjective sleep quality, sleep continuity, and slow-wave sleep diminished in the subjects 75 years and older, whereas these measures were relatively stable in the subjects younger than 75. Changes in medical status did not correlate with these declines in sleep outcomes. Thus, complaints of deterioration in sleep quality would appear to increase with age in the elderly and are associated with psychiatric and general medical symptoms.

Alcohol abuse or dependence in the elderly can lead to decreases in subjective sleep quality, increased number of nocturnal wakings, increased sleep apnea, and complaints of daytime sleepiness (J. W. Smith 1995; Wooten 1992). Thus, in addition to the evaluation of general medical conditions and psychiatric conditions, an evaluation of alcohol use in elderly patients with complaints of poor sleep quality or daytime sleepiness is indicated (see Chapter 17 in this volume).

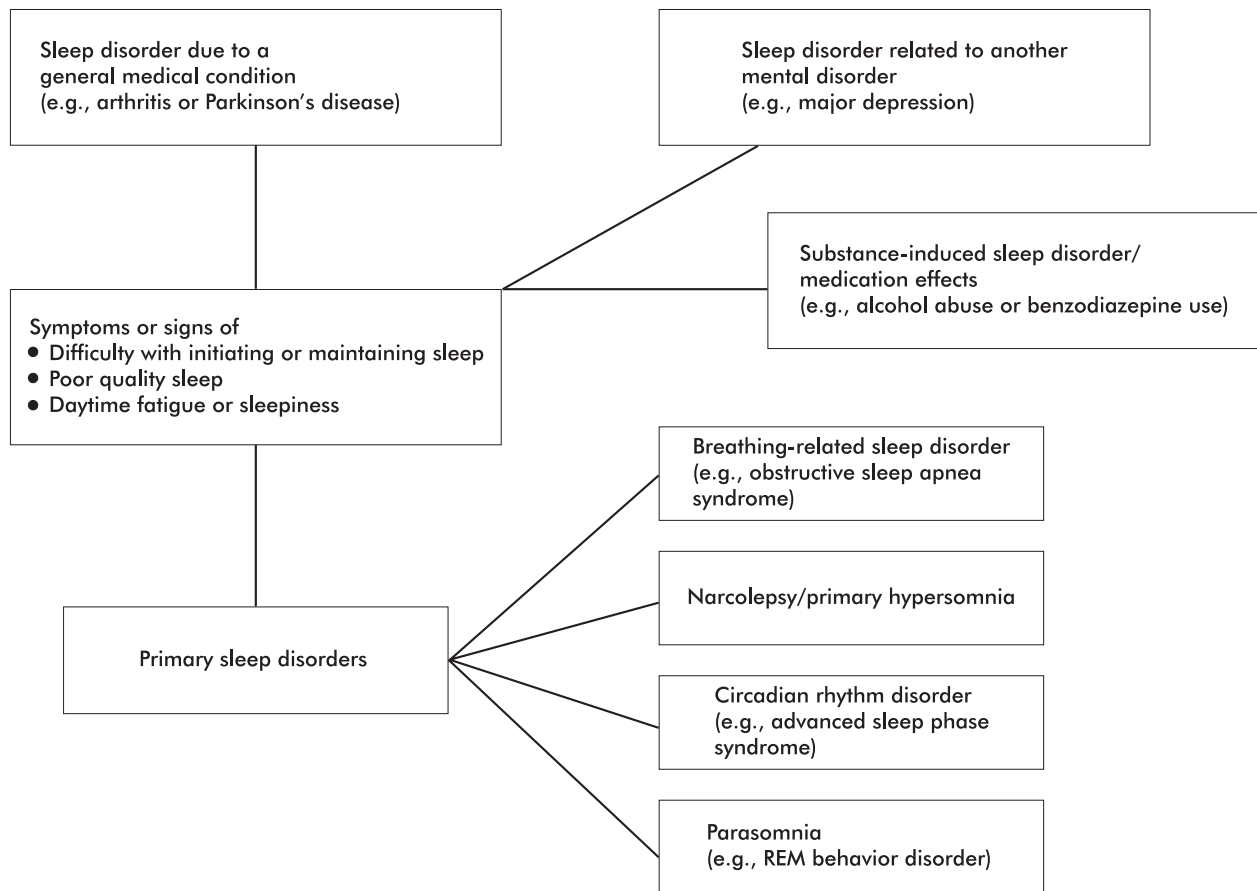

Supplementing epidemiological studies of the prevalence of sleep complaints, more recent clinical studies of sleep symptoms have considered the clinical relevance of such symptoms. For example, nosological systems such as DSM-IV require that, in addition to symptom clusters, some level of clinically significant distress and impairment be present before a syndrome or disorder is considered to be present. This requirement has raised interesting questions about potential discrepancies between the deterioration of sleep quality with aging and the difficulty in measur-

ing daytime impairments presumably resulting from sleep loss in the context of chronic insomnias. For example, in a study of 239 women and 113 men (mean age 77 years), sleep disturbance was a significant predictor in multivariate analysis of perceived limitations in usual role activities (Kutner et al. 1994). However, in a related study, 124 retirement community residents were interviewed about sleep patterns and given neuropsychological assessments, but no correlations between sleep variables and neuropsychological performance were found. The authors conclude that in nonclinical populations nighttime sleep problems are not associated with neuropsychological deficits (Hayward et al. 1992). Thus, samples identified by epidemiological studies and those identified by help-seeking patients or from clinical populations can yield different results. We summarize principles of diagnosis in Figure 17-2.

## ■ Sleeping Pills, Behavioral Treatments, and the Elderly

The indications for the use of hypnotics and the optimal strategies to treat complaints of poor sleep quality in the elderly are still being developed. For a general review of the issues, see Folks and Burke (1998), who emphasize differential diagnosis and advocate combined nonpharmacological and pharmacological approaches. For a review of nonpharmacological interventions, see Morin et al. (1994), whose meta-analysis suggests that stimulus control and sleep restriction therapies may be the most efficacious behavioral interventions, though the studies reviewed were not specifically of the elderly. For specific studies of various behavioral interventions in aging populations, see D. L. Bliwise et al. 1995; Edinger et al. 1992; Engle-Friedman et al. 1992; Lichstein and Johnson 1993; Morin et al. 1993, 1999; Riedel et al. 1995; and Reynolds et al. 1999. For a review of pharmacological interventions in the elderly, see Shorr and Robin (1994) who advocate time-limited treatments of low-dose hypnotics, with regular and frequent assessment of side effects, and a planned taper schedule. As discussed by Bandera et al. (1984), hypnotics with short and intermediate half-lives are preferable in the elderly because of altered pharmacokinetics and the potential for next-day side effects.

It may be interesting to note a general trend in prescribing practices away from sedative-hypnotics to antidepressants, especially in the institutionalized elderly (Walsh and Engelhardt 1992) (see also Chapter 37 in this volume). In a study of 330 nonagenarians from the general popula-

**FIGURE 17-2.** Principles of diagnosis chart. REM = rapid eye movement.

tion, half received some form of psychotropic medication, the most common being a hypnotic (Forsell and Winblad 1997). However, the authors noted that the rate of differential treatment after differential diagnosis was low. Little empirical evidence suggests that antidepressants are more effective than sedative-hypnotics in managing complaints of poor sleep quality in patients whose sleep disorder is not secondary to a primary psychiatric disorder. However, further studies are needed to evaluate the utility of using antidepressants in the place of sedative-hypnotics for primary insomnia (Nowell et al., in press). In at least one study of 262 residents admitted to nursing homes, psychotropic drugs, including hypnotics, were initiated within the first 2 weeks of admission, but the rate of use of such drugs was only slightly increased 6 months later (Wancata et al. 1997). The authors suggest that a large percentage of intake of psychotropic drugs is a result of new nursing home orders rather than continuation of medications that had been initiated in the community.

In a study of a stratified sample of 600 community-dwelling elderly subjects, use of hypnotics increased with age in both men and women (Seppala et al. 1997).

Multivariate analyses demonstrated that aging and poor health were independently associated with the use of hypnotics but, curiously, not with poor quality sleep or insomnia. In another study of a random sample of 516 community-living elderly over the age of 70 years, self-reported difficulties with falling asleep and global dissatisfaction with poor sleep were associated with the use of sleep medications (Englert and Linden 1998). In univariate and multivariate analyses, neither the duration of sleep time nor difficulties with sleeping through the night differentiated between those who did or did not take sleep medication. More studies are needed to identify factors that lead patients to seek treatment, as well as factors that lead providers to prescribe hypnotics in the elderly.

## ■ Sleepiness and Aging

Considerable attention has been paid in recent years to the impact of increasing shift work and restricted sleep schedules on the health of the national population. Considerably fewer studies, however, have addressed the prevalence and

clinical significance of excessive daytime sleepiness in the elderly.

In Ganguli et al.'s 1996 study, described above, 19% of elderly subjects reported symptoms of daytime somnolence. In the Cardiovascular Health Study, described above, 20% of subjects demonstrated excessive daytime sleepiness as measured by the Epworth Sleepiness Scale (Newman et al. 1997; Whitney et al. 1998). Daytime sleepiness was related strongly to poor health and limitations in activities of daily living and was correlated with age. In a 4-year, multisite, prospective cohort study that included annual interviews, 3,962 subjects over the age of 65 years were evaluated for sleep-related symptoms and health status. The point prevalence of excessive daytime sleepiness was estimated at 25%. Daytime nappers were reported to more likely be male, urban, and heavier and have more depressive symptoms, more limited physical activity, and more functional impairments. The 4-year mortality rate was accelerated 1.73 times among older people who nap most of the time and make two or more errors on a cognitive status examination (Hays et al. 1996). Thus, excessive daytime sleepiness is a significant symptom associated with morbidity and mortality in the elderly. As with the symptom of poor sleep quality and insomnia, differential diagnosis of daytime sleepiness is important in the elderly. Among causes of daytime sleepiness in the elderly are narcolepsy, breathing-related sleep disorders, movement disorders in sleep, drug-related sedation and interactions, changes in circadian function, sleep deprivation from poor sleep habits, and sleepiness in the context of other general medical conditions (see Figure 17-2).

### **Narcolepsy**

Although narcolepsy is generally believed to be a disorder arising in adolescence and early adulthood, patients with narcolepsy may present later in life. In one case series, 51% of retrospectively reviewed cases of narcolepsy seen in clinics were reported as presented by patients older than the age of 40 (Rye et al. 1998). Among the older patients, the diagnosis was delayed because of mild symptom severity, late-life expression of cataplexy, or absence of cataplexy with late-life expression of excessive daytime sleepiness. The authors concluded that narcolepsy should be considered in the differential diagnosis of sleepiness or transient loss of muscle tone in older patients.

### **Breathing-Related Sleep Disorders**

It is generally held that breathing-related events in sleep increase with age. However, considerable controversy ex-

ists as to the clinical significance of such events. When breathing-related events occur frequently enough to fragment sleep and lead to excessive daytime sleepiness, then treatment to reduce daytime sleepiness is warranted. It remains unclear, however, whether sleep apnea syndromes, particularly mild or moderate sleep apnea, are risk factors for cardiovascular events in the elderly.

One way to measure the potential prevalence of breathing-related sleep disorders is to use home oximetry to gauge the frequency of oxygen desaturations. This method has the advantage of low cost and ease of application but can be limited by defining breathing-related disorders as desaturations rather than arousals from sleep. One such epidemiological study of nocturnal desaturations (defined in this study by a decrease in SaO<sub>2</sub> exceeding 4%) was conducted in 239 elderly subjects (mean age 76 years) from the general population (Philip et al. 1997). Twenty-seven percent had 10 or more episodes an hour of such desaturations, and 4.4% had 30 or more episodes per hour. Multivariate analysis demonstrated that snoring, male gender, body mass index, and advanced age in women were all correlated with 10 or more episodes per hour. However, no association was found between desaturations and daytime somnolence, difficulty with falling asleep, hypertension, or dysrhythmia. This finding led the authors to suggest that there is a high prevalence of sleep-related respiratory disturbance in elderly persons, but that there may be fewer consequences of such disturbance in the elderly than for younger groups.

Another method of trying to gauge the clinical impact of breathing-related sleep disorder in aging populations is to assess the frequency and subsequent correlates of snoring. In the Cardiovascular Health Study described above (Whitney et al. 1998), snoring, awakenings, awakening short of breath, depression, and limited activities of daily living were all independently associated with elevated Epworth scores, a self-report measure of situational sleepiness. The authors noted that neither cognitive function, magnetic resonance imaging evidence of brain atrophy or white matter abnormalities, nor cardiovascular disorders were independently associated with levels of daytime sleepiness. These findings were interpreted as calling into question the mediating role of hypersomnia on cognitive function or cardiovascular consequences in apnea.

In a two-stage random sample of the general population, both clinical screening and laboratory polysomnography were used to determine the prevalence and clinical significance of sleep apnea across the life span (Bixler et al. 1998). A total of 4,364 men (age 20–100 years) were screened by telephone, and a subset of 741 were evaluated in the sleep laboratory. Obstructive sleep apnea syn-

drome was found in 3.3% of the entire sample by using clinical criteria combined with an apnea-hypopnea index greater than 10. The maximum prevalence was found in the 45–64 age range. The prevalence of any type of sleep apnea increased monotonically with age. The severity of sleep apnea, as indicated by both number of events and minimum oxygen saturation, decreased with age when any sleep apnea criteria were used and when controlling for body mass index. The authors concluded that the prevalence of sleep apnea tends to increase with age, but that the clinical significance (severity) of apnea decreases. Based on these findings, the authors also suggested that the sleep laboratory criteria for diagnosis of sleep apnea should be adjusted for age.

In terms of the cognitive consequences of apnea in the elderly, Stone et al. (1994) administered neuropsychological tests to 45 older patients with insomnia (mean age 65 years) with and without sleep apnea. The results suggested that when the severity of sleep disruption was controlled for, minimal differences were found in neuropsychological functioning of older adults with mild to moderate sleep apnea compared with those without apnea. However, in a different study by Dealberto et al. (1996), 1,389 community-dwelling persons ages 60–70 years were evaluated with clinical scales and neuropsychological tests. In cross-sectional analyses, snoring and breathing pauses during sleep were found to be associated with daytime sleepiness and were risk factors for low cognitive performance in tests requiring visual attention skills.

Thus, the precise prevalence of breathing-related sleep disorder in elderly men and women and the health consequences of breathing-related sleep disorder in the elderly remain to be determined.

## Movement Disorders

Periodic limb movements and the restless legs syndrome are syndromes that receive wide attention from the sleep disorders community (Williams 1996). Although research has been progressing, focus specifically in elderly populations remains limited. As with breathing-related sleep disorder, the prevalence of both periodic limb movements and restless legs syndrome is thought to increase with age, but the clinical significance of these syndromes in the elderly is unclear. Treatment is generally geared toward symptomatic reduction of restless legs syndrome or the excessive daytime sleepiness that is attributed to periodic limb movements during sleep (Williams 1996).

A different movement disorder, REM behavior disorder, is more properly considered a parasomnia. Yet, it can also be described as consisting of abnormal movements occurring during sleep (Schenck et al. 1986). These move-

ments are believed to parallel the content of dreams ostensibly occurring in REM sleep. REM behavior disorder may be considered a sleep disorder somewhat more specific to the elderly. Although not well studied, the disorder is thought to arise in mid- to later life and to be associated with neurodegenerative disorders such as dementia (Schenck et al. 1987). Thus, differential diagnosis of new onset of abnormal movements in sleep becomes more important in the elderly because the presence of REM behavior disorder suggests that a more extensive assessment of the central nervous system be conducted before symptomatic treatment is instituted.

## Circadian Rhythms in Aging

In older adults, many 24-hour rhythms are dampened and/or advanced. For review of circadian rhythms and psychiatric disorders in the elderly, see Myers and Badia (1995) and Sloan et al. (1996). The most marked change in circadian rhythms with age is an attenuation of amplitude. An advance of phase, a shortening of period, and a desynchronization of rhythms may also be evident. Examples of such rhythms are reflected in cortisol and growth hormone levels (reviewed by Vancauter et al. 1998). Amplitude reduction and phase advance of 24-hour rhythms may represent age-related changes in the central nervous system underlying circadian rhythmicity, for example, the suprachiasmatic nucleus and its afferents and efferents. On the other hand, age-related alterations in circadian function could also reflect decreased exposure or reactivity to photic and nonphotic information (Vancauter et al. 1998). Age-related changes in the retina, suprachiasmatic nucleus, and pineal gland, as well as behavioral changes such as a reduction in physical activity and exposure to light, can all interact to produce the changes in circadian rhythms observed in aging.

Changes in circadian rhythms are frequently associated with a reduction in nighttime sleep quality, a decrease in daytime alertness, and an attenuation in cognitive performance. In a study of young (19- to 29-year-old) and middle-aged (53- to 59-year-old) workers, three consecutive nights of shift work resulted in better phase adjustment (as measured by core body temperature) in younger subjects than in middle-aged subjects (Harma et al. 1994). The phase adjustment was correlated with subjective daytime recuperative sleep quality. In a series of studies examining circadian adjustment across the life span, Carrier and Monk (1997) and Monk et al. (1995) demonstrated that the declines in circadian phase adjustments apparent in middle age approach levels of severity similar to those observed in elderly samples (age 70 years and older). The question

remains whether the changes in circadian rhythms result from changes in central nervous system functioning during aging or from changes in lifestyle such as daily activity and routines (Monk et al. 1997). Reversing such changes in circadian rhythms could enhance medical-related quality of life for a large and rapidly increasing percentage of the population (Myers and Badia 1995). Interventions to reverse such changes in circadian rhythms might include bright light therapy, melatonin, and scheduling of daily activities.

### **Bright Light Exposure and Sleep Quality in the Elderly**

For an overview, see the Consensus Report for Light Treatment of Sleep Disorders (Campbell et al. 1995). The review describes the beneficial effects of bright light on sleep maintenance insomnia in the elderly. In addition, the review describes the effects of bright light on the behavioral disturbances that accompany dementia. For example, Campbell et al. (1993) examined 16 patients, ages 62–81 years, with sleep maintenance insomnia. Patients received 12 days of bright light exposure, which resulted in improvements in sleep quality and sleep efficiency. In another study (Satlin et al. 1992), 10 inpatients with Alzheimer's disease received 2 hours of exposure to bright light between 7:00 P.M. and 9:00 P.M. daily for 1 week. Patients wore activity monitors. Clinical ratings of sleep-wakefulness on the evening nursing shift improved with light treatment in 8 of the 10 patients. The proportion of total daily activity occurring during the nighttime decreased during the light-treatment week. The relative amplitude of the circadian locomotor activity rhythm, a measure of its stability, increased during the light-treatment week. In a more recent study by Cooke et al. (1998), 10 community-residing women between 67 and 87 years old who complained of poor sleep received bright light (2,000 lux) by visor for 30 minutes in the evening for 14 days in an unblinded, ABA design using self-report and home actigraphy as outcome measures. The authors reported improvements in sleep quality and sleep efficiency. Although the general results have been encouraging, bright light therapy has not received widespread acceptance as a medical intervention in the elderly, and more research is needed to define parameters such as dosing and duration of treatment.

### **Melatonin and Sleep Quality in the Elderly**

Considerable controversy exists over the indications and physiological effects of melatonin. For an introduction to the debate, including issues related to the elderly, see

Kryger (1997). The issue of melatonin as a hypnotic is unresolved, despite the ease of acquiring this hormone from health food stores. In general, melatonin has not been shown to be a robust hypnotic. As discussed in the article cited above, it has been suggested that elderly patients with insomnia who are deficient in melatonin may benefit from "replacement" of melatonin by exogenous administration. However, there remains the question of optimal time of administration and the optimal dose necessary. In addition, some evidence suggests that younger patients with accumulated sleep debt may experience the strongest hypnotic effect to exogenous melatonin administration. In at least one recent study specific to the elderly (Youngstedt et al. 1998), neither self-reported sleep measures nor actigraphy outcomes were related to melatonin excretion. At present, research evidence is insufficient to guide clinicians in the use of melatonin in elderly patients with complaints of insomnia. No studies examine the use of melatonin to treat jet lag in the elderly.

