It has been estimated that 20%–40% of patients with MR who are diagnosed as having a chronic mental illness actually have one or more physical disorders that cause or exacerbate their neuropsychiatric symptoms (Ryan and Sunanda 1997) (see Chapter 31 in this volume). A recent community survey reported that people with MR who are residing in the community have no more medical problems than the general population (McDermott et al. 1997). In stark contradiction to this finding, a survey of New Jersey Medicare health care expenditures for acute care admissions for alternate years between 1983 and 1991 found that, although expenditures for the general population had actually dropped during this period, the number of admissions and length of stay for individuals with MR had increased by 56% and 42%, respectively (Walsh et al. 1997). The total hospital charges for people with MR during the period 1983–1991 rose 206%, almost twice that of the general population (Walsh et al. 1997). These statistics suggest that current health services for persons with MR are inefficient and ineffective—a situation that is likely to increase with the aging of the MR community. The increased utilization of health care services by people with MR in this study was found to be attributable to an increased number of psychiatric admissions and a significant number of “outliers” for whom appropriate community placements could not be found. In addition, elderly patients with MR were found to have unusually long medical and surgical hospitalizations. The authors concluded that these expenditure burdens could have been reduced through coordinated case management and subsequent effective discharge planning (Walsh et al. 1997). Fortunately, the fiscal inefficiencies highlighted in the New Jersey study are likely to focus increasing attention upon the needs of the MR community.

When evaluating the patient with MR, it should be borne in mind that certain syndromes predispose the individual to specific disorders (e.g., hypothyroidism with DS). Ryan et al. (1997) recently reported the results of their survey of the medical problems of 1,135 adults with MR who underwent an extensive medical evaluation (Ryan and Sunanda 1997) (Table 21–2). Conditions that were most likely to produce a behavioral disorder included epilepsy, chronic arthritic pain, hypothyroidism, and lupus. This

study highlights the importance of obtaining a thorough medical evaluation of all patients with MR and also suggests that the neuropsychiatrist may be the most appropriate physician to assume the role of primary care provider.

The neuropsychiatrist may frequently encounter elderly patients with MR in whom the etiology of their neurodevelopmental disability has not been previously ascertained. Although certain phenotypic characteristics make the identification of the disability clear (e.g., DS, Angelman syndrome), in the large majority of patients no specific syndrome can be identified. It is important, however, that the clinician be alert for those conditions that have predictable neurobehavioral sequelae (e.g., tuberous sclerosis, Angelman syndrome). The appropriate diagnostic work-up to identify the etiology of MR in a particular elderly patient is open to debate. It is our experience that a thorough history and physical examination provide an adequate screen for those conditions that may warrant specific therapeutic or diagnostic interventions (e.g., hydrocephalus). Although genotyping may provide information regarding inheritability, it is unlikely to provide any helpful clinical data.

## ■ Neuropsychiatric Disorders in the Elderly Patient With Mental Retardation

The research literature on the prevalence of neuropsychiatric disorders in the elderly with MR remains extremely

**TABLE 21-2. Most common medical conditions seen in a cohort of adults with mental retardation referred for psychiatric evaluation**

Condition	Percentage of cases
Epilepsy	45.8%
Hypothyroidism	12.7%
Gastroesophageal reflux	9.7%
Chronic pain	6.3%
Abnormal electroencephalogram	5.4%
Autoimmune arthritis	5.0%
Hypertension	4.7%
Scoliosis	4.1%
Peptic ulcer disease	4.0%
Insulin-dependent diabetes mellitus	3.5%
Asthma	3.0%

sparse. In addition, what data are available are confounded by the fact that researchers have studied different patient samples (e.g., community dwellers versus institutionalized subjects) and employed varying and usually imprecise diagnostic methods (e.g., retrospective chart reviews versus diagnostic interviews) and outcome measures. Using a clinical diagnostic interview, Day (1987) reported that approximately one-fifth of 99 patients with MR over age 55 were experiencing a psychiatric disorder. Based on an interview of patient caretakers, Lund (1985) reported that 30% of a random sample of 302 adults with MR met DSM-III criteria (American Psychiatric Association 1980) for a psychiatric disorder. A more recent report (Crews 1994), based on a diagnostic interview of 124 institutionalized patients with MR between the ages of 60 and 94, reported that 12.9% had a dementing illness, 8.9% an affective disorder, and 6.5% schizophrenia (all according to DSM-III-R criteria [American Psychiatric Association 1987]). As might be expected, the prevalence of neuropsychiatric disorders is higher in the elderly population with MR. Cooper (1997a, 1997b) has reported that the psychiatric morbidity among elderly patients with MR is 68.7% compared with 47.9% in younger control subjects with MR. In particular, the prevalence rate for depression (6% versus 4.1%), anxiety disorders (9.0% versus 5.5%), and dementia (21.6% versus 2.7%) is higher in the elderly population with MR (Cooper 1997b).

Myriad factors appear to be responsible for the increase in psychiatric disorders among the elderly with MR. The limited cognitive reserve of the patient with MR makes him or her particularly vulnerable to manifesting the clinical sequelae of dementia, which in turn is more likely to manifest itself in behavioral rather than cognitive symptoms (see discussion below). Furthermore, underlying neurological dysfunction linked to the patient's developmental delay can also produce progressive functional decline; for example, the consequences of repeated seizures and anticonvulsant medication. Unfortunately, as a consequence of self-injurious behavior (SIB) or assault, many patients with MR experience repeated minor neurotrauma throughout their lives—producing a cumulative decline in cognitive capacity (see Chapter 28 in this volume). In addition to physical burden, factors such as social stigmatization, isolation, loss of loved ones and unstable support systems are all likely to place an increasing psychosocial burden upon the elderly person with MR and increase his or her vulnerability to psychiatric illness.

## Depression

Adults with DS appear to be more susceptible to depression and dementia, but less susceptible to other psychiatric dis-

orders, compared with the general population of individuals with MR (Collacott et al. 1992). Although depression may be causally related to hypothyroidism, this association has not been established in patients with DS (Collacott et al. 1992). In addition, although the stereotypic characterization of people with DS as happy, loving, and outgoing may be exaggerated, they do appear to manifest a lower incidence of conduct disorders, psychosis, and aggression than other people with MR (Collacott 1992).

Research on the prevalence and clinical characteristics of depression in adults with MR has been largely neglected, and what studies have been undertaken have produced conflicting results. Factors that have led to this confusion include 1) the belief that individuals with impaired intelligence and an immature ego-defense are incapable of becoming depressed, 2) the inability of many patients with MR to provide a subjective report of their depression, and 3) the unusual clinical features of depression in individuals who are severely retarded.

The symptoms of depression in adults with MR are likely to differ from those of the general population. In particular, the person with MR who is depressed is less likely to report subjective feelings of sadness, hopelessness, and guilt and is more likely to manifest external behavioral manifestations such as irritability, aggression, SIB, and declining function (Charlot 1997). This differential in clinical symptomatology is further emphasized in people with more severe degrees of intellectual handicap who are statistically more likely (than those who are mildly retarded) to exhibit SIB, screaming, stereotypy, incontinence, and vomiting. Although no data are available, patients with MR who are experiencing the additional burden of age-related cognitive deficits or a neurodegenerative disorder are also more likely to exhibit these atypical features of depression.

Sovner (1986) has recommended behavioral criteria for the diagnosis of depression in subjects with MR. Under these criteria, a diagnosis of depression is made if there is a disturbance of mood characterized by sadness, withdrawal, or agitation and any four of the following eight symptoms: 1) change in appetite or weight, 2) onset or increase in severity of SIB, 3) apathy, 4) psychomotor retardation, 5) loss of activity of daily living skills (e.g., onset of incontinence), 6) catatonic stupor or rigidity, 7) spontaneous crying, and 8) fearfulness. (In patients with a family history of depression, only three symptoms are required). Although these criteria have not been validated empirically, they do provide a useful reference point for assessing the presence of depression in the person with MR.

Contrary to commonly held beliefs, the depressed person with MR is at risk for suicidal ideation and behavior. The only systematic study in this regard reported that 30%

of the patients with depression who were mildly retarded and 8% of patients with depression who were severely retarded experienced suicidal ideation or attempts (Meins et al. 1995).

As discussed above, the atypical clinical features associated with depression in the patient with MR have made research in this area fraught with difficulties. These methodological difficulties are reflected in the conflicting results of epidemiological studies. Community studies have reported that the population with MR experiences a reduced prevalence of depression compared with that of the general population, that is, 1.7% (Lund 1985) compared with 5.4% (Corbett 1979), respectively. In the only study of the prevalence of depression in the elderly population with MR residing in the community, Cooper (1997a) has reported that they are more likely to be diagnosed as having depression than their younger counterparts (6% versus 4.1%, respectively).

Within institutions, the frequency of affective disorders has been reported as between 1.2% (Heaton-Ward et al. 1977) and 24.4% (Duncan et al. 1936). The study with the soundest methodological design (i.e., employing a psychiatric interview and DSM-III-R criteria) reported a prevalence of 8.4% for affective disorders in adults with MR who were residing in institutions (Sansom et al. 1994).

Although a number of case reports have described the efficacy of antidepressants in treating depression in individuals with MR, no controlled studies have addressed this question (Davis et al. 1997; Rummans et al. 1999). In a recent review of the research literature, Mikkelsen et al. (1997) reached the following generalizations about the use of antidepressants in patients with MR: 1) patients with MR experience a positive response and adverse side effects at lower doses than are typically demonstrated in the general population, 2) adverse behavioral responses to antidepressants occur in 5%–20% of subjects, 3) hallucinations and delusional thought content are related to either an adverse response or no response to antidepressant medication, and 4) serotonergic agents appear to be better tolerated and more effective antidepressants than noradrenergic medication (Mikkelsen et al. 1997).

The phenomenology and demographic characteristics of bipolar affective disorder in the elderly with MR remain unexplored. The limited data available suggest only that patients with MR and bipolar disorder are less likely to respond to lithium than to anticonvulsant mood stabilizers.

A small literature of uncontrolled clinical reports (and our clinical experience) also suggest that electroconvulsive therapy may be an effective and well-tolerated treatment for mood disorders in patients with MR (Krystal and Coffey 1997). Electroconvulsive therapy may also be effective

tive for self-injurious and other aggressive behaviors (see below) when they occur secondary to a mood disorder in patients with MR.

## Anxiety Disorders

Estimates of the prevalence of anxiety disorders within the population with MR vary between 1% and 25% (Benson et al. 1985; Eaton and Menolascino 1982). This wide variance in estimated prevalence reflects the difficulty in assessing both the subjective and objective clinical features of anxiety disorders in patients with MR.

Generalized anxiety disorder in persons with MR typically presents as an increase in maladaptive and oppositional behaviors, increased somatization, nausea, shortness of breath, and fatigue and can become the impetus for a downward spiral in social functioning (Khreim and Mikkelsen 1997). Clinically, it is helpful to remember that the person with MR is likely to experience fears similar to those of children at a similar developmental stage (Duff et al. 1981; Vandenberg 1993). Behavioral therapy remains the mainstay of treatment for generalized anxiety disorder, and although several psychotropic agents including buspirone and clonazepam have received anecdotal support (Khreim and Mikkelsen 1997; Ratey et al. 1989), no controlled studies have addressed the issue of drug therapy for general anxiety disorders in people with MR (see Chapter 15 in this volume).

Because in most cases it is not possible to assess the presence of cognitive obsessions, the diagnosis of obsessive-compulsive disorder in the patient with MR relies primarily upon the observation of compulsive ritualistic behavior. Distinguishing compulsive rituals from stereotypic motor behaviors, perseveration, and stimulus-bound responses presents the clinician with a formidable challenge. Furthermore, virtually every person with MR feels most comfortable in a well-structured routine, and the anxiety they experience when their schedule is disrupted may be misinterpreted as indicating compulsive behavior. Case studies have reported that clomipramine and sertraline are effective treatments for obsessive-compulsive disorder in patients with MR (Barak et al. 1995).

Although specific phobias are thought to occur more commonly among individuals with MR, the incidence of this disorder in this population remains unknown (Vitiello and Behar 1992). The authors' experience suggests that school and workplace phobias, social phobia, and specific phobias produce significant psychiatric morbidity in the patient with MR and result in a downward spiral of oppositional behavior, somatization, and diminishing functional status. Specific phobias, agoraphobia in particu-

lar, are likely to be prevalent among the elderly population with MR who tend to have limited social interactions or are likely to be intimidated by younger, more aggressive residents in institutional settings. Panic disorder should of course be considered as an historical antecedent to the development of any specific phobia.

The physical and emotional vulnerability and limited cognitive coping capacity of the person with MR, as well as the difficult and sometimes abusive environments they have encountered in institutional and community settings, would suggest that they are at extreme risk for developing posttraumatic stress disorder (PTSD). The prevalence of PTSD within the MR community remains unknown, despite the predictable susceptibility to PTSD of persons with MR. As with other psychiatric disorders, the pathologic effects of MR upon the clinical manifestations of PTSD render the diagnosis extremely difficult to make. However, a close review of the clinical cornerstones of the disorder, that is, hyperarousal, intrusive memories, flashbacks, reenactments, and interpersonal irritability, will assist in distinguishing the disorder from other causes of aggression (Ryan 1994, 1996).

## Dementia

The identification of dementing illness in individuals with MR presents the clinician and researcher with major challenges. Although attempts are under way to establish standard assessment and diagnostic criteria, currently no gold standard exists for the diagnosis of dementia in the person with MR (Aylward et al., in press).

The increasing life span of people with MR dictates that they will experience an increasing incidence of dementia. A recent study (Holland et al. 1998) of all elderly (i.e., > 65 years) residents of Leicestershire, United Kingdom, who were mentally retarded reported a dementia prevalence of 21.6% (against an expected prevalence of 5.7% in the general population). The prevalence of dementia was found to increase with advancing age. Because this cohort contained few patients with DS, other reasons for the increased prevalence of dementia need to be identified, that is, decreased cognitive reserve, progressive neurological disorders (e.g., hydrocephalus, seizures), acquired neurotrauma, and medication effects.

Patients with MR who have a comorbid dementing process are likely to present to clinicians with a decline in functional capacity or with behavioral symptoms (Cooper 1997a). Psychotic symptoms with persecutory content are the most common neuropsychiatric symptoms in dementia associated with MR and occur in 27.6% of patients (Cooper 1997a). In addition, the patient with MR and dementia is

likely to exhibit or experience disrupted sleep, irritability, social withdrawal, aggression, and weight loss (Ballard and Oyeboode 1995; Moss and Patel 1995).

The linkage between DS and AD is well established. Several studies have reported that AD-like neuropathological changes occur in virtually all subjects with DS over age 30. The earliest changes of AD (i.e., cerebral amyloid deposition) appear to begin as early as age 10 (Mann and Esiri 1989). The prevalence of AD in patients with DS has been reported at 3.4%, 10.3%, and 40% in the 30–39, 40–49, and 50–59 age groups, respectively (Holland et al. 1998). The association between AD and DS is further strengthened by the finding of an increased risk of AD among the relatives of individuals with DS (Heston et al. 1981). These findings suggested that chromosome 21 might be a possible locus for a candidate gene for familial AD—an association further supported by the identification of the gene responsible for B-amyloid production on chromosome 21 (q11-q22). Royston et al. (1994) have reported a correlation between the presence of dementia and the presence of diffuse and classic amyloid plaque formation in the temporal cortex of 21 patients with DS. These findings have led to the hypothesis that excess amyloid production or abnormalities in the processing of amyloid protein and its subsequent deposition are the critical pathology underlying the pathophysiology of AD. Abnormalities in the distribution of paired helical filament tau protein have also been postulated as an etiological factor in AD, as evidenced by one study that reported a significant reduction in tau protein in patients with DS and dementia, but not those without dementia (Mukaetova-Ladinska, in press). The connection between the apolipoprotein E genotype and AD in DS remains unclear. A recent review of published studies indicates that the risk of the individual with DS of developing AD is probably not influenced by her or his E genotype (Cooper 1998). The possible therapeutic benefits of cholinesterase inhibitors in subjects with MR with depression remains to be explored. (Also see Chapter 24 in this volume.)

### **Self-Injurious Behavior and Stereotypic Movement Disorder**

SIB in the patient with MR has a number of possible etiologies, including depression, psychosis, stereotypic movement disorder, and hyperarousal states including PTSD. In its broadest sense, SIB could be used to cover a wide range of behaviors including self-destructive acts such as smoking or risk-taking behavior. However, in the context of MR, the term SIB is most commonly used to describe the repetitive, sometimes rhythmic acts that are characteristic of ste-

reotypic movement disorder (SMD) and produce concomitant self-injury. Head banging, head hitting, eye gouging, biting, and scratching are the most common stereotypic (and self-injuring) behaviors encountered in individuals with MR. SMD occurs in more than 50% of the population with MR, and the incidence of SMD is inversely related to the subjects' degree of MR (Stein et al. 1998). The incidence of SIB and SMD appears significantly lower in older compared with younger subjects with MR (Stein et al. 1998). Several neurodevelopmental disorders, including autism, pervasive developmental disability, Lesch-Nyhan syndrome, Cornelia de Lange syndrome, and Prader-Willi syndrome, are characterized by SMD.

A number of theories have been developed to understand the functional utility of SMD. Psychological constructs posit that the rhythmic movements represent the individual's attempt to reenact an idealized nurturing relationship with the mother. One behavioral model of SMD suggests that, through their ability to modulate arousal, the behaviors are reinforcing and therefore self-propagating. Another behavioral model suggests that SMD represents a form of displacement behavior that the subject uses to reduce the anxiety produced in situations that engender helplessness.

Although the biochemical basis of SMD still remains to be elucidated, the abnormalities in striate dopaminergic innervation found in rhesus monkeys who have been separated from their mothers early in life have supported the hypothesis that SMD is a consequence of dopaminergic supersensitivity within these striatal systems. In support of this hypothesis, high doses of methylxanthines produce SMD in animals through an effect thought to be mediated through striatal D<sub>2</sub> receptors. Haloperidol has been shown to be effective in reducing stereotypic behaviors in cats and pigs (Willemsse 1992; von Burrell and Hurnik, 1991). The efficacy of selective serotonin reuptake inhibitors (SSRIs) and the association of SMD with conditions believed to involve dysregulation of serotonergic systems (e.g., autism, Cornelia de Lange syndrome) have provided indirect evidence that serotonergic dysregulation plays an important role in the genesis of SMD.

Two primary hypotheses have been posited to suggest a pivotal role for endogenous opiates in the genesis of SMD. The *excessive opioid hypothesis* suggests that SMD occurs as a consequence of excessive endogenous opiate release that raises the subject's pain threshold (Hermann et al. 1989). The alternate hypothesis, *opiate addiction hypothesis*, suggests that SMD elicits self-reinforcing opiate release and subsequent dependence upon the reinforcing motor trigger (Cataldo and Harris 1982). In support of these opiate hypotheses, increased plasma enkephalin levels have

been found in subjects with MR (Sandman 1988). The results of studies on the clinical efficacy of opiate antagonists remain inconclusive, with various studies on naltrexone reporting that the drug is effective in 0%–50% of subjects with SIB (Bauermeister et al. 1993; Sandman et al. 1993). Those studies that have documented that naltrexone is effective have noted, however, that the opiate antagonist is effective in reducing the subject's SIB but not any associated SMD (Sandman et al. 1993). In addition, it is important to appreciate that many patients receiving opiate antagonists will exhibit an increase in SIB (i.e., preextinction burst) before administration of the medication reducing these behaviors.

The pharmacological management of SMD remains poorly studied and consequently somewhat controversial. Several studies have reported that typical antipsychotics exert a selective effect in inhibiting SMD without producing any significant sedation or deterioration in general function (Aman et al. 1989; Cohen et al. 1980; Heistad et al. 1979). Several other studies have reported that, although neuroleptics are effective in reducing SMD, their efficacy comes at the price of reducing the patient's overall functional capacity (Anderson et al. 1982; Campbell et al. 1982). A recent open-label study reported that risperidone was effective in reducing SIB and aggressive behavior in a small case series of 13 patients (Khan 1997). Although the clinical efficacy of other currently available atypical neuroleptics (i.e., olanzapine and quetiapine) in SMD has not been formally studied, our clinical experience indicates that olanzapine, in particular, may have significant efficacy in this regard. In our experience, the potent sedating and anticholinergic side effects of clozapine limit its use in many patients with MR.