## **Principles of Therapeutic Intervention**

We believe that it is important to consider disturbed sleep in late life as symptomatic of underlying causes, with typically more than one factor operating in combination, and that therapy should address causes and related mediating factors (e.g., depression, as proposed in the model described above). Promising avenues of nonpharmacological intervention for persistent insomnia in late life usually address behaviors with a negative effect on sleep (e.g., sleep compression approaches to limit time in bed to enhance sleep efficiency and depth) or help to realign sleep and circadian rhythms with external time cues (e.g., via the use of bright light exposure). Useful pharmacological approaches tend to be simple, for example, monotherapy of depression, which uses a single antidepressant medication and avoids the premature use of adjunctive sleeping pills. Further research is strongly needed to address the utility of maintenance medication, such as low-dose antidepressants or intermittent benzodiazepines, for insomnia in late life.

# Pain

Michael R. Clark, M.D., M.P.H.

## ■ Definition and Assessment

Pain is a complex experience that integrates affective, cognitive, and behavioral factors with an extensive neurobiology (Turk et al. 1983). The formulation of pain simply as a disease of the body fails to appreciate the role of these factors and usually results in poor treatment outcome. Pain is not synonymous with a sensory event that is due to a nociceptive input resulting from injury or disease. Pain has been defined by the International Association for the Study of Pain as “an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage” (Merskey et al. 1986). Pain is the most common reason a patient presents to a physician for evaluation (Kroenke and Mangelsdorff 1989; Kroenke et al. 1990). This physician is rarely a neuropsychiatrist. If the patient suffers from chronic pain, pain persisting on a daily basis for a month beyond what would be considered the usual time for healing of underlying pathology, then many specialists may be involved in the care of the patient (Bonica 1990).

Elderly patients with cancer pain are less likely to receive proper pain management than younger patients (Cleary and Carbone 1997). Unfortunately, elderly pa-

tients are often less likely to report pain or take opioids and other medications for pain because of fears of addiction, future tolerance coinciding with disease progression, and side effects and a belief that pain is an indicator of disease that may distract the doctor from primary and possibly curative treatment. Studies examining the use of patient-controlled analgesia in postoperative patients found that older patients “require” less opioids (Woodhouse and Mather 1997). However, it remains controversial whether older patients experience equivalent pain relief with less medication, are unable to report their pain, or continue to endure higher levels of pain despite medication being available to them. It would certainly be inappropriate and inaccurate to begin the evaluation of elderly patients believing that they experience less pain and suffering than younger patients (Ferrell 1991).

Although elderly patients may present to physicians with unusual complaints or lacking cardinal symptoms for a given illness, pain perception probably does not change with age (Harkins 1996). Pain is difficult to assess, especially in patients with terminal illnesses, cognitive impairments, and other chronic degenerative diseases of the brain (Nikolaus 1997; Parmelee 1996). Pain rating scales attempt to measure the severity and intensity of pain. Many factors can influence these ratings including disease states,

mental disorders, distress, personality traits, and meaningful interpretations based on personal beliefs. Even the simplest self-report measures to record the presence of pain cannot be effectively used by many elderly individuals (Ferrell et al. 1995). The elderly often have deficits in abstract ability that make it difficult for them to rate pain by using a visual analogue scale (VAS) or a verbal descriptor scale (VDS) with terms such as “discomforting,” “distressing,” and “excruciating.”

Increased age is associated with a greater frequency of incorrect responses to the VAS. In a comparison study of several pain rating scales, such as a vertical-oriented VAS, a VDS, a pain thermometer, and a numeric rating scale, the VDS was rated as the preferred, easiest, and best assessment tool for rating pain by the elderly (Herr and Mobily 1993). However, the ratings of pain intensity using these scales were poorly correlated with one another. Alternative tools for evaluating pain, such as pain drawings or maps and observations of pain behaviors, have been studied with positive results, but these methods are limited by reliance upon an outside observer to rate a patient's pain (Weiner et al. 1996, 1998). Animal studies also suggest that behavioral signs of pain are reduced in older rats with neuropathic pain (Chung et al. 1995). Different patient populations will probably require different pain rating instruments, depending on sensory, language, and neurological deficits. A comprehensive evaluation should be done for any patient who complains of pain, becomes agitated, or experiences deterioration in his or her functioning. This evaluation should incorporate simple standardized tools for rating pain severity, observations by others to determine the presence of pain-related behaviors including any problems with activities of daily living that would indicate the presence of pain, and clinical examination to elicit evidence of pain and the signs of possible etiologies.

## ■ Epidemiology

Pain is a common problem in the general population (Karlsten and Gordh 1997). The U.S. Center for Health Statistics conducted an 8-year follow-up survey and found that 32.8% of the general population suffered from chronic pain symptoms (Magni et al. 1993). A recent World Health Organization study of more than 25,000 primary care patients in 14 countries found that 22% of patients suffered from pain that was present for most of the time for at least 6 months (Gureje et al. 1998). In the community-dwelling elderly population, 25%–50% will suffer from pain (Gagliese and Melzack 1997; Gloth 1996). In a 24-year longitudinal study of chest, abdomen, and musculoskeletal

pain, symptoms increased with aging, and women reported more persistent and severe pain (Brattberg et al. 1997). In people 65 years of age or older, musculoskeletal pain is associated with three times the likelihood of significant difficulty performing three or more physical activities (Scudds and Robertson 1998). In persons over the age of 75, more than two-thirds reported pain, almost half reported pain in multiple sites, and a third rated pain as severe in at least one location (Brattberg et al. 1996). Pain is even more common in residents of long-term care facilities and associated with significant decreases in function and quality of life. Sixty-six percent of nursing home residents over 65 reported chronic pain, which was not detected by physicians in 34% of residents (Stein and Ferrell 1996).

In patients surviving hospitalization for serious illness, those reporting moderately severe pain occurring most of the time or extremely severe pain occurring more than half of the time, 40% reported this pain up to 6 months after discharge from the hospital (Desbiens et al. 1997). The Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatment (SUPPORT) has demonstrated that pain, dyspnea, and fatigue are the most prevalent symptoms experienced by patients with terminal illnesses at the end of life (Lynn et al. 1997). Sixty-three percent of patients at the end of life had difficulty tolerating physical or emotional symptoms.

Acute pain in the elderly is usually the result of trauma from a surgery, injury, or exacerbation of chronic disease, especially musculoskeletal conditions. Approximately 80% of the elderly suffer from some type of arthritis (Davis 1988). Treatment is focused on controlling inflammation and preventing tissue destruction. Recently, more emphasis has been placed on pain relief. Preliminary studies indicate that, compared with placebo, amitriptyline and fluoxetine significantly reduce pain (Rani et al. 1996). Older adults are likely to undergo surgery for degenerative problems, fractures, and cardiovascular disease (Ferrell 1996).

The approach to acute pain management in the elderly will usually be successful with straightforward strategies such as relaxation, immobilization, pharmacological agents (aspirin, acetaminophen, nonsteroidal anti-inflammatory drugs, opioids), massage, and transcutaneous electrical nerve stimulation (Acute Pain Management Guideline Panel 1992). To avoid delirium, side effects, and toxicity of the gastrointestinal, hepatic, and renal systems, the normal physiology of aging and presence of chronic diseases must be taken into consideration when using pharmacological treatments for pain. Although age and illness are risk factors for poor outcome, the elderly are more similar to the general population than they are different and

benefit most when they receive excellent care rather than treatment by specialized algorithms.

## ■ Psychiatric Comorbidity

Patients with depression, anxiety, or psychological distress may experience increased pain or describe aspects of their suffering other than pain. Some patients cope with pain better than others, as reflected in their reports of pain, pain behaviors, and functional disabilities. In particular, elderly patients will often not report pain because they fear it means a deterioration of their condition, that it will distract practitioners from their underlying illness, or that it will upset others around them who are concerned about their well-being (Nishikawa and Ferrell 1993).

## Pain Disorder

Pain “caused” by emotional factors was first classified in DSM-II under psychophysiological disorders (American Psychiatric Association 1968). DSM-III specifically addressed the problem of chronic pain with the introduction of psychogenic pain disorder, in which pathophysiology was either absent or insufficient to explain the severity and duration of pain (American Psychiatric Association 1980). In somatoform pain disorder (DSM-III-R), psychological factors were no longer required as an etiology of pain (American Psychiatric Association 1987). A preoccupation with pain instead of pain itself was established as the core criterion.

DSM-IV introduced pain disorder as a refinement of the DSM-III-R diagnosis of somatoform pain disorder (American Psychiatric Association 1994; S. A. King and Strain 1992). The primary criteria require 1) pain as the chief complaint, and 2) pain causing significant distress or functional impairment. In addition, psychological factors are recognized as having an important role in the pain, and the pain must not be the result of another mental disorder such as a factitious disorder, a mood disorder, or an anxiety disorder. If another mental disorder is present, the diagnosis of pain disorder cannot be given to a patient. It must be further specified if the pain disorder is acute or chronic and whether it is associated with just psychological factors or both psychological factors and a general medical condition. Unfortunately, the concept of psychological and physical dualism is still inherent in this diagnosis. Although it is difficult, the evaluation of a patient with pain should attempt to determine and enumerate all relevant diagnoses regardless of what specialty typically treats a particular diagnosis.

## Somatization

Symptoms, not specific diseases, are the most common reason for seeking medical care (Brown et al. 1971; Koch 1978; Kroenke et al. 1990). Usually, a medical cause is never found for these “somatization” symptoms (Kroenke and Mangelsdorff 1989). As the number of medically unexplained symptoms increases, associated morbidity such as functional disability, increased health care utilization, inappropriate treatment with medications, excessive evaluations, and higher rates of psychiatric disorders increases (Katon et al. 1991; Kouyanou et al. 1998). These patients were more likely to exhibit catastrophic thinking and believe the cause of their pain to be a mystery. They often have feelings of losing control and that physicians believe their pain is imaginary. Patients with chronic pain and medically unexplained symptoms were also found to suffer iatrogenic consequences of their symptoms such as excessive medical evaluations and long-term treatment with inappropriate medications.

Although the actual diagnosis of somatization disorder is rare in patients with chronic pain, somatization is a common phenomenon in the practice of medicine, manifests itself along a spectrum of severity, and can emerge from and is shaped by many factors both in and around the patient. Somatization is conceptualized as at least three overlapping, distinct patterns of illness behavior “in which given symptoms may be differentially perceived, evaluated, and acted upon by different kinds of persons” (Mechanic 1962). These three forms have been operationalized and include 1) high levels of medically unexplained symptoms in multiple physiological systems; 2) levels of somatic preoccupation or illness worry beyond what is expected from demonstrable disease; and 3) the predominantly or exclusively somatic clinical presentation of psychiatric disorders, such as depression or anxiety (Atkinson et al. 1991; Katon et al. 1985; Kirmayer and Robbins 1991). Environmental forces such as the societal stigma of psychiatric disorders, history of physical and sexual abuse, and the reliance of physicians on the biomedical paradigm predispose to and reinforce somatization (Kroenke 1993; Walling et al. 1994).

Characterizing somatization as a psychophysiological process rather than a categorical psychiatric diagnosis or a psychological trait is probably more appropriate (Sullivan and Katon 1993). The process of somatization starts with symptom perception that varies along a continuum from minimization to amplification of sensory information. Once the symptom has been perceived, the individual attributes it to a cause, which could include a health problem. Finally, a decision is made about how to react to this symptom, and perhaps consultation with a health care profes-

sional will be sought. Fortunately, somatization can be managed effectively when the specific components of the process are addressed individually with understanding and rational treatments (Sullivan and Katon 1993).

## Substance Use

Terms such as addiction, misuse, overuse, abuse, and dependence have been used inconsistently to describe various behaviors, making interpretation of many research studies difficult. The underreporting of medication use complicates accurate assessment of actual use patterns by patients with chronic pain (Ready et al. 1982). However, in patients with chronic pain who develop new substance use disorders, the problem most commonly involved the medications prescribed by their physicians (Long et al. 1988; Maruta et al. 1979). The mechanism of relapse to substance abuse in these patients is not well understood and probably involves multiple factors; however, a cycle of pain followed by relief after taking medications is an example of operant reinforcement of their future use (Fordyce et al. 1973).

In a study of patients attending a clinic specializing in pain, almost 90% of patients were taking medications (Kouyanou et al. 1997). Opioid analgesics were prescribed to 70%, whereas antidepressants and benzodiazepines were being taken by only 25% and 18%, respectively. In this population, 12% met DSM-III-R criteria for substance abuse or dependence; however, the misuse and abuse of medications was not limited to just psychoactive substances. In a review of 24 studies of drug/alcohol dependence/addiction in patients with chronic pain, only 7 studies met their standard of using acceptable criteria for these substance use disorders, and the prevalence ranged from 3.2% to 18.9% (Fishbain et al. 1992b). In a study of patients with chronic low back pain, 34% had a substance use disorder, yet in all cases such use was present before the onset of the chronic pain (Polatin et al. 1993). Those individuals with a history of substance abuse were found to be at increased risk for substance abuse during treatment for chronic pain, as well as increased risk of further physical injury (Savage 1993).

Substance abuse research has demonstrated abnormalities in pain perception and tolerance. In a study of persons who abused opiates and cocaine, cold pressor pain tolerance was significantly lower in individuals with current as opposed to former abuse (Compton 1994). Patients with alcoholism and nonalcoholic men with high familial-genetic risk for alcoholism demonstrate greater sensitivity to painful stimuli and pain reduction induced by alcohol (Stewart et al. 1995). These men rated an aversive shock as more painful, but differences from control subjects

could be “normalized” with pharmacologically significant levels of ingested alcohol. This increased sensitivity to pain coupled with the relief experienced with substance use suggests at least one mechanism for the development of substance dependence in patients with chronic pain. (See also Chapter 16 in this volume.)

## Depression

The National Health and Nutrition Study found that depression was more common in the elderly independent of the presence of pain (Harkins et al. 1984). However, the relationship between pain and depression remains controversial. Physical symptoms are common in patients suffering from major depression (Lipowski 1990). Approximately 60% of patients with depression report pain symptoms at the time of diagnosis (Magni et al. 1985; Von Knorring et al. 1983). The presence of a depressive disorder has been demonstrated to increase the risk of developing chronic musculoskeletal pain, headache, and chest pain 3 years later (Leino and Magni 1993; Magni et al. 1993, 1994; Von Korff et al. 1993). Older adults with depression were at increased risk for neck, back, and hip pain. Even after 8 years, previously depressed patients remained twice as likely to develop chronic pain as the nondepressed.

In 1,016 members of health maintenance organizations, the prevalence of depression was 12% in individuals with three or more pain complaints compared with only 1% in those with one or no pain complaints (Dworkin et al. 1990). The prevalence of major depression in patients with chronic low back pain is more than three times the rate in the general population (Sullivan et al. 1992). In groups of patients with medically unexplained symptoms such as back pain and dizziness, two-thirds of patients have a history of recurrent major depression compared with less than 20% of medically ill control groups (Atkinson et al. 1991; Katon and Sullivan 1990; Sullivan and Katon 1993). In patients with chronic pain referred to comprehensive pain programs for evaluation, 8%–50% have been reported to have a current major depression (Smith 1992). If pain resulted in a loss of independence or mobility that decreased an individual's participation in activities, the risk of depression was significantly increased (Williamson and Schulz 1992). Individuals with chronic physical complaints also have higher rates of lifetime major depression.

Depression is not simply a comorbid condition but interacts with chronic pain to increase morbidity and mortality. Patients with chronic pain and depression reported greater pain intensity, less life control, and more use of passive-avoidant coping strategies (Magni et al. 1985). They also described greater interference from pain and exhibited

more pain behaviors than patients with chronic pain and without depression (Haythornthwaite et al. 1991; Weickgenant et al. 1993). The presence of preoperative depression in patients undergoing lumbar discectomy was predictive of poorer surgical outcome at 1-year follow-up (Junge et al. 1995). In patients with rheumatoid arthritis, depressive symptoms were significantly associated with negative health and functional outcomes as well as with increased health services utilization (Katz and Yelin 1993). Depression has been shown to be a significant predictor of pain persistence and the best predictor of application for early retirement (Hasenbring et al. 1994; Magni et al. 1993).

Patients with migraine, chronic abdominal pain, and orthopedic pain syndromes report increased rates of suicidal ideation and suicide attempts (Magni et al. 1998). In patients who attempted suicide, 52% had a somatic disease and 21% were taking analgesics on a daily basis for pain (Stenager et al. 1994). Patients with chronic pain completed suicide at two to three times the rate in the general population (Fishbain et al. 1991). Oncology patients with pain who also suffered from depression were significantly more likely to request assistance in committing suicide as well as to have taken steps to end their lives such as seeking information about suicide plans or hoarding medications. However, even if in pain, when depression was not present, they were unlikely to request the interventions of euthanasia and physician-assisted suicide (Emanuel et al. 1996). Depression should be treated aggressively and not simply “understood” as an expected outcome of having chronic pain. (See also Chapter 13 in this volume.)

## Anxiety

Although anxiety is a common and expected component of acute pain, patients with chronic pain are also at increased risk for comorbid anxiety disorders. Patients with a variety of pain syndromes ranging from chronic low back pain, chronic neck pain after whiplash injury, and chronic pain from prostate cancer have increased rates of both anxiety symptoms and disorders (Heim and Oei 1993; Lee et al. 1993; Polatin et al. 1993; Weissman and Merikangas 1986). Almost 50% of patients report anxiety symptoms, and 19% of patients have an anxiety disorder such as panic disorder and generalized anxiety disorder (Devlen 1994; Fishbain et al. 1986; Katon et al. 1985). One prospective study of 1,007 young adults found that a baseline history of migraine was significantly associated with an increased risk (odds ratio = 12.8) of first-incidence panic disorder (Breslau and Davis 1993).

Conversely, anxiety disorders have been shown to be

associated with high levels of somatic preoccupation and physical symptoms. In a study of patients with panic disorder, almost 40% reported chronic pain symptoms and more than 7% were using analgesics on a daily basis (Kuch et al. 1991). When compared with the other patients with panic disorder, this subset had significantly higher rates of illness behaviors. The self-reported pain intensity of patients with rheumatoid arthritis was most significantly influenced by the presence of anxiety and depression even when controlling for disease activity (Smedstad et al. 1995). Other studies have argued that attentional focus and not anxiety exerts a more important influence on pain (Arntz et al. 1994). (See also Chapter 15 in this volume.)

## Neurobiology

The neurobiology of pain is complex and described in numerous textbooks, chapters, and review articles (Borsook 1997; Cesaro and Ollat 1997; Wall and Melzack 1994). Ongoing nociceptive or neuropathic stimulation causes changes in peripheral nerves, spinal cord structures, and supraspinal structures (Siddal and Cousins 1995, 1998). Continuing neurobiological discoveries generate new ideas for the development of pharmacological agents to treat pain. Examples are *N*-methyl-*D*-aspartate (NMDA) receptor antagonists, adenosine receptor agonists, nitric oxide synthase inhibitors, and cyclo-oxygenase-2 inhibitors (Lane 1997; Lipman 1996).