Several studies have confirmed that the SSRIs are effective in reducing self-injurious stereotypic behaviors such as trichotillomania and nail biting (Gordon et al. 1993; Sovner 1993; Swedo et al. 1993) in patients with SIB who are autistic (McDougle et al. 1996). The serotonergic tricyclic clomipramine has been shown to be superior to desipramine (a predominantly noradrenergic reuptake inhibitor) and placebo for the treatment of SMD (Castellanos et al. 1996; Garber 1992; Lewis 1996).

One study has reported the efficacy of valproic acid in reducing SIB in 12 of 18 patients (Kastner et al. 1993). Clinical response in this study was associated with a history of seizure disorder and affective symptoms. Two small studies have reported that the  $\beta$ -blockers propranolol (dose range 90–410 mg/day) and pindolol (40 mg/day) were effective in reducing SIB in small samples of patients with MR (Luchins and Dojka 1989; Ratey and Lindem 1991).

In summary, although SMD and SIB are extremely common and disabling symptoms in patients with MR, their pharmacological treatment remains in its infancy. The development of animal models of stereotypy promise to provide new insights into the neurobiology and treatment of these disorders (Stein and Simeon 1998).

Behavioral modification techniques provide a safe and effective treatment of SMD and SIB that is unfortunately increasingly overlooked (Ammerman 1998; Keuthen and O'Sullivan 1998). Unfortunately, these behavioral approaches are often construed to involve aversive techniques that have been "outlawed" within the MR community. Research data indicate that behavioral modification techniques are effective in reducing SMD, provided the intervention is developed by a skilled behavioral analyst who is able to perform a detailed functional assessment of the particular behaviors and select appropriate behavioral interventions (Keuthen and O'Sullivan 1998). These programs are expensive to implement, however, and require the cooperation of the patient's entire social milieu.

## Aggression

Aggression toward others and destruction of property is extremely common among people with MR and has been reported to occur in 30% of the residents of public facilities and in 16% of community facilities (Hill and Bruinicks 1984). Aggression is the most frequent reason why persons with MR are admitted to psychiatric facilities or are prescribed psychotropic medications. Despite the magnitude of the problem and its devastating impact on individuals and public health resources, little is known about its etiology and treatment in persons with MR. It is our clinical experience that these behaviors frequently persist or increase in late life and are the genesis of significant social morbidity among this group.

A number of studies have addressed the efficacy of psychotropic medications in reducing aggression in persons with MR. Unfortunately all of these studies share the same methodological pitfall, that is, they fail to appreciate that, rather than representing a unitary disorder, aggressive behavior in the person with MR may be the manifestation of distinct psychopathological processes. Given the heterogeneity of aggression within the population with MR, any attempt to undertake a clinical trial of any single psychotropic agent in a sample of patients with MR who are aggressive is likely to produce conflicting results.

Numerous studies have reported that neuroleptics (including thioridazine, trifluoperazine, haloperidol, chlorpromazine, and clopenthixol) are effective in reducing aggressive behavior (Bauermeister et al. 1993; Kiernan

1995; Rubin 1997). However, in virtually all studies, in addition to reducing aggressive behaviors, neuroleptics have been reported to produce a decline in the patient's functional status (Bauermeister et al. 1993). Limited case series have reported that clozapine is helpful in reducing the aggression of patients with MR who have any of a wide range of psychiatric disorders (Cohen and Underwood 1994).

Although at least 10 published studies have addressed the efficacy of lithium in aggression in MR, only two of these were methodologically sound (Bauermeister et al. 1993). All these studies have reported that lithium is effective in reducing aggressive behavior with particular susceptibility to the drug's side effects (Bauermeister et al. 1993).

Several recent reports have indicated that SSRIs may be effective for aggressive behavior—most particularly in patients with autism (Markowitz 1992; McDougle et al. 1997). Other medications that have been reported (in poorly controlled studies) to be beneficial in treating aggression in MR include propranolol, reserpine, and diazepam (Bauermeister et al. 1993).

The association between depression and aggression has been described above. Reiss et al. (1993) reported an incidence of depression of 8.9% among 528 individuals with MR who were receiving community-based services. Of particular note, 40% of subjects with depression exhibited aggressive behavior compared with 10% of nondepressed subjects. Charlot et al. (1993) reported that, within a cohort of 16 subjects with MR with depression, 75% displayed aggressive behavior and 50% displayed SIB. The aggression exhibited by these subjects with MR with depression was characterized by interpersonal irritability, dysphoria, and frequent remorse. It is interesting to note that “irritable” mood is an acceptable alternative for the DSM-IV diagnostic criteria for depression in children. Although the issue has not been scientifically assessed, one can reasonably assume that the aggression associated with depression should respond to effective antidepressant treatments.

Sociopathic behavior represents an important cause of aggressive behavior in MR. As in any other social group, people with MR who live together will develop hierarchical patterns of dominance and subordination. Changes in the social milieu, challenges to the social hierarchy, or the arrival of new members into the community will result in power struggles that frequently manifest as aggression. This predatory aggression is typically directed toward a particular individual or individuals and is purposeful, sustained, nonstereotypic, not associated with remorse, and is “cold-blooded” (i.e., there are no associated autonomic symptoms). It is important that predatory aggression be distinguished from other forms of aggression so that behavioral, rather than pharmacological, interventions can

be established. In our experience, elderly patients with MR are typically the victims, rather than the perpetrators, of predatory aggression.

Because some patients with MR may have sustained neurotrauma, they are likely to exhibit the intermittent, stimulus-bound, short-lived, explosive aggression stemming from damage to the orbitofrontal cortex. In addition to behavioral interventions, SSRIs appear to be the treatment of choice for reducing disinhibited violence (Ranen et al. 1996). (Also see Chapter 22 in this volume.)

## Seizure Disorders

The epidemiology of seizure disorders in the elderly population with MR has not been studied. However, an extrapolation of data available in the younger population with MR suggests that seizure disorders are a significant problem that produces major behavioral and physical morbidity. Although the data remain contradictory, the overall prevalence of epilepsy in mild MR is approximately 15% and increases to at least 30% in patients with severe MR (Sillanpaa 1996). As one would expect, the prevalence of epilepsy is higher in institutionalized patients and in those with cerebral palsy or specific congenital disorders associated with seizures (e.g., Angelman syndrome, West's syndrome, tuberous sclerosis). As many as 75% of patients with DS and comorbid AD experience seizures (Collacott 1993). Recurrent partial and generalized seizures occur in 25% of patients with fragile X syndrome, many of whom live into old age (Forsgren et al. 1990).

Attempts to classify seizures in the patient with MR according to the classification system of the International League Against Epilepsy are fraught with difficulties. Mariani et al. (1993) reported that they were able to specifically classify the seizure type of only 28% of their sample of patients with MR. Convulsive status epilepticus appears to be more common in this patient population, with one study reporting an incidence of 18.7%. The differential diagnosis of paroxysmal alteration in consciousness is outlined in Table 21–3.

Pseudoseizures appear to be more common in patients with MR with or without epilepsy, and making the diagnosis presents the clinician with a formidable challenge. Although some clinical characteristics aid in distinguishing pseudoseizures from epilepsy (e.g., duration > 3 minutes, gradual termination, absence of cyanosis, whole-body rigidity, pelvic thrusting, absence of a postictal confusion), a definitive diagnosis of pseudoseizures is usually difficult to reach. In particular, temporo-limbic or frontal partial seizures can mimic pseudoseizures and can be difficult to diagnose even with videotelemetry, prolactin assays, and depth electrode studies.

**TABLE 21-3. Differential diagnosis of nonepileptic “spells” in mental retardation****Cerebral hypoxia**

 Posttraumatic stress disorder

**Metabolic derangements**

Hypoglycemia  
 Hypokalemia

Patients with MR who experience seizures are more likely to demonstrate behavioral problems such as aggression, emotional lability, and SIB compared with matched control subjects (Hermann 1982). The largest study in this regard reported that, of patients with MR who had seizures, “behavior disorders” occurred in 40%; “temper tantrums” in 38%; hyperkinesia in 30%; and “autism” in 15% (Corbett et al. 1975). The relationship of seizures to secondary thought, mood, and personality disorders in persons with MR has not been investigated.

The effective treatment of epilepsy in patients with MR demands a team approach that takes into account the physical and psychological antecedents and sequelae of the patient’s seizures. Caretakers should be educated to identify unusual seizure events such as staring or motor automatisms and are important allies in identifying and avoiding environmental seizure precipitants. The vulnerability of the patient with MR to the adverse effects of anticonvulsants presents the clinician with difficult pharmacological challenges. In particular, agents with sedating

side effects (e.g., phenobarbitone, phenytoin) are seldom tolerated and typically produce an unacceptable decline in functional status (Corbett et al. 1985). In addition, the patient with MR and seizures is likely to be sensitive to the ataxic side effects of anticonvulsants. A recent case series described five patients who developed unprovoked aggressive behavior after starting lamotrigine to control their seizures (Beran and Gibson 1998). Wherever possible, the clinician should attempt to employ monotherapy with an anticonvulsant known to exhibit positive psychotropic effects (e.g., carbamazepine, valproic acid, vigabatrin, gabapentin). However, despite the best efforts of the treatment team, epilepsy in the patient with MR is likely to present a formidable therapeutic challenge (also see Chapter 29 in this volume).

**Conclusion**

In this chapter, we attempt to provide a broad overview of the neuropsychiatric assessment and treatment of elderly patients with MR. Although the scientific foundations of clinical practice remain sparse, by adhering to the basic principles of a thorough clinical assessment and close monitoring, the clinician can provide effective, respectful, and safe care to a population whose needs have been overlooked for too long.

# Aggression

Constantine G. Lyketsos, M.D., M.H.S.

Human aggression is a complex topic because of uncertainties in defining the term, because of limited understanding of the underlying neuroscience, and because the environmental contributions to the development of the aggression are also not well delineated. Knowledge regarding aggression among the elderly is further limited by the relative absence of specific research in this age group. Thus, it is necessary to extrapolate knowledge from younger samples to develop a rudimentary understanding of aggression in the elderly. The reader should keep in mind that inferences drawn from the young might not always apply to the old. Nevertheless, from the existing literature, it does appear clear that aggression in the elderly is strongly associated with the presence of neuropsychiatric disorders, particularly dementia.

In this chapter, I focus on physically aggressive behavior (PAB), defined as any observable behavior that threatens to or actually inflicts harm on an individual or on an inanimate object. This definition does not require intent to harm because of the difficulty in ascertaining intent among the elderly, particularly those with dementia. Additionally,

this definition excludes other behaviors among the elderly that have been described as “agitated,” such as non-threatening verbal outbursts, wandering, intrusiveness, uncooperativeness, or other aberrant motor behaviors (see Chapter 24 in this volume). In this chapter, I do not discuss aggression directed against the elderly. Although an important public health problem, aggression directed at the elderly is usually perpetrated by younger persons, placing it beyond the scope of this chapter.

The impact of PAB on elderly patients and those around them should immediately be apparent. Physically aggressive elderly patients are at greater risk of harming themselves and others. Additionally, they are much more likely to be restrained, treated with medications, hospitalized, or placed in an institutional setting such as a nursing home (see Chapter 37 in this volume). Similarly, the care of physically aggressive elderly patients is much more labor intensive for direct care providers, whether family or professional, and for clinicians and psychiatrists. Thus, physically aggressive behavior in the elderly represents a serious clinical problem.

---

Supported in part by National Institute of Mental Health Grant 1R01-MH56511 and by the Copper Ridge Institute. The author is grateful to Cynthia Steele, R.N., M.P.H., for her comments and to Betty Burgeois for preparing this chapter for publication.

In this chapter, I begin with a consideration of the epidemiology of PAB in the elderly as well as its risk factors. A discussion follows of the etiology of PAB by applying the epidemiological causal model of *host, agent, environment*. A segment on the evaluation and differential diagnosis of aggression in the elderly is next, and then I conclude with a review of management approaches for aggression in the elderly. Every effort is made to base the content of this chapter on the empirical literature. Where there are limitations in the available evidence, the discussion is based on the aggression literature in nonelderly populations and on my clinical experience.

## ■ Epidemiology

Direct estimates of the prevalence and incidence of PAB among the elderly are not available, and essentially no literature exists on incidence. The general population prevalence is probably approximately 10–20 cases per 1,000 elderly people. This indirect estimate is derived from the prevalence of aggression among a random sample of community-residing elderly persons with dementia in the United Kingdom (Burns et al. 1990). Another indirect estimate comes from the Cabe County Study of Memory in Aging. In that study, 1,002 elderly residents underwent comprehensive neuropsychiatric evaluations and were also rated on the Cummings Neuropsychiatric Inventory. Those without dementia had a prevalence of “agitation-aggression” of 3% (19/672), and those with dementia had a prevalence of 24% (78/330) (Lyketsos et al., unpublished observations, 1999).

Prevalence data from clinical settings are much more widely available. Almost all are from studies of individuals who have cognitive impairment. Most studies reviewed involve small samples ( $N < 100$ ), although a few included a sample size of several hundred.

From community-residing samples, typically of patients who attend geriatric, geropsychiatric, or dementia clinics, it is estimated that 10%–15% of elderly had been physically aggressive in the past month, and that 15%–30% had been physically aggressive in the past year (Aarsland et al. 1996; Deutsch et al. 1991; Eastley et al. 1997; Gibbons et al. 1997; Gilley et al. 1997; Hamel et al. 1990; Malone et al. 1993; Mendez et al. 1990; Paveza et al. 1992; Ryden 1988; Shah 1993; Swearer et al. 1988; Tsai et al. 1996). Some estimates suggest that as many as 50%–60% of elderly patients had been aggressive in the past year (Patel and Hope 1993; Ryden 1988). In our study of community-residing outpatients with dementia, by using a strict definition of physically aggressive behavior we

found that 15% of patients had been aggressive in the past 2 weeks (Lyketsos et al. 1999a).

Samples from nursing homes indicate a somewhat higher prevalence of PAB among elderly patients, with estimates ranging from a low of 23% (Zimmer et al. 1984) to a high of 91% for all types of aggressive behavior (Winger et al. 1987) (see Chapter 37 in this volume). The most consistent estimates suggest that PAB is exhibited by 40%–48% of nursing home residents over a year’s time (Chandler and Chandler 1988; Rovner et al. 1986).

Hospital samples from geropsychiatric units indicate that between 20% (Burns et al. 1990) and 47% of elderly are physically aggressive (Rabins et al. 1982). Thus, although physical aggression is uncommon in the community, it is a frequent problem in specific clinical samples.

Studies of the characteristics of PAB among elderly persons have also been reported. In most of these studies, it is unclear what proportion suffered from dementia and what proportion did not. However, it is likely that most elderly in these samples had dementia because these were studies from clinical settings, such as nursing homes or geriatric psychiatry clinics, where the prevalence of dementia is high.

Physical aggression among the elderly usually takes the form of pushing, shoving, kicking, pinching, or hitting (Cohen-Mansfield and Billing 1986; Patel and Hope 1993). Less frequent are biting, scratching, and destroying property (Cohen-Mansfield and Billing 1986; Patel and Hope 1993). Occasionally, elderly patients will trip others, hit themselves, or bang on tables and walls (Cohen-Mansfield and Billing 1986; Patel and Hope 1993). Male elderly patients will also at times exhibit what has been described as “sexually aggressive behaviors,” usually meaning grabbing the breasts of women or slapping women on the buttocks (Cohen-Mansfield and Billing 1986; Patel and Hope 1993). These physically aggressive behaviors have been found to be distinct from the other 11 “agitated” behaviors in the elderly in factor analytic and similar studies (Cohen-Mansfield and Billing 1986; Patel and Hope 1992).

Precise estimates of the frequency of individual behaviors (e.g., hitting) are rare and depend on the clinical setting. Ryden (1988) reported that, over a year’s time, 27% of elderly persons with dementia in the community exhibited threatening or physical aggression at some point: 26% pushed or shoved, 24% threw an object, 16% damaged property, 14% pinched or squeezed, and another 14% hit. Other aggressive behaviors were much less frequent. In contrast, in a nursing home study (Malone et al. 1993)—with prevalence of dementia uncertain—it was re-

ported that 57% of aggressive behaviors consisted of hitting; 17% of grabbing or throwing; 6% of kicking; 6% of punching; 5% of pushing; 5% of scratching; and 2.1% of biting.

A different study (Bridges-Parlet et al. 1994) investigated to whom the physically aggressive behaviors in a nursing home were directed. Here too, the prevalence of dementia in the sample was unknown. Eighty-two percent of PAB was directed toward nursing staff, and 18% was directed toward other nursing home residents. Fifty-four percent of PAB occurred during personal care, such as bathing, dressing, grooming, etc. Eighteen percent occurred during redirection of the patient. Only 11% had no apparent antecedent.

Evidence indicates two subgroups of elderly patients who exhibit PAB. (This distinction probably applies best to elderly with dementia.) First are the majority who engage in few or infrequent aggressive acts, usually during daily care. Second are a minority who commit repetitive and frequent aggressive acts of a wide variety, who are hard to manage, and who frequently require restraint. For example, in a prospective, 1-year study of aggressive behaviors in a nursing home, Malone et al. (1993) reported that, of a sample of 349 residents (with the proportion with dementia unknown), 47 exhibited PAB at some point during the year. Of these, 6 patients (13%) accounted for 44% of all PAB episodes, whereas the other 41 patients were aggressive fewer than two times.

We had similar findings in routine resident surveillance at Copper Ridge, a specialty residence that includes a nursing home and an assisted-living facility for 126 persons with dementia. At admission to the facility, approximately 28% of residents (of a sample of 116) had been aggressive in the past week. After admission, 9 residents (7 of them men) were responsible for 48% of aggressive acts over a year's time (M. Lavrisha, personal communication, May 1998).

With regard to the temporal characteristics of aggressive episodes among the elderly, reports from nursing home settings provide mixed results. One unreplicated study (Meyer et al. 1991) reported an increased prevalence of aggression in the winter months. Cohen-Mansfield and Billing (1986), in their studies of "agitation" in nursing home elderly, found that aggression was more likely to occur in the late afternoon and evening. In contrast, others suggest that it is more common in the daytime, especially in the morning (Meyer et al. 1991; Patel and Hope 1992). In the surveillance of PAB at Copper Ridge (both in the assisted-living and in the skilled nursing facility), no consistent variation between daytime and evening nursing shifts was found in the frequency of the patients' aggressive behaviors, although they were much less frequent on night

shifts. Also, there was no apparent variation by season or lunar cycle (M. Lavrisha, personal communication, May 1998).

Several risk factors for physical aggression in elderly patients have been described. The most consistent across studies are dementia, delirium, male gender, and the presence of psychotic symptoms (Aarsland et al. 1996; Burns and Levy 1990; Deutsch et al. 1991; Eastley et al. 1997; Gilley et al. 1997; Hamel et al. 1990; Lyketsos et al. 1999a; Malone et al. 1993; Mendez et al. 1990; Mungas 1983; Paveza et al. 1992; Ryden 1988; Shah 1993; Swearer et al. 1988; Tsai et al. 1996). Other risk factors include depression (Lyketsos et al. 1999a), greater severity of dementia (Eastley et al. 1997; Hamel et al. 1990; Ryden 1988; Swearer et al. 1988), earlier age at dementia onset (Tsai et al. 1996), wandering (Tsai et al. 1996), concurrent medical illness (Malone et al. 1993), limited space and living arrangements (Paveza et al. 1992), and sleep disorder (Tsai et al. 1996).

Several environmental risk factors for aggression among the elderly have been described. These factors relate both to the people around the patient, particularly their caregivers, as well as to the ambient environment. Environmental noise, inadequate lighting, and moving to unfamiliar places are risk factors for aggression (Silliman et al. 1988). Also, specific caregiver characteristics are important. Caregivers who are depressed or irritable might precipitate aggression among elderly patients (Tsai et al. 1996). The approach of the caregiver to the patient is also critically important. Caregivers who are demanding, intrusive, confrontational, or who rush patients through tasks that are difficult for them might also precipitate aggression (Minde et al. 1990). One study has found that nursing home caregivers who have "subtly adversarial management styles" may also precipitate aggression from elderly patients (Cooper et al. 1989).

The relationship between physical aggression and psychopathology must be underlined. Several studies have found a relationship between PAB in the elderly, particularly elderly with dementia, and symptoms of psychosis (delusions and hallucinations) or depression (reviewed by Lyketsos et al. 1999a; Patel and Hope 1993). In a study of PAB in outpatients with dementia who were residing in the community, we found that PAB was closely linked to the presence of moderate to severe depressive symptomatology and that this association remained strong after adjusting for severity of dementia, delusions, or hallucinations. Indeed, after adjusting for severity of dementia and depression, the association between aggression and delusions or hallucinations was no longer significant (Lyketsos et al. 1999a).

## ■ Etiology of Aggression in the Elderly

The expression of aggressive behavior is phylogenetically quite old. "Adaptive" aggression is present throughout the order Mammalia (Saver et al. 1995). Such adaptive aggression, which is readily observed in animals, has a variety of purposes. These purposes were classified by Moyer (Saver et al. 1995) into seven types of hostile behavior: predatory, territorial, intermale, fear-induced, maternal, irritable, and instrumental. Each of these types of aggression appears to have its own "eliciting stimulus." For example, a natural prey might elicit predatory aggression, whereas frustration, deprivation, or pain might elicit irritable aggression. Each of these aggressive subtypes is probably controlled by a distinct, albeit overlapping, neural system, which in humans is located in the more primitive aspects of the brain (Saver et al. 1995).

As the human species evolved, it developed complex regulatory mechanisms for these more basic aggressive "drives" (Saver et al. 1995). Areas of the brainstem, in particular in the pons and mesencephalon, mediate certain stereotypic movements associated with aggression, including facial expression and the autonomic aspects of aggression (Saver et al. 1995). The hypothalamus appears to be a basic regulator and suppressor of aggression (Saver et al. 1995). Specific cortical structures such as the amygdala, temporo- limbic cortex, and prefrontal cortex also appear to be higher level regulators of aggression (Saver et al. 1995). Thus, existing neuroscience proposes that aggression in humans has its origin in basic, phylogenetically old drives, each with a specific purpose and neural structure (Krakowski 1997). These drives are regulated by complex interplay of more primitive and more advanced regulating mechanisms that involve cognitive and affective components.

Several neurotransmitter systems have been found to modulate aggressive behaviors (Saver et al. 1995; Volavka 1997). The systems include serotonin, acetylcholine, dopamine, norepinephrine, and  $\gamma$ -aminobutyric acid (GABA). Serotonin is associated with reduction of aggression; serotonin brain levels are lower in persons who die of violent suicide, and serotonin metabolites in cerebrospinal fluid are decreased in violent criminal offenders (Saver et al. 1995; Volavka 1997). Serotonin agonists, such as buspirone, a relatively selective serotonin subtype 1A agonist, reduce certain types of aggression in mice (Saver et al. 1995; Volavka 1997). The effect of serotonin is most specific in types of aggression that are mediated by testosterone (Saver et al. 1995; Volavka 1997). Also, among patients with Alzheimer's disease who have come to autopsy, absence of aggression has been associated with relative sparing of serotonergic neurons (Proctor et al. 1992).

Acetylcholine is associated with increased aggression,

particularly predatory aggression. As well, cholinesterase inhibitors have led to aggressive behavior in humans, as noted in case reports (Volavka 1997).

Catecholamine systems are also associated with aggression (Saver et al. 1995; Volavka 1997). Norepinephrine, particularly when acting on the  $\alpha_2$  receptor, increases aggressive behavior. For example, patients with Alzheimer's disease who were aggressive before death have higher counts of  $\alpha_2$ -adrenergic receptors in the cerebellum at autopsy (Russo-Neustadt and Cotman 1997). Norepinephrine antagonists, such as clonidine, reduce such behavior. Adrenergic blocking agents, such as propranolol, reduce aggressive behavior in laboratory animals and in diverse patient groups exhibiting violent behaviors (Saver et al. 1995; Volavka 1997).

Dopamine antagonists also tend to reduce aggression, and dopamine agonists such as apomorphine induce aggressive fighting in rats (Saver et al. 1995; Volavka 1997). In humans with dementia, aggression is associated with relative preservation of the dopaminergic system at autopsy (Victoroff et al. 1996).

GABA is widely known to inhibit aggression in animals and humans (Saver et al. 1995; Volavka 1997). GABA antagonists can induce mouse-killing behavior in mice, and benzodiazepines, which are GABA mediators, can attenuate aggression in animals (Saver et al. 1995; Volavka 1997).

Testosterone and other androgens are important mediators of certain types of aggression in males. Multiple studies suggest that aggression is more common in males across species (Saver et al. 1995). Additionally, androgen antagonists have been associated with reductions of violent behavior across species, including in humans (Saver et al. 1995; Volavka 1997). One small study found that serum testosterone level was correlated with the likelihood of aggression in male elderly patients with dementia (Orengo et al. 1997). Case reports indicate alleviation of aggression in the elderly with dementia by antiandrogen treatment, such as with progesterone and leuprolide (Amadeo 1996; Kyomen et al. 1991; Lyketos et al. 1998).

Given this rudimentary understanding of the neuroscience and risk factors relating to aggression, and assuming that it applies to the elderly, it is useful to consider an epidemiological model of host, agent, environment as it applies to the development of aggression. Aggressive behaviors among the elderly might be considered the product of one or more perturbations in the host, agent, environment triangle. Different types of aggressive behavior might be the product of different perturbations, and different magnitudes and types of perturbation might give rise to different types of aggressive behavior.

Host factors to consider include direct damage to the

neural substrate regulating aggression (see above). This damage may involve inhibitors of aggression, although it may also involve overactivity of aggressive drives. Damage or dysfunction may come from diseases of the brain, with conditions causing dementia being the most common. Thus, Alzheimer's disease, frontotemporal degeneration (Hooten and Lyketsos 1996), and stroke with damage in amygdala temporolimbic structures, dorsolateral prefrontal cortex, hypothalamus, medulla, or mesencephalon may be most relevant here. Similarly, metabolic disturbances might disrupt brain inhibitory pathways and give rise to aggression. Therefore, elderly people who have brain damage from one of the diseases causing dementia or who have a metabolic disturbance (including delirium) from a general medical condition are more likely to exhibit PAB, as noted by the epidemiological findings.

Brain disease leading to concurrent damage in areas that exercise inhibitory control over aggression might account for the more serious cases of aggression reported in nursing homes and that are chronic and hard to treat. The occurrence of aggression at certain times of day might also be associated with effects of the circadian rhythm on the inhibitory control of aggression.

Other factors that influence a host's ability to modulate aggressive drives include the mood state or the presence of other abnormal mental states, such as delirium, delusions, and hallucinations. A low mood state, such as depression, or an irritable, expansive, or anxious mood state might make an elderly person more likely to exhibit aggression. Delirium, by impairing an elderly person's level of consciousness, might lead to fear, suspiciousness, and irritability and thus be a predisposition to PAB. Similarly, the presence of a delusion or a hallucination might make an elderly person more likely to misinterpret a stimulus or a situation that is otherwise nonthreatening.

As noted, the great majority of aggressive episodes in the elderly are associated with specific antecedent, perhaps provoking, stimuli. The stimulus or provocation plays the role of the agent in the epidemiological triangle. Several features of this stimulus might be considered, including the occurrence of a random stimulus presented to a vulnerable host. For example, hungry elderly persons with dementia might become aggressive if they smell or see food. Agnosia may also increase the likelihood of aggression as frustrated patients attempt to communicate with or assess their surroundings. Patients with aphasia who cannot understand what they are being told might become aggressive in self-defense when someone intrudes in their personal space and attempts to help them bathe or clean. This phenomenon would account for PAB episodes in patients with dementia occurring during daily and physical care. In the same way,

caregivers who approach a vulnerable patient in an inappropriate way might provoke an aggressive behavior.

Environmental features that facilitate the expression of aggressive behaviors may interfere with the host's ability to modulate aggressive behavior, may accentuate certain aspects of the stimulus, or may themselves provide an adverse stimulus to the host. Loud environments might distract a patient's attention and make it harder to inhibit an aggressive drive if the patient is hungry. An unfamiliar environment might provide a stimulus for irritable aggression. The presence of many other people in the environment, such as in a nursing home, might stimulate threat-induced aggression or territorial aggression.

In summary, the etiology of aggression in the elderly is complex and is best understood as an inappropriate display of phylogenetically old, adaptive behavior that is being inappropriately modulated. Damage to modulating systems, specific stimuli that might provoke the expression of aggression, or environments that might interfere with modulation or provide particular stimulation increase the chances of expression of PAB.

## ■ Evaluation of Aggression in an Elderly Person

The evaluation of any elderly person with aggression should attempt to *define* the areas outlined in Table 22-1 (Lyketsos et al. 1998). The first goal of evaluation is careful clinical description (define the case). The actual aggressive behavior should be noted in detail as well as its impact, such as injury to the patient and others or damage to property. The temporal characteristics and modifying variables of the behavior (e.g., apparent precipitants) should be described in detail. Other features of the case should also be understood. For example, does the patient show any evidence of cognitive decline or dementia (amnesia, agnosia, aphasia, apraxia, executive disorder)? Does the patient have evident psychiatric symptoms such as depression, anxiety, delusions, or hallucinations? Is there evidence of a medical disorder or symptom (most common are urinary tract infection, pain, constipation)? Exacerbations of preexisting medical conditions should also be considered. What medicines is the patient taking? Are they being consumed properly or could there be a possibility of undermedication or overmedication by accident or on purpose? What is the patient's personal, social, and family history?

The information necessary to describe a PAB should be collected in a standard neuropsychiatric examination as described elsewhere in this textbook (see Chapters 5 and 6 in this volume). A careful history of present illness, sub-

**TABLE 22–1. Evaluation of an elderly person with aggression**

stance use (especially alcohol), medical status, review of systems, personality, and psychiatric status should all be reviewed and updated. An examination should be conducted including general medical, neurological, cognitive, and general mental status examination directed at describing the behaviors and the associated features of the case.

The evaluation should also include laboratory and other necessary studies as part of determining potential contributing causes of the aggression. Blood tests to investigate abnormalities in electrolyte levels and liver and thyroid function should be considered. Toxicology screens or medication levels to investigate acute intoxication with substances or chronic use of substances should also be conducted. To rule out a urinary tract infection, urinalysis and urine culture with sensitivity should be considered in almost every case of aggressive behavior in an elderly person. If clinically appropriate, electrocardiography and chest X ray should also be ordered. In cases where the aggression is stereotypical and episodic, electroencephalography might be considered to rule out a seizure disorder (see Chapter 29 in this volume). If there is evidence of injury or an acute neurological event, head computed tomography or magnetic resonance imaging should be considered to investigate an intracranial cause of aggression. It is presumed that in patients with dementia who exhibit aggression a complete dementia work-up has already been conducted.

After the evaluation, the psychiatrist should *decode* the case—this is essentially a process of differential diagnosis, looking at host, agent, and environment as they relate to

the particular case. Are there important host factors that likely have made the patient vulnerable to expressing aggression by affecting her or his ability to modulate aggression? For example, is the aggressive behavior occurring independently or is it occurring in the context of coexisting brain damage, dementia, psychopathology, delirium, or an active (new or exacerbated) medical condition? Could the aggression be related to one or more medications? Is it linked to specific aspects of dementia, such as aphasia? Physical aggression that occurs in the context of other conditions (e.g., depression, pneumonia) should generally be considered as secondary to these other conditions. The implication is that removal or treatment of the host vulnerability will lead to resolution of the aggression.

Next, stimulus factors should be considered. For example, is the aggression always provoked? What are the features of the provoking stimulus? If there is no apparent stimulus, is additional observation needed to confirm the absence of a provocation? If provoked, is the provocation daily care or some other circumstance? If aggression is occurring during daily care, what exactly is the provocation: caregiver approach, specific activities, other? Does the aggression always occur with a specific caregiver (e.g., a spouse or a nursing aide)? What else in a stimulus may be contributing to the expression of aggression?

Finally, environmental factors should be considered. What is the ambient environment like at the time of the PAB? Is it too cold or hot? Too loud or quiet? Too bright or too dark? Is there inadequate stimulation to the patient by the environment? Does the aggression occur at specific times of day? Are there any other environmental patterns associated with the aggression?

At the conclusion of the decoding process, the clinician should have a good understanding of the aggressive behavior and the contributing causes to its expression from the point of view of host, stimulus, and environment. The neuropsychiatrist should also have a sense of the modifiable and unmodifiable contributors to the aggression. For example, if a contributing factor is believed to be the presence of a depressive illness, this factor may be modifiable through appropriate treatment. The same is true if the contributing factor is a delusion. However, if the contributing factor is advanced dementia, resolution of the underlying disease is more difficult.

## ■ Management of Aggressive Behavior in the Elderly

The define and decode process above typically will leave the neuropsychiatrist with an understanding of the causes

of aggression in a particular case and with a set of potentially modifiable contributing features. For example, if the patient has a mood disorder, a psychotic disorder, delusions, hallucinations, delirium, or a comorbid medical disorder, primary treatment of those conditions should be initiated first. The principle is that treatment of an underlying primary condition causing aggression should be pursued with the hope that removal of the contributing cause or concurrent removal of several contributing causes will lead to resolution of the aggression.

If the aggression is exacerbated or caused by an environmental circumstance, then steps should be taken to modify the environment. This approach is particularly relevant to patients who have dementing disorders and other brain diseases and for whom modification of brain disease is not always possible. If patients become aggressive in overstimulating, unfamiliar environments, then they should receive one-on-one support in more familiar environments that are less stimulating.

Aggression may also be provoked by factors related to the state of the patient, for example, pain, hunger, and constipation. Attention to these conditions can markedly alleviate aggressive behavior.

If the decode process reveals that the aggression is occurring exclusively in the context of daily care assistance, every effort should be made to modify the approach to the patient during daily care. An experienced clinician should first observe the provision of the care in which the aggression arises in order to study in detail the antecedents of aggression. Is it that the patient strikes out when approached from one particular direction? Does the problem occur when someone makes an effort to take off the patient's pants or to wash particular parts of his or her body? What has the caregiver tried to reduce the behavior? This approach allows the clinician to determine the stimuli and provocations that are immediately followed by aggressive behavior and to find alternative approaches to daily care not involving the aggression-provoking stimuli.

If aggression is provoked by a caregiver who is hostile or otherwise inappropriate with the patient, this caregiver should be provided with education and hands-on modeling of a proper approach to the patient. For example, if a patient with dementia asks a caregiver repetitive questions and the caregiver responds by criticizing the patient for asking these questions, thus leading to aggression, the caregiver should be taught why the patient repeats the questions and given alternative ways to respond other than being critical of the patient.

Caregivers of patients who are at risk for PAB should be instructed in various management techniques. They should be reminded that it is possible to prevent PAB by us-

ing structure and routines in the patient's day-to-day life. They should be shown how to approach patients with dementia in a nonconfrontational manner and how to communicate with patients based on what means of communication patients understand best (e.g., to use body language and not words in very aphasic patients). Caregivers should be assisted in learning how to detect when a patient is escalating toward a PAB in order to set limits and attempt a de-escalation before the expression of the PAB.

The success of a variety of nonpharmacological interventions for aggression in the elderly, such those presented above, has been investigated in the literature (Beck et al. 1994; Fritz et al. 1995; Maxfield et al. 1996; Mishima et al. 1994; Satlin et al. 1992). Most studies have supported the use of nonpharmacological interventions in managing aggression or in reducing its impact on the clinical situation. However, the interventions reported have often been unstandardized, expensive, hard to replicate, or assessed in studies without control subjects. The latter issue is important because any intervention, and even no intervention at all, has been associated with a reduction of aggression over time in 40%–50% of aggressive elderly patients, particularly those with dementia. Thus, in the absence of a control condition for intervention studies addressing aggression in the elderly, it is not clear that patients are being helped by anything more than the nonspecific common features of these interventions.

Examples of successful interventions reported from noncontrolled studies include: behavioral analysis, validation, therapy, conditioning, differential reinforcement strategies, and environmental modification (reviewed by Beck et al. 1994). The use of activity programs, stimulus enhancement techniques, relaxation, ambient light manipulation, ambient sound manipulation, and increased social interaction have also been shown in noncontrolled studies to reduce aggression among elderly patients (reviewed by Beck et al. 1994).

Maxfield et al. (1996) provided a detailed behavior analysis approach accompanied by classroom and bedside education for nurses working in a geriatric hospital. The intervention was targeted at preventing and reducing aggressive incidents during bathing and grooming. The intervention was found to impart significant new knowledge to the nursing staff on pretest and posttest assessment. Additionally, the intervention led to a 54% reduction in aggressive incidents during bathing and grooming in the units to which this was applied and a 49% reduction in the use of as-required medications to facilitate the provision of bathing and grooming.

Another study (Fritz et al. 1995) investigated the effect of exposing elderly patients with dementia to companion animals. These patients were residing in the community

and being cared for by a family caregiver. Assignment to exposure or nonexposure to animals was not randomly set by the investigators. Over the months after exposure to pets, it was noted that patients exposed to pets had significantly lower rates of aggression, approximately one-third the rates in patients not exposed to pets. Similarly, noncognitive symptoms and other behavior disturbances, including verbal aggression and anxiety, were overall lower in patients exposed to pets.

Noncontrolled studies of bright light therapy (BLT) have indicated some efficacy in reducing aggressive behaviors in patients with dementia (Mishima et al. 1994; Satlin et al. 1992). We recently conducted a study at Copper Ridge assessing the efficacy of BLT versus a control condition (staff attention with dim lights) in reducing aggressive and agitated behavior in patients with dementia (Lyketsos et al. 1999b). Patients in both the control and bright light condition had a 30%–35% reduction in scores on the Behavior Pathology in Alzheimer's Disease Scale (Reisberg et al. 1987). No statistically significant difference was found between the active and control conditions, however, suggesting no specific benefits of BLT in reducing aggression in dementia.

Given that in most cases in the elderly aggression is likely in part the result of a brain dysfunction affecting the patient's ability to modulate aggressive drives, several pharmacological interventions have been attempted and investigated.

It is important to note that, although medications are often efficacious in reducing aggression in elderly patients, this indication has been primarily based on an understanding of the putative neurochemical activity of the medications and of aggression and less so on controlled, randomized clinical trials. The antipsychotic medications (e.g., thiothixene, haloperidol, risperidone, quetiapine, olanzapine) have repeatedly been found superior to placebo in randomized, controlled clinical trials in treating "agitation" in elderly persons or in patients with dementia (Birkett 1997; Katz et al. 1999; Scheider et al. 1990).

A few clinical trials were found that have specifically investigated treatment of aggression in the elderly (reviewed by Rummans et al., in press). One of the notable findings from placebo-controlled trials to treat aggression and agitation in elderly patients, particularly in those with dementia, is that there is a high placebo response, as high as 60% in some cases (Katz et al. 1999). Thus, it is critical that medication treatments for PAB in the elderly be evaluated in rigorously designed and implemented controlled trials, typically with a placebo control.

Placebo-controlled trials of medications for aggression in the elderly have assessed several classes of medications. Most often assessed are the antipsychotic neuro-

leptic agents. Petrie et al. (1982) compared haloperidol and loxapine in the treatment, among other symptoms, of hostility and agitation in 61 elderly persons with dementia. Both antipsychotics were superior to placebo, and similar to each other, in efficacy, although they both produced sedation in study participants. In other studies using similar methods, thioridazine (Barnes et al. 1982), milenperone (DeCuyper et al. 1985), and thiothixene (Finkel et al. 1995) were reported superior to placebo in efficacy for aggression in patients with dementia.