## Peripheral Mechanisms

Peripheral mechanisms of pain begin with the primary afferent nociceptors that respond to mechanical, thermal, and chemical stimuli (Meyer et al. 1994). The myelinated A $\delta$  fibers transmit mechanothermal information (phasic pain with sharp, pricking quality), but unmyelinated C-fiber nociceptors are polymodal (tonic pain with burning, aching quality). The effect of age on the pain threshold is dependent on multiple factors such as sensory modality, location in the body, and experimental paradigm (Chakour et al. 1996; Heft et al. 1996; Lasch et al. 1997). The pain threshold may be raised in the elderly, as indicated by decreased reports of pain with esophageal distension and thermal stimulation to the skin, but unaffected in heat/cold pain sensation on the skin of the face or detection of electrical stimulation to the skin. In studies of heat nociception in leg skin, pain intensity ratings were not affected by age (Harkins et al. 1996). However, in the elderly, slow temporal summation (C fibers) failed to develop, and response

times to pain (A $\delta$  fibers) were delayed. In another study using a compression block of the superficial radial nerve, older adults exhibited an increase in pain threshold consistent with impaired A $\delta$ -fiber function and not that of preserved C-fiber function (Chakour et al. 1996).

Usually, stimulation activates high-threshold nociceptors but, in conditions of inflammation or nerve injury, neurogenic inflammation occurs with the release of peptides from nociceptive afferents such as substance P and neurokinin A (Levine et al. 1993; Woolf and Chong 1993). As a result, nerve fibers become more excitable, vascular structures dilate, plasma proteins are extravasated, and inflammatory cells release a variety of chemical mediators (e.g., bradykinin, histamine, arachidonic acid metabolites). When these chemicals alter the response of high-threshold nociceptors, peripheral sensitization has occurred. Afterward, low-intensity stimuli can activate low-threshold A $\beta$ -mechanoreceptors and produce pain. A zone of primary hyperalgesia is produced around the site of injury. The decrease in sensory nerve function with age may also be manifested by poor tissue healing, which can be reversed with the vasodilation produced by exogenous sensory peptides such as substance P and calcitonin gene-related peptide (Khalil and Helme 1996; Khalil et al. 1994; Merhi et al. 1998). High-frequency electrical stimulation of sensory nerves in aged rats produced an increased latency and decreased vasodilation response in injured tissues. The decrease in neurogenic inflammatory response that occurs with age as measured by the axon reflex flare response may be a result of decreased substance P content in skin (Helme and McKernan 1986).

When local tissues are injured, opioid receptors are produced in the dorsal root ganglion and transported to both the dorsal horn of the spinal cord and peripheral sites, where they become "unmasked" (Stein 1997). When a nerve is damaged, peptide production increases, the end of the nerve fiber sprouts, sensitivity to mechanical stimulation and noradrenaline increases, and the nerve fires spontaneously (Devor 1994). Similar changes occur at sites of demyelination and in the dorsal root ganglion of damaged nerves. Sympathetic efferent fibers release prostanoids during inflammation that sensitize primary nociceptive afferents, innervate the dorsal root ganglion, and excite primary afferents at  $\alpha$ -adrenoceptors (Janig 1996). In studies of tissue inflammation in aging rat skin, the inhibitory modulation of sympathetic efferents is increased for high-frequency stimulation (Merhi et al. 1998). Silent nociceptors are a class of unmyelinated primary afferent neurons that respond only when sensitized by the chemical mediators of inflammation (McMahon and Koltzenburg 1990).

## Dorsal Horn Mechanisms

The primary afferent nociceptors terminate in laminae I, II, and V of the dorsal horn (Willis and Coggeshall 1991). The second-order neurons can be classified into nociceptive-specific/high-threshold or wide dynamic range/convergent neurons. The nociceptive-specific neurons are located more superficially in the dorsal horn and respond only to noxious stimuli. In contrast, wide dynamic range neurons are more deeply located and respond to all types of stimuli. Allodynia, nonnoxious tactile stimuli perceived as painful, occurs when wide dynamic range neurons become sensitized and hyperexcitable and fire at increased frequency. The allodynia is manifested in a zone of secondary hyperalgesia in normal tissue adjacent to injured tissue. Local interneurons provide inhibitory modulation.

Central sensitization occurs in the dorsal horn, which is the site of action of many neurotransmitters and neuromodulators such as the excitatory amino acids (glutamate, aspartate) and peptides (Price et al. 1994). These act at several receptors including NMDA, kainate, metabotropic glutamate, opioid, neurokinin,  $\alpha$ -adrenergic, serotonin, adenosine, and  $\gamma$ -aminobutyric acid (GABA) receptors. The prolonged activation of non-NMDA receptors (e.g.,  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid) readies the NMDA receptor to produce more long-term changes to the processing of sensory information (Dubner and Ren 1994; Woolf and Thompson 1991). These modifications include windup (progressive increases in neuronal activity throughout the stimulus duration), facilitation (magnification and prolongation of the duration of neuron response), action potential threshold reduction, receptive field expansion, oncogene induction, and long-term potentiation (strengthening of synaptic transmission efficacy after activity across the synapse). When calcium enters the cell with the activation of the NMDA receptor, second messengers such as protein kinase C, cGMP, and polyphosphoinositides are generated.

Approximately 75% of the opioid receptors in the dorsal horn are presynaptic and, when stimulated, reduce the release of neurotransmitters from primary nociceptive afferents. During inflammation and nerve injury, opioids increase NMDA activity promoting central sensitization and tolerance to opioids, cholecystikinin interferes with opioid analgesia, morphine-3-glucuronide antagonizes opioid analgesia, and presynaptic opioids are lost (Basbaum 1994).  $\alpha$ -Adrenoceptors are activated by noradrenaline, which has a synergistic effect with opioid receptor agonists and is released by descending inhibitory pathways (Meert and DeKock 1994). GABA and glycine tonically inhibit nociception. When activated, GABA<sub>E</sub>

receptors suppress the presynaptic release of excitatory amino acids from primary afferent terminals, whereas GABA<sub>A</sub> receptors have postsynaptic actions (Sivilotti and Woolf 1994).

### **Ascending Tract and Descending Inhibition Mechanisms**

Second-order neurons project to supraspinal structures in the ascending tracts of the contralateral anterolateral spinal cord (spinothalamic, spinoreticular, spinomesencephalic) and a latent ipsilateral pathway. The ventroposterior nuclei of the thalamus represent the sensory-discriminative (temporal and spatial) aspects of pain, and the medial nuclei are involved with the affective-motivational features of pain. Increased thalamic activity has been associated with acute experimental pain in contrast with chronic pain states, which are associated with decreased thalamic activity on positron-emission tomography (Iadarola et al. 1995; Jones et al. 1991). Most of the other subcortical structures (e.g., basal ganglia, hypothalamus, amygdala, cerebellum) are postulated to function in the transmission of nociception and perception of pain.

The role of the cortical structures in pain and suffering is less well understood. The parietal lobes and somatosensory cortex probably contribute to the sensory-discriminative component, and the cingulate cortex, with the affective component of pain (Jannetta et al. 1990; Talbot et al. 1991). Pain can be decreased by descending inhibition as first postulated by the gate theory of Melzack and Wall (1965). Many structures (e.g., locus ceruleus, nucleus raphe magnus, periaqueductal gray matter, hypothalamus) and neurotransmitters (e.g., endogenous opioids, serotonin, noradrenaline, GABA) contribute to descending inhibition (Fields and Basbaum 1994). Serotonin and dopamine levels have been found to be decreased in studies of nociception in aged rats (Goicoechea et al. 1997). Treatment modalities involving electrical stimulation (e.g., deep brain stimulation, dorsal column stimulation, transcutaneous electrical nerve stimulation) attempt to activate descending inhibition to decrease chronic pain.

### **■ Treatment**

A large body of research now supports the use of traditional neuropsychiatric treatments in the management of chronic pain. Pharmacological, psychological, and multidisciplinary treatments have proven effective for many different pain syndromes. In the elderly, most chronic diseases are disproportionately represented, including cancer,

vascular disease, peripheral neuropathy, temporal arteritis, polymyalgia rheumatica, postherpetic neuralgia (PHN), stroke, and Parkinson's disease (Foley 1994; Gordon 1979). Several are described below to highlight a few of the more common conditions and the wide number of pathophysiological mechanisms that have been discovered.

For any specific disease, no single algorithm can dictate the modalities of treatment to be prescribed. Several classes of medications have proven efficacy for the treatment of neuropathic pain. However, the relief provided by these medications is usually incomplete and difficult to predict in advance. The selection of a particular medication will depend on multiple factors. The disease itself may change over time such that the efficacy of a treatment is altered, one treatment may be selected over another based on the response to previous treatments, and the patient's psychiatric comorbidity, temperament, coping skills, and personal history cannot be neglected.

### **Postherpetic Neuralgia**

PHN is defined as pain persisting or recurring at the site of shingles at least 3 months after the onset of the acute varicella zoster viral rash (Bowsher 1997b). This condition is more likely to occur with age, and more than half of patients over 65 years old with shingles develop PHN. Patients with cancer, diabetes mellitus, and immunosuppression are more likely to develop PHN. Approximately 15% of referrals to pain clinics are for the treatment of PHN. Although degeneration and destruction of motor and sensory fibers of the mixed dorsal root ganglion characterize acute varicella zoster, other forms of neurological damage have been described. These changes include inflammation of the spinal cord, myelin disruption, axonal damage, and decreases in the number of nerve endings from the affected skin.

These same changes persist in patients with PHN, but the actual mechanism of pain is not well understood. Studies have suggested the role of both peripheral and central mechanisms, probably resulting from the loss of large-caliber neurons and subsequent central sensitization, but adrenergic receptor activation and alterations in C-fiber activity have also been reported (Fields et al. 1998). Early treatment of varicella zoster with low-dose amitriptyline has reduced the prevalence of pain at 6 months by 50% (Bowsher 1996, 1997a; Johnson 1997). A recent review of randomized controlled trials and meta-analysis concluded that tricyclic antidepressants (TCAs) are the most effective agents for the treatment of PHN (Volmink et al. 1996). Anticonvulsants and opioids are also under investigation.

## Peripheral Neuropathy Pain

Sensory neurons are damaged by many diseases, both directly and indirectly (Scadding 1994). If C-fiber input is preserved but large-fiber input is lost, paresthesias and pain are the predominant sensory experiences. The pain of a peripheral neuropathy can range from a constant burning to episodic, paroxysmal, and lancinating in quality. These phenomena are primarily the manifestation of axonal degeneration and segmental demyelination. Sites of ectopic impulse generation can be found at any point along the peripheral nerve including the dorsal root ganglion regardless of where the nerve is actually damaged. Other changes can alter the magnitude and frequency of impulse generation such as sensitivity to mechanical or neurochemical stimuli. Ephaptic impulse transmission and crossed after-discharge have been described as models of peripheral neuropathic pain. Voltage-dependent sodium channels in the dorsal root ganglion undergo both upregulation and downregulation, depending on the subpopulation (Rizzo 1997). Many changes also occur in the central nervous system when a peripheral nerve is damaged. This central sensitization can amplify and sustain neuronal activity by a variety of mechanisms such as reduced inhibition of dorsal horn cells.

## Parkinson's Disease

Pain is the most common sensory manifestation of Parkinson's disease and reported by half of patients (Goetz et al. 1986; Koller 1984; Starkstein et al. 1991). The pain is typically described as cramping and aching, located in the lower back and extremities, but not associated with muscle contraction or spasm. These pains often decrease when the patient is treated with levodopa, which suggests a central origin. The loss of dopaminergic input could explain how pain is produced. Specifically, studies of the rat rostral agranular insular cortex suggest a role in modulation of nociception probably through a loss of descending inhibition in the spinal cord (Burkey et al. 1996). The basal ganglia neurons in rats exhibit nociceptive-specific responses to noxious stimulation, and the marginal division of the neostriatum has high concentrations of substance P, met-enkephalin, and dynorphin-B (Chudler and Dong 1995; Chudler et al. 1993).

## Central Poststroke Pain

Approximately 5% of patients who have suffered a stroke experience intractable pain in addition to other neurological deficits (Bowsher 1995). Patients typically have hemibody sensory deficits and pain associated with

dysesthesias, allodynia, and hyperalgesia. Radiographic lesions are present in the thalamus, although other sites are often involved. Excitatory amino acids may be involved in the development of this syndrome. Pharmacological treatment is usually not effective, and medications such as ketamine, an NMDA receptor antagonist, reduce pain in less than 50% of patients (Yamamoto et al. 1997). In contrast, patients with spinal cord injury experience reductions in continuous and evoked pain with ketamine and opioid receptor agonists, suggesting different mechanisms in different central pain states (Eide et al. 1995).

## Migraine

The peak incidence of migraine occurs between the third and sixth decade of life and then decreases with age. However, over the life span, 18% of women and 6% of men will suffer from migraine (Lipton et al. 1997). The pathogenesis is still not well understood but probably involves the trigeminovascular system and plasma protein extravasation, antagonism of serotonin receptors, modulation of central aminergic control mechanisms, membrane-stabilizing effects through action at voltage-sensitive calcium channels, and substance P (Goadsby 1997; Solomon 1995). The common migraine is defined as a unilateral pulsatile headache, which may be associated with other symptoms such as nausea, vomiting, photophobia, and phonophobia (Szirmai 1997). The duration is usually up to several days. The classic form of migraine adds visual prodromal symptoms such as scintillating scotomata. The complicated migraine includes focal neurological signs such as cranial nerve palsies and is often described as the name of the primary deficit, for example, vestibular migraine, basilar migraine. The calcium channel blockers, antidepressants, and anticonvulsants are the treatments with best-documented efficacy.

## Pharmacological Treatments

**Opioids.** The use of opioids in nonmalignant chronic pain remains a subject of considerable debate (Chabal et al. 1992a). Until recently, opioids were reserved for use only in the treatment of acute and cancer pain syndromes. Nonmalignant chronic pain was considered to be unresponsive to opioids, which were associated with too many risks. Fears of regulatory pressure, medication abuse, and the development of tolerance create a reluctance to prescribe opioids, and many studies have documented this "underutilization" (Maruta et al. 1979; Morgan 1985; Schug et al. 1991). Studies investigating the risk of opioid abuse have been reassuring. In one study of 12,000 medical patients

treated with opioids, only 4 patients without a history of substance abuse developed dependence on the medication (Porter and Jick 1980). Other studies of chronic opioid therapy found that patients who developed problems with their use of the medication all had a history of substance abuse (Portenoy and Foley 1986; Taub 1982). Even when the diagnosis of dependence is suspected in patients taking opioids for chronic pain, maladaptive behaviors such as stealing or forging prescriptions rarely occur (Fishbain et al. 1992b; Sees and Clark 1993). Fortunately, recent studies of physicians specializing in pain, as well as those who do not, have shown that prescription of long-term opioids is increasingly common (Turk et al. 1994). Surveys and open-label clinical trials support the safety and effectiveness of opioids in patients with chronic nonmalignant pain. Recently, several controlled trials have documented the effectiveness of opioids in the treatment of chronic nonmalignant pain.

A randomized double-blind crossover study of oral continuous-release morphine found a significant decrease in musculoskeletal pain compared with that found with placebo (Moulin et al. 1996). Although 9 weeks of therapy did not produce any evidence of addiction, patients did not experience significant psychological or functional improvement. Another randomized placebo-controlled clinical trial found that treatment with controlled-release codeine reduced reports of pain as well as pain-related disability (Arkininstall et al. 1995). Opioids are now being considered for the specific treatment of neuropathic pain. Recent studies of the treatments for neuropathic pain support the use of opioids to provide direct analgesic actions and not just to counteract the unpleasantness of pain (DelleMijn and Vanneste 1997; Watt et al. 1996). Other studies have documented the presence of opioid receptors in the peripheral tissues that become activated by inflammation (Stein et al. 1997). These findings suggest a role for opioids in the treatment of chronic inflammatory diseases.

Once the decision is made to prescribe opioids, several recommendations have been suggested to minimize the risks and optimize the potential benefits (Mendelson and Mendelson 1991; Schug 1991). The Agency for Health Care Policy and Research has produced guidelines for the treatment of acute and cancer pain (Acute Pain Management Guideline Panel 1992; Cancer Pain Management Guideline Panel 1994). The Federation of State Medical Boards (1998) has recently formulated guidelines for the treatment of chronic pain. The American Academy of Pain Medicine and the American Pain Society have produced a consensus statement (*The Use of Opioids for the Treatment of Chronic Pain*) to provide education and general principles for practitioners in this area. The American Geriatric Soci-

ety (1998) has recently published clinical practice guidelines for the management of chronic pain in older persons.

Opioids with a short duration of analgesic activity generally create more problems than they solve. These medications must be taken multiple times a day, often interfering with the patient's daily activities, including sleep. But more importantly, opioids with short duration result in serum levels of considerable variability. Analgesia is difficult to achieve and side effects are more likely to occur. Controlled-release formulations of morphine, oxycodone, and fentanyl are now available. Multiple studies describe the more favorable pharmacokinetic and pharmacodynamic profiles of these medications. A recent study found comparable analgesia, with more vomiting occurring with controlled-release morphine and more constipation with controlled-release oxycodone (Heiskanen and Kalso 1997). Transdermal fentanyl is an effective analgesic with generally fewer side effects than oral medications and more than 90% of patients choosing to continue the medication after completion of a study trial (Donner et al. 1996). In the treatment of chronic low back pain, transdermal fentanyl significantly decreased pain and improved functional disability (Simpson et al. 1997). Tolerance leading to dosage escalation is generally not a problem in the management of patients taking long-term opioids (France et al. 1984; Portenoy 1990).

The most common side effect of chronic opioid therapy is decreased gastrointestinal motility, causing constipation (Portenoy and Foley 1987). However, concerns about potential cognitive impairment are more often the reason opioids are not prescribed. Again, the available research has not demonstrated these deleterious effects on neuropsychological testing or electroencephalography except in patients prescribed multiple types of medications, especially sedatives and hypnotics (Hendler et al. 1980; Lomardo et al. 1976; McNairy et al. 1984; Zielger 1994). Elderly patients are more susceptible to delirium than younger patients (see Chapter 19 in this volume). Although no studies have examined this risk of delirium in chronic pain syndromes treated with opioids, postoperative patients are less likely to develop cognitive impairment with fentanyl than with morphine (Herrick et al. 1996). Another similar study found that cognitive performance was poorer in patients receiving hydromorphone compared with those receiving morphine (Rapp et al. 1996). Many metabolites of opioids are excreted by the kidney and can cause toxicity in the elderly, especially those of methadone (Forman 1996). Creatinine clearance should be monitored to titrate dosing for adequate analgesia with minimal toxicity.

If treatment with opioids is unsuccessful in decreasing pain, discontinuation should be carefully monitored to

minimize physiological withdrawal symptoms. The essential element for successful opioid detoxification is the gradual tapering of the dose of medication. Opioid withdrawal is generally not dangerous except with patients at risk from increased sympathetic tone, such as those with increased intracranial pressure or unstable angina. However, opioid withdrawal is very uncomfortable and distressing to patients. Tapering opioids often results in exacerbation of the patient's primary pain symptom (rebound pain). Increases in pain can occur even if the analgesic effects of opioid therapy had not been appreciable. Although it is generally not possible to avoid discomfort completely, the goal of detoxification is to ameliorate withdrawal.

Several nonopioid pharmacological agents are commonly used as adjunctive agents to provide patients additional relief from withdrawal symptoms. Clonidine, an  $\alpha_2$ -adrenergic agonist that decreases adrenergic activity, is the most commonly prescribed (Fishbain et al. 1992a). Clonidine can help relieve many of the autonomic symptoms of opioid withdrawal such as nausea, cramps, sweating, tachycardia, and hypertension, which result from the loss of opioid suppression of the locus ceruleus during the withdrawal syndrome. Other adjunctive agents include nonsteroidal anti-inflammatory drugs for muscle aches, bismuth subsalicylate for diarrhea, anticholinergics for abdominal cramps, and antihistamines for insomnia and restlessness.