More recent studies have reported efficacy for newer "atypical" antipsychotics for the treatment of aggression in patients with dementia. The latter studies have had several hundred participants and have been well-designed multicenter studies. In one study of the treatment of aggression in institutionalized patients with dementia (Katz et al. 1999), approximately 72% of those on risperidone, as compared with approximately 68% of those on haloperidol and 60% of patients on placebo, had 30% or greater reductions in scores on the Behavioral Pathology in Alzheimer's Disease Scale (Reisberg et al. 1987). Similar data regarding olanzapine have been reported recently as well (Street 1998).

Attention has also been paid to "mood-stabilizing" anticonvulsants as treatments for PAB in the elderly. However, only one randomized placebo-controlled study involving carbamazepine has been reported (Tariot et al. 1998). After 6 weeks of treatment for agitation and aggression, Brief Psychiatric Rating Scale scores (Overall and Gorham 1962) declined from a mean of 53 to a mean of 52 on placebo and from a mean of 55 to 47 in patients treated with carbamazepine. Overt Aggression Scale (Yudofsky et al. 1986) scores in patients treated with placebo were reduced by approximately 15% as compared with approximately 45% in patients treated with carbamazepine.

Serotonin reuptake inhibitors that elevate brain serotonin levels, antipsychotic agents providing dopamine blockade, direct serotonin agonists (buspirone), and  $\beta$ -blockers such as propranolol are useful in reducing PAB in certain elderly patients (Lyketsos et al. 1998; Steinberg and Lyketsos 1997; Yudofsky et al. 1990).

Anecdotal evidence also suggests that other anticonvulsants including divalproex sodium, gabapentin, and lamotrigine have a role to play in the management of episodic aggression in elderly people whether or not seizures are present (Lyketsos et al. 1998; Steinberg and Lyketsos 1997). The anticonvulsants appear to be most effective in patients with advanced dementia, in patients without provoking stimuli, and in patients who have other features of mood instability or evidence of mania and/or hypomania (Lyketsos et al. 1998; Steinberg and Lyketsos 1997).

Medications, such as progesterone and leuprolide, that

interfere with the actions of testosterone are also reported to be effective in reducing PAB in the elderly, particularly if sexual aggression is evident (Amadeo 1996; Kyomen et al. 1991). Combinations of medications have also been useful in this regard. Benzodiazepines, being GABA agonists, also appear effective in reducing aggression (Lyketsos et al. 1998; Steinberg and Lyketsos 1997). However, in some elderly patients, benzodiazepines may have a disinhibiting effect. That effect, coupled with their propensity for addiction, their sedating properties, and their interference with cognitive processing, make benzodiazepines less preferable. Table 22-2 provides a summary of medications useful in treating aggression in the elderly, including reasons why they might be useful and approximate doses.

Carefully designed clinical trials of benzodiazepines, antiandrogens,  $\beta$ -blockers, and other medications, such as stimulants, for PAB in elderly patients have not been conducted. Their use is primarily supported by anecdotal evidence and case reports. However, a substantial literature of noncontrolled studies (e.g., Lyketsos et al. 1998; Steinberg and Lyketsos 1997; Yudofsky et al. 1990) exists on the use of such medications for "agitation" and aggression in dementia, based on the putative ability of these medications to manipulate neurotransmitter systems associated with the modulation of aggression.

No empirical data have been published regarding the reduction of aggression presumed secondary to other psychiatric disorders in an elderly person. For example, if a patient with depression and aggression (or delusions and aggression) is successfully treated for the depression (or the delusions), does the aggression also resolve? Although most clinicians probably would agree that this is the case, no studies substantiating this could be located.

Similarly, clinical belief suggests that detection and treatment of comorbid medical disorders, particularly urinary tract infections, pain, and constipation, will lead to reductions in aggression in the majority of patients. Nevertheless, this belief too has received inadequate research support. In one study, the use of acetaminophen to treat presumed pain in aggressive elderly residents of a nursing home led to significant reductions in aggression and also to reductions in psychotropic drug use (Douzjian et al. 1998).

As reviewed, aggression in elderly persons is often multifactorial in cause and precipitants. Thus, the integration of environmental, educational, caregiver, and pharmacological interventions based on the findings of a solid evaluation as described in this chapter is often the key to effective management of aggression. An example of integrated interventions managing aggression is demonstrated in an important study by Rovner et al. (1996). In this randomized controlled clinical trial, an integrated approach

using staff education, activities programming, and careful psychotropic management led to significant reductions in aggression and in use of restraints and psychotropic agents in nursing home patients with dementia.

Currently, recommended treatment for PAB in elderly patients includes the removal of causative or precipitating factors as determined by the evaluation of the patient. Nonpharmacological interventions should be tried next. If pharmacological interventions become necessary, they should be introduced with caution, at low doses, and with slow titration followed by careful side-effect monitoring. The atypical antipsychotics, such as risperidone and olanzapine, are probably the best first-line agents, given their demonstrated efficacy and better tolerability than that of the traditional antipsychotics. These latter should then be considered as second-line treatments, followed by the anticonvulsants, selective serotonin reuptake inhibitors, other antidepressants,  $\beta$ -adrenergic blockers, antiandrogens, and the other medications mentioned in this section.

## Conclusion

Physical aggression among the elderly as a whole is relatively uncommon, but it is quite frequent in a variety of geroneuropsychiatric settings. When PAB occurs, it invariably presents a difficult management problem and can be catastrophic. Most instances of PAB in the elderly are associated with a dementing illness or another neuropsychiatric disorder. A basic understanding of the neuroscience underlying human aggression is important to appreciate the complexities of etiology and management. When confronted with elderly patients who are physically aggressive, the neuropsychiatrist must consider host, stimulus, and environmental factors that are underlying the aggression. That evaluation leads to a rational series of interventions whose goal is to modify factors that provoke or contribute to the aggression. In many instances, the aggression is then managed in an empirical fashion by using a variety of integrated behavioral, environmental, and pharmacological approaches. Much research needs to be done in the field of aggression in the elderly, given that most of our understanding of this problem is rudimentary.

**TABLE 22-2. Medications that may be useful for the treatment of aggression in the elderly**

Agent	Starting dose	Weekly titration	Peak effective dose
<b>Antidepressants</b>			
<i>Selective serotonin reuptake inhibitors</i>			
Sertraline	25 mg in A.M.	25 mg/day	175–200 mg/day
Fluoxetine	10 mg in A.M.	10 mg/day	60–80 mg/day
Paroxetine	10 mg at bedtime	10 mg/day	30–50 mg/day
<i>Tricyclics</i>			
Nortriptyline	10 mg at bedtime	10 mg/day	Blood level of 50–150 ng/dL
Desipramine	10 mg at bedtime	10 mg/day	Blood level of 150–200 ng/dL
Clomipramine	25 mg at bedtime	25–50 mg/day	Blood level of 150–200 ng/dL
<i>Other antidepressants</i>			
Venlafaxine	25 mg bid	25 mg bid	400 mg/day
Bupropion	75 mg bid	50 mg bid	40 mg/day
Trazodone	25–50 mg at bedtime	50–100 mg/day	500–600 mg/day
Nefazodone	50 mg at bedtime	50 mg bid	500 mg/day
<b>Neuroleptics</b>			
Haloperidol	0.5 mg at bedtime	0.5 mg/day	500–600 mg/day
Thioridazine	10 mg at bedtime	10 mg/day	60–80 mg/day
Risperidone	0.5 mg at bedtime	0.5 mg/day	4 mg/day
Thiothixene	1 mg at bedtime	1 mg/day	8–10 mg/day
Trifluoperazine	1 mg at bedtime	1 mg/day	8–10 mg/day
Olanzapine	2.5 mg at bedtime	2.5 mg/day	10–15 mg/day
Clozapine	12.5 mg at bedtime	12.5 mg/day	100 mg/day
<b>Other medications</b>			
<i>Anticonvulsants</i>			
Divalproex sodium	125 mg at bedtime or bid	125–250 mg/day	Blood level of 50–100 ng/dL
Carbamazepine	100 mg bid or tid	100–200 mg/day	Blood level of 6–10 ng/dL
Gabapentin	200–300 mg bid or tid	300–600 mg/day	2–3,000 mg/day
<i>Others</i>			
Lithium	150 mg bid	150 mg/day	Blood level of 0.5–0.8 mEq/dL
Amantadine	50–100 mg bid	50–100 mg bid	300 mg/day
L-dopa (with carbidopa)	100 mg tid	100–200 mg/day	750–1,000 mg/day
Propranolol	10 mg bid	10 mg bid	160 mg/day
Buspiron	10 mg bid	5–10 mg/day	60–80 mg/day
Methylphenidate	2.5 mg bid	2.5–5 mg/day	40–60 mg/day
Progesterone	10 mg/day	10 mg/day	20 mg/day
Leuprolide	2.5–5 mg im q2w	NA	10 mg im q2w

Note. bid = twice per day; im = intramuscularly; NA = not available; q2w = twice per week; tid = three times per day.

# Nondegenerative Dementing Disorders

William E. Reichman, M.D.

**D**ementia is a syndrome of acquired persistent decline in several realms of intellectual ability. Individuals display combinations of impaired memory, disturbed language, visuospatial abnormalities, and loss of cognitive abilities such as calculation, abstraction, and problem solving. In concert with these changes, patients may manifest impaired recognition (agnosia) and disturbances in motor planning and sequencing (executive functions deficits).

In addition to the intellectual impairment that characterizes dementia, alteration often occurs in the patient's behavior and mood. Neuropsychiatric symptoms such as hallucinations, delusions, anxiety, aggression, and excessively disinhibited or passive behavior commonly occur. Many patients with dementia develop sleep-wake cycle abnormalities, alterations in sexual behavior, and dietary changes. Performance in the activities of daily living such as grooming, dressing, eating, toileting, and managing household and personal affairs is universally disturbed in dementia. These clinical features of the syndrome, taken together with any concomitant neurological or medical disability, severely impede the patient's ability to fulfill important vocational, social, and familial obligations. The

emotional and financial costs associated with the care of patients with dementia have achieved staggering proportions. Dementia has become and will continue to be a major public health concern.

In this chapter, I review the nondegenerative dementing disorders with emphasis on their recognition, underlying pathophysiology, and treatment. Alzheimer's disease and frontotemporal dementia are discussed in Chapter 24 and dementia associated with movement disorders is addressed in Chapters 25 and 26 in this volume.

## ■ Nondegenerative Causes of Dementia

The nondegenerative causes of dementia in the elderly population are a heterogeneous group of conditions that include cerebrovascular disease (vascular dementia [VaD]) and other less common states such as hydrocephalus, the dementia syndrome of depression (DOD), infections of the central nervous system, neoplasms, toxic and metabolic encephalopathies, endocrinopathies, and trauma (Table 23–1). Although these individual conditions may alone cause dementia, they may also exacerbate the dementia

**TABLE 23–1. Nondegenerative dementing disorders**

resulting from degenerative diseases such as Alzheimer's disease or Parkinson's disease.

With the exception of VaD, many of the nondegenerative causes of dementia have been described as "reversible" (Cummings et al. 1980; Rabins 1981). In such cases, implementation of a specific therapy, such as thyroid hormone replacement in hypothyroidism or vitamin B<sub>12</sub> supplementation in pernicious anemia, is expected to result in restoration of intellectual function. The proportion of dementia cases that actually fulfill this criterion is unknown. The reversibility of dementia associated with such conditions has been subjected to increasing scrutiny and

challenge (Barry and Moskowitz 1988; Clarfield 1988; Larson et al. 1986). Across several studies, potentially reversible conditions compose approximately 13% of all cases of dementia (Clarfield 1988). Although substantially more research is needed to explore the validity of "reversibility" of dementia, it appears that many of the so-called reversible conditions may be more accurately referred to as "modifiable." Treatment of the underlying cause of a nondegenerative dementia may halt or slow the progression of intellectual decline but not necessarily result in complete restoration of function.

## ■ Vascular Dementia

VaD is a clinical syndrome of acquired intellectual and functional impairment resulting from the effects of cerebrovascular disease. VaD is characterized by a wide range of neurological and neuropsychological signs and symptoms reflecting the heterogeneity of responsible lesions. Different causes of VaD demonstrate variability in onset (abrupt or insidious) and course (static, remitting, or progressive) (Roman et al. 1993). Until recently, the lack of established diagnostic criteria for VaD hampered effective research into its causes, prognosis, and treatment. The application of different terms to describe dementia resulting from cerebrovascular disease such as *multi-infarct* (MID) or *arteriosclerotic dementia* has been imprecise or misleading. For example, it is now clear that neither multiple large infarctions nor arteriosclerosis is a necessary prerequisite for the development of dementia associated with vascular causes. Whereas multiple large cortical infarctions invariably cause VaD, single, strategically placed lesions; small-vessel disease including lacunar infarction; hemorrhage; and hypoperfusion may all independently cause dementia syndromes (Roman et al. 1993).

The risk factors for stroke leading to dementia are still incompletely understood. Factors such as arterial hypertension, cardiac disease, diabetes, hyperlipidemia, and smoking are noted to increase the risk for stroke. Factors that may increase the likelihood that stroke is associated with dementia include the presence of aphasia, a major dominant stroke clinical syndrome, a history of prior cerebrovascular disease, and low educational level (Pohjasvaara et al. 1998).

Importantly, the contribution of stroke to the cause of dementia in an individual patient remains a matter of clinical judgment (Hachinski 1991). In older patients, it is frequently unclear as to whether identified cerebrovascular lesions are the sole cause of dementia, are significantly contributing to the clinical features of an underlying

neurodegenerative disease (“mixed dementia”), or are neuropsychologically silent (Erkinjuntti and Sulkava 1991). In recent years, it has been noted that “pure” VaD may actually be uncommon as the sole cause of dementia (Hulette et al. 1997). Many, if not most, cases appearing as VaD may actually represent cerebrovascular disease complicating Alzheimer’s disease (mixed dementia). Diagnostic criteria for research in VaD are readily available that attempt to provide improved clarity of diagnosis and standardization of nomenclature (Roman et al. 1993) (Table 23–2).

### Epidemiology of Vascular Dementia

Historically, the lack of an accurate definition for dementia of vascular etiology has confounded attempts to reliably establish the epidemiology of the condition (Kase 1991; Mirsen and Hachinski 1988). In studies of the causes of dementia, the diagnosis may have been established by clinical criteria or neuroimaging data such as computed tomography (CT) or magnetic resonance imaging (MRI). Only a few studies have had confirmatory pathological diagnoses. In some studies, the co-occurrence of stroke and Alzheimer’s disease is described as “mixed dementia” or is not addressed. As a result, the percentage of all cases of dementia that are secondary to stroke has varied among studies from 4.5% to 39%. The frequency of VaD is generally quoted in the 12%–20% range (Kase 1991). Despite the methodological limitations of epidemiological surveys, it appears that after Alzheimer’s disease VaD is the second most common cause of dementia in Western societies (Roman 1991).

### Clinical Features of Vascular Dementia

The Ischemia Scale (IS) (Hachinski et al. 1975) and subsequent modifications (Loeb and Gandolfo 1983; Small 1985) have enumerated the clinical features of VaD in an attempt to distinguish it from Alzheimer’s disease. These general features include all or some of the following: abrupt onset, prior history of stroke, fluctuating course, focal neurological signs, focal neurological symptoms, stepwise deterioration, nocturnal confusion, relative preservation of personality, depression, somatic complaints, emotional lability, hypertension, and associated atherosclerosis. Despite a sensitivity and specificity of 70%–80% in separating VaD from Alzheimer’s disease (Chui et al. 1992), the IS is less able to reliably diagnose the co-occurrence of these two conditions in the same individual and may significantly overdiagnose VaD in patients later found to have Alzheimer’s disease (Roman et al. 1993).

### Subtypes of Vascular Dementia

As a result of improved recognition of the clinical and pathological variability produced by cerebrovascular disease, subtypes of VaD have been described (Table 23–3). These subtypes present with variable combinations of motor, sensory, and neuropsychological impairment reflecting the anatomical region disrupted. In addition to clinical features such as hemiparesis and hemisensory loss, patients may demonstrate parkinsonism, gait instability, urinary incontinence, visual field defects, hemineglect, and pseudobulbar palsy (dysarthria, dysphagia, exaggerated facial and gag reflexes, and pseudobulbar affect). Along with neuropsychological deficits such as impaired memory, language, cognition, and visuospatial ability, patients may also manifest impairment in frontal systems functions (Wolfe et al. 1990). Disturbances of mood, behavior, and perception (hallucinoses) may complicate the clinical course of VaD. In some patients, delusional thinking develops. In most cases of VaD, many different types of lesions are identified in the brain parenchyma and its vascular supply. The clinical features of VaD reflect the location of the lesions, the volume of infarcted tissue, the number of lesions, and their laterality (Olsson et al. 1996).

**Multi-infarct dementia.** The cumulative effect of multiple large complete cortical infarctions throughout the distributions of the anterior, middle, or posterior cerebral artery circulations can result in dementia. Generally, occlusion of these arteries is the consequence of atherosclerotic thrombosis or cardiac embolization. Multi-infarct dementia is typically reported as having an abrupt onset with stepwise progression. The resulting clinical picture is characterized by variable impairment across several areas of intellectual function. Patients may demonstrate “patchiness” of deficits such that certain intellectual functions are spared, and others are significantly affected. As the syndrome progresses, most areas of intellectual function become disturbed. Patients typically manifest neurological signs and symptoms such as dysarthria, hemiparesis, hemisensory loss, visual field disturbances, and pathological reflexes or reflex asymmetries. Disturbances of recognition (agnosia) and praxis (apraxia) are occasionally noted. In many patients, multi-infarct dementia results from a combination of cortical and subcortical infarctions (see below).

**Strategic single-infarct dementia.** A solitary infarction may abruptly cause dementia if it occurs in a cortical or subcortical region critical to intellectual functions. Strategically placed single lesions in the distributions of the

**TABLE 23–2. Diagnostic criteria for probable, possible, and definite vascular dementia**

- I. The criteria for the clinical diagnosis of *probable* vascular dementia include *all* of the following:
1. *Dementia*, defined by cognitive decline from a previously higher level of functioning and manifested by impairment of memory and of two or more cognitive domains (orientation, attention, language, visuospatial functions, executive functions, motor control, and praxis), preferably established by clinical examination and documented by neuropsychological testing; deficits should be severe enough to interfere with activities of daily living not due to physical effects of stroke alone.
  2. *Cerebrovascular disease* (CVD), defined by the presence of focal signs on neurological examination (e.g., hemiparesis, lower facial weakness, Babinski's sign, sensory deficit, hemianopsia, and dysarthria) consistent with stroke (with or without history of stroke) and evidence of relevant CVD by brain imaging (computed tomography [CT] or magnetic resonance imaging [MRI]) including multiple large-vessel strokes or a single, strategically placed infarct (angular gyrus, thalamus, basal forebrain, posterior cerebral artery, or anterior cerebral artery territories), as well as multiple basal ganglia and white matter lacunes or extensive periventricular white matter lesions or combinations thereof.
  3. A relationship between the above two disorders, manifested or inferred by the presence of one or both of the following:
    - a. Onset of dementia within 3 months after a recognized stroke.
    - b. Abrupt deterioration in cognitive functions or fluctuating, stepwise progression of cognitive deficits.
- II. Clinical features consistent with the diagnosis of *probable* vascular dementia include the following:
1. Early presence of a gait disturbance (small-step gait or *marché à petits-pas*, magnetic, apraxic-ataxic, or parkinsonian gait).
  2. History of unsteadiness and frequent unprovoked falls.
  3. Early urinary frequency, urgency, and other urinary symptoms not explained by urological disease.
  4. Personality and mood changes, abulia, depression, emotional incontinence, other subcortical deficits including psychomotor retardation, and abnormal executive function.
- III. Features that make the diagnosis of vascular dementia uncertain or unlikely include:
1. Early onset of memory deficit and progressive worsening of memory and other cognitive functions such as language (transcortical sensory aphasia), motor skills (apraxia), and perception (agnosia), in the absence of corresponding focal lesions on brain imaging.
  2. Absence of focal neurological signs other than cognitive disturbance.
  3. Absence of cerebrovascular lesions on brain CT or MRI.
- IV. Clinical diagnosis of *possible* vascular dementia: May be made in the presence of dementia (Section I) with focal neurological signs, but in the absence of brain imaging confirmation of definite CVD; or in the absence of clear temporal relationship between dementia and stroke; or in patients with subtle onset and variable course (plateau or improvement of cognitive deficits and evidence of relevant CVD).
- V. Criteria for diagnosis of *definite* vascular dementia are:
1. Clinical criteria for probable vascular dementia.
  2. Histopathological evidence of CVD obtained from biopsy or autopsy.
  3. Absence of neurofibrillary tangles and neuritic plaques exceeding those expected for age.
  4. Absence of other clinical or pathological disorder capable of producing dementia.
- VI. Classification of vascular dementia for research purposes may be made on the basis of clinical, radiological, and neuropathological features for subcategories or defined conditions such as:
- Cortical vascular dementia
  - Subcortical vascular dementia
  - Binswanger's disease
  - Thalamic dementia
- The term *AD with CVD* should be reserved to classify patients fulfilling the clinical criteria for probable AD and who also present clinical or brain imaging evidence of relevant CVD. Traditionally, these patients have been included with vascular dementia in epidemiological studies. The term *mixed dementia* used hitherto should be avoided.