**Antidepressants.** In 1960, the first report of imipramine used for trigeminal neuralgia was published (Paoli et al. 1960). Since then, the antidepressants, particularly the TCAs, have been commonly prescribed for the treatment of many chronic pain syndromes, especially neuropathic pain. Animal models have been established for the study of nociception and neuropathic pain (Ollat and Cesaro 1995). Current research suggests that antidepressant effects on pain are mediated by the blockade of norepinephrine and serotonin reuptake that increases the levels of these neurotransmitters and enhances the activation of descending inhibitory neurons (R. B. King 1981; Magni 1987). Other aspects of monoaminergic systems have been implicated in the analgesic action of antidepressants.  $\beta$ -Adrenoceptors have been demonstrated to mediate the analgesic effects of desipramine and nortriptyline (Mico et al. 1997). Imipramine demonstrated differential hypoalgesic effects depending on the experimental paradigm used to assess pain (Poulsen et al. 1995). TCAs may reduce hyperalgesia but not tactile allodynia because different neuronal mechanisms underlie different manifestations of neuropathic pain (Jett et al. 1997). Generally, amitriptyline or TCAs with a similar pharmacological profile are considered most

effective, but randomized controlled trials have not demonstrated consistent differences among the TCAs (Bryson and Wilde 1996).

In a review of 39 placebo-controlled studies, 80% found antidepressants superior to placebo (Magni 1991). These findings have been challenged because of poor study design and protocol criteria (Goodkin et al. 1995). A recent systematic review of randomized controlled trials and meta-analysis concluded that TCAs are the only agents proven to benefit PHN (Volmink et al. 1996). TCAs have been most effective in relieving neuropathic pain and headache syndromes, with the analgesic activity independent of effects on mood (Gruber et al. 1996; MacFarlane et al. 1997; Max et al. 1987; McQuay et al. 1996; Vrethem et al. 1997; Wesselmann and Reich 1996). A recent placebo-controlled, double-blinded, randomized clinical trial of nortriptyline for patients with chronic low back pain without depression demonstrated significant reduction in pain intensity scores (Atkinson et al. 1998).

A variety of treatment studies of PHN and painful diabetic peripheral neuropathy have used TCAs with mean daily doses ranging from 100 to 250 mg (Max 1994; Onghena and Van Houdenhove 1992). More than 60% of patients reported improvement usually beginning in the third week of treatment, with serum levels in the low end of the therapeutic range for the treatment of depression. The results of investigations of drug concentrations needed for pain relief remain contradictory, and no clear guidelines have been established (Kishore-Kumar et al. 1990; Sindrup et al. 1989). In a study of TCA utilization, 25% of patients in a multidisciplinary pain center were prescribed these medications. However, 73% of patients treated received only the equivalent of 50 mg or less of amitriptyline (Richeimer et al. 1997). Although tertiary amines have been used most commonly, they are metabolized to the secondary amines possessing fewer side effects such as decreased gastrointestinal motility and urinary retention. Desipramine and nortriptyline had significantly fewer side effects leading to discontinuation of the TCA than clomipramine, amitriptyline, and doxepin. Nortriptyline, the major metabolite of amitriptyline, causes less sedation, less orthostatic hypotension, and fewer falls than imipramine and has been demonstrated to be as effective as amitriptyline in treating chronic pain (Roose et al. 1981; Watson et al. 1988). The cost of TCAs for pain treatment is generally much lower (less than \$5.00 per month) than other antidepressants and medications with analgesic activity such as  $\beta$  blockers and calcium channel blockers (Adelman and Von Seggern 1995).

The selective serotonin reuptake inhibitors produce weak antinociceptive effects in animal models of acute pain

(Gatch et al. 1998; Paul and Hornby 1995; Schreiber et al. 1996). This antinociception is blocked by serotonin receptor antagonists and enhanced by opioid receptor agonists. A large number of studies have investigated the role of serotonin receptor subtypes in both nociceptive and hyperalgesic mechanisms of pain; however, controversy remains and the relationships between various findings are complex (Belcheva et al. 1995; Tokunaga et al. 1998). The serotonin reuptake inhibitors have not been found to be as effective as the TCAs for many chronic pain conditions. For example, desipramine was superior to fluoxetine in the treatment of painful diabetic peripheral neuropathy (Max et al. 1992).

Inconsistencies still exist because another study of patients with diabetic neuropathy did find beneficial effects with paroxetine (Sindrup et al. 1990). Other studies indicate that fluoxetine significantly reduces pain in patients with rheumatoid arthritis and is comparable to amitriptyline (Rani et al. 1996). Recently, the serotonin reuptake inhibitors have demonstrated effectiveness in the treatment of headache, especially migraine, and were well tolerated by patients (Bank 1994; Foster and Bafaloukos 1994; Saper et al. 1994). In a study of chronic tension-type headache, amitriptyline significantly reduced the duration of headache, headache frequency, and the intake of analgesics, but citalopram, a serotonin reuptake inhibitor, did not (Bendtsen et al. 1996). Until the results with serotonin reuptake inhibitors are more consistent, they are not recommended as first-choice medications unless a specific contraindication exists for TCAs (Max et al. 1991).

The role of biogenic amines in the descending inhibition of pain suggests a potential efficacy for all antidepressants, despite their different pharmacological actions, in the treatment of chronic pain. Norepinephrine and dopamine reuptake inhibitors such as bupropion can produce antinociception in studies of thermal nociception (Gatch et al. 1998). Monoamine oxidase inhibitors have been found to decrease the frequency and severity of migraine headaches (Merikangas and Merikangas 1995). Buspirone has been found effective in the prophylaxis of chronic tension-type headache; however, patients used more drugs for short-term treatment of headache than those patients treated with amitriptyline (Mitsikostas et al. 1997). Protriptyline decreased chronic tension-type headache frequency by 86% in a study of women with this condition (Cohen 1997). Trazodone was ineffective in decreasing pain in a double-blind, placebo-controlled study of patients with chronic low back pain (Goodkin et al. 1990; Marek et al. 1992). Venlafaxine inhibits the reuptake of both serotonin and norepinephrine with fewer side effects. In an animal model of neuropathic pain, venlafaxine re-

versed hyperalgesia as well prevented its development (Lang et al. 1996). Nefazodone possesses both the actions of analgesia and potentiation of opioid analgesia in the mouse hot-plate assay (Pick et al. 1992). Other antidepressants that inhibit serotonin reuptake and block certain serotonin receptor subtypes such as mirtazapine will need to be studied in the treatment of pain (Galer 1995).

**Anticonvulsants.** Anticonvulsants are considered most effective in the treatment of trigeminal neuralgia, diabetic neuropathy, and migraine recurrence (McQuay et al. 1995). Many anticonvulsants block the activity of use-dependent sodium channels. This property stabilizes the presynaptic neuronal membrane, preventing the release of excitatory neurotransmitters, and decreases the spontaneous firing rate in damaged and regenerating nociceptive fibers. Subsequently, the activation of secondary spinal nociceptive neurons via NMDA receptors is prevented. Phenytoin was first reported as a successful treatment for trigeminal neuralgia in 1942 (Bergouignan 1942). Carbamazepine is the most widely studied anticonvulsant demonstrating effective treatment of neuropathic pain (Tanelian and Victory 1995).

However, anticonvulsants have many other pharmacological actions that may play a role in analgesia, making them potential treatments for a variety of chronic pain syndromes. Phenytoin regulates many aspects of nerve function such as ATPase activity, synaptic transmission, neurotransmitter release, and ion conductances, suggesting a large number of central nervous system effects (Lorenzo 1989). In spinal nerve-ligated rats with cooling and mechanical allodynia, carbamazepine has inhibitory effects on electrical C- and A-fiber neuronal responses (Chapman et al. 1998). Carbamazepine lowers the concentration of tryptophan bound to plasma proteins and subsequently elevates brain serotonin levels in rats (Pinelli et al. 1997). Carbamazepine has also been found to inhibit the development of different types of inflammation in the rat (Bianchi et al. 1995). In this model of inflammatory hyperalgesia, carbamazepine reduced the inflammatory exudate, prostaglandin E<sub>2</sub> activity, and substance P concentrations. Unfortunately, the use of carbamazepine can be limited by intolerable side effects such as sedation, ataxia, and aplastic anemia. Therapeutic serum levels have not been clearly established, with some evidence suggesting that lower levels may be effective in decreasing pain (Moosa et al. 1993).

Newer classes of anticonvulsants represent novel pharmacological actions that could potentially produce analgesia. Valproic acid is most commonly used in the prophylaxis of migraine but is also effective in the treatment of neuropathic pain (R. Jensen et al. 1994c). In studies of mi-

graine, valproate was an effective prophylactic treatment in more than two-thirds of patients, with minimal side effects such as nausea, dizziness, and tremor (Mathew et al. 1995). Effectiveness is usually defined as improvement in a combination of variables such as frequency of headache, duration or headache-days per month, intensity of headache, use of other medications for acute treatment of headache, the patient's opinion of treatment, and ratings of depression and anxiety (Kaniecki 1997; Klapper 1997; Rothrock 1997).

The mechanism of action of valproate is probably related to increased GABA levels by the inhibition of GABA transaminase and enhanced GABA synthesis. Analgesia may result from the suppression of neuronal activity in the cortex, perivascular parasympathetic fibers, nociceptive trigeminal neurons innervating the meninges, or the trigeminal nucleus caudalis. However, other actions could include decreasing neurogenic inflammation via GABA<sub>A</sub> receptor-mediated mechanisms, altering levels of excitatory and inhibitory neurotransmitters, and having direct stabilizing effects on neuronal membranes (Cutrer et al. 1996, 1997). Valproate is generally well tolerated but requires regular monitoring because of potential hepatotoxicity and bone marrow suppression.

Gabapentin has been reported in open trials to reduce the pain of neuropathic states such as multiple sclerosis, migraine, PHN, and reflex sympathetic dystrophy (Houtchens et al. 1997; Wetzel and Connelly 1997). The mechanism of action of gabapentin may be related to binding with the  $\alpha_2\delta$  subunit of voltage-dependent calcium channels (Field et al. 1997). Gabapentin selectively modulated the facilitation of spinal nociceptive processing generated by persistent small-fiber afferent input that resulted from tissue injury in an animal model of thermal hyperalgesia (Jun and Yaksh 1998). In the formalin test, gabapentin had antinociceptive activity (Shimoyama et al. 1997). Other studies have shown that gabapentin can reverse cold and tactile allodynia as well as heat hyperalgesia (Xiao and Bennett 1995).

Case reports indicate that lamotrigine may be effective in reducing the pain of phantom limbs, neuroma hypersensitivity, trigeminal neuralgia, causalgia, central poststroke pain, and PHN (Canavero and Bonicalzi 1996; Harbinson et al. 1997). Lamotrigine produced significant analgesia, as measured by the cold pressor test in healthy volunteers (Webb and Kamali 1998). Analgesia was correlated with serum drug concentrations and comparable to that obtained with phenytoin and dihydrocodeine. In contrast to gabapentin, lamotrigine reversed cold, but not tactile, allodynia (Hunter et al. 1997). The mechanism of action of lamotrigine may be a result of its ability to decrease

long-term excitatory effects of nociceptive glutamergic transmission mediated by NMDA receptors, but it also blocks use-dependent voltage-gated sodium channels (Cheung et al. 1992; Leach et al. 1995; Lees and Leach 1993). Topiramate, tiagabine, vigabatrin, and zonisamide are new anticonvulsants with a spectrum of pharmacological actions that include enhancing neuronal inhibition, decreasing neuronal excitability, and protecting neurons from free radical damage (Marson et al. 1997).

**Antiarrhythmics.** The use-dependent sodium channel-binding properties of local anesthetics such as lidocaine and mexiletine have also proven effective in decreasing ectopic neural activity. Lidocaine and mexiletine reduce spontaneous and evoked neuronal activity in experimental neuroma models (Galer et al. 1996). However, mexiletine has also been shown to have an antinociceptive effect in the rat tail pinch model that was mediated by the delta 1-opioid receptor (Kamei et al. 1995). In a rat model of central sensitization and neuropathic pain, mexiletine decreased both the hyperalgesia and tactile allodynia (Jett et al. 1997). Mexiletine is structurally related to lidocaine and has similar electrophysiological properties, yet can be administered orally (Campbell 1987). Relief of pain with an intravenous infusion of lidocaine has been investigated as a predictive test of successful treatment with mexiletine (Galer et al. 1996; Zehender et al. 1988).

Current research supports mexiletine as an effective treatment for neuropathic pain such as painful diabetic neuropathy, peripheral nerve injury pain, alcoholic neuropathy, and phantom pain (Boulton 1993; Chabal et al. 1992b; Davis 1993; Nishiyama and Sakuta 1995). In one double-blind crossover study, mexiletine not only decreased reports of pain but also the accompanying paresthesias and dysesthesias (Dejgard et al. 1988). Another study found that mexiletine decreased pain and sleep disturbances associated with painful diabetic neuropathy (Oskarsson et al. 1997). No significant correlation was found between plasma concentrations of mexiletine and either therapeutic effect or adverse events.

**Calcium channel blockers.** Several classes of calcium channel blockers are available. Verapamil is the most commonly prescribed calcium channel blocker for chronic pain treatment and has proven effective in the treatment of migraine and cluster headaches (Lewis and Solomon 1996; Markley 1991). It is still unclear whether the mechanism of action is primarily related to cerebral artery vasodilation or interaction with serotonergic systems. In 922 subjects of the Hypertension Optimal Treatment study, intensive treatment to lower blood pressure also significantly

reduced headaches and increased measures of well-being (Wiklund et al. 1997). In a rat model of peripheral neuropathy, repeated electroconvulsive treatments, which affect voltage-dependent calcium channels, reduced pain responses to heat stimulation (Shibata et al. 1998). Another possible mechanism of pain relief involves cortical L-type calcium channels as measured by  $^3\text{H}$ -nitrendipine-binding sites (Antkiewicz-Michaluk et al. 1991). Chronic use of antidepressants has been shown to increase the density of cortical calcium channels, possibly limiting their analgesic effect and even contributing to hyperalgesia.

High-threshold, voltage-dependent P- and Q-type calcium channels are involved in neurotransmitter release. In animal studies of joint inflammation, the P-type calcium channels mediate the excitation of spinal cord neurons by mechanosensory input from inflamed tissue, resulting in pain generation (Nebe et al. 1997). Other studies of calcium channel subtypes have shown that L-, N-, and P-type channels are involved in the development of mechanical hyperalgesia and allodynia (Sluka 1997). On the other hand, calcium channel blockers have demonstrated opioid receptor agonistic activity in animals and augmentation of opioid analgesia in animals and humans (Hasegawa and Zacny 1997; Weizman et al. 1997). The L-type calcium channel blockers such as diltiazem and verapamil have also been found to potentiate morphine analgesia, but the results are inconsistent (Hodogluligil et al. 1996; Taniguchi et al. 1995). However, the neuron-specific, N-type, voltage-sensitive calcium channel blocker, ziconotide, possesses potent analgesic, antihyperesthetic, and antiallodynic activity (Bowersox et al. 1996; Brose et al. 1997; Xiao and Bennett 1995). Another action of calcium channel blockers may result in a reduction of neural nitric oxide synthase activity, with subsequent decreases in nitric oxide concentrations in perivascular nerves, limiting cerebral vasodilation (Ayajiki et al. 1997).

**Benzodiazepines.** Benzodiazepines are commonly prescribed for insomnia and anxiety in patients with chronic pain (Holister et al. 1981; S. A. King and Strain 1990). No studies demonstrated any benefit for the target symptoms of insomnia and anxiety frequently reported by these patients. In an extensive review, only a limited number of chronic pain conditions such as trigeminal neuralgia, tension headache, and temporomandibular disorders were found to improve when treated with benzodiazepines (DelleMijn and Fields 1994). Clonazepam has been reported to provide long-term relief of the episodic lancinating variety of phantom limb pain (Bartusch et al. 1996). Benzodiazepines have been used for the detoxification of patients with chronic pain from sedative/hypnotic

medications. Benzodiazepines were superior to barbiturates for minimizing symptoms of withdrawal (Sullivan et al. 1993).

Not only are the benefits of benzodiazepines difficult to document, but the negative effects are well studied and extend beyond the usual concerns of abuse, dependence, withdrawal, and secondary effects on mood. The elderly are particularly sensitive to the adverse effects of benzodiazepines such as sedation (Ganapathy et al. 1997; Max et al. 1988; Platten et al. 1998; Yosselson-Superstine et al. 1985). Benzodiazepines also cause cognitive impairment, as demonstrated by abnormalities found by neuropsychological testing and electroencephalography (Hendler et al. 1980). Benzodiazepines have been associated with exacerbation of pain and interference with opioid analgesia (France and Kirshman 1988; Sawynok 1985). These effects appear to be the result of activating supraspinal GABA<sub>A</sub> receptors known to antagonize opioid analgesia. Similarly, a study of the benzodiazepine antagonist, flumazenil, enhanced postoperative morphine analgesia in patients who received preoperative diazepam for sedation (Gear et al. 1997).

## Psychological Treatments

**Cognitive-behavior models.** Psychological treatment for chronic pain was pioneered by Fordyce using an operant conditioning behavioral model (Fordyce et al. 1973). The behavioral approach is based on an understanding of pain occurring in a social context. The behaviors of the patient with chronic pain not only reinforce the behaviors of others but also are reinforced by others. Pain behaviors such as grimacing, guarding, and taking pain medication have been found to be indicators of perceived pain severity and functional disability (Chapman et al. 1985; Fordyce et al. 1984; Keefe et al. 1986; Romano et al. 1988; Turk and Matyas 1992). In a study of medical practice patterns, only observed pain behaviors were predictive of whether opioid medications were prescribed to patients with chronic pain (Turk and Okifuji 1997). Other aspects of the patient's presentation to a health care practitioner such as reports of functional disability, distress, pain severity, objective physical pathology, duration of pain, and demographic variables were not predictive. If pain behaviors are reinforced, the behavioral model assumes that pain and disability will continue. In treatment, productive behaviors are targeted for reinforcement, and pain behaviors for extinction.

Many psychological interventions such as distraction, relaxation, biofeedback, and hypnosis have been useful in

the reduction of pain and its associated distress (Turner 1982b; Turner and Chapman 1982). The cognitive-behavior model of chronic pain assumes that individual perceptions and evaluations of life experiences affect emotional and behavioral reactions to these experiences. Pain and the resultant pain behaviors are influenced by biomedical, psychological, and socioenvironmental variables (Keefe et al. 1996). If patients believe pain, depression, and disability are inevitable and uncontrollable, then they will experience more negative affective responses, increased pain, and even more impaired physical and psychosocial functioning. The components of cognitive-behavior therapy (CBT) such as relaxation, cognitive restructuring, and coping self-statement training interrupt this cycle of disability. Patients are taught to become active participants in the management of their pain through the utilization of methods that minimize distressing thoughts and feelings. Specifically, elderly patients benefit from CBT that presents information in concrete, well-organized, and brief formats (Manetto and McPherson 1996). Outcome studies of CBT in patients with a variety of chronic pain syndromes have demonstrated significant improvements in pain intensity, pain behaviors, distress, depression, and coping (Keefe et al. 1990a; Turner 1982a; Turner and Romano 1990). Pain reduction and improved physical function have been found to continue up to 6 months after the completion of active cognitive-behavior treatment (Keefe et al. 1990b).

**Beliefs.** The success of CBT in chronic pain treatment has led to focused attention on many elements of the chronic pain experience. The relationship between beliefs about pain and subsequent patient adjustment central to the cognitive-behavior model has been reviewed (M. P. Jensen et al. 1991a). Adjustment is defined as the ability to carry out normal physical and psychosocial activities. The three dimensions of adjustment have been defined as social functioning, morale, and somatic health (Lazarus and Folkman 1984). Examples of these dimensions include pain intensity, medication use, depression, anxiety, employment, health care utilization, and functional ability.

Beliefs are conceptualized as the thoughts of an individual about their personal pain problem and have been categorized in several different domains (M. P. Jensen et al. 1987; Morley and Wilkinson 1995). Psychosocial dysfunction has been correlated with solicitous responses from family, believing emotions are related to pain, and attributing the inability to function to pain (M. P. Jensen et al. 1994b). In contrast, although physical disability was also correlated with beliefs about pain interfering with function, patients also endorsed the belief that pain signifies in-

jury and, therefore, activity should be avoided.

Other related cognitive variables under study in patients with chronic pain include self-efficacy, outcome expectancies, and locus of control (Anderson et al. 1995; Keefe et al. 1992). A self-efficacy expectancy is a belief about one's ability to perform a specific behavior, whereas an outcome expectancy is a belief about the consequences of performing a behavior. These variables have been derived from social learning theory (M. P. Jensen et al. 1991b). Individuals are considered more likely to engage in coping efforts that they believe both are within their capabilities and will result in a positive outcome.

Patients with a variety of chronic pain syndromes who score higher on measures of self-efficacy or have an internal locus of control report lower levels of pain, higher pain thresholds, increased exercise performance, and more positive coping efforts. However, in one study of patients with chronic pain being treated with a procedure, expectations of pain relief were not correlated with actual changes in pain ratings (Galer et al. 1997). Interestingly, physician expectations of pain relief were significant predictors of patient pain relief ratings, supporting the important role of other persons in an individual's chronic pain experience. Similarly, acceptance of pain was found to be associated with reports of lower pain intensity, less pain-related anxiety and avoidance, less depression, less physical and psychosocial disability, more daily up time, and better work status (McCracken 1998).

**Coping.** Coping has been defined as "a person's cognitive and behavioral efforts to manage the internal and external demands of the person-environment transaction that is appraised as taxing or exceeding the person's resources" (Folkman and Lazarus 1986). The Coping Strategies Questionnaire defines seven specific coping strategies (Rosenstiel and Keefe 1983). A comprehensive review of the research in this area concluded that the coping strategies concept generally supported the cognitive-behavior model of chronic pain (M. P. Jensen et al. 1991a). Higher levels of disability were found in persons who remain passive or use coping strategies such as catastrophizing; ignoring or reinterpreting pain sensations; diverting attention from pain; and praying or hoping for relief. In a 6-month follow-up study of patients completing an inpatient pain program, improvement was associated with decreases in the use of passive coping strategies and beliefs about pain being an illness (M. P. Jensen et al. 1994a).

The effectiveness of particular coping strategies with improved adjustment to chronic pain is dependent on many aspects of a patient's experience with illness. For example, reinterpreting pain sensations as not being signs of

ongoing injury has been typically formulated as useful for reducing the effects of experimentally induced pain. However, in a study of amputees with phantom limb pain, this coping strategy was not associated with reduced pain levels but instead with greater psychosocial dysfunction (Hill et al. 1995). Attempting to reinterpret pain sensations may not be an appropriate technique for individuals with persistent pain because it requires greater amounts of time spent focusing on pain and disability. This may prevent patients from engaging in social activities. Catastrophic thinking about pain has been attributed to the amplification of threatening information and interference with the attentional focus needed to facilitate patients remaining involved with productive instead of pain-related activities (Crombez et al. 1998).

Some evidence indicates that older patients with chronic pain utilize different patterns of coping strategies. Older patients were more likely to use passive strategies such as praying and hoping for relief from pain, less likely to ignore pain, and benefited most from coping self-statements that emphasize an ability to actively manage pain (Corran et al. 1994). In contrast, younger patients were more likely to get benefit from ignoring pain. Training older adults to use adaptive coping strategies resulted in lower levels of both pain and psychological disability (Keefe et al. 1987, 1990b). These results were achieved when patients perceived an increase in the effectiveness of their new skills and reduced their use of maladaptive coping strategies such as catastrophic thinking.

**Patient classifications.** Controversy over the type of psychological treatment most effective in the treatment of chronic pain still persists, as exemplified by a recent study finding no differences between the treatment effects of cognitive and behavior therapies in patients mildly disabled by chronic low back pain (Turner and Jensen 1993). As a result, attempts to define more homogeneous subgroups of patients with chronic pain have led to several empirical classifications based on factor analyses of the responses on a variety of instruments (Deardorff et al. 1993; Sanders and Brena 1993; Williams et al. 1995). In a cluster analysis of patients with chronic pain, a subgroup was defined in the elderly that combined high levels of depression and impact of pain on daily living despite low levels of pain intensity (Corran et al. 1997).

Three groups have been described based on a cluster analysis of responses on the Multidimensional Pain Inventory (Kerns et al. 1985; Turk and Rudy 1990). The “dysfunctional” group scored higher on pain severity, life interference as a result of pain, and psychological distress. This

group also scored lower on perceptions of control and performance of daily activities. The “interpersonally distressed” group was characterized by the perception of poor support from others. The “adaptive copers” described lower ratings of pain severity, pain interference, affective distress, physical disability, and perceptions of being out of control. Differential patterns of improvement across subgroups in patients with temporomandibular disorders receiving an interocclusal appliance and biofeedback/stress management treatment protocol have been demonstrated (Rudy et al. 1995). The “dysfunctional” group showed the best response to multidisciplinary treatment, with greater improvements in pain intensity, interference, catastrophizing, depression, and negative thoughts when compared with the other groups.

Another classification of patients with chronic low back pain has been described based on responses to the McGill Pain Questionnaire (Melzack 1975), the Sickness Impact Profile (Bergner et al. 1976a, 1976b; Gilson et al. 1975; Pollard et al. 1976), and the Beck Depression Inventory (Beck 1978; Klapow et al. 1995). Again three groups were identified based on levels of pain, impairment, and depression. The group with higher levels of pain, impairment, and depression reported greater life adversity, more reliance on passive coping strategies, and less satisfaction with social support networks. The patients reporting lower levels in these domains were characterized by the opposite findings. The group with higher levels of pain but lower levels of impairment and depression reported less life adversity and more satisfactory social support, but continued reliance on passive coping strategies.

## Multidisciplinary Treatment

**Methodology.** Patients with chronic pain suffer dramatic reductions in physical, psychological, and social well-being, with health-related quality of life rated lower than that for those with almost all other medical conditions (Becker et al. 1997; Skevington 1998). A study of sequential trials of different treatment modalities found that the success of nerve blocks was diminished when used later in the treatment sequence. These results suggest that early failures of a single modality treatment for chronic pain can have devastating consequences for future treatment attempts (Davies et al. 1997). In another study of more than 1,200 treated patients and 1,700 follow-up patients with low back or neuropathic pain, wide variations in medical practice changed significantly after feedback was given to the practitioners. This information simply informed practitioners about treatment modalities being used in the

clinic and other options that were available for treatment (Davies et al. 1996). The multidisciplinary pain center offers the setting to provide the full range of treatments for the most difficult pain syndromes, including those of the elderly (Gibson et al. 1996; Helme et al. 1996).

A distinction between *multidisciplinary* and *interdisciplinary* pain centers has been described (Turk and Stieg 1987). A multidisciplinary approach is a serial evaluation by multiple specialists. Usually, this process leads to diagnoses by exclusion and implies a hierarchy of diagnostic importance. Neuropsychiatry is often the last specialty to evaluate the patient, reinforcing the belief that pain is truly mysterious and “just a figment of your imagination.” Even attempts at simultaneous evaluation by multiple specialists including a neuropsychiatrist or psychologist can be misconstrued as trying to determine if symptoms are “real.”

Interdisciplinary approaches are characterized by combining areas of expertise to form a shared view of chronic pain. The individual team members, although representatives of different fields of study, recognize that all symptoms can have a variety of causes. These etiologies are organized by specialty for clarity, but the classification structure does not invalidate certain diagnoses, such as psychiatric disorders, as a cause for the patient's symptoms. This approach emphasizes that all diagnoses are real and can be made by any number of specialists if properly trained. When a specific diagnosis cannot be made, an etiology for the patient's symptoms has simply not yet been discovered. As a result, the patient can remain in treatment to receive symptomatic interventions and the coordination of future evaluations. The patient is no longer stigmatized as having a “false” condition but instead recognized as having a legitimate problem with understandable distress.

**Effectiveness.** Substantial evidence indicates that multidisciplinary pain programs improve patient functioning in a number of areas (Cutler et al. 1994; Fishbain et al. 1993; Flavell et al. 1996). In one of the most comprehensive reviews to date, a meta-analysis of 65 studies evaluated the efficacy of treatments in patients who attended multidisciplinary pain clinics (Flor et al. 1992). Although significant limitations were found, the study concluded that multidisciplinary pain clinics are efficacious. Combination treatments were superior to unimodal treatments or no treatment, treatment effects were maintained over a period of up to 7 years, and improvements were found not only on subjective but also on objective measures of effectiveness such as return to work and decreased health care utilization.

The elderly with chronic pain are often considered more likely to fail treatment because they have more

chronic medical conditions, take twice as many medications, and have four times the rate of health care utilization when compared with that of younger patients with chronic pain. It is argued that younger patients with more years of potential productivity should have preferential access to scarce medical resources. However, multidisciplinary outcome studies of elderly patients with chronic pain demonstrate a variety of benefits from treatment (Gibson et al. 1996; Middaugh et al. 1988). Types of improvement include increased activity, decreased magnitude of pain, reductions in the use of medical services, improvement in depression and anxiety, and decreased use of medications. In general, the elderly experience a level of improvement that is the same or even greater than that of younger patients. Therapeutic nihilism is not justified and should never be the treatment of choice for any patient suffering from chronic pain.

Ultimately, the goal of treating patients with chronic pain is to end disability and return people to work or other productive activities. In the longest follow-up study of an inpatient pain management program, patients with chronic pain did not demonstrate an increased risk of mortality 13 years after treatment (Maruta et al. 1998). Only half of the patients were unemployed compared with almost 90% of the patients at the time of their admission for treatment. In a 30-month follow-up study of patients with chronic pain receiving multidisciplinary treatment, employment status was predicted by the patient's voiced “intent” to return to work as well as the perception of a job's dangerousness and the patient's education level (Fishbain et al. 1997). Patients not intending to return to work were more likely to complain of their job's excessive physical demands and reported more job dissatisfaction and feelings of disability (Fishbain et al. 1995; Hildebrandt et al. 1997).

## ■ Summary

Chronic pain is a significant public health problem and frustrating to everyone affected by it, especially the elderly who believe that health care has failed them but who wish to remain in their own homes, live independently, and avoid becoming a burden to others (Anikeeff and Mueller 1998; Bendelow and Williams 1996). Neuropsychiatrists as medical specialists should take an active role in the care of these patients. Neuropsychiatrists offer skills with pharmacological and psychological treatments now recognized as effective in the management of chronic pain. Recent advances in the treatment of chronic pain include the diagnosis and treatment of psychiatric comorbidity, the application of neuropsychiatric treatments to chronic pain,

and the development of interdisciplinary efforts to provide comprehensive health care to the patient suffering with chronic pain. Specifically, the neuropsychiatrist provides the expertise of examining mental life and behavior as well as understanding the individual person and the systems in which he or she interacts. And finally, neuropsychiatrists can facilitate the integration of the delivery of medical care with other health care professionals and medical specialists.

# Delirium

Larry E. Tune, M.D.

**D**elirium is a serious and often undetected neuropsychiatric syndrome. Delirium is particularly common in elderly patients in hospitals, where as many as 32%–67% of all cases of delirium are undetected (Beresin 1988; Inouye et al. 1990). Failure to identify delirium can have serious consequences. Delirium is associated with increased morbidity and mortality. In-hospital mortality rates for elderly patients with delirium are 10%–65% (Gottlieb et al. 1991; Levkoff et al. 1986). Outcome studies of patients with delirium at 1 month and at 1 year postdischarge from hospital also show increased mortality rates (Rabins and Folstein 1982). A few studies have matched elderly patients both with and without delirium by severity of concomitant medical illnesses. Under this condition, delirium may be a risk for significantly increased morbidity and mortality independent of medical status (Flacker and Lipsitz 1998).

The financial impact of delirium is enormous. Approximately 35% of all Americans over the age of 65 were hospitalized in 1993 (accounting for 40% of all inpatient days). By using a 20% prevalence estimate for delirium in the elderly, it is estimated that 7% of all persons over the age of 65 become delirious annually. Delirium will complicate the hospital stay for over 2.2 million patients (for 17.5 million inpatient days). Based on these estimates, the cost of delirium exceeds \$8 billion annually (Inouye 1998). Delirium in

the hospital is associated with increased morbidity, closer nursing surveillance, higher hospital costs per day, longer hospitalizations, and increased rates of nursing home placements (Inouye and Charpentier 1996; Thomas et al. 1986). Delirium in the nursing home is associated with significantly increased morbidity and mortality and with increased requirement for nursing time (Fries et al. 1993).

Because delirium is often treatable, early detection and aggressive medical treatment, including management of associated neuropsychiatric symptoms, should result in substantial reduction in morbidity and mortality.

## ■ Diagnostic Terminology

Detection of delirium has been hampered by the absence of reliable and valid diagnostic criteria, a dearth of rating instruments, and a wide array of terms applied to the condition. Table 19–1 lists a number of “diagnoses” that have been used synonymously with delirium. Most of these terms (with the exception of metabolic encephalopathy) have little or no explicit diagnostic criteria. When this wide array of terms is applied to patients in the same clinical setting, the magnitude of the unitary underlying problem is often unappreciated.

The later versions of the DSM (American Psychiatric

**TABLE 19-1. Alternative diagnostic labels for delirium**

Acute toxic psychosis
Metabolic encephalopathy
Subacute befuddlement
Toxic brain syndrome
Toxic encephalopathy

---

Association 1952) have provided more rigorous diagnostic criteria. DSM-IV criteria (Table 19-2) represent the most current criteria to date (American Psychiatric Association 1994).

### Clinical Features

The essential clinical features of delirium are 1) relatively acute onset with fluctuating course, 2) disorganized thinking, 3) alteration in level of consciousness, and 4) inattention. Other symptoms are associated with delirium; for example, inappropriate behavior, disorientation, and psychosis (e.g., hallucinations, paranoid ideation) are common in cases of delirium (Gottlieb et al. 1991). However, these symptoms are not absolute requirements for the diagnosis.

**Onset.** The disturbance of consciousness usually evolves over hours to days and often fluctuates through the day. It is this disturbance of consciousness that distinguishes delirium from most cases of dementia and affective disturbance.

Although the onset of delirium is usually acute, it can present subacutely. Psychopathology tends to fluctuate through the day in most cases, although reliance on this clinical feature will likely lead to underdetection. It is common for a subsyndromal prodrome phase, lasting many days to (occasionally) weeks, to precede the onset of the full syndrome of delirium. During this prodrome, the most common symptoms are restlessness, sleep disturbance (insomnia and daytime sleeping), behavioral problems including anxiety and irritability, and subjective difficulty thinking (Inouye and Charpentier 1996).

### Disturbance in attention and concentration.

Many aspects of cognitive functioning are impaired in delirium, including orientation, memory, and information acquisition, processing, and retrieval. Specific impairments include diminished awareness of the environment, disorientation to time and place, and diminished capacity

**TABLE 19-2. DSM-IV criteria for delirium**

- 
- A. Disturbance of consciousness (i.e., reduced clarity of awareness of the environment) with reduced ability to focus, sustain, or shift attention.
  - B. A change in cognition (such as memory deficit, disorientation, language disturbance) or the development of a perceptual disturbance that is not better accounted for by a preexisting, established, or evolving dementia.
  - C. The disturbance develops over a short period of time (usually hours to days) and tends to fluctuate during the course of the day.
  - D. There is evidence from the history, physical examination, or laboratory findings that the disturbance is caused by the direct physiological consequences of a general medical condition.
- 

to focus or sustain attention (e.g., in response to questions asked at the bedside). Part of a routine clinical examination of any patient suspected of having delirium should include questions about orientation to time and place, ability to recall several items after a few minutes, and ability to focus attention on a particular task (e.g., subtracting serial 7s or spelling “world” backwards). These types of questions are incorporated into a number of short screening instruments (Mini-Mental State Examination [Folstein et al. 1975], the Short Portable Mental Status Questionnaire [Pfeiffer 1975]).

Thinking is usually disorganized and often incoherent. The content of the patient’s language may be either rich in imagery or impoverished. The ability to think in a logical, goal-directed manner is usually compromised. This disturbance will often include rambling, unpredictable switching from topic to topic, or responses that are irrelevant to questions asked of the patient.

Detection of disturbances in consciousness is often difficult, partly because the concept of “disturbance of consciousness” is inherently vague. This disturbance is nonetheless a critical feature of the syndrome. Disturbance of consciousness refers to impairments in attention and the ability to be aware of and sustain attention to the environment. The patient may sit in bed with his or her eyes open. Through the course of a routine clinical examination, it is clear that the patient’s ability to mobilize and sustain attention for a reasonable period of time is seriously impaired. Her or his overall level of alertness is usually impaired (i.e., the patient is either hypervigilant or hypovigilant).

This disturbance in consciousness tends to fluctuate through the day. Patients will often “sundown” (much like that seen in patients with dementia), with their symptoms, including hallucinations and delusions, worsening at night.

The patient may have a “lucid interval,” during which he or she becomes more aware of his or her situation. The explanation for these fluctuations is poorly understood. They have been attributed to fluctuations in disease state or to environmental or psychosocial factors (e.g., greater stimulation during the day, more environmental cues).

The practical result of these impairments is that the patient usually cannot 1) learn new information, 2) solve problems, or 3) engage in meaningful goal-directed behavior. It is for these reasons that even the patient who is mildly delirious is usually disabled.

**Phenomenology.** Delusions and hallucinations occur in as many as 90% of patients with delirium. The most typical delusion is of persecution, but all types of delusions can be found. The delusions are often poorly articulated, are often related in some way to environmental stimuli, and tend to fluctuate through the day. At some point in the course of the syndrome, 40%–90% of patients have hallucinations, which are usually visual and less commonly auditory. The hallucinations may be dramatic and vivid, often threatening in nature. The patient, who is usually unable to appreciate that these hallucinations are unreal, often responds with fear and agitation. Hallucinations tend to fluctuate through the day, though many patients hallucinate only at night.

## ■ Clinical Subtypes

Attempts to distinguish subtypes of delirium according to etiology (e.g., infection, drug toxicity) have failed (Lipowski 1987; Wolf and Curran 1935). Generally, the two clinical subtypes of delirium are the hypervigilant and the somnolent. Hypervigilant delirium is more commonly found in drug or alcohol intoxication or withdrawal. It is also seen in delirium resulting from other causes. The typical hypervigilant patient is agitated, psychotic, and often uncooperative with medical therapy; the typical somnolent patient is lethargic or sluggish. A large number of etiologies have been associated with somnolent delirium, and it is this type of delirium that is most frequently undiagnosed.

## ■ Neurobiology of Arousal and Consciousness

The central features of delirium are alterations in arousal and attention and disorders of cognition. The normal physiology of arousal and attention is only partially under-

stood, but pathway tracing techniques and chemical anatomical techniques have identified ascending systems likely to be involved in maintenance of normal arousal and attention (see Ross 1991; Saper 1986; Shute and Lewis 1974).

The classic picture of a central arousal system involves the reticular activating system diffusely distributed in the brainstem and projecting multisynaptically to the thalamic intralaminar nuclei (Chedru and Geschwind 1972; Lindsley et al. 1950; Moruzzi and Magoun 1949). Studies using modern anatomical techniques (for a review, see Saper 1986) have shown that the so-called nonspecific afferents to the superficial cortex, which are believed to be involved in maintenance of cortical arousal, do not arise exclusively from the thalamus. Critical sources of nonspecific cortical afferents may be extrathalamic regions such as basal forebrain, hypothalamus, and caudal brainstem. These extrathalamic cortical afferent systems contain several neurotransmitters (discussed below) that may relate to the pathophysiology of delirium.