**TABLE 23–3. Subtypes of vascular dementia**

Subtype	Features
<b>Multi-infarct</b>	Abrupt onset, stepwise progression, “patchy” neuropsychological deficits, pyramidal signs, hemiparesis, hemisensory loss, and impaired memory
<b>Strategic single-infarct</b>	Abrupt onset
Carotid artery	Aphasia (left-sided), visuospatial deficits, and contralateral hemiparesis and hemisensory loss
Anterior cerebral artery	Abulia, dyspraxia, transcortical motor aphasia, dysarthria, apraxia, impaired memory; contralateral hemiparesis and hemisensory loss in lower extremities, and incontinence
Middle cerebral artery	Severe aphasia (left-sided) <sup>a</sup> , alexia, agraphia, dyscalculia, psychosis, contralateral pyramidal signs, hemiparesis, hemisensory loss, and visual field deficits
Dominant angular gyrus	Aphasia, alexia, agraphia, impaired verbal memory, visuospatial deficits, right-left disorientation, finger agnosia, and dyscalculia
Posterior cerebral artery	Impaired memory, agnosia, alexia without graphia, visual field deficits, brainstem signs
Branches to thalamic region	Aphasia (left-sided), impaired attention and memory, and variable motor and sensory loss
<b>Hypoperfusion of watershed (borderzone)</b>	Transcortical aphasias, impaired memory, apraxia, and visuospatial deficits
<b>Small-vessel disease</b>	
Lenticulostriate arteries (lacunar state)	Memory loss, psychomotor slowing, apathy, depression, multifocal motor symptoms, parkinsonism, and pseudobulbar palsy
Subcortical arterioles	Memory loss, psychomotor slowing, euphoria, psychosis, symmetric hemiparesis, ataxia supranuclear palsy, incontinence, and parkinsonism (often without tremor)

<sup>a</sup>In the setting of severe aphasia, one cannot adequately determine whether, in fact, dementia exists.

carotid, anterior, middle, and posterior cerebral arteries (left angular gyrus, thalamus, caudate nucleus) give rise to well-recognized dementia syndromes with a variety of neurological and neurobehavioral features (Mahler and Cummings 1991) (Table 23–3).

**Hypoperfusion of watershed areas (borderzone infarction) producing dementia.** The borderzone regions exist at the borders between the vascular territories of the major cerebral arteries. Reduced cerebral perfusion resulting from cardiac arrest, severe hypotension, or loss of blood volume causes stroke in these cortical areas. The most vulnerable border-zone region appears to be the area between the territories of the middle and posterior cerebral arteries.

**Small-vessel disease dementia.** Occlusion of small vessels most prominently causes lesions of subcortical structures such as the basal ganglia, thalamus, internal capsule, and subhemispheric white matter. Disruption of these structures and their connections to the dorsolateral frontal cortex leads to a syndrome called

*subcortical dementia*. This state is characterized by psychomotor slowing, dilapidation in cognitive functions, memory impairment, frontal systems dysfunction, and behavioral alterations such as depression and apathy (Cummings 1990). Neurologically, such patients frequently manifest parkinsonism, ataxia, and urinary incontinence.

*Lacunar state (etat lacunaire)* refers to a pattern of infarction in which multiple small lesions in the basal ganglia, thalamus, and internal capsule produce dementia. Neurological signs and symptoms include, but are not limited to, pseudobulbar palsy, gaze abnormalities, psychomotor slowing, and pyramidal and extrapyramidal disorders. Depression, apathy, and emotional lability are frequent accompanying psychiatric features. Dementia often features prominent frontal systems dysfunction (Ishii et al. 1986; Wolfe et al. 1990). Affected patients typically have a history of hypertension.

Ischemic injury of the frontal hemispheric white matter produces a chronic progressive state called *subcortical arteriosclerotic encephalopathy* or *Binswanger’s disease* (Babikian and Ropper 1987; Peterson and Summergrad

1989; Summergrad and Peterson 1989). Like lacunar infarction, the signs and symptoms of Binswanger's disease reflect pathology localized to subcortical structures. Disturbances of cortical origin such as agnosia or apraxia are generally absent. Hypertension has been noted in 80% or more of cases (Kinkel et al. 1985). Because the clinical triad of dementia, gait disturbance, and urinary incontinence may be seen in Binswanger's disease, it is occasionally misdiagnosed as normal-pressure hydrocephalus (NPH), in which these features have been considered pathognomonic. As compared with patients with NPH, patients with Binswanger's disease demonstrate an earlier age at onset, less frequent early gait abnormalities, longer illness duration, and more prominent signs of hypertension and cerebrovascular disease (Gallassi et al. 1991).

### Evaluation of Vascular Dementia

After review of the patient's history, the evaluation of VaD includes thorough physical, neurological, and mental status examinations. This approach is complemented by CT or MRI of the brain to identify changes consistent with vascular lesions such as gray matter infarctions or ischemic white matter changes.

The frequency of infarctions noted on CT scans of patients given the clinical diagnosis of VaD has varied considerably (from 20% to 86%) (Erkinjuntti and Sulkava 1991). Infarctions appear on CT as regions of lucency. With the advent of MRI, the ability to detect ischemic changes in the subhemispheric white matter has improved, leading to increased speculation regarding their significance. In many intellectually and neurologically intact older patients, MRI may demonstrate patchy and diffuse white matter changes evident as increased signal, especially on T2-weighted images (Almkvist et al. 1992; Boone et al. 1992; Leys et al. 1990). These lesions frequently appear in close proximity to the ventricles and may consist of caps or thickened, irregular rims. These changes have been often referred to as *leukoariosis*. When these lesions are confined to the periventricular region, their clinical significance is unclear (Bondareff et al. 1990). In general, these changes are thought to represent localized areas of demyelination and increased amounts of free water (Zimmerman et al. 1986). In some patients, the periventricular findings are accompanied by single or multiple lesions of the basal ganglia, internal capsule, and thalamus. Large confluent lesions in the subhemispheric white matter may also be noted. Arteriosclerosis may or may not be identified in these subcortical lesions and seems to occur depending on their location (Chimowitz et al. 1992). In general, widespread white matter lesions on neuroimaging are a frequent finding in

patients with VaD (Erkinjuntti and Sulkava 1991) (Figure 23–1). However, it remains that these lesions have different pathological correlates and may be of variable clinical significance (Chimowitz et al. 1992).

In VaD, functional neuroimaging techniques such as single photon emission computed tomography (SPECT) and positron-emission tomography (PET) (Figure 23–2) demonstrate focal areas of hypoperfusion and hypometabolism, respectively.

Although most cases of VaD occur on the basis of arteriosclerosis in the setting of prominent vascular risk factors, in some patients, stroke can result from inflammatory vasculitis. In these individuals, the clinician often encounters other prominent signs of collagen-vascular disease such as an elevated sedimentation rate and confirmatory serologic abnormalities. Inflammatory diseases such as systemic lupus erythematosus, temporal arteritis, and sarcoidosis have been associated with VaD. Hematologic disorders such as polycythemia, sickle-cell disease, and thrombotic thrombocytopenic purpura may also cause stroke and should be considered when routine blood work is reviewed. Attention to potential embolic sources such as cardiac valvular disease is an important component of the diagnostic assessment.

### Treatment of Vascular Dementia

At present, no medication has demonstrated definitive sustained efficacy in preventing, reversing, or modifying the course of VaD. Smoking cessation and optimal control of hypertension or diabetes mellitus have been found to reduce mortality from stroke but have not yet been sufficiently studied to demonstrate such an effect specifically in VaD (Hier et al. 1989). Some data suggest intellectual improvement with moderately lowered blood pressure in hypertensive patients, but other individuals with VaD may experience further cognitive decline (Meyer et al. 1986). Meyer and colleagues (Meyer et al. 1988, 1989; Wade 1991) have observed therapeutic benefit from cigarette smoking abstinence, aspirin therapy, and surgical interventions such as endarterectomy and/or cardiac bypass surgery. Though stroke prophylaxis has been shown with the antiplatelet agent ticlopidine, its usefulness for the treatment of VaD is unproven (Gent et al. 1989).

Pharmacological approaches to the treatment of VaD have included vasodilating agents such as dihydroergotamine (Hydergine) and pentoxifylline (Trental) and calcium channel blocking agents. Although data analysis is still preliminary, no agent has demonstrated unequivocal efficacy over placebo.

**FIGURE 23-1.** Magnetic resonance image of a patient with vascular dementia. Large irregular periventricular hyperintensities, as well as large confluent deep white matter hyperintensities, are shown.

## ■ Hydrocephalic Dementia

The clinical hallmarks of hydrocephalic dementia include dementia, gait instability, and urinary incontinence. Symptoms usually evolve over several months or years. The dementia syndrome has subcortical features including slowness, bradyphrenia, and inattentiveness. Although memory is invariably impaired, patients also appear apathetic and excessively concrete (Benson 1985).

NPH is associated with normal intracranial pressure (Adams et al. 1965). The disorder results from impaired absorption of cerebrospinal fluid into the venous circulation at the level of the arachnoid granulations. Although NPH can be idiopathic in occurrence, it can follow cerebral trauma, subarachnoid hemorrhage, encephalitis, or meningitis. Despite its frequent consideration in the differential diagnosis of dementia, NPH is a rare cause of dementia, accounting for less than 2% of cases (Clarfield 1988).

In addition to NPH, other forms of hydrocephalus cause dementia in elderly people. Mass lesions or inflammatory conditions such as ependymitis or arachnoiditis can obstruct the normal flow of cerebrospinal fluid (CSF) (obstructive, noncommunicating hydrocephalus). When obstruction due to these causes is relatively acute, the patient demonstrates signs of increased intracranial pressure (headache, papilledema, lethargy, nausea, and emesis) and eventually progresses to somnolence and coma. Bilateral abducens palsies and quadriplegia also can be present. When the obstruction is subacute, however, the onset of symptomatology is more gradual and frequently presents as dementia without other neurological signs (Benson 1985).

Ataxia and urinary incontinence associated with hydrocephalic dementia are thought to result from displacement by the enlarging lateral ventricles of those periventricular corticospinal tracts that control lower-extremity and bladder-motor function. Ataxia with hydrocephalus tends to vary in severity and may be accompanied by

**FIGURE 23-2.** Positron-emission tomography scan of a patient with vascular dementia. Multiple areas of reduced glucose metabolism are shown.

spasticity of the legs and extensor plantar responses. Difficulty initiating gait is common. Once the patient is ambulatory, however, the patient's strides are noted to improve (Fisher 1982).

Whereas ataxia is often a prominent feature of hydrocephalic dementia, urinary incontinence may be mild or only late occurring (Benson 1985). Although frequently cited as a pathognomonic feature of hydrocephalus, urinary incontinence is a common feature of Alzheimer's disease and other dementing disorders and is of limited diagnostic specificity.

### Evaluation of Hydrocephalic Dementia

The accurate diagnosis of NPH is often difficult as the characteristic signs and symptoms of the disorder occur in other progressive causes of dementia (Cox et al. 1988). Classically, the radiological appearance of NPH has been

reported to consist of ventricular dilation in the absence of sulcal widening. Although this finding on CT or MRI strengthens the diagnosis of NPH, it is not invariably present; cortical atrophy can be present in some hydrocephalic patients. In some cases, elderly patients with dementia and with clear radiological evidence of NPH may not have the associated features of incontinence or ataxia (Mulrow et al. 1987). Additional diagnostic techniques including radioisotope or CT cisternography are of limited value in improving diagnostic accuracy (Vanneste et al. 1992). Although most patients with NPH may be expected to decline intellectually over time, some may remain stable without additional intervention (Clarfield 1989).

### Treatment of Hydrocephalic Dementia

The treatment of hydrocephalic dementia, particularly NPH, involves surgical shunting procedures. Surgical suc-

cess rates have been variable, and treatment complications have been common (Graff-Radford et al. 1989). Dementia appears to be the symptom of NPH that is least responsive to treatment. Even when the diagnosis is reasonably certain, accurate, consistent predictive tests for surgical outcome are still lacking. In general, those patients best suited for shunt placement are those who initially present with the full clinical triad, have a readily identified cause for NPH, and have had a relatively short duration of symptoms (Clarfield 1989).

## ■ Dementia Syndrome of Depression

*Pseudodementia* has been the term historically applied to describe memory and other cognitive impairments caused by psychiatric disorders such as depression, mania, and schizophrenia (Kiloh 1961). It has been argued that dementia could be “mimicked” or “caricatured” by functional psychiatric illness, implying a hysterical component to the clinical presentation (Wells 1979). Although still controversial, it is now generally accepted that the intellectual deficits that result from psychiatric illness, in particular depression, constitute a “true dementia” that may be modifiable or perhaps reversed with appropriate therapy.

Four essential criteria have been proposed to diagnostically define dementia resulting from functional psychiatric disorders (Caine 1981). First, there must be evidence of a primary psychiatric disorder accompanied by intellectual impairment. Second, the clinical features of the disorder must resemble those noted in degenerative brain disorders with neuropathological confirmation. Third, the intellectual deficit should reverse with psychiatric treatment. Fourth, there must not be evidence of a primary neurodegenerative process that can cause dementia.

Dementia specifically resulting from depressed mood has been aptly termed the *dementia syndrome of depression* (Folstein and McHugh 1978). The true prevalence of DOD among the elderly population is unknown, reflecting variability in sampled populations and assessment methods. Across studies, from 2% to 32% of patients evaluated for dementia meet criteria for pseudodementia, of whom 50%–100% have DOD (Cummings and Benson 1992). In elderly patients, depression is the psychiatric state most often responsible for dementia. In younger patients, there may be greater variability in the psychiatric causes of intellectual impairment.

The onset of DOD is most typically subacute, occurring in an elderly individual with a personal or family history of depression. As the major depressive episode evolves, intellectual impairment rapidly progresses. Pa-

tients appear dysphoric and may complain of poor motivation, anhedonia, and feelings of worthlessness. Heightened levels of anxiety and nihilistic or persecutory delusions also may be present. Neurovegetative features of depression are evident and include disrupted sleep, impaired appetite, anergia, constipation, and impotence. Patients are often hypophonic and appear cognitively and psychomotorically slowed; they may demonstrate diminished affective intensity and range.

The neuropsychological deficits of DOD tend to be variable, and they include some or all of the following: impaired attention and concentration, restricted verbal fluency, memory-retrieval deficits, visuoconstructional disturbances, concreteness, and disrupted calculation ability (Weingartner et al. 1981). Disturbances such as aphasia, apraxia, and agnosia are notably absent. The severity of the patient’s underlying depression is highly correlated with the motivation to perform and the level of intellectual impairment (Cohen et al. 1982). The degree of depression is also strongly correlated with the individual’s tendency to complain about memory impairment, irrespective of its severity (Kahn et al. 1975; O’Connor et al. 1990). Patients with depression often complain about forgetfulness, as well as indecisiveness, poor concentration, and mental slowing (O’Connor et al. 1990). The degree of awareness and concern verbalized by the typical patient with DOD is far greater than that evidenced by the patient with a degenerative cause of dementia such as Alzheimer’s disease.

Several studies have documented reduced complaints of impaired memory (Plotkin et al. 1985) and improved intellectual functioning following successful treatment of depression with pharmacotherapy (tricyclic antidepressants and monoamine oxidase inhibitors) or electroconvulsive therapy (Janowsky 1982; Kral and Emery 1989; McAllister and Price 1982). It remains uncertain whether intellectual improvement is complete or whether some deficits persist despite a fully recovered mood (Ames et al. 1990; Greenwald et al. 1989; Jacoby et al. 1981; Savard et al. 1980).

The long-term prognosis of DOD is also uncertain. Some studies suggest that, over time, many patients with DOD develop a progressive dementia (Ames et al. 1990; Kral 1983; Reding et al. 1985), whereas other studies, using relatively rigorous criteria for the diagnosis of DOD, have concluded that the risk for developing an irreversible progressive dementia is no greater in patients who have had DOD than in nondepressed elderly patients (Pearlson et al. 1989; Rabins et al. 1984).

Preliminary neuroimaging investigations have demonstrated some structural abnormalities in DOD. In one study (Pearlson et al. 1989), CT scans of patients with

DOD had ventricle-to-brain ratios that were smaller than those of patients with Alzheimer's disease, but larger than those recorded in depressed, age-matched control subjects without dementia. However, in another series, no significant differences between control subjects and patients with DOD were detected with CT (Abas et al. 1990). Elderly patients with late-onset depression have significantly more white matter ischemic changes on MRI than do psychiatrically healthy, age-matched control subjects (Coffey et al. 1990). Whether these lesions predispose to the development of DOD is unknown. In patients with left-hemisphere stroke, concurrent major depression further impairs neuropsychological test performance irrespective of lesion size, lesion location, or other clinical variables (Bolla-Wilson et al. 1989; Robinson et al. 1986).

The diagnosis of DOD rests on the demonstration of a major depressive episode in a patient with secondarily acquired intellectual impairment. The patient must not meet diagnostic criteria for another dementing illness that may cause similar clinical features (especially Parkinson's disease or subcortical cerebrovascular disease). It is also crucial to exclude potentially toxic effects of medications. Centrally acting antihypertensive drugs (reserpine, clonidine, and propranolol) or neuroleptics can disrupt intellectual ability and produce depression, confounding diagnostic accuracy. Final certainty in the diagnosis depends on discriminating improvement in intellectual function with resolution of the mood disorder.

Although less common in elderly patients, dementia has also been noted to secondarily arise from mania or schizophrenic psychosis (Wright and Silove 1988). Patients with mania are generally easily distractible and forgetful and exhibit psychomotor agitation. Their mood is grandiose or exceptionally irritable. They may have relatively florid hallucinations or delusions and disturbances of thought processes such as circumstantiality or flight of ideas. Other manic features are variable. Dementia arising solely from the manic phase of bipolar disorder must be distinguished from manic-like behavior encountered in dementia syndromes that disrupt frontal systems. Disorders such as the frontal lobe degenerations, general paresis, alcoholic dementia, cerebral neoplasms, strokes, trauma, and the toxic effects of medications (steroids and levodopa) may cause manic symptoms (secondary mania).

In many patients with schizophrenia, dementia has been noted, especially when "negative symptoms" (withdrawal, emotional blunting, loss of reactivity, and apathy) dominate the clinical picture. These features have been correlated with frontal ventricular prominence and sulcal widening (Andreasen et al. 1982). The neuropsychological profile of dementia in patients with schizophrenia who

have prominent negative symptoms has been shown to preferentially, but not exclusively, consist of impaired executive functions (Breier et al. 1991; Perlick 1992). Less frequently, impaired intellectual ability in subjects with schizophrenia can be seen during episodes of psychotic agitation. During such periods, impaired motivation to perform and inattentiveness may underlie the observed deficits. Lastly, a subgroup of elderly subjects with schizophrenia demonstrate chronic neuropsychological deficits.

Treatment of DOD follows the usual approach to treatment of depression in the elderly and is described in elsewhere in this volume.