Anatomical studies (see Saper 1986) suggest a differing organization of cortical nonspecific afferents within the thalamus. The diffuse innervation of superficial cortex may arise less from the intralaminar nuclei and more from the ventromedial thalamic nucleus, as well as the ventro-anterolateral nucleus, the lateral dorsal nucleus, and the posterior and lateral posterior nuclei (Herkenham 1980). Physiological studies of the role of the thalamus in sleep and arousal have yielded contradictory results. Ranson (1939) found little effect of large lesions of the thalamus on sleep and arousal from sleep in the monkey. However, a hereditary condition involving the selective degeneration of certain thalamic nuclei is associated with abnormalities of sleep and consciousness (Lugaresi et al. 1986), supporting other clinical observations. Little is known of the neurotransmitters involved in these thalamic projections.

## Basal Forebrain Cholinergic Projections

Cholinergic neurons in the basal forebrain provide widespread topographically organized innervation of layers 1, 3, 5, and 6 of the cerebral cortex (Saper 1984, 1986). Application of acetylcholine within the cortex causes predominantly excitatory responses. These cholinergic projections may be involved in the generation of cortical and hippocampal electroencephalogram (EEG) rhythms. Basal forebrain cholinergic neurons degenerate in Alzheimer's disease (see Chapter 24 in this volume). Drugs with anticholinergic properties are important contributors to the problem of delirium in some hospitalized patients. It may be that disruption of the function of the basal forebrain

cholinergic cortical afferents explains some of the features of anticholinergic delirium. This hypothesis would be consistent with the fact that patients with Alzheimer's disease, in whom these neurons are already compromised, are unusually sensitive to anticholinergics. Under most circumstances, patients with Alzheimer's disease do not have changes in consciousness, despite their loss of basal forebrain cholinergic neurons, suggesting that abnormalities of other cholinergic neurons (e.g., cholinergic neurons in the brainstem) may be more important in delirium.

### Hypothalamic-Cortical Projections

Classic physiological experiments suggested an important role for the hypothalamus in the regulation of sleep and arousal (Nauta 1946). More recent experiments, such as those using injections of excitatory amino acid toxins (Jouvet 1988), have suggested a particular role for the posterolateral hypothalamus in regulation of sleep and waking. Although traditional views of the reticular formation assume that the hypothalamus projects through the thalamus to reach the cortex, modern pathway tracing techniques have demonstrated direct hypothalamic projections to the cerebral cortex (Kievit and Kuypers 1975; Saper 1985). The areas that project directly to the cortex are the fields of Forel, the posterior lateral hypothalamic area, and the tuberal lateral and tuberal mammary hypothalamic areas. The hypothalamus contains more neurons innervating the cerebral cortex than does the basal forebrain. Most suggestive for the pathophysiology of delirium are neurons in this region of hypothalamus containing  $\gamma$ -aminobutyric acid (GABA) and histamine.

Double-label retrograde transport immunocytochemical techniques have identified GABA-synthesizing neurons residing in the posterior hypothalamus and projecting to the cerebral cortex (Vincent et al. 1983). These systems may be involved in the pathophysiology of hepatic encephalopathy. Alterations of GABA or benzodiazepine-like systems in animal models with hepatic encephalopathy are suggested by reports of altered benzodiazepine receptor binding (Baraldi et al. 1984; Basile et al. 1991). Benzodiazepine antagonists can ameliorate hepatic encephalopathy in animal models and in patients (Bansky et al. 1985; Baraldi et al. 1984; Bassett et al. 1987). Clinical studies in humans have suggested that benzodiazepine antagonists may be helpful in treating hepatic encephalopathy.

Histamine-synthesizing hypothalamic neurons 1) are present in the posterior hypothalamus, 2) are concentrated in the magnocellular nuclei and the tuberal regions (Wada et al. 1991), and 3) project diffusely to the cerebral cortex. Jouvet (1988) suggested that histaminergic neurons in the

hypothalamus have a function in arousal. These neurons may be involved in the delirium caused by anticholinergic drugs because many drugs with anticholinergic properties are also antihistaminergics.

### Brainstem Neuronal Groups

In addition to projections from the hypothalamus and basal forebrain, well-known monoaminergic nuclei in the pons and midbrain project diffusely to the cerebral cortex. These nuclei include midbrain dopaminergic groups in the midbrain ventral tegmentum, cholinergic neurons in the rostral pons, noradrenergic neurons in the locus ceruleus, and serotonergic neurons in the raphe complex. Dopaminergic systems appear to have no clearly identified role in the pathophysiology of delirium. Neurons in the locus ceruleus have been implicated in the control of attention and arousal (Foote et al. 1980). Serotonergic neurons have been linked to the visual hallucinations after ingestion of lysergic acid diethylamide (LSD)-like hallucinogenic drugs (Glennon et al. 1984). Hallucinogens induce an oneiroid state resembling delirium. Unlike the characteristic auditory hallucinations of schizophrenia or bipolar disorder, the hallucinations induced by hallucinogens and seen in delirium tend to be visual.

## ■ Pathophysiology of Delirium

Delirium has been investigated with animal models (Gibson et al. 1991; Posner and Plum 1960), human EEG studies (Romano and Engel 1944), and functional brain imaging studies (Gjedde et al. 1978). Several animal models of encephalopathy have identified a disturbance of cortical glucose metabolism. These models support an early pathophysiological hypothesis that cerebral metabolic insufficiency is the underlying mechanism or final common pathway in delirium. This mechanism is generally thought of as a threshold-related phenomenon: the cumulative effects of multiple cerebral insults lead to "depletion of cortical reserves" and then to an insufficiency in global metabolism. A few brain imaging studies of cerebral blood flow (in patients with delirium tremens and with traumatic brain injury) have also shown impairments in cerebral glucose metabolism.

EEG data support involvement of white matter generally and of thalamocortical projections particularly. The commonest EEG abnormality in somnolent delirium is diffuse, nonparoxysmal delta-wave slowing. This finding has been taken to suggest that the cortex is deafferented. In some cases of delirium, the posterior dominant rhythm

is slowed, possibly implicating thalamocortical projections. Patients with hypervigilant delirium associated with alcohol withdrawal often have EEGs with low-voltage fast activity. This finding represents a global disturbance that may reflect a hyperactivity of catecholaminergic neurotransmission.

Of the possible neurotransmitters, disturbances in cholinergic transmission are the most consistently implicated in preclinical and clinical investigations. One animal model found dose-dependent effects of the cholinergic antagonist atropine (Trzepacz et al. 1992). The behavioral results resemble the EEG and cognitive-behavior changes found in patients with delirium. In autoradiographic studies of the effects of atropine, dose-dependent reductions in glucose metabolism were found in cortex (Gibson et al. 1991). In drug-induced delirium in the elderly, where anticholinergic medications are additive with age-related decreases in cholinergic neurotransmission, the relationship is stronger (see Chapter 4 in this volume). Anticholinergic medications have been shown to impair memory, especially in the elderly (Miller et al. 1988).

Several investigations have found correlations between elevated anticholinergic levels, as measured by serum radioreceptor assay, and the presence of delirium in elderly patients. Mach et al. (1995) found that delirious inpatients have 1) higher serum anticholinergic levels, 2) greater impairments in activities of daily living that correlated with anticholinergic levels, and 3) lower serum anticholinergic levels as the delirium resolved. In a separate study, Flacker et al. (1998) found that elevated serum anticholinergic levels were independently associated with delirium. Self-care capacity in the nursing home is negatively associated with elevated serum anticholinergic levels (Rover et al. 1988). Tollefson et al. (1991) conducted a blinded intervention study of nursing home patients who received more than one anticholinergic medication for more than 2 weeks. Patients were randomly assigned to an intervention (where an attempt was made to reduce anticholinergics by 25%) or nonintervention group. At the conclusion of the study, baseline and end-of-study anticholinergic levels were compared. Patients in the intervention group showed significant improvements in measures of delirium and cognition.

## ■ Epidemiology of Delirium

Epidemiological research has been difficult because of differences in study populations and the absence of clear, operationalized criteria for delirium. DSM-IV has provided suitable criteria so that cross-study comparisons are

more likely to yield meaningful results. Other methodological issues include 1) absence of reliable and valid research instruments, 2) differences in case-finding methods, and 3) comorbidity, especially with dementing illnesses. For these reasons, it is not surprising that prevalence estimates for medical inpatient units vary from 10% to 30% and incidence estimates range from 4% to 53%. Levkoff et al. (1992) reviewed five previously published studies and applied DSM-III diagnostic criteria. Using these criteria, instead of widely fluctuating incidence and prevalence estimates, the prevalence of delirium was 11%–16%, with an incidence of 4%–10% for five separate groups of medical inpatients. The Commonwealth-Harvard Study (Levkoff et al. 1992) assessed all patients over the age of 65 who were admitted over a 1-year period to the Beth Israel Hospital. Patients came either from a long-term rehabilitation center for the elderly or from a local community catchment area (East Boston). Of the 211 community-based elderly patients who were admitted, 24% satisfied criteria for delirium. Of the 114 patients admitted from the long-term care facility, 65% were delirious on admission. Data from the Epidemiological Catchment Area survey of East Baltimore found that 0.4%–1.1% of the community-based population over the age of 55 were delirious (Folstein et al. 1991).

## ■ Etiology and Risk Factors

The commonest identifiable “etiologies” include 1) intoxication syndromes, including drug toxicity resulting from polypharmacy, benzodiazepines, anticholinergics, or alcohol; 2) cerebrovascular diseases; 3) systemic metabolic disorders with known effects on brain function, for example, tumors, heart failure, and infections, especially urinary tract infections and pneumonia; and 4) withdrawal from addicting substances. Table 19–3 provides an expanded list of the commonest causes of delirium. The major risk factors for delirium include age (Schor et al. 1992; Michocki and Lamy 1988), prior brain damage (Berggren et al. 1987; Erkinjuntii et al. 1986; Francis et al. 1990; Schor et al. 1992), drug intoxication (Berggren et al. 1987; Michocki and Lamy 1988), and dementia (Erkinjuntii et al. 1986).

Among hospitalized elderly, several immediate risk factors have been identified and included into predictive models for delirium. Francis et al. (1990) found that the risk of delirium in the elderly was 60% when three or more of the following risk factors were present: hypothermia, severity of illness, dementia, fever, azotemia, and psychoactive drug use. In a separate investigation, the risk of delirium among elderly patients admitted to a medical or surgical ward was greatest among those patients who 1) had

prior cognitive impairment, 2) were older than 80 years, 3) had a fracture on admission, 4) had symptomatic infection, 5) were male, and 6) received either antipsychotic or narcotic analgesic medication (Schor et al. 1992).

Inouye et al. (1996, 1998) incorporated five independent risk factors into a predictive model for delirium. These risk factors were 1) use of physical restraints, 2) malnutrition, 3) more than three medications added while in the hospital, 4) use of bladder catheter, and 5) any iatrogenic event. In one cohort of 196 inpatients, the delirium rate was 3% in patients who had none of these risks in the 24-hour period before admission, 20% in patients with one to two risk factors, and 59% in patients with three or more risk factors. For this latter category, the delirium rate per 100 person-days was 21.3%. Table 19-4 provides a list of risk factors for delirium.

**Age and Delirium**

One of the most consistently identified risk factors for delirium is age. Potential explanations for this relation in-

clude structural brain disease, reduced capacity for homeostasis, impairments in vision and hearing, high prevalence of chronic diseases, reduced resistance to acute disease, age-related changes in pharmacokinetics, and pharmacodynamics of drug disposition. Common psychosocial precipitants of delirium in the elderly include sleep loss, sensory deprivation, sensory overload, and severe psychosocial stress (e.g., death of spouse, relocation).

**Dementia and Delirium**

One important risk factor for delirium is preexisting cognitive impairment or dementia (Erkinjuntii et al. 1986; Inouye 1998). In a study of patients with delirium admitted to a general medical service, dementia was present in 9.1% of all patients over the age of 55 and in 31% of all patients over the age of 85. Of the patients with dementia, 41% were delirious on admission. Of the delirious patients, 25% were found, on subsequent examination, to have some evidence of prior cognitive impairment. Patients with delirium have more evidence of preexisting cerebrovascular disease (e.g., lacunar infarcts, periventricular white matter disease) on brain imaging than do control subjects.

The relationship between delirium and dementia is less clear, when considering the transition from delirium to dementia. Recovery from delirium in elderly patients with dementia is much less common than that in patients with delirium without dementia. Levkoff et al. (1996) found that only 17.7% of patients with both dementia and delirium had complete resolution of symptoms of delirium at 6-month follow-up.

**Drug Toxicity:  
Focus on Anticholinergic Effects**

Drugs are a common cause of delirium. Possible reasons for this relation include 1) age-related changes in drug metabolism and disposition (see Chapters 33 and 34 in this volume), 2) polypharmacy, 3) lack of knowledge regarding drug-drug interactions of multiple medications, 4) medication errors arising from complex regimens that patients who are cognitively impaired are unable to follow, and 5) age-related decreases in neurotransmitter production and turnover. Drug toxicity is one of the commonest causes of delirium in the hospitalized elderly and one of the commonest "treatable dementias" (Larsen et al. 1985; Report of Royal College of Physicians 1984).

The cumulative effect of anticholinergic medications is one likely mechanism of drug-induced delirium in the elderly. Cholinergic neurotransmission declines with age. Many neurodegenerative diseases of brain, especially de-

**TABLE 19–4. Risk factors for delirium**

Study	Patient sample	Age range	Source	Percent delirious	Risk factors
Schor et al. 1992	291 patients not delirious on first evaluation	> 65	Medical and surgical wards	Incidence in hospital = 31.3%	Prior cognitive impairment Age > 80 Fracture on admission Symptomatic infection Male gender Neuroleptic or narcotic use
Michocki and Lamy 1988	46 orthopedic patients	Mean age = 67.5	Orthopedic inpatient unit	26%	Primary aging factors: slower thought and metabolic factors Secondary aging factors: hypoxia, ischemia, sepsis, uremia, fluid electrolyte imbalance, and anemia Tertiary aging factors: psychosocial stress Drug factors: alcohol, antidepressants, sedatives, and anticholinergics
Rogers et al. 1989	46 orthopedic patients	Mean age = 67.5	Orthopedic inpatient unit	26%	Drugs: propranolol, flurazepam, scopolamine
Berggren et al. 1987	57 patients with femoral neck fracture	> 64 years	Orthopedic inpatients	44%	History of mental confusion History of anticholinergic drug use
Erkinjuntii et al. 1986	2,000 consecutive patients	≥ 55 years	Medical inpatients	41.4% of patients with dementia 12.4% of patients without dementia	Early postoperative hypoxemia and dementia
Francis et al. 1990	229 elderly patients	≥ 70 years	Medical inpatients	22% overall	Predictors include abnormal sodium level, severe illness, chronic cognitive impairment; fever or hypothermia; psychoactive drug use; azotemia

mentia (most notably Alzheimer's disease), have a central cholinergic lesion that further diminishes cholinergic neurotransmission (see Chapter 24 in this volume). These cholinergic impairments are then compounded by medications. More than 600 medications have known anticholinergic effects, and these medications are disproportionately administered to elderly patients (Blazer et al. 1983; Report of Royal College of Physicians 1984; Tollefson 1991). Many commonly prescribed medications have modest anticholinergic effects. In one study, 11.60% of patients with suspected dementia had drug-related cognitive impairments. The risk of drug-induced cognitive toxicity was greatly increased in those patients receiving four to five prescription medications. This study did not in-

clude nonprescription medications (Lamy 1986).

Many commonly prescribed medications not typically associated with anticholinergic effects have modest antimuscarinic effects when measured by radioreceptor assay. Table 19–5 shows that 14 of the 25 medications most frequently prescribed for the elderly (Tune et al. 1992) have modest anticholinergic effects. Although many of these medications cannot be avoided, and by themselves usually do not pose a significant challenge to the cholinergic system, physicians must be aware of the potential cumulative effects of these medications. This problem may well be compounded when known potent anticholinergic psychotropic medications (e.g., amitriptyline, clomipramine, imipramine, and doxepin) are added.

**TABLE 19–5. Anticholinergic drug levels in 25 medications ranked by the frequency of their prescription for elderly patients**

Medication <sup>a</sup>	Anticholinergic drug level (ng/mL of atropine equivalents)

## ■ Detection

The Mini-Mental State Examination (MMSE) (Figure 19–1) is useful in detecting the presence and global severity of cognitive impairments. Although not specifically created to distinguish delirium from dementia, the full MMSE contains a clinical assessment of the patient's level of consciousness. Although this measure may seem a bit simplistic, it serves to identify alterations in level of consciousness. The MMSE is sensitive (87%) and specific (82%) com-

pared with a clinical diagnosis of delirium (Anthony et al. 1982). Thus, the MMSE can be of considerable value in primary care in both the inpatient and outpatient setting. The major caveats are the false-positive ratio for detection of significant cognitive impairment—39%—largely a result of patient-related variables (e.g., low educational status, impaired vision, impaired hearing).

MMSE items most likely to be missed by the patient with delirium are calculation, orientation (especially to time), and three-item recall at 5 minutes. Naming and registration are relatively preserved, even in patients with delirium who are severely impaired. This preservation of naming and registration may partially explain why delirium is often undetected in a routine clinician examination.

Numerous other screening methods are available for detecting delirium. One of the simplest instruments is the Confusion Assessment Method (CAM) (Inouye et al. 1990) (Table 19–6). This scale incorporates the nine operationalized criteria from DSM-III-R into a reliable rating instrument that can be quickly administered by incorporating the elements of the CAM into a routine clinical examination. The CAM has a sensitivity of 94%–100%, a specificity of 90%–95%, and a positive predictive accuracy of 91%–94% for the clinical diagnosis of delirium.

## ■ Management

Few systematic studies of the management of delirium have been undertaken. The following recommendations are based largely on collective clinical experience. The first step is the identification of underlying medical condition(s). At times, the etiology is unclear either because it cannot be identified or, more commonly, because multiple etiologies have been identified. It is important to provide an appropriate, supportive environment (Table 19–7).

Because the patient with delirium has a primary disturbance in attention and concentration, professional and family visits should usually be short but frequent. Reassurance and reorientation are often helpful and will likely be required on a frequent basis throughout the day. One goal is to not tax the patient needlessly. Care should be taken to avoid approaches that distress the patient. For example, some patients are comforted by the explanation that they are encountering side effects from their medications or are confused because of their infection. Others are distressed by this news. It is important to observe the patient's response to this type of conversation. If the patient is visibly distressed, then further discussion should be avoided.

Moving the patient out of stressful environments (e.g., the intensive care unit) as soon as medically safe may prove

helpful. Having a limited number of family or friends (who have been properly appraised of the circumstances) at hand to reassure and reorient the patient may prove beneficial. Psychiatric consultation is often helpful to provide behavioral management recommendations and to serve as a liaison to staff and family. Many patients with delirium do better in psychiatric environments rather than in a typical medical unit. The general medical management of the patient with delirium includes prevention and/or management of fluid and electrolyte disturbances, aspiration, decubitus ulcers, nutritional status, and other less common medical complications of delirium.

Agitation is a serious problem in patients with delirium (see Chapter 22 in this volume). These patients are at greater risk of falls and of injury to both themselves and their caregivers (Berggren et al. 1987). Because agitation often occurs in response to psychotic symptoms (hallucinations, delusions), short-term pharmacotherapy is often necessary. Although few controlled trials of medications for management of delirium have been performed, haloperidol is the most widely used and accepted medication. Typical well-tolerated doses of haloperidol are 0.5-2.0 mg intramuscularly or intravenously, repeated every 30 minutes to 1 hour as needed to suppress the agitated

**TABLE 19–6. Confusion Assessment Method**

- (1) Acute onset and fluctuating course  
Is there evidence of an acute change in mental status from the patient's baseline?  
AND  
Did this behavior fluctuate during the past day, that is, tend to come and go or increase and decrease in severity?
- (2) Inattention  
Does the patient have difficulty focusing attention, for example being easily distractible, or having difficulty keeping track of what was being said?
- (3) Disorganized thinking  
Is the patient's speech disorganized or incoherent, such as rambling or irrelevant conversation, unclear or illogical flow of ideas, or unpredictable switching from subject to subject?
- (4) Altered level of consciousness  
Overall, how would you rate this patient's level of consciousness?
- Alert (normal)  
Vigilant (hyperalert)  
Lethargic (drowsy, easily aroused)  
Stuporous (difficult to arouse)  
Comatose (unarousable)

The diagnosis of delirium requires the presence/abnormal rating for criteria: (1), (2), and either (3) or (4).

behavior. Side effects include drug-induced parkinsonian symptoms. Of concern is akathisia and motor restlessness, which can easily be confused with agitation. A few recent investigations have used atypical antipsychotic medications, such as risperidone, successfully (Sipahimalani et al. 1997). One advantage to these antipsychotics is their favorable side-effect profile. An alternative to antipsychotics is the addition of a short- or intermediate- acting benzodiazepine. Lorazepam 0.5–1.0 mg intravenously, repeated hourly as necessary, has been shown to be effective in the management of agitated delirium.

## Summary

Delirium is a common, often unrecognized clinical syndrome characterized by potentially reversible disturbances in attention and other aspects of cognition. The clinical examination is the mainstay of diagnosis, though several screening instruments (e.g., MMSE, CAM) have made the

**TABLE 19–7. Management of delirium**

- A. Pharmacological interventions and physical restraints
1. Avoid physical restraints if possible. Evaluate their need daily. Consider alternatives, including the use of sitters and family members to calm the patient.
  2. Use lowest possible doses of neuroleptics and/or benzodiazepines.
  3. Reassess need for these interventions *at least* daily. The goal is to discontinue neuroleptics as soon as possible.
  4. When patients are administered neuroleptics, carefully monitor and document the patient's neurological status for presence of extrapyramidal side effects.
- B. Psychosocial aspects (providing a predictable, orienting environment)
1. The room should be adequately lit, including the use of night lights in the evening, to decrease illusions.
  2. Avoid excessive stimulation. Keep exposure to chaotic environments (e.g., intensive care units) to a minimum because many delirious patients are hyperresponsive to stimuli.
  3. The room should have a large calendar and clock.
  4. The staff and family should make an effort to remind the patient of the day and date *frequently*.
  5. If possible, familiar items from home should be brought in.
  6. If clinical state allows, provide eyeglasses and hearing aids to patients who had them before the illness.
  7. Encourage *frequent* interactions with staff and family.
  8. Consider telling the patient he or she is confused and disoriented.

process easier. The neurobiology of delirium may include specific alterations in ascending pathways as well as diffuse disturbances in glucose metabolism. The most consistent risk factors for delirium include age, prior cognitive impairment, increasing number of comorbid medical conditions, and drug toxicity.

# Contemporary Personality Psychology

Paul T. Costa, Jr., Ph.D.

Robert R. McCrae, Ph.D.

Personality may seem to be too vague and metaphysical a topic to belong in a modern textbook of neuropsychiatry, but in fact it connects squarely with that discipline on two levels. First, it has become increasingly clear in the past decade that personality traits have a biological basis. Although convincing theories of the specific neurological or neurohormonal mechanisms involved are still lacking, strong collateral evidence indicates that such mechanisms must exist. Second, personality is directly relevant to the thoughts, feelings, and behaviors of patients, caregivers, and physicians. Forms of psychopathology, medical compliance, symptom reporting, caregiver burden (Hooker et al. 1998), and the physician's bedside manner are all influenced to a substantial degree by the pervasive and enduring characteristics that define personality.

The personality of patients with neuropsychiatric disorders is often ignored in the belief that neuropsychy-

chological assessment is sufficient to understand the patient (Cahn and Gould 1996). When personality is considered, it is typically construed either in terms of personality disorders—as when the premorbid personality of an individual with late-life-onset psychosis is described as paranoid or schizoid (Pearlson and Petty 1994)—or as a catalog of traits discerned by clinical judgment (Todes and Lees 1985). In this chapter, we present a contemporary model of normal personality and discuss its relevance to geriatric neuropsychiatry.

## ■ Definition and Measurement of Personality

Although a textbook of personality theories can offer a bewildering array of definitions of its subject matter, two

---

The authors thank Jamie Berry and Jeffrey Herbst for assistance in the preparation of this chapter.

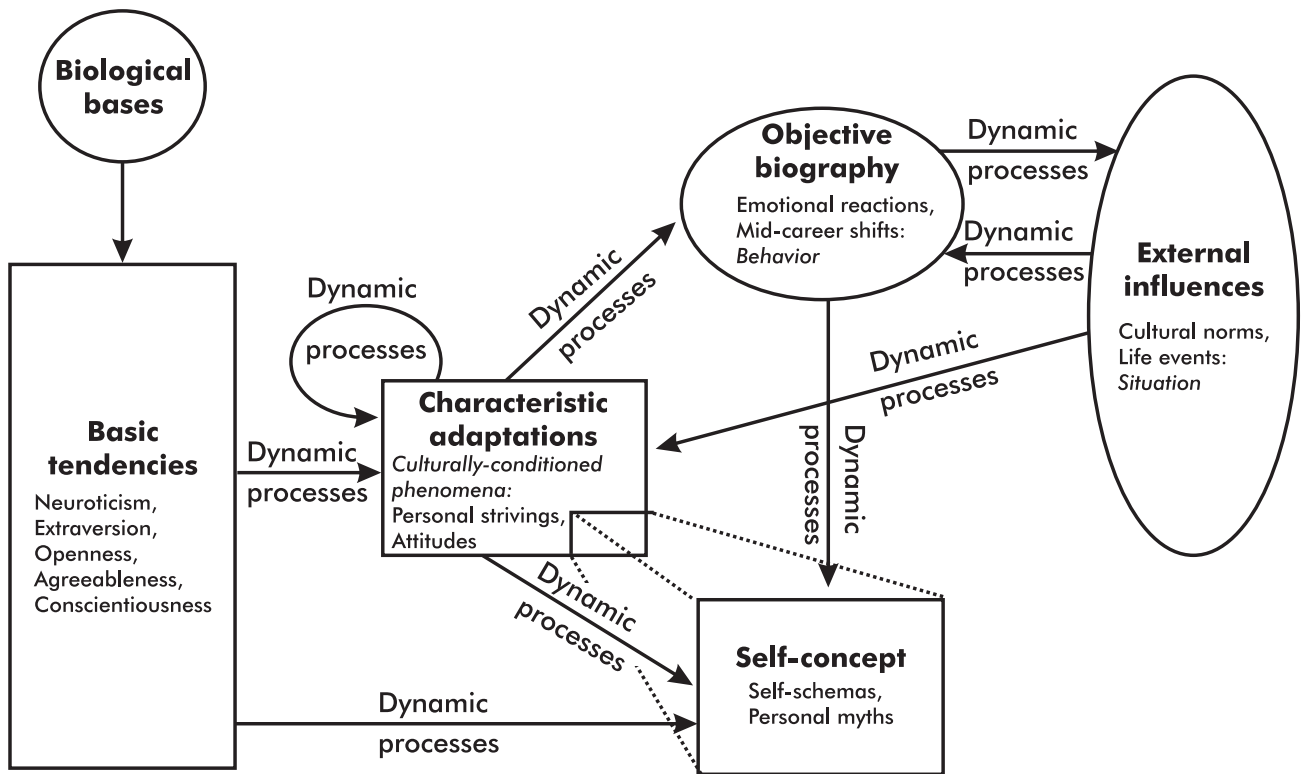

common and complementary approaches are in use. The first sees personality as a system that organizes and directs the behavior of the individual in ways that allow the satisfaction of needs and the expression of the self. Figure 20–1 provides a contemporary example of this type of model. In this view of the personality system, biologically based basic tendencies interact over time with external influences to create a repertoire of characteristic adaptations (skills, habits, attitudes, preferences, roles, relationships, and so on). These adaptations in turn interact with the immediate situation to determine what the individual does and experiences at a particular moment (McCrae and Costa 1996).

Some such model of the personality system is required to understand how human beings function. For example, Figure 20–1 calls attention to the biological bases of personality dispositions, consistent with a wealth of literature on the heritability of most personality traits (Loehlin 1992; Riemann et al. 1997). But the system approach is limited as a definition of personality because—with the possible exception of patients with severe psychosis or dementia—it applies equally to everyone. The second approach commonly used to define personality calls attention to individual differences.

From the perspective of individual differences, personality refers to the psychological features that confer both individuality and identity. Among the most important of these features are *personality traits*, defined as pervasive and enduring styles of thinking, feeling, and acting. Because they reflect something intrinsic to the person, these traits are manifested in a wide range of situations; because they form a core part of one’s identity (McCrae and Costa 1988), they must endure over substantial periods of time. Personality traits are thus to be distinguished from situationally bound habits and relationships and from transient moods and motives, and they are located in Figure 20–1 in the category of basic tendencies.

Personality traits are ubiquitous in laypersons’ descriptions of themselves and others, and traitlike constructs have been measured by psychologists for decades. Needs, temperaments, characters, folk concepts, cognitive styles, and a variety of personality disorders have all been proposed as the basic units of personality psychology. For many years, one of the central problems in the field was that so many individual difference variables had been identified that little progress could be made in understanding any of them.

**FIGURE 20–1.** A model of the personality system, showing the major components of the system and the principal paths by which they are related.

Source. Adapted from McCrae and Costa 1996.

It was clear, however, that all these different constructs were heavily redundant: poor ego strength was akin to low psychological resiliency and to general anxiety and negative affectivity (Watson and Clark 1984). Factor analysts such as Cattell (1973) and Eysenck (1960) attempted to summarize the redundancy in terms of a few broad personality factors or dimensions. After years of research and debate, a general (if not universal) consensus has emerged that most specific traits can be understood in terms of five broad factors, usually labeled neuroticism, extraversion, openness to experience, agreeableness, and conscientiousness (Digman 1990; McCrae 1992).

These five factors were initially identified in studies based on English-language trait adjectives, but they were soon replicated in a variety of theoretically based personality questionnaires. One of the first inventories designed specifically to measure the Five-Factor Model was the NEO Personality Inventory (NEO-PI) (Costa and McCrae 1985); Table 20–1 lists the 30 facets that define the five factors and gives some indication of their scope and nature. For example, the table shows that individuals high in openness to experience have an active fantasy life, appreciate art and beauty, are keenly aware of their feelings and emotions, prefer variety and novelty, are intellectually curious, and have liberal value systems.

The Five-Factor Model has proven to be generalizable not only over a wide range of personality instruments but over many different populations. Similar factor structures are found in young and old adults, men and women, and

white and nonwhite subsamples (Costa et al. 1991). Perhaps more importantly, the structure has also been replicated in studies using translations of the revised NEO-PI (NEO-PI-R) into such languages as Portuguese, Korean, and Filipino (McCrae and Costa 1997; McCrae et al. 1998). These cross-cultural replications suggest that personality traits are a specieswide characteristic. Finally, recent studies (Bagby et al., in press; Yang et al., in press) have reported the same structure in psychiatric samples as that found in psychiatrically healthy samples.

Personality trait assessment has been the topic of extensive research for decades. Because traits are abstract constructs that must be inferred from patterns of behavior and experience, no single method or instrument is perfect, but several approaches yield reasonably accurate assessments. Most common are self-report questionnaires or checklists (e.g., Costa and McCrae 1992; Trapnell and Wiggins 1990) that ask respondents to describe their own interests, behaviors, and feelings. More familiar to psychiatrists are structured interviews (Trull and Widiger 1997), in which self-reports are elicited and evaluated by a trained professional. Informant ratings have also been shown to be valid alternatives to self-reports, especially valuable in situations in which self-reports may not be trustworthy. For example, considerable research has been done on personality in patients with dementia by using ratings from spouses or caregivers (Glosser et al. 1995; Siegler et al. 1991).

## ■ Personality and Aging

Personality development from infancy through adolescence has been a major focus of personality theory and research for most of this century. From the time of Freud on, however, most psychologists assumed that personality development had ended by adulthood. Until Erikson's (1950) influential epigenetic model extended psychosocial development into old age, little attention was paid to adult personality. Erikson's stage model has received only partial support (e.g., Van de Water and McAdams 1989), but it stimulated cross-sectional and longitudinal research that has led to a clear and consistent picture of what happens to personality in the normal course of aging.

Two important and distinct questions need to be asked about personality and aging. The first concerns the preservation of individual differences; the second, stability or change in mean levels. The first question requires assessment at different points in time and is usually addressed by longitudinal studies that measure the same group of individuals on multiple occasions separated by intervals of years or decades. Questions about mean levels can also be

**TABLE 20–1. Revised NEO Personality Inventory Facet scales defining the five basic personality factors**

<b>Neuroticism</b>	Actions
Anxiety	Ideas
Angry hostility	Values
Depression	<b>Agreeableness</b>
Self-consciousness	Trust
Impulsiveness	Straightforwardness
Vulnerability	Altruism
<b>Extraversion</b>	Compliance
Warmth	Modesty
Gregariousness	Tender-mindedness
Assertiveness	<b>Conscientiousness</b>
Activity	Competence
Excitement seeking	Order
Positive emotions	Dutifulness
<b>Openness to experience</b>	Achievement striving
Fantasy	Self-discipline
Aesthetics	Deliberation
Feelings	

addressed by longitudinal data, but they are often approached through cross-sectional comparisons of different age groups.

By definition, traits are enduring dispositions, so if they exist at all, they must show some stability of rank order over a period of months or years. But traits might well change across longer portions of the life span, and most researchers anticipated that life events, changes in physical health, and changing roles and responsibilities would each have profound impact on personality traits. That view is tenable during the first part of adulthood (Siegler et al. 1990); personality scores at age 30 are only moderately predictable from scores at age 18. After age 30, however, evidence shows impressive predictability and thus stability. Longitudinal studies covering periods of up to 30 years (Costa and McCrae 1992; Finn 1986) find substantial stability in rank order for traits from all five factors. Costa and McCrae (1992), for example, reported retest correlations ranging from .61 to .71 over a 24-year interval for a set of 10 traits. In the normal course of aging, extraverts at age 40 are still likely to be relatively extraverted at age 70; conscientious people remain conscientious across the adult life span.

Retest correlations, however, reflect only relative standing; they do not reflect developmental trends that may be common to an entire age group. It is entirely possible to show high retest correlations even when there are dramatic changes in mean level, and reasons have been suggested to hypothesize a number of changes in personality that might accompany aging. Popular stereotypes suggest that old age brings depression, withdrawal, rigidity, and crankiness—although popular stereotypes also suggest that it brings mellowness and wisdom. If predictable age changes in personality do exist, that fact is of considerable importance. Rival disengagement (Cumming and Henry 1961) and activity (Maddox 1963) theories of aging lead to public policy debates on how society should deal with the elderly (Neugarten 1982): should they be allowed to fade away with dignity or should they be surrounded with opportunities and incentives for social interaction?

The major finding from subsequent research is one of stability: most cross-sectional studies of adults over age 30 reported only a small age difference across long portions of the life span (Costa et al. 1986), and many longitudinal studies found no consistent evidence of change at all (Costa and McCrae 1988). Stereotypes about depression, withdrawal, and rigidity are myths, applicable, if at all, only to a small percentage of the elderly.

Coupled with the findings of stability in rank order, mean level stability implies that personality traits are essentially constant across the adult life span. The same range

of individual differences is thus found in older men and women as in younger men and women. Social planners—and geriatric physicians—cannot prepare for the “typical” old person; they must learn to appreciate and respond to the full range of individual differences.

Although the major lesson from studies of adult personality development is that personality changes little, more recent research has confirmed that the little it changes is predictable. Between age 18 and age 30, moderately large changes—on the order of one-half standard deviation—are found in the mean levels of all five traits. The pattern, seen in both men and women, makes considerable sense: neuroticism, extraversion, and openness decline and agreeableness and conscientiousness increase—changes that collectively might be described as an increase in psychological maturity. Further, these same trends continue, at a slow rate, after age 30.

So small are these changes that they can be detected usually only by very large samples observed across very long intervals. For example, the correlation of age with neuroticism in a national sample of individuals ages 32 to 88 was  $-.12$  (Costa et al. 1986). It would be easy to dismiss such small effects as meaningless were it not for the fact that similar trends are found in Germany, Croatia, South Korea, Portugal, and Italy (McCrae et al. 1999). Despite differences in language, culture, and recent history, the same developmental pattern appears everywhere. One interpretation of this phenomenon is that personality development is not so much the result of life experience as it is an intrinsic maturational process common to the species.

## ■ Normal and Abnormal Personality

Neuropsychiatrists are likely to be most familiar with personality in the form of DSM-IV Axis II personality disorders (American Psychiatric Association 1994). Personality disorders—including borderline, paranoid, and antisocial disorders—are marked by extreme and inflexible styles of behaving and experiencing and cause personal distress or social impairment. Ten specific disorders are currently cataloged in DSM-IV, along with a category for disorders “not otherwise specified.”

Personality disorders clearly represent significant clinical conditions to which neuropsychiatrists ought to attend. But for many reasons, Axis II is not an optimal system for describing personality (McCrae 1994). The selection of disorders is based on no clear rationale—indeed, several disorders have come and gone in successive editions of the DSM. Many individuals meet criteria for several personality disorder diagnoses—the problem of comorbid-

ity—whereas most people receive no Axis II diagnosis at all and can be characterized only as “normal.” Little empirical evidence exists to indicate that the defining symptoms cohere as syndromes (Livesley et al. 1989) or to substantiate the postulated categorical breaks between normal and abnormal personalities (Trull et al. 1990).

In 1989, Wiggins and Pincus proposed a radical alternative to Axis II: they hypothesized that the characteristic maladaptive styles described by personality disorders were in fact variants of the normal personality traits assessed by the Five-Factor Model. Borderline personality disorder, for example, is associated with high neuroticism; histrionic disorder with extraversion; antisocial and paranoid disorders with (low) agreeableness. That hypothesis has subsequently been supported by a number of studies using different samples and measures of the personality disorders (Ball et al. 1997; Costa and Widiger 1994).

From this perspective, personality disorders can be viewed as personality-related problems, the kinds of affective, cognitive, and interpersonal difficulties toward which different personality traits predispose people. Most people have problems and all people have personalities, so the limited applicability of Axis II diagnoses is avoided in this approach. Instead, the clinician can obtain useful insight into the strengths and weaknesses of all patients.

Normal personality traits are also relevant to a number of Axis I disorders (Widiger and Trull 1992). For example, low extraversion is associated with major depression (Bagby et al. 1995); low conscientiousness with substance abuse (Brooner et al. 1993); and high neuroticism with posttraumatic stress disorder (Hyer et al. 1994). Personality traits may predispose individuals to the development of certain forms of psychopathology or they may themselves result from neuropsychiatric disorders. In a later section, we review a body of literature on the effects of Alzheimer’s disease on personality traits.

## ■ Biological Basis of Personality

Figure 20–1 presented a model of the personality system in which both biology and the environment play prominent shaping roles, reflecting the truism that personality is the result of both nature and nurture. But Figure 20–1 differs fundamentally from most earlier conceptualizations of personality by presuming that personality traits themselves are endogenous and that the environment affects only their expression in acquired habits, tastes, attitudes, and so on. Doubtless the model oversimplifies, but it rests on a rapidly growing body of information on the biological basis of personality.