## ■ Infectious Disorders

Infectious disorders of the central nervous system are uncommon causes of dementia in the elderly population. Dementia resulting from chronic fungal, helminthic, or protozoan infectious processes most often presents clinically as a chronic confusional state with impaired attention and arousal. Along with features of meningeal irritation, signs of increased intracranial pressure such as papilledema, headache, nausea, and emesis can be present. Seizures and cranial nerve dysfunction can also be evident.

Bacterial infection (meningitis or brain abscess) more often develops as an acute, rapidly progressive clinical state with neuropsychiatric features more reminiscent of delirium than of dementia. Chronic treponemal infections of the nervous system that can cause dementia include neurosyphilis and Lyme disease.

Dementia can be a long-term consequence of viral encephalitis. In herpes simplex encephalitis, severe memory impairment can be a chronic residual feature reflecting the virus's predilection for the anterior medial temporal cortex. Affected patients may demonstrate aphasia and mild cognitive deficits. Apart from herpes simplex infection, other viral encephalitides can also cause enduring intellectual deficits.

Creutzfeldt-Jakob disease is a rare disorder with onset in the sixth or seventh decade. The disorder, arising from a proteinaceous infectious particle (prion), is rapidly progressive, leading to death within several months. Patients manifest progressive dementia with prominent language disturbance, myoclonus, extrapyramidal features, and pyramidal signs. Cerebellar signs, cranial nerve pathology, and choreoathetosis also can occur (Brown et al. 1986; Cummings and Benson 1992).

Patients infected with the human immunodeficiency virus (HIV) can have a variety of neuropsychiatric disorders including depression, anxiety, and dementia

(Faulstich 1987; Hintz et al. 1990; Perry 1990). Dementia is the most frequent neurological complication of acquired immunodeficiency syndrome (AIDS) (Navia and Price 1987). Since early reports of the AIDS epidemic, the tendency of HIV to cause neuropsychological impairment has been well established. Although originally dementia was thought to be the result of opportunistic infection, it has been increasingly recognized that dementia can occur as the direct consequence of HIV infection of the central nervous system (Lunn et al. 1991; Navia et al. 1986). The acquired intellectual impairment directly resulting from HIV infection has been termed the *AIDS dementia complex* (ADC) or *AIDS cognitive-motor complex*. The disorder may be a presenting manifestation of AIDS (Navia and Price 1987) and has been noted in at least two-thirds of patients who die from an AIDS-related illness (Navia et al. 1986).

ADC has clinical features indicative of subcortical dysfunction including impairment in concentration, forgetfulness, and slowed psychomotor speed. Additionally, patients have poor balance, lower-extremity weakness, hyperreflexia, and an action tremor. Headache, impaired handwriting, and loss of motivation have also been noted frequently (Benson 1987). Other associated behavioral features such as depression and hallucinations can be present also. In the end stage of AIDS, patients may be incontinent, strikingly apathetic, and mute (Lunn et al. 1991). Though not having AIDS, people with asymptomatic HIV infection may demonstrate subclinical impairment in verbal memory and psychomotor speed (Lunn et al. 1991; Stern et al. 1991).

It remains unclear how HIV enters the central nervous system to produce ADC. One view is that the retrovirus is initially contained within macrophages that cross the blood-brain barrier. With evolving immunosuppression, the virus replicates within the brain in an uncontrolled fashion (Perry 1990).

Although ADC is most commonly seen in younger age groups, in which risk factors such as homosexuality, intravenous drug use, and prior blood transfusion increase the risk of HIV infection, the disorder may also be seen in the elderly. The diagnosis should be considered in the older patient with any of the above risk factors and a subcortical dementia.

The treatment of ADC involves substantial psychological support for patients and their caregivers, augmented by pharmacotherapy. Antiviral therapy, specifically zidovudine (AZT), has been shown to improve intellectual impairment associated with AIDS (Schmitt et al. 1988; Yarchoan et al. 1987), and many patients with combination ADC receive protease inhibitors and antiviral treatment regimens. Psychotropic, neurological, and anal-

gesic medications are used where indicated for pertinent symptoms. Specifically, psychotropic agents including psychostimulants for withdrawal and apathy and high-potency neuroleptics for associated psychosis have demonstrated consistent efficacy (Ostrow et al. 1988; Perry 1990).

## ■ Neoplasia-Associated Dementia

Primary neoplasms that arise from the brain parenchyma, cerebral blood vessels, pituitary, meninges, and cranial nerves may all sufficiently disrupt neural function to produce dementia. Metastatic lesions from extracranial tumors, granulomas, and lymphomas can all invade the central nervous system to exert profound effects on mentation. The wide variety of cerebral neoplasms that can cause dementia accounts for significant variability in the onset and progression of intellectual impairment and the occurrence of associated neurological signs and symptoms (Rowland 1989).

The clinical features associated with intracranial tumors arise from parenchymal invasion, mass effects, hydrocephalus, vascular occlusion, or any combination of these. Most often, signs and symptoms of intracranial mass lesions arise insidiously and are progressive. Symptoms such as depression, lethargy, apathy, impaired concentration, disturbed memory, and headache can slowly evolve over several weeks to months (Anderson et al. 1990). When other symptoms such as unsteady gait, incontinence, and emesis are noted, a cerebral mass lesion must be strongly suspected. Additional features consistent with the presence of a brain tumor include papilledema, vasomotor symptoms, focal motor or sensory signs, diplopia, vertigo, and visual field defects (Bannister 1986). Less frequently, the initial manifestations of a cerebral tumor include the abrupt onset of a seizure, focal motor weakness, or hemisensory loss (Adams and Victor 1989).

The pattern of intellectual impairment noted with a cerebral mass lesion is in part a function of neuroanatomic location. Direct pressure effects can cause relatively focal disturbances in language, praxis, or memory. In certain locations, dementia is particularly likely to occur. For example, global intellectual impairment is found in 70% of patients with frontal tumors, whereas language disturbances are particularly prominent with left-temporal masses (Cummings and Benson 1992). Increased intracranial pressure gives rise to altered arousal, attention, and concentration. Tumors disrupting subcortical structures such as the basal ganglia also cause dementia in which there are prominent attentional disturbances and depression.

Masses affecting the diencephalic structures can cause dementia associated with personality changes, endocrinological abnormalities, dietary disturbances, and sleep alterations (Cummings and Benson 1992).

Widespread metastasis to the meninges with dissemination throughout the ventricles has been termed *meningeal carcinomatosis*. Malignant melanoma and carcinomas of the breast, lung, and gastrointestinal tract have been associated with this condition. Affected patients demonstrate signs of increased intracranial pressure, cranial nerve dysfunction, and dementia typified by prominent attention and concentration difficulties (Theodore and Gendelman 1981).

Distant tumors such as occult neoplasms of the lung (oat-cell carcinoma), ovary, or breast may be associated with limbic encephalitis. This disorder has been considered a paraneoplastic condition of unknown pathogenesis. Intellectual impairment is often accompanied by depression and anxiety. There can be impairment of arousal and hallucinatory phenomena. Signs or symptoms of cerebellar dysfunction such as ataxia, nystagmus, tremor, hyporeflexia, dysarthria, and impairment of rapid alternating movements may be noted. Seizures, myopathy, and myeloradiculoneuropathy have been documented in this condition (Posner 1989). Although the medial temporal lobe appears to be the site most severely affected, neuronal loss and inflammatory changes have been discovered throughout the cortex and subcortical regions. Paraneoplastic dementia is an untreatable condition that typically progresses to death within 2 years of onset (Cummings and Benson 1992).

The diagnosis of an intracranial mass is contingent on confirmation by CT or MRI. The addition of contrast enhancement to these procedures increases their sensitivity to detect cerebral neoplasms. These procedures also help to differentiate other dementing conditions such as stroke, cerebral abscess, subdural hematoma, and NPH from brain tumors. Electroencephalography (EEG) may demonstrate diffuse or excessive focal slow-wave activity. CSF examination often reveals a mild leukocytosis with elevated protein and normal glucose levels. (For a more complete discussion of the neuropsychiatric aspects of neoplastic, demyelinating, infectious, and inflammatory diseases of the brain, see Chapter 30 in this volume.)

## ■ Metabolic and Toxic Encephalopathies

Elderly people are particularly vulnerable to the neuropsychiatric effects of systemic illness, nutritional deficiency, and toxin exposure. In most cases, metabolic or toxic de-

rangements of the central nervous system produce acute, time-limited disturbances in cognition and behavior (delirium). However, when the effects persist for an extended period of time, dementia results. The most prominent effects of metabolic and toxic disorders on mentation include fluctuating arousal, impaired attention, and disturbances in memory. Depending on the underlying disorder, other associated neuropsychological deficits may appear. However, severe disturbances of language and the other higher cortical functions such as apraxia and agnosia are uncommon. Motor system abnormalities including tremor, asterixis, and myoclonus often accompany the observed confusional state. EEG shows diffuse slow-wave activity, whereas CT and MRI are generally unrevealing.

## Systemic Disorders

Disturbances of the cardiopulmonary, hematological, hepatic, renal, and endocrinological systems produce transient or chronic disruptions in intellectual function. Such systemic disorders can cause dementia in the elderly or, more commonly, contribute to the intellectual impairment caused by other conditions such as Alzheimer's disease or stroke. Diseases such as systemic lupus erythematosus, sarcoidosis, temporal arteritis, and rheumatoid arthritis also cause dementia through inflammation of cerebral vessels leading to stroke.

## Nutritional Deficiencies

Deficiency of vitamins such as cyanocobalamin (vitamin B<sub>12</sub>), folic acid, and niacin has been associated with dementia in elderly patients (Bell et al. 1990a, 1990b). Cyanocobalamin and folic acid are biochemically interrelated vitamins that exert both a separate and concomitant influence on cognition and mood (Bell et al. 1990a). Most often, vitamin B<sub>12</sub> deficiency leads to impaired memory, psychosis, and depression. Additional neuropsychological impairment is an infrequent finding. Clouding of consciousness appears to be a consistent feature of the alteration in mental status associated with this nutritional cause of dementia (Hector and Burton 1988). The neuropsychiatric manifestations of vitamin B<sub>12</sub> deficiency and associated neurological deficits such as myelopathy, neuropathy, and seizures may occur in subtle or atypical vitamin B<sub>12</sub> deficiency states in which hematological indices and the Schilling test results are normal (Karnaze and Carmel 1990).

The diagnosis of dementia caused by vitamin B<sub>12</sub> deficiency rests on demonstration of diminished serum cobalamin levels. Diagnostic accuracy can be improved by

measurement of pretreatment and posttreatment serum levels of methylmalonic acid and/or total homocysteine (Lindenbaum et al. 1988).

Replacement therapy of vitamin B<sub>12</sub> deficiency rarely leads to complete restoration of intellectual function. In some patients, however, supplementation with the deficient vitamin can lead to partial improvement in neuropsychological function (Gross et al. 1986).

It is less clear to what extent isolated folic acid deficiency may cause dementia. Some have speculated that increased levels of folic acid in elderly patients cause a variety of neuropsychiatric symptoms, most importantly depression. In general, disruptions in the delicate balance between cyanocobalamin and folic acid probably underlie the emergence of most neuropsychiatric features. The complex relationship between these two vitamins and neuropsychiatric syndromes is uncertain. However, dysfunction in brain cyanocobalamin and folic acid status does appear to have important consequences for neurotransmitter metabolism, particularly those pathways related to serotonergic function (Bell et al. 1990b).

## Toxic Disorders

The neuropsychological impairment of chronic alcoholism has been historically considered to be a severe amnesic disorder related to a nutritional deficiency of thiamine (Korsakoff's psychosis). Contemporary research, however, supports the view that, along with anterograde and retrograde memory impairment, alcoholism is associated with visuosperceptual and problem-solving disability. Impaired performance of verbal fluency tasks and poor abstract concept formation have also been noted (Butters 1985; Cummings and Benson 1992; Tuck et al. 1984). Improvement of dementia may occur with abstinence, but complete restoration of intellectual function is rare.

Alcohol-associated dementia is more common in the elderly population than in younger alcoholic populations; this finding is independent of the duration of excessive intake of alcohol (Cummings and Benson 1992). The dementia associated with alcoholism may be in part a product of thiamine deficiency but is likely also to reflect a direct toxic effect of alcohol. Also largely unexplained is the reversible CT scan finding of enlarged ventricles and widened cortical sulci in the brains of alcoholic patients. The degree of atrophy does not appear to correlate with the severity of intellectual impairment. In elderly alcoholic patients with dementia, the EEG frequently shows abnormal slowing.

Although hemorrhagic lesions of the medial diencephalon have been thought to underlie the memory impairment of alcoholism, evidence has arisen implicating

pathology of the nucleus basalis of Meynert and cortical structures (Butters 1985). Postmortem studies of alcoholic patients reveal greater degrees of white matter atrophy than of cortical atrophy, implicating a toxic effect of alcohol on myelin (Cummings and Benson 1992).

With aging of patients, the risk of medication toxicity increases as a consequence of alterations in drug metabolism, distribution, binding, and excretion. Aside from being vulnerable to excessive dosing or polypharmacy, elderly patients can be vulnerable also to pharmacotoxicity because of increased sensitivity to the psychotropic effects of various medications (Mahler et al. 1987). Centrally acting antihypertensive agents, anticholinergic drugs, neuroleptics, benzodiazepines, hypnotics, and antidepressants can all impair intellectual function in the susceptible elderly patient.

## ■ Posttraumatic Dementia

Elderly people are especially at risk for suffering closed head injury (see Chapter 28 in this volume). Physical frailty, disturbances of gait secondary to orthopedic disability, and an increased occurrence of orthostatic hypotension in this population increase the risk of falls and traumatic brain injury. Injury to the brain in this fashion includes hemorrhage, contusion, laceration, or shearing effects. With subtle trauma, older patients have an increased tendency for the bridging veins to rupture and hemorrhage as they course from the cortical surface to the dural sinuses. As a result, subdural collections of blood may form (subdural hematoma), giving rise to altered mentation. The onset of dementia may be subacute or chronic. Affected patients manifest a gradually progressive, chronic confusional state with transient, relatively minor, focal neurological signs that can be mistaken for stroke or tumor.

With chronic subdural hematomas, the collection of blood can be isodense on CT scanning of the brain and thus difficult to detect unless there is obvious shift of the midline structures or obscuring of the cortical sulci. For this lesion, MRI provides significantly improved imaging sensitivity and is the diagnostic procedure of choice (Cummings and Benson 1992). When the patient is symptomatic, subdural collections of blood may be surgically evacuated to produce some clinical improvement.

## ■ Standard Evaluation of Dementia

The standard evaluation of the nondegenerative causes of dementia includes assimilating a thorough history of the patient's present illness, with comprehensive attention to

cognitive, medical, neurological, and psychiatric features. The interview must review the patient's medical, educational, social, vocational, and family histories. Any significant exposure of the individual to alcohol, medications, and other potential toxins must be considered. Because the intellectually impaired individual can only rarely provide such comprehensive data accurately, it is recommended that the caregiver be extensively interviewed with and without the patient present. Physical, neurological, and mental status examinations should be conducted. A quantifiable screening assessment of the patient's intellectual ability, such as the Mini-Mental State Exam (MMSE) (Folstein et al. 1975), allows the physician to establish a baseline of function for the patient and follow disease course. More extensive neuropsychological assessment can help fully elucidate the patient's deficits.

Several laboratory studies should be conducted to augment evaluation of the body's cardiopulmonary, renal, hepatic, endocrinological, and hematological systems. When cardiac or pulmonary dysfunction is clinically apparent, electrocardiography, chest radiography, or arterial blood gas determinations may be indicated. Additionally, an assay for vitamin B<sub>12</sub> should be accompanied by blood tests to detect the presence of systemic infection or inflammation.

The thorough evaluation of dementia requires a neuroimaging study such as CT or MRI of the brain to document the presence of atrophy, mass lesions, stroke, or hydrocephalus. When diagnostic uncertainty is prominent, functional neuroimaging techniques, such as SPECT or PET, if available, can be useful to detect perfusion or metabolic abnormalities characteristic of dementing disorders such as Alzheimer's disease or the frontal lobe degenerations.

When infection or inflammation of the brain parenchyma or meninges is suspected, lumbar puncture is indicated. EEG is an especially useful study to support the presence of seizures or an infectious, toxic, or metabolic encephalopathy. Additionally, EEG studies can be repeated to monitor disease progression or response to treatment (Table 23-4). A diagnostic brain biopsy is infrequently indicated in the evaluation of dementia. The procedure is associated with substantial morbidity and rarely leads to the diagnosis of a reversible condition (Hulette et al. 1992; Kaufman and Catalano 1979). Brain biopsy can be helpful for the diagnosis of Creutzfeldt-Jakob disease (Gajdusek et al. 1977). However, this technique is being largely supplanted by the recent availability of CSF protein markers for the disease (Zerr et al. 1998). Published practice parameters for the diagnosis and evaluation of dementia are readily available for reference (Quality Standards Subcommittee of the American Academy of Neurology 1994).

**TABLE 23-4. History of illness**

Review of systems
Medical history
Medication review
Family history
Psychiatric interview
Physical examination
Neurological examination
Mental status examination (with rating of dementia severity)
Laboratory evaluation (mandatory)
Complete blood count with differential
Liver function tests
Serum electrolytes, calcium, phosphorus, and glucose
High-sensitivity thyroid-stimulating hormone
Syphilis serology
Erythrocyte sedimentation rate
Serum creatinine and blood urea nitrogen
Urinalysis
Serum B <sub>12</sub> and folic acid
Laboratory evaluation (selective)
Lyme disease antibody titer
Human immunodeficiency virus titer
Rheumatologic studies (rheumatoid factor, antinuclear antibody titer, and so on)
Endocrine studies (serum cortisol, parathyroid hormone, and so on)
Arterial blood gas determination
Neuroimaging (mandatory)
Computed tomography or magnetic resonance imaging of the head
Neuroimaging (selective)
Single photon emission computed tomography
Positron-emission tomography
Ancillary studies
Chest radiograph
Electrocardiogram
Electroencephalogram
Neuropsychological evaluation

The comprehensive evaluation of dementia must be augmented by careful surveillance for caregiver anxiety or depression. It is necessary to define any potential causes of excessive burden such as disruptive patient behavior, a lack of familial or social supports, or any financial losses, real or imagined. On establishing a diagnosis, the patient and his or her caregiver must be fully informed and apprised of the prognosis and any potential treatment options. Referral should be made for specialized medical evaluation and care

as indicated. Additionally, caregivers often need to be referred for legal counseling and ancillary social services such as home health care, day care, and nursing home care.

## ■ Treatment of Dementia: General Considerations

For the nondegenerative dementing disorders, improvement in intellectual function following treatment is often incomplete. Therapies such as resection of a mass lesion, ventricular shunting for NPH, or correction of a metabolic disorder such as vitamin B<sub>12</sub> deficiency or hypothyroidism often lead to symptomatic improvement, but rarely to complete recovery. The essential requirement for therapy is to halt disease progression and minimize disability. In VaD, for example, this generally entails optimal control of risk factors such as hypertension, smoking, and hyperlipidemia.

Although the neuropsychological features of dementia are rarely completely reversible, accompanying neuropsychiatric symptoms such as depression, anxiety, psychosis, sleep disorders, and aggressivity are often successfully treated with a combination of behavioral approaches and pharmacotherapy. The contribution of disruptive behavior to caregiver burden cannot be overemphasized and must receive comprehensive attention.

The nonpharmacological approaches to dysfunctional behavior generally consist of reassurance, distraction, redirection, and structure. Generally, the caregiver should try to respond to the behavior in a calm and direct manner. In the setting of aggressive behavior, caregivers must ensure their own safety before attempting to relax the patient. When patients experience hallucinations or verbalize

persecutory thoughts such as delusions of theft or infidelity, caregivers should acknowledge the expressed fears and offer calm reassurance and distraction. Wandering behavior should be accommodated whenever possible by providing an open space that is secure and well lit. Exceptionally restless patients or those who frequently wander must be observed for signs of dehydration and the development of sores on the bottom of the feet.

Disrupted sleep is best treated with improvements in sleep hygiene. This often includes avoiding stimulants and nocturnal fluids, limiting daytime naps, and discouraging all non-sleep-related activities in bed (with the possible exception of sexual relations). A diligent search for coexistent medical conditions that may disturb sleep is also required. (For a fuller discussion of sleep disorders in the elderly, see Chapter 17 in this volume.)

Augmentation with pharmacotherapy is often necessary to effectively treat disruptive behavior in dementia. Tables 23–5 through 23–7 provide guides for the pharmacotherapy of behavioral changes in dementia. (Pharmacotherapy in the elderly is covered more extensively in Chapter 34 in this volume.) In addition to managing disruptive behavior, treatment of dementia must also include astute attention to the other causes of excessive caregiver burden, such as social isolation and inadequate social and familial supports.

## ■ Summary

The nondegenerative causes of dementia in the elderly population include cerebrovascular disease, hydrocephalus, psychiatric disorders such as depression, infectious and

**TABLE 23-5. Pharmacotherapy of behavioral changes in dementia—antidepressants**

Agent	Dosing guidelines	Side effects
Nortriptyline, desipramine	Initiate at 10 mg/day; increase dose by 10 mg/week until treatment response or side effects emerge.	Confusion, sedation, anticholinergic effects, and cardiac conduction delay
Trazodone	Initiate at 50 mg/day; increase dose by 50 mg/week until response or side effects emerge.	Sedation, orthostasis, confusion, and priapism (in males)
Fluoxetine, paroxetine	Initiate at 10 mg/day; increase dose to 20 mg/day after 1 week.	Restlessness, insomnia, anxiety, anorexia, and confusion
Sertraline	Initiate at 25 mg/day; increase dose to 50 mg/day after 1 week (may need to go to 150 mg/day depending on clinical response).	Restlessness, insomnia, anxiety, anorexia, diarrhea
Bupropion	Initiate at 75 mg/day; increase dose after 4 days to 150 mg/day; maintain at 300 mg/day maximum.	Insomnia, anxiety, confusion, seizures

**TABLE 23-6. Pharmacotherapy of behavioral changes in dementia—antipsychotics**

Agent	Starting daily dose <sup>a</sup>	Relative side effects	
		Parkinsonism	Anticholinergic/sedation
Haloperidol	0.5–1 mg	High	Low/low
Trifluoperazine	1 mg	Moderate	Moderate/moderate
Thiothixene	1 mg	Moderate	Moderate/low
Thioridazine	10 mg	Low	High/high
Risperidone	0.5 mg	Low	None/low
Olanzapine	2.5 mg	Very low	Low/moderate
Quetiapine	12.5 mg	Very low	Low/moderate
Clozapine	12.5 mg	Very low	High/high

<sup>a</sup>Maintain dosage at lowest possible effective dose; increase as needed every 4–7 days.

**TABLE 23-7. Pharmacotherapy of behavioral changes in dementia—alternative agents for agitation and aggressivity**

Agent	Starting daily dose <sup>a</sup>	Side effects
Carbamazepine <sup>b</sup>	100 mg bid	Sedation, ataxia, dysarthria, bone marrow suppression, and hepatotoxicity
Sodium valproate	125 mg bid	Sedation, ataxia, dysarthria, bone marrow suppression, and hepatotoxicity
Trazodone	50 mg/day	Sedation, orthostasis, and priapism (in males)
Buspirone	5 mg bid	Dizziness, nausea, and sedation
Clonazepam	0.5 mg bid	Sedation, ataxia, and dysarthria
Propranolol <sup>c</sup>	10 mg bid	Sedation, bradycardia, hypotension, depression, and worsening of chronic obstructive pulmonary disease

<sup>a</sup>Dosing will need to be increased for all agents at weekly intervals until response or emergence of side effects.

<sup>b</sup>Monitor serum levels, complete blood count, and liver function tests.

<sup>c</sup>Monitor pulse and blood pressure closely.

of the major organ systems, endocrinopathies, nutritional deficiencies, toxic disorders, and trauma. Although any of these conditions may be the primary cause of acquired intellectual impairment, more characteristically, their presence complicates the clinical course of degenerative disorders such as Alzheimer's disease. The standard evaluation of these disorders must be sufficiently broad in scope to detect their occurrence but should be specifically guided by the data available. Treatment of the nondegenerative dementing disorders is directed at halting progression, restoring intellectual function, managing associated neuropsychiatric features, and relieving caregiver burden.

# Alzheimer's Disease and Frontotemporal Dementia

Bruce L. Miller, M.D.

Andrew Gustavson, M.D.

Recent advances in the diagnosis and treatment of the degenerative disorders have been enormous. Both Alzheimer's disease (AD) and frontotemporal dementia (FTD) have distinct epidemiological, clinical, and pathological profiles, and recent work suggests that the two can be differentiated during life (Miller et al. 1997a). Accurate diagnosis is no longer purely academic because new disease-specific treatments for AD and FTD have emerged. Another exciting advance related to these disorders has been the discovery of a series of different genetic mutations causal for AD or FTD. These findings are beginning to change our understanding of the pathogenesis of these disorders, and ultimately they offer hope for the development of disease-specific therapies that will modify disease progression.

AD is still considered a unitary disorder despite clinical, genetic, and pathological variability. In contrast, with FTD there is marked controversy as to how to classify the clinically and pathologically diverse syndromes associated with progressive frontotemporal degeneration. Some experts lump patients with Pick's disease, FTD without Pick's

bodies, progressive subcortical gliosis, primary progressive aphasia, and corticobasal degeneration into the same category (Kertesz 1997), whereas others insist that these are each distinct disease entities (Neary 1997). A problem associated with previous attempts to classify these diseases was that little was known concerning the primary cause of FTD. This led to a taxonomy based largely upon clinical and pathological phenomenology. However, genetic breakthroughs are changing the understanding of both FTD and AD. In this chapter, we discuss AD and FTD separately and address the evolving understanding of their epidemiological, clinical, genetic, imaging, chemical, and pathological features.

## Alzheimer's Disease

### Epidemiology

During the final stages of AD, the patient is bedridden and unable to swallow or mobilize, so that death often is sec-

ondary to dehydration or sepsis. Therefore, many deaths of patients with end-stage AD are coded on death certificates as caused by infection. This problem, along with serious obstacles associated with determining a proper diagnosis, make ascertainment of the exact prevalence of AD difficult (Hay and Ernst 1987). In addition, the clinical and pathological standards regarding what constitutes AD, although improving, continue to be flawed, which also complicates accurate determination of AD prevalence. One community-based study (Evans et al. 1989), estimates the prevalence of AD at four million cases in the United States. Assuming this is correct, AD is the fourth leading cause of death in adults, ranking behind heart disease, cancer, and stroke (Office of Technology Assessment Task Force 1988).

A major risk factor for AD is aging, and AD rises with each decade of life. AD has a prevalence of approximately 6.2% over age 65 (Roth 1978), 20% over 80 (Mortimer 1983), and 45% over 95 (Gottfries 1990). The reason for the increase of AD with age is complex and multifactorial, although the cumulative loss of neuronal synapses is one important factor. Monozygotic twin studies (Gatz et al. 1997; Nee et al. 1987) suggest a strong genetic component to AD; when one twin manifests AD, approximately 40% of the co-twins also develop the disorder. However, often there is a long delay between the onset of AD for the second twin, suggesting both environmental and genetic contributions to AD (Creasey et al. 1989).

Nearly all patients with Down's syndrome who live beyond 40 years develop amyloid plaques in the cortex (Ropper and Williams 1980). Because Down's syndrome is caused by an extra chromosome 21, it was suggested that a gene on this chromosome might be key in the pathogenesis of AD. Subsequent studies of familial AD led to the discovery of a mutation in the amyloid precursor protein (APP) on chromosome 21 (Goate et al. 1991; St. George-Hyslop et al. 1990). Although such patients represent only 3% of all familial AD, they firmly connect amyloid to AD pathogenesis. Transgenic mice with the APP mutation develop a progressive dementing disorder (D'Hooge et al. 1996) with AD-like neuropathology (Hsiao et al. 1995), further implicating amyloid in the pathogenesis of AD. Therefore, overproduction of amyloid as occurs with Down's syndrome or the presence of a mutation on chromosome 21 in the gene coding for amyloid predispose to AD.

Beyond amyloid, a complex picture regarding AD and genetics is emerging. The most common mutation associated with early onset AD is found in the presenilin 1 gene on chromosome 14 (Schellenberg 1995), and it accounts for approximately 50% of all early onset familial AD. With this mutation, AD usually begins in the fifth decade. A mu-

tation in a homologous protein on chromosome 1 (presenilin 2) has been found in a few families (Rogaev et al. 1995). The function of the presenilins is unknown, but this is an area of intense research (Mattson and Guo 1997).

Finally, apolipoprotein E4 greatly increases the risk that the carrier will develop AD. Unlike the presenilin and APP mutations, most cases associated with this allele develop AD after the age of 60. Carrying one apolipoprotein E4 increases the risk for AD by 2.5 times. Two E4 proteins increase the risk by 20-fold, with 90% of carriers developing AD by age 90 (Mayeux et al. 1998; Roses 1995). As with the APP mutations, transgenic mice carrying the apolipoprotein E4 allele also develop a progressive dementing disorder. Some researchers suggest that screening for apolipoprotein E4 will help the clinician to pinpoint cases of dementia that are not a result of AD (Mayeux et al. 1998). However, this concept is still controversial because there are individuals with dementias not the result of AD who carry the apolipoprotein E4 allele, and there are patients with AD in whom the E4 allele is not present.

Environmental risk factors play a role in the pathogenesis of AD. Head injury (Graves et al. 1990) and possibly small head size (Graves et al. 1996) increase the risk for AD. Also, there is a greater prevalence of AD in low socioeconomic groups (Zhang et al. 1990). Diminished idea density in a young group of nuns proved to be a risk factor for developing AD later in life (Snowdon et al. 1996). The association between low education and AD is now accepted, although the exact mechanism for the association is still unknown. Whether it is related to diminished education or represents a genetic factor (Gatz et al. 1997; Pedersen et al. 1996) that influences the likelihood that an individual will obtain a good education is debated. However, an emerging consensus has developed that individuals with diminished synaptic concentration, whether genetic or acquired, are at greater risk for AD.

Various studies have found nongenetic factors offering protection from AD. Women who take estrogen postmenopause appear to be at a lower risk for AD than women who do not (Paganini-Hill and Henderson 1994). Inflammation is an important component of AD pathology (McGeer and McGeer 1997) and nonsteroidal anti-inflammatory compounds may lower the risk for developing AD (Stewart et al. 1997). Currently, larger studies are under way to determine whether or not these purported protective agents will truly benefit those at risk for AD.

## Cognitive Features

AD is a progressive dementia characterized by a slow decline in memory, language, visuospatial skills, personality,

and cognition (Cummings and Benson 1992). Often, the first symptom of AD is loss of the ability to learn new information—amnesia. Three major types of memory—episodic, semantic, and working—are lost with AD. Episodic memory, or memory for events, is highly dependent on the hippocampus, and loss of episodic memory is a key deficit in AD (Graham and Hodges 1997). Initially, the patient is forgetful and repetitive, losing objects, repeating stories, and missing appointments. Eventually, both storage and retrieval of episodic memory become severely impaired. Unlike the memory problems seen with frontal or subcortical injury, clues do not dramatically help the patient to remember.

Semantic memory, or memory for facts and general information, deteriorates in AD. In the early stages of AD, it is not as severely impaired as episodic memory. The deficit in semantic memory leads to loss of recall for historical facts or names. Work with a subgroup of patients with FTD (Hodges et al. 1992) suggests that semantic memory is highly dependent on the function of the left anterior temporal neocortex, a region that is also vulnerable to AD pathology.

Also abnormal in AD is working memory, the ability to briefly hold and then manipulate small bits of information. This relies upon intact prefrontal cortex and posterior temporoparietal cortex (Waltz et al., in press) and is markedly impaired with AD. The amnesia of AD is the result of the deficiency of brain acetylcholine (Bartus et al. 1982; Whitehouse et al. 1981) and pathological damage in areas involved with learning and memory.

Language decline follows a characteristic course. Diminished list generation is the first deficit, and this is followed by word-finding trouble. Then, a fluent aphasia emerges, associated with diminished comprehension (Cummings et al. 1985). Neuropathology is extensive in brain regions posterior to Wernicke's area, and a transcortical sensory aphasia often develops. Next, AD spreads anteriorly to Wernicke's area, and a Wernicke's aphasia is seen. Finally, patients become mute.

Visuospatial deficits develop early. Navigating, cooking, or manipulating mechanical objects in the home are visuospatial tasks, and the ability to perform them is often lost in the first stages of AD. Drawing becomes abnormal, and one should question the diagnosis of AD if the patient can copy intersecting pentagons or a three-dimensional figure. Eventually, ability to perform overlearned visuospatial tasks such as using household items and dressing are lost. Simultaneously, many patients develop an apraxia and lose the ability to perform organized motor movements. Injury to the right parietal lobe is largely responsible for the visuospatial deficits, whereas left parietal dysfunction accounts for the apraxia.

Deficits occur in cognition, the ability to manipulate new information. Mathematical and business skills, judgments about wills, and driving ability deteriorate. At times, this impairment in cognition can lead to complex legal problems. Driving, in particular, has been an area of intense research (Fitten et al. 1995; Lundberg et al. 1997), and patients with AD are more likely to suffer serious consequences (Friedland et al. 1988) than elderly patients without dementia. Therefore, many states require that patients with a diagnosis of dementia be reported to the department of motor vehicles. Parietal and frontal injury both contribute to this aspect of the disease.

The period from onset to death typically takes from 7 to 11 years. In some patients, AD progresses with extreme rapidity over several years, whereas in others, it advances slowly over many decades. Initially, deficits in higher cortical function predominate, whereas during the middle stages of the disease patients often develop behavioral and motor problems that progressively impair movement. Finally, inability to swallow leads to aspiration pneumonia, often the cause of death.

## Neuropsychiatric Features

Subtle personality changes occur in AD, sometimes as an early symptom (Petry et al. 1989; Rubin et al. 1987). Patients may show decreased energy, indifference, egocentricity, impulsivity, or irritability. Sometimes, social withdrawal and selfishness develop. However, in contrast to patients with FTD, many with AD show normal social skills. Also, profound changes in judgment or behavior are unusual in the early stages of AD.

Estimates for the prevalence of depression in AD range from zero to 57% (Cummings et al. 1987). Major depression is uncommon, but many patients with AD have periods of depressed mood associated with a feeling of inadequacy and hopelessness. This depression is often modifiable by environmental manipulations, although pharmacological treatment with the selective serotonin reuptake inhibitors is sometimes necessary and can be highly effective. As AD progresses, delusions, agitation, and even violence are seen. Delusions in AD often relate to theft, infidelity, or Capgras's syndrome (Cummings et al. 1987; Ponton et al. 1995). Hallucinations are unusual until the later stages and can signify a confusional state. The anatomical basis for these psychiatric syndromes is injury to the parietal, frontal, and limbic cortex (Cummings 1992).

Disorders of sleep, eating, sexual behavior, and psychomotor activity are common. Over 50% of caregivers describe sleep disturbances in the AD patient (Swearer et al. 1988). Telemetry with electroencephalography (EEG)

shows more awake time in bed, longer latencies to rapid-eye-movement (REM) sleep, and loss of slow-wave sleep (Prinz et al. 1982). Decreased appetite is common, although weight gain is seen. Loss in sexual drive is more common than increased drive. Psychomotor activity is increased, and motor restlessness, wandering, agitation, and aggression occur. These behaviors lead to severe problems for the caregivers and often precipitate institutionalization. Pathological changes in the hypothalamus and ascending catecholaminergic, serotonergic, and cholinergic cortical projection systems may account for these alterations in behavior.

### Differential Diagnosis

Inaccuracy of diagnosis continues to plague AD research and clinical care. In one study (Boller et al. 1989), the diagnosis of two clinicians was compared with findings at pathology. In 63% of cases, both clinicians were correct; in 17% of cases, one was correct; and in 20% of cases, neither was correct. Still, diagnostic accuracy rarely reaches 95%, and studies with this degree of accuracy usually come from the assessment of groups of highly selected patients for whom diagnosis is more certain (Galasko et al. 1994; Read et al. 1995). In many settings, AD is overdiagnosed and patients with FTD, Parkinson's disease, Lewy body disease, and vascular dementia often are diagnosed during life as having AD. In addition, medically treatable dementias continue to be reported in postmortem studies from research centers (Joachim et al. 1988).

Research has helped improve diagnostic accuracy for AD and non-AD dementias. The National Institute of Neurological and Communicative Disorders and Stroke–Alzheimer's Disease and Related Disorders Association (NINCDS-ADRDA) work group established research criteria for probable and possible AD (McKhann et al. 1984). The Mini-Mental State Examination (MMSE) (Folstein et al. 1975) is a simple test that allows quantification of dementia severity. The Ischemia Scale identifies those patients in whom a vascular contribution to dementia is likely (Hachinski et al. 1975). Such tools have helped to refine AD diagnosis.

AD is no longer a "diagnosis of exclusion," that is, diagnosed by excluding other treatable disorders. Rather, an effective approach has been championed by various researchers (Cummings and Benson 1992; Gustafson 1987; Neary et al. 1988) who diagnose AD and other disorders by their clinical phenomenology. Because AD leads to dysfunction in brain regions different from those affected in FTD and most cases of vascular dementia, a clinical (and imaging) evaluation that focuses upon the brain areas that

are not functioning properly can be effective in improving diagnosis (Read et al. 1995).

Many metabolic and toxic illnesses cause cognitive impairment, and elderly patients are particularly vulnerable to developing delirium or dementia from systemic insults. Examples of systemic diseases and conditions that can lead to a dementia are thyroid disease, hyponatremia, B<sub>12</sub> deficiency, depression, vasculitis, and brain hypoxia from pulmonary disease or arrhythmia (Giombetti and Miller 1990); see also Chapter 26 in this volume. Psychoactive medications can also lead to dementia. Primary brain diseases that may mimic AD include brain tumor, stroke, hydrocephalus, syphilis, Lyme encephalopathy, and Whipple's disease. Some of these conditions are treatable, and the dementia can be reversed.

### Neuroimaging

Neuroimaging techniques show promise for further improving diagnosis. Computed tomography (CT) helps to identify focal brain masses or hydrocephalus and detects many, but not all, previous strokes. AD leads to generalized cerebral atrophy, although atrophy also occurs in elderly individuals without AD and in patients with non-AD degenerative dementias. Therefore, atrophy by itself is unreliable as a diagnostic marker for AD.

Magnetic resonance imaging (MRI) is better than CT at defining pathology in the temporal and basofrontal lobes, brainstem, and white matter. However, as with CT, atrophy on MRI cannot be used to make a presumptive diagnosis of AD, although quantitative analyses using MRI distinguish most patients with AD from elderly control subjects without AD by showing reductions in brain size and increases in cerebrospinal fluid in the AD group (DeCarli et al. 1990, 1996). MRI is better than CT for defining vascular disease, particularly white matter disease, a common finding in elderly populations (Boone et al. 1992).

White matter disease has many causes, with hypertension and genetics the strongest known risk factors (Carmelli et al. 1998; Pedersen et al., in press; Salerno et al. 1992). White matter hyperintensities can cause dementia, but large confluent lesions must be present before gross cognitive impairment is seen (Boone et al. 1992; DeCarli et al. 1996; Liu et al. 1992).

Positron-emission tomography (PET) and single photon emission computed tomography (SPECT) help to define dysfunctional brain areas in AD. With both PET (Benson et al. 1983; DeCarli et al. 1996) and SPECT (Jagust et al. 1987), marked deficits in metabolism or perfusion in the temporoparietal cortex and hippocampus, areas where plaques, tangles, and neuronal loss are most intense,

can be seen. In contrast, in brain regions where function is better, such as motor, sensory, and visual cortex, these techniques reveal relatively normal metabolic activity or perfusion.