A long tradition links personality traits directly to neurophysiology. Perhaps most influential is the work of Hans Eysenck (1967), whose theories of the biological basis of neuroticism and extraversion have stimulated many programs of research. More recently, Cloninger (1988) has proposed that personality traits (or at least those related to temperament) reflect activity of the serotonergic, dopaminergic, and noradrenergic systems. Some evidence supports these claims. For example, Cloninger links dopamine to a set of traits he calls novelty seeking, and both novelty seeking (Cloninger et al. 1994) and  $D_2$  dopamine receptors (Roth and Joseph 1994) decline with age.

But the human brain is extraordinarily complex, and personality/brain associations are not readily amenable to experimental study, so it is perhaps not surprising that, at the present time, overall support for Eysenck’s and Cloninger’s theories is weak (Amelang and Ullwer 1991; Ebstein et al. 1997; Vandenberg et al. 1997). However, a wealth of evidence shows that personality is firmly rooted in biology and thus that the neurophysiological mechanisms are there to be discovered eventually.

Perhaps the most persuasive evidence comes from adoption and twin studies that have conclusively demonstrated the importance of genetic influences on all five personality factors (Bouchard 1994; Riemann et al. 1997) and on the specific traits that define them (Jang et al. 1998). By contrast, shared environmental influences (such as social class, parental role models, and religious training) appear to have little or no influence on adult personality traits, although they clearly have major effects on characteristic adaptations. In recent years, attempts have been made to identify specific genes associated with personality traits (Benjamin et al. 1996); so far, these findings have not proven to be replicable (Malhotra et al. 1996; Vandenberg et al. 1997). It seems likely that a large number of genes influence each trait, so the effects of any single gene are small and difficult to detect.

A second line of evidence for the biological basis of personality comes from cross-cultural studies. Both personality structure (McCrae and Costa 1997) and personality development (McCrae et al. 1999) appear to follow universal patterns that transcend language, culture, and history. Although such universal patterns might be attributable to shared experiences—for example, humans everywhere are aware of their own mortality—it is more plausible to see these as results of a common biology.

That argument is even stronger when comparisons are made not across cultures but across species. Research on both primates (King and Figueredo 1997) and nonprimates (Gosling and John 1998) shows that personality characteristics resembling those found in humans can be reliably

observed in other animal species. Some personality factors— notably conscientiousness—are absent or difficult to detect, but stable individual differences in aggressiveness, activity level, and shyness are easily demonstrated. Whatever their evolutionary function (if any; see Tooby and Cosmides 1990), personality traits appear to be a part of human beings' mammalian heritage.

A final source of evidence on the neurological basis of personality comes from studies of neuropsychiatric disorders. It has long been recognized that both dementia and traumatic brain injury could affect such characteristics as motivation, mood, and impulse control. However, adequate descriptions of personality changes associated with these conditions was impeded by the lack of a comprehensive model of personality to guide systematic study and by difficulties in personality assessment among impaired patients. Recent advances associated with the Five-Factor Model have resolved both these problems.

Self-report questionnaires are the mainstay of personality assessment in both normal and psychiatric samples, but the validity of such instruments in cognitively impaired individuals is questionable. Instead, most personality assessments of individuals with dementia or those who are otherwise incapacitated have relied on clinician ratings. Although these are of considerable value in describing the current functioning of the patient, they are of limited use in assessing personality changes because clinicians rarely know the premorbid status of the individual. Instead of a consequence, personality traits might be long-term predictors of the neuropsychiatric condition in question.

In the first of a series of papers, Siegler and colleagues (Siegler et al. 1991) asked caregiver informants (spouses and children) to provide personality ratings of 35 patients with memory impairment. Informants described both premorbid and current personality characteristics using the observer rating version of the original NEO-PI (a version that measured all five factors but identified specific facets for only the first three). Premorbid personality profiles showed slightly lower than average levels of openness, but otherwise, mean scores were in the normal range. By contrast, current ratings depicted patients as being high in neuroticism, especially vulnerability to stress, low in extraversion, and very low in conscientiousness. These results were clearly replicated in three other studies (Chatterjee et al. 1992; Siegler et al. 1994; Welleford et al. 1995). Results (expressed as difference between premorbid and current ratings) from all four studies are plotted in Figure 20–2.

These dramatic and remarkably consistent findings are the basis for a number of conclusions. First, they clearly demonstrate that neuropsychiatric status can have profound effects on rated personality—in clear contrast to the

general absence of effects from such physical conditions as heart disease and cancer (Costa et al. 1994). The widespread clinical belief that personality changes are among the more important signs of dementing disorders is apparently well-founded.

Next, these data point to specific traits and factors that are likely to change. At the facet level, the greatest change for patients with Alzheimer's disease is in vulnerability, an inability to deal effectively with stress. At the factor level, these patients became higher in neuroticism and lower in extraversion, but changed relatively little in openness or agreeableness. The largest changes are in conscientiousness, a factor defined by such traits as competence, order, achievement striving, and self-discipline. It is impairment in purposeful, goal-directed striving that most characterizes these individuals.

In hindsight, that finding seems intuitively reasonable because even individuals with mild dementia have difficulty in organizing and directing their lives. But the importance of conscientiousness could not have been predicted from the prior literature. Most attention has been paid to memory loss and other forms of cognitive decline, but conscientiousness is not related to cognitive ability (McCrae and Costa 1985), and neuropsychiatrists should not assume that they can infer levels of conscientiousness from cognitive tests such as measures of executive function. Closer to personality, in the PsycLIT database, of more than 4,000 articles involving Alzheimer's disease that were published between 1991 and 1997, 464 included the word "depression," but only 4 included "conscientiousness"—all from studies informed by the Five-Factor Model. One of the chief advantages of a comprehensive model of personality is that it allows systematic exploration of personality correlates, including traits that might otherwise have been overlooked.

These studies suggest that informant ratings may be useful in the assessment of personality in many neuropsychiatric conditions. Additional studies by Strauss and colleagues (Strauss and Pasupathi 1994; Strauss et al. 1993) show that retrospective ratings are consensually valid and temporally stable and that current ratings are sensitive to progression of the disease. Standardized questionnaires provide an effective way to enlist the aid of caregivers in the comprehensive assessment of the patient.

## ■ Personality in Geriatric Neuropsychiatry

The methods and findings of contemporary personality psychology are potentially useful at two levels: in research

**FIGURE 20-2.** Mean changes from premorbid to current personality ratings in four studies of patients with Alzheimer’s disease.

on the causes and consequences of neuropsychiatric disorders and in understanding and helping patients and their families. Research on personality correlates of disease is valuable for several reasons. Patterns such as those shown in Figure 20-2 may offer insights into brain/behavior relationships; for example, something about the neurohormonal and neuroanatomical changes that accompany the progression of Alzheimer’s disease profoundly affects planning and goal-directed behavior, while leaving intact the quality of interpersonal orientation (agreeableness versus antagonism) (see Chapter 24 in this volume). A comparison of patterns across many different disorders would be particularly illuminating.

Some of that research has already been conducted. Two studies (Glosser et al. 1995; Mendelsohn et al. 1995) have used similar designs to investigate Parkinson’s disease and found increased neuroticism and decreased extraversion, openness, and conscientiousness—a pattern very similar to that seen in Alzheimer’s disease. Two unpublished studies of patients with traumatic brain injury

(Costa 1996) also showed similar patterns of personality changes. It appears that diffuse brain damage, with or without cognitive impairment, leads to predictable patterns of personality change.

That information has important clinical implications as well. These changes in personality can be detected by lay observers and can provide early signs of dementing disorders. Because these changes are progressive in Alzheimer’s disease (Strauss and Pasupathi 1994), their recognition can help caregivers anticipate how the patient is likely to change over the course of the disease. Memory loss is not the only, or even necessarily the most troubling, effect of Alzheimer’s disease; loss of purposefulness and vulnerability to stress also present problems with which the caregiver may have to deal.

But information on personality can be valuable to geriatric neuropsychiatrists at a broader level because all patients have personality traits that influence their interactions with physicians (McCrae and Stone 1997). Individuals high in neuroticism are prone to exaggerate medical

complaints, whereas those who are low may minimize them. Extraverts are talkative and may more readily volunteer information about their medical condition or ask questions about treatment. Open individuals are unconventional and willing to experiment; they may prefer innovative or nontraditional medical therapies. Disagreeable people are suspicious, demanding, and frequently dissatisfied with the medical treatment they receive (Roter and Hall 1992). Conscientious people have better health habits to begin with and comply more diligently with prescribed medical regimens. Those persons who are chronically low in conscientiousness, such as those whose initial levels of conscientiousness are decreased by dementing disorders, may require extra assistance from family caregivers. For all these reasons, physicians are better equipped to understand, diagnose, and treat their patients if they appreciate the role of enduring individual differences.

# Mental Retardation

James D. Duffy, M.B., Ch.B.

Eleanore Hobbs, M.D.

Although 1%–3% of the population meet diagnostic criteria for mental retardation (MR), the physical and mental health needs of this large segment of society have remained largely unexplored. In addition, little rigorous research on the assessment and treatment of behavioral disorders in people with MR has been undertaken. Bearing these caveats in mind, and with the understanding that considerable research still needs to be done, in this chapter we attempt to provide a broad overview of the current scientific data available on the neuropsychiatry of MR, with a particular emphasis on the elderly.

## ■ Definition of Mental Retardation

Reaching a consensus on the most appropriate definition of MR remains elusive. The diagnostic approach subsumed under DSM-IV provides clear criteria based on the patient's measurable IQ (American Psychiatric Association 1994). Although this approach is concrete and therefore easy to operationalize, it fails to identify many individuals with MR who, through an enriched environmental experi-

ence or because of intellectual competence, are able to score above the cutoff IQ scores. In recognition of these limitations of the DSM-IV's "uni-dimensional" IQ-driven approach, the American Association on Mental Retardation (1992) has proposed a broader definition that is based on an assessment of functional capacity:

Mental retardation refers to substantial limitations in present functioning. It is characterized by significantly subaverage intellectual functioning, existing concurrently with related limitations in two or more of the following applicable adaptive skills areas: communication, self-care, home living, social skills, community use, self-direction, health and safety, functional academics, leisure and work. Mental retardation manifests before age 18. (American Association on Mental Retardation 1992)

The American Association on Mental Retardation approach also includes a multidimensional classification system that contains a description of the individual's status within the domains of intellectual, psychological, physical, and environmental functioning. This approach provides a broader perspective of the individual's clinical status and assists with treatment planning.

## ■ Demographics

Because of the “graying” of the postwar baby boomers and of their increasing life expectancy, the number of elderly persons with MR in the United States is growing rapidly. Current estimates suggest that 6.1%–15.7% of the population with MR in the United States is over age 55, with the greatest proportion of these older individuals residing in state institutions (Jacobson et al. 1985). Current demographic trends indicate that this rate can be expected to double in the next 30 years (National Institute on Aging 1987). The remarkable increase of individuals with MR is reflected in the statistic that between 1932 and 1976 the number of 10-year-old children who were mentally retarded who could expect to survive to age 60 increased from 28% to 46% (Balakrishnan and Wolf 1976; Dayton et al. 1932). This upward trend is most evident in people with Down’s syndrome (DS), whose life expectancy has increased from 9 years in 1929 to at least 70% surviving beyond age 30 in 1987 (Penrose 1949). As would be expected, people with mild MR are most likely to live longer than those with severe MR, a fact that dictates that the elderly population with MR is overrepresented by individuals with mild compared with those with severe MR.

Deinstitutionalization programs have resulted in an elderly person with MR being more likely to reside in the community and therefore seek services from community-based health care professionals. Unfortunately, the health care system has failed to anticipate or respond to this demographic trend, with the result that few clinicians possess the skills necessary to provide adequate medical or mental health care for patients with MR. Indeed, in most regions, including urban and suburban areas, the person with MR has difficulty even finding health care professionals willing to provide medical services. This situation is even more dire in the elderly patient with MR whose particular needs demand a composite of skills not currently taught in any professional training programs.

## ■ Normal Aging in Mental Retardation

The neurobiology of normal aging is described elsewhere in this text (see Chapter 3 in this volume). People with MR are particularly vulnerable to age-related changes in sensory and cognitive functioning. Hearing loss has been found to be common in people with DS. More than half of patients with DS develop hypothyroidism that is frequently associated with cognitive deficits that may be misinterpreted as indicating Alzheimer’s disease (AD). Although little is known about the sleep pattern of persons

with DS, they are predisposed to developing sleep apnea, which, in turn, produces cognitive and behavioral deficits that may become disabling. The association between DS and AD is discussed below.

## ■ Social Aspects

Although little is known about the social functioning of the elderly population with MR, the research studies that have been undertaken have reported similar findings. Anderson et al. (1984) examined the living arrangements of adults age 63 and older in four settings: state institutions, private facilities, foster homes, and group homes. Their major finding was that across all settings the subjects with MR had a very low level of social integration. This finding was supported by several other studies that have reported that, regardless of their community placement, elderly patients with MR are likely to be socially withdrawn (Legault 1992; Markova et al. 1992). Interestingly, the most comprehensive study of social integration by elderly patients with MR has reported that those individuals exhibiting mild “anti-social” behavior are more likely to become involved in community activities, probably because of their more assertive and socially aggressive behavior (Moss et al. 1992). The social isolation of the elderly patient with MR is likely to be compounded by the fact that almost three-quarters are physically limited and require mobility aids (e.g., wheelchairs, crutches, canes) (Parette and Vanbiervliet 1992). These findings indicate that community placement programs for elderly patients who are mentally retarded require adequate staffing and support services to ensure that these individuals are able to take advantage of social opportunities.

Although most group homes are willing and able to continue caring for their aging residents with MR, an increasing number of elderly people with MR are residing in nursing homes. Unfortunately, few of these facilities have the resources necessary to provide the most appropriate care environment for their residents with MR (also see Chapter 37 in this volume).

## ■ Clinical Assessment of the Elderly Patient With Mental Retardation

The neuropsychiatric assessment of the elderly patient with MR requires a wide range of clinical diagnostic skills. Indeed, probably no other patient population challenges the clinician with such a complex interplay of neuropsychiatric, psychological, and social factors. The clinician

repeatedly faces the challenge of diagnosing a specific DSM-IV or ICD-10 disorder in which clinical manifestations are obscured or modified by a premorbid developmental disability. Bearing in mind the complexity of achieving a valid neuropsychiatric diagnosis, a few guiding principles are helpful when evaluating any behaviorally disturbed patient with MR:

- *Individuals with MR have the same psychiatric disorders as those found in the general population.* As many as 40%–70% of individuals with MR have a diagnosable psychiatric disorder, yet their behavioral disturbances are frequently dismissed by clinicians as simply being a manifestation of the patient's premorbid developmental disability. This failure to identify a specific psychiatric disorder inevitably results in a downward spiral of ineffective behavioral strategies or inappropriate psychopharmacological interventions.
- *Whenever possible, psychiatric diagnoses should be made using DSM-IV behavioral checklists and behavioral questionnaires developed specifically for individuals with MR.* DSM checklists have been demonstrated to be more sensitive and specific than either case record reviews or clinical interviews in making a definitive psychiatric diagnosis. These behavioral checklists do, however, have the disadvantage of being skewed toward current or recent behaviors. In addition, the pathological significance of a behavior may be unclear in the case of a person with a developmental disability (Sturmev 1993). Two behavioral questionnaires, the Psychopathology Instrument for Mentally Retarded Adults (PIMRA) (Mattson et al. 1984) and the Diagnostic Assessment for the Severely Handicapped (Mattson et al. 1991), are specifically designed to identify behavioral disorders in the mentally retarded and have demonstrated adequate reliability and inter-

nal consistency. Ideally, the clinical assessment of behaviorally disturbed individuals with MR should employ one of these behavioral checklists in conjunction with a thorough clinical evaluation.

- *The clinical presentation of psychiatric disorders in the patient with MR are modified by his or her comorbid neurodevelopmental disorder.* Most people with MR possess an extremely limited repertoire of behavioral responses. Different subjective states and environmental stressors are therefore likely to produce overtly similar behavioral responses, thereby making it difficult to identify the underlying primary psychiatric disorder or the person's subjective behavioral state. The pathoplastic effects of MR and their impact on the phenomenology of psychiatric disorders have been elegantly distilled by Sovner (1986) (Table 21-1).
- *Patients with MR frequently manifest behavioral symptoms as the herald sign of an underlying physical complaint.* The limited behavioral repertoire of patients with MR dictates that they often have difficulty in localizing the source of their subjective discomfort (e.g., an ear infection can manifest as aggressive irritability). Therefore, it is important that any neuropsychiatric evaluation should include a thorough physical assessment (see Chapter 5 in this volume).
- *Individuals with MR are exquisitely sensitive to their social milieu.* When taking a psychosocial history, the clinician should carefully note all recent changes in the patient's history. Social changes that might normally be considered of little importance (e.g., change of bus route or group home routine) can have an enormous impact upon the patient with MR, who is likely to respond poorly to any change in routine. It is important that the clinician obtain a detailed psychosocial history and be cognizant of the potential significance of apparently minor stressors.

**TABLE 21-1. Pathoplastic effects of mental retardation and their clinical impact**

Factor	Definition	Clinical impact
Intellectual distortion	Concrete thinking and impaired communication skills	Inability to name and label subjective feeling state
Psychosocial masking	Impoverished social skills and life experience	Inappropriate social behavior can inhibit or modify typical behavior markers for psychopathology.
Cognitive disintegration	Stress-induced disruption of information processing	Cognitive disorganization can be difficult to distinguish from psychopathology.
Baseline exaggeration	Increase in severity of preexisting cognitive deficits and maladaptive behaviors	Atypical clinical features can dominate (increase in incontinence).

Source. Adapted from Sovner 1986.

- *The etiology of the patient's developmental disability is often an important predictor of behavioral patterns and a predictor of treatment responses.* Although few neurodevelopmental syndromes have a specific behavioral phenotype (e.g., Williams syndrome), an understanding of the patient's neurodevelopmental disorder is often helpful in developing a diagnostic formulation and treatment plan. In particular, the clinician should be alert to the consequences of seizure disorders (see below).
- *Neurodiagnostic studies have only a limited role to play in the clinical assessment of patients with MR.* Patients with MR, particularly those with more severe disability, are usually unable to tolerate the claustrophobia or inertia necessary to complete a neurodiagnostic study such as a magnetic resonance imaging study or electroencephalogram. This intolerance necessitates that these studies are usually performed under general anesthesia or conscious sedation.
- *The groups of individuals or community agencies responsible for the care of patients with MR each have their own group dynamics.* The professionals and volunteers who work with people who are mentally retarded have developed a remarkable network of competent agencies that provide outstanding care, sometimes in extremely difficult circumstances. However, each of these groups or agencies has its particular group dynamics. It is important that the clinician understand the dynamics of each patient's living situation, regarding staff and other residents. Changes in group home membership or staffing will usually result in significant stress and consequent behavioral change among other group home residents. In some circumstances, it may be appropriate for the clinician to work with several group home members or staff to identify and treat maladaptive transactional patterns.
- *Treatment decisions should be driven by a specific diagnostic hypothesis, and treatment response should be monitored with quantified behavioral outcome data.* All too often, clinicians attempt to treat behavioral disorders in patients with MR by simply targeting the most prominent symptom (e.g., aggression) rather than developing a DSM-IV–based diagnosis. This symptom-driven approach inevitably results in a series of medication trials that has only a modest chance of success. In addition to developing a solid testable diagnostic hypothesis, it is important that the clinician and community caregivers work together to develop measurable behavioral data that can be used to assess treatment response. These data are necessary if the clinician is to avoid the trap of reacting to each “cri-

sis.” For example, a single destructive act by an aggressive patient may overshadow the fact that a treatment has produced a 50% reduction in the frequency of aggressive acts.

## ■ Medical Evaluation in the Elderly Patient With Mental Retardation