Neither technique has perfect sensitivity nor specificity. Temporoparietal hypoperfusion is not specific to AD and is seen with hypoxia, sleep apnea, and sometimes vascular dementia or Creutzfeldt-Jakob disease (Miller et al. 1990). Many patients with AD show marked asymmetry with SPECT or PET (Grady et al. 1990), and others show normal patterns. However, functional imaging is helpful in the differential diagnosis of degenerative brain disease, particularly in separating AD from FTD (Brun et al. 1994). Several groups (Read et al. 1995; Risberg et al. 1993) report that greater than 90% of patients with FTD can be differentiated from those with AD based upon SPECT. Also, many, but not all, patients with Creutzfeldt-Jakob disease show with PET a mottled multifocal pattern of cerebral metabolism (Benson 1983), which is distinct from that of AD or FTD. With PET (Kuhl et al. 1984) and SPECT (Miller et al. 1996), many patients with parkinsonian dementia show temporoparietal hypometabolism. However, this overlap does not reflect a deficiency of functional imaging because many patients with parkinsonian dementia have AD (Hansen and Samuel 1997).

With PET and SPECT and perfusion MRI (Sandson et al. 1996), temporoparietal changes are shown occurring early. Using SPECT, Johnson and colleagues (1998) found deficits in memory circuitry before the onset of clinical disease. With PET, apolipoprotein E4-positive subjects showed temporoparietal metabolic deficits in preclinical stages (Reiman et al. 1996; Small et al. 1996). Other researchers have used activation paradigms with functional MRI to determine the earliest deficits associated with this illness (Gabrieli 1996).

Finally, magnetic resonance spectroscopy shows promise for AD diagnosis. In AD, decreased *n*-acetyl-aspartate (a neuronal marker) and increased myoinositol are found (Miller et al. 1993a). More recently, Weiner and colleagues (Schuff et al. 1998) have developed a sophisticated technique for quantifying both hippocampal atrophy and neuronal loss. The combination of these two parameters led to the correct classification of 94% of control subjects and 90% of subjects with AD. Comparisons between spectroscopy and functional imaging have not yet been performed.

## Neurochemistry

Many neurochemical deficits occur in AD. The cholinergic deficit was discovered approximately 20 years ago

(Bowen et al. 1976; Davies and Malony 1976; Perry et al. 1977), and this finding was the theoretical basis for the anticholinesterase medications that were developed for the treatment of AD. Other AD-related neurochemical deficits include the loss of somatostatin and serotonin (Bowen and Davison 1986), whereas dopamine loss is more variable. In contrast, patients with FTD have normal levels of cortical acetylcholine, but marked decreases in brain serotonin (Sparks and Markesbery 1991).

## Neuropathology

The main features of AD are amyloid plaques, neurofibrillary tangles, and neuronal and synaptic loss. The center of the amyloid plaque consists of a 42-amino acid protein derived from the APP (Glenner and Wong 1984) found on chromosome 21 (St. George-Hyslop et al. 1990). Surrounding the plaque is an area of gliosis and degenerating synapses. Plaque density is greatest in hippocampus and posterior temporoparietal cortex. Although plaques are found in elderly individuals without AD, plaque concentration is far less than that in patients with AD (Blessed et al. 1968). Amyloid accumulates in meningeal vessels (Vinters et al. 1990) and fatal hemorrhages can occur as a result of the effect of amyloid on these vessels (Vinters and Gilbert 1983).

Neurofibrillary tangles are present within neurons and stain positively with antibodies to both tau and ubiquitin (Dickson et al. 1990). Abnormal phosphorylation of the neuronal tau protein is a major factor in the formation of the tangle. Few or no tangles are seen in the neocortex of elderly subjects without AD, but tangles occur with many non-AD dementing conditions including subacute sclerosing panencephalitis, dementia pugilistica, aluminum intoxication, postencephalitic parkinsonism, and the parkinsonian-amyotrophic lateral sclerosis (ALS)-dementia complex of Guam (Wisniewski et al. 1979).

Because elderly individuals without AD have both plaques and tangles, research criteria for AD (Khachaturian 1985) use both the patient age and the concentration of plaques and tangles to determine diagnosis. To meet AD research criteria, patients younger than 50 years must have two to five senile plaques per high-power field in the cortex, whereas subjects between 50 and 65 must have eight plaques per high-power field.

The role of cerebrospinal fluid markers in the diagnosis of AD is still limited. Cerebrospinal fluid tau is elevated in patients with AD compared with that in control subjects without AD (Galasko et al. 1997), but it is also elevated in other dementing disorders such as vascular dementia (Andreasen et al. 1998), FTD, and diffuse Lewy body dis-

ease (Arai et al. 1997). Similarly, APP is diminished in AD (Motter et al. 1996), although this may not differentiate subjects with AD from subjects without AD (Southwick et al. 1996). Efforts toward imaging amyloid as a diagnostic test are ongoing (Walker 1991).

## Treatment

Both nonpharmacological and pharmacological therapies are beneficial in the treatment of AD. The patient's caregivers will require advice and education regarding the dementia, superimposed psychiatric and medical conditions, and psychosocial problems and resources. The best therapies for psychiatric symptoms associated with dementia often involve manipulation of the environment. For example, the patient who awakens during the night will sleep during the day. Increasing daytime exercise and eliminating naps is often more effective than a sleeping medication. It is difficult to manage aggressive behaviors in the home, and their presence often means that the patient will require long-term care.

Most families need extensive advice regarding psychosocial issues. The physician will need to know when the patient might benefit from day care and when a nursing home is required. Similarly, families will need advice regarding the nursing homes most appropriate for their relative. Families often benefit from consultation with attorneys. The Alzheimer's Association, a lay organization dedicated to helping patients and families of patients with AD, is an excellent community resource for family referrals.

Many medications have been unsuccessful in the treatment of the dementia associated with AD. These include calcium channel blockers, vasodilators, anticoagulants, nootropic agents, and acetylcholine precursors (Mody and Miller 1990). But, recently, a variety of medications have shown efficacy in the treatment of AD. Such treatments can be divided into drugs targeted at acute symptom management, improvement of cognition, slowing progression of the disease, and prevention.

Anticholinesterases such as tacrine and donepezil ameliorate deficits in cognition and activities of daily living. Donepezil has a major benefit over tacrine in that it does not have liver toxicity and has become the treatment of choice for AD. Although the gains seen with these compounds are often modest (Growdon 1992), there are patients in whom these medications can lead to spectacular enhancement of day-to-day functions (Kaufer and Cummings 1996). Memory is not the only component of the dementia that will improve, and some subjects showed striking changes in attention, focus, or neuropsychiatric symptoms. In fact, Kaufer and Cummings (1996) found

that improvement on anticholinesterases was greatest in patients in the middle stages of the illness and in whom psychiatric symptomatology was prominent.

Recent efforts have attempted to predict which patients will respond to therapy. In preliminary neuroimaging studies, pretherapy perfusion deficits of the dorsolateral parietal, orbitofrontal, and anterior cingulate regions predicted anticholinesterase responders (Mega et al. 1998). Similarly, the anticholinesterase inhibitor metrifonate has been shown to improve behavioral symptoms, in addition to the cognitive deficits, of patients with AD (Cummings et al. 1998).

Preventive therapy is directed at increase of neuronal survival, inhibition of amyloid plaque formation, and suppression of abnormal tau protein formation. Nonsteroidal anti-inflammatory compounds, selective COX-2 inhibitors, neurotrophic factors, vitamin E, and other antioxidants are being investigated as possibly increasing neuronal survival. In a large clinical trial (Sano et al. 1996), 2000 IU of vitamin E delayed institutionalization and death. Attempts to replicate a benefit for vitamin E in patients with early AD are under way.

As is noted earlier in this chapter, estrogen replacement therapy in postmenopausal women has been shown to prevent cognitive decline (Paganini-Hill and Henderson 1994). The mechanisms for estrogens are not completely known although they can increase neuronal sprouting and survival. Androgens are also being explored as a potential therapeutic agent for men.

Treating superimposed medical conditions can be difficult, as they are often subtle and hard to diagnose. The patient with advanced AD who has little or no verbal expression cannot communicate, and even small problems such as constipation or a tooth cavity can go unrecognized, leading to serious complications such as bowel obstruction or orofacial abscess. Immobility and aspiration pneumonia are the major causes of mortality in AD. Because patients do not suddenly deteriorate as a result of AD, when sudden deterioration occurs one should suspect an infection, stroke, myocardial infarction, or drug-induced delirium (Giombetti and Miller 1990).

Drug therapies for AD-associated psychiatric symptoms often have substantial side effects. Depression responds to antidepressants, but also to placebo (Teri et al. 1991). Violent psychosis is improved with traditional antipsychotics, but these medications are sedating, and sudden death has been described in patients with AD who exhibit parkinsonian features (McKeith et al. 1992). New atypical antipsychotics such as risperidone and olanzapine may be safer based on clinical experience, though controlled trials have not been conducted. Benzodiazepines

rarely help anxiety and may cause a paradoxical increase in agitation.

## ■ Dementia With Lewy Bodies

Dementia with Lewy bodies (DLB) is a clinicopathological entity with histological features overlapping with those of AD. The clinical characteristics of DLB include a dementia syndrome and two of the three following features: fluctuating cognition, visual hallucinations, and parkinsonism. The typical dementia syndrome of DLB resembles that of AD, but the patients typically have less severe memory impairments early in their clinical course and may have more evidence of executive dysfunction. Fluctuating cognition refers to relatively dramatic day-to-day fluctuations in patient cognitive function. In some cases, periods of loss of consciousness or syncope can occur. The typical visual hallucinations of DLB are silent, well-formed images of people, objects, or animals that the patient endorses as real. Parkinsonism in DLB is usually mild and features rigidity and bradykinesia with little tremor. Supportive features of the diagnosis of DLB include delusions, hallucinations in other sensory modalities, hypersensitivity to neuroleptic medication, falls, syncope, and episodic loss of consciousness (McKeith et al. 1996). The course of DLB from recognition of symptoms to death is 6–8 years, shorter than the natural history of AD. Death may be hastened by the use of conventional neuroleptic medication.

Neuropathologically, patients with DLB are found at autopsy to have extensive neurotic plaque similar to that found in patients with AD. Patients with DLB have few neurofibrillary tangles, and they have extensive Lewy body formation, particularly in paralimbic cortical areas such as anterior cingulate gyrus, insular cortex, and medial temporal regions. Lewy bodies also are found in neocortex. Patients with DLB have brainstem pathology, with Lewy bodies in the substantia nigra. The pathological changes in the brainstem are typically less extensive than those found in Parkinson's disease.

Patients with DLB have a marked deficit in choline acetyltransferase and a consequent deficiency in acetylcholine synthesis in the cortex (Perry et al. 1990). The cholinergic deficiency is more marked in patients with prominent visual hallucinations than those without. Also, a modest loss of dopamine in the striatum is seen, corresponding to the reduction of cells in the substantia nigra (Perry et al. 1990).

The approach to treatment of DLB is similar to that for AD. Cholinesterase inhibitors may ameliorate the cognitive deficit and often produce a beneficial behavioral

response. Conventional neuroleptic medications must be avoided because of excessive neuroleptic sensitivity, but delusions and hallucinations may respond well to novel antipsychotics including risperidone, olanzapine, or quetiapine. Depressive symptoms are common in DLB and should be treated with selective serotonin reuptake inhibitors.

## ■ Frontotemporal Dementia

### Nosology

The second group of dementing disorders, the FTDs, are associated with degeneration of the anterior frontal and temporal lobes. The taxonomy connected with FTD is both confusing and controversial, related in large part to our fundamental lack of knowledge concerning the pathogenesis of these conditions. Compounding this problem, many researchers have described new disease entities (or resurrected diagnoses from prior decades) to describe patients in whom clinical or pathological findings are slightly different from those found in classical Pick's disease.

Some terms used to describe diverse syndromes with similar pathology include progressive subcortical gliosis (Neumann and Cohn 1967), dementia of frontal lobe type (Neary et al. 1988), frontal lobe dementia of non-Alzheimer type (Brun 1987), dementia lacking distinctive histological features (Knopman et al. 1990), primary progressive aphasia (Mesulam 1982), semantic dementia (Snowden et al. 1992), and the temporal lobe variant of FTD (Edwards-Lee et al. 1997). Further complicating this nomenclature dilemma is the discovery that some patients with ALS develop FTD and, in these patients, the pathological findings in cortex suggest Pick's disease (Sam et al. 1991) or FTD without Pick's bodies (Mitsuyama 1984). Recently, some have suggested that corticobasal degeneration is a subtype of FTD due to the clinical and pathological overlap of the two conditions (Jackson and Lowe 1996; Kertesz 1997).

The Lund and Manchester research groups established guidelines for diagnosis and suggested the term frontotemporal dementia (Brun et al. 1994); this term is used in this chapter. As described below, new genetic findings related to FTD may help to clarify whether or not these entities should be split or lumped together.

### Epidemiology

The prevalence of FTD is hard to estimate, in part, because many patients with FTD are either not recognized during

life or are misdiagnosed as having AD (Mendez et al. 1993). The best data on prevalence come from studies in Lund, Sweden, and Manchester, England. In the Swedish study (Gustafson et al. 1990), 20 of 150 (13.3%) patients with presenile dementia had the characteristic pathological findings of FTD including frontal and usually anterior temporal lobe gliosis, spongiosis, and neuronal dropout. Only four patients (2.7% of total) had classical Pick's disease, whereas 16 (10.6% of total) had FTD without Pick's bodies. In the Manchester study (Neary et al. 1987), 21.9% of 41 patients with a presenile dementia had FTD.

The typical age at onset for FTD is the sixth to seventh decade, with duration of illness being approximately 7 years. Between 38% and 60% of patients with FTD have a family history of dementia; often the history suggests a dominantly inherited illness (Gustafson 1993; Miller et al. 1998; Stevens et al. 1998). In the University of California–Los Angeles (UCLA) cohort, approximately one-half of the patients had at least one first-degree relative with FTD or a related disorder such as ALS. Of this group, 86% appeared to have a dominant pattern of inheritance (Chow et al. 1999).

The genetic basis for FTD is being aggressively studied. Some suggest that the E4 allele is slightly over-represented in FTD (Stevens et al. 1997), whereas others disagree with this (Geschwind et al. 1998; Mesulam et al. 1997). Wilhelmsen and colleagues (1994) showed linkage of FTD to chromosome 17 in a large family with “disinhibition–dementia–Parkinsonism and amyotrophy.” Later, linkage to this region was also found in patients with progressive subcortical gliosis, multiple tauopathy, hereditary dysphasic dementia, pallidopontonigral degeneration, and bilateral amygdala degeneration (Foster et al. 1997). In some families with 17-linkage there are mutations in the tau gene (Clark et al., in press; Hutton et al. 1998; Poorkaj et al., in press). In contrast to the rapid advances in FTD genetics, epidemiological studies have yielded little fruit because clinical cohorts used to study FTD have been too small for study results to make meaningful statements about other risk factors.

## Clinical Features and Differential Diagnosis

Although the varied syndromes associated with FTD have slightly different clinical features, similarities among the different entities are far outweighed by differences. Usually, changes in personality precede gross dementia by several years (Miller et al. 1991). Many patients are socially withdrawn and apathetic (Cummings and Duchon 1981; Gustafson 1987; Neary et al. 1987). Also, behavioral

disinhibition and loss of judgment and insight are common. This can lead to legal difficulties; in one study, nearly 50% of patients with FTD committed an antisocial act that either led to or could have led to arrest (Miller et al. 1997a). Insight or concern into these legal problems is usually diminished or absent.

The symptoms of apathy and disinhibition can be explained by dysfunction of the frontal lobes. Blumer and Benson (1975) called these the pseudodepressed and pseudopsychopathic personality disorders of frontal lobe dysfunction. Apathy occurs as a result of medial frontal injury, whereas disinhibition is the result of basofrontal dysfunction (Cummings 1993). Both areas are usually involved in FTD.

Peculiar behaviors develop that are in part a result of involvement of the anterotemporal lobes. Klüver–Bucy syndrome was described in macaque monkeys after the anterotemporal lobes and amygdala were removed (Klüver and Bucy 1939). These monkeys developed hyperorality, hypersexuality, visual hypermetamorphosis, placidity, and sensory agnosia. In addition, anterotemporal lobectomized primates lose socially affiliative behavior (Kling and Steklis 1976). Common behavioral findings that can be attributed to anterotemporal lobe dysfunction include hyperorality, placidity, compulsive motor behaviors, bizarre and remote affect, hyperreligiosity, and development of eccentric ideas.

Another possible explanation for the hyperorality, carbohydrate craving, and compulsions found in FTD is the loss of brain serotonin associated with this condition (Sparks and Markesbery 1991). Approximately two-thirds of subjects with FTD show hyperorality, carbohydrate craving, and compulsions (Miller et al. 1995). These symptoms are manifested by compulsive gum chewing or smoking, massive weight gain, and an intense craving for sweets. Compulsive collecting and ritualistic obsessions related to urination or bowel movements are common.

Once cognitive symptoms develop, a characteristic pattern of decline ensues. Initially, language output is economical, and, as the disease progresses, verbal stereotypes, such as “let's go, let's go,” are seen. Some patients become mute while other cognitive skills are still relatively intact. As in AD, an early change in language is difficulty in generating a word list, but, unlike in AD, semantic anomia is common, particularly in those patients with left anterotemporal lobe dysfunction. With this anomia, the patient is not helped by clues, and, when told that an object is a key, the patient might say, “Key, key, I don't know what a key is.” Hodges and colleagues (1992) and Snowden and colleagues (1992) have named this *semantic dementia*. Patients with predominantly frontal lobe pathology do not

typically show this type of language disorder.

Parietal and posterior language functions such as reading, writing, and calculation are spared in the early and even middle stages of FTD (Neary et al. 1988). Unlike in AD, visuospatial skills are usually normal or near normal, and many patients can draw in three dimensions without difficulty. Some patients can draw complex designs and multiply three-number integers at a time when they are mute and behaviorally impaired.

Neuropsychological testing shows selective impairment of executive skills in the early stages. This includes perseveration and difficulties in set shifting, impairments in verbal and design fluency, poor attention, and impaired response inhibition. Word retrieval, memory, calculation, and pencil-and-paper constructional skills are generally spared relative to executive abilities (Miller et al. 1991). However, it is difficult to use neuropsychological testing alone to differentiate patients with FTD from those with AD (Pachana et al. 1996).

Motor systems are initially normal. However, as FTD advances, parkinsonian symptoms including diminished eye movements, tremor, and bradykinesia develop in some patients. Some patients develop ALS months to years after the onset of their dementia, whereas in others manifestations of ALS precede dementia. In the end stages, FTD is difficult to distinguish from AD.

The EEG shows frontal slowing over a normal background in the early phases (Yener et al. 1996). CT and MRI can be normal at first, although often both show anterior atrophy at the time of presentation (Gustafson et al. 1990; Miller et al. 1991). SPECT and PET detect cerebral dysfunction in the frontal and temporal regions even in patients without major cognitive deficits. SPECT shows frontal and sometimes temporal hypoperfusion in early FTD (Brun et al. 1994; Jagust et al. 1989; Neary et al. 1988) (Figure 24–1). In some patients, the temporal lobes are more severely involved than the frontal regions. Unlike in AD, posterior temporal areas show relatively normal perfusion. PET demonstrates frontotemporal hypometabolism (Kamo et al. 1987). Using careful clinical parameters and SPECT, several groups (Read et al. 1995; Risberg et al. 1993) achieved diagnostic accuracy of greater than 90%. SPECT and PET show promise for improving clinical diagnosis; with these modalities, patients with FTD can usually be distinguished from those with AD (see SPECT images in Figure 24–2).

The Lund and Manchester research groups have suggested a series of items that help to diagnose FTD. They listed 26 items, all graded as “yes” or “no.” The items are divided into the following categories: behavior, speech, affect, spatial orientation/praxis, physical signs, investiga-

tions, and supportive findings. Also, there are 14 exclusion items. We studied the sensitivity and specificity of these items in separating patients with FTD from those with AD. We scored every patient on each item and compared the two groups. A discriminant function showed that loss of personal awareness, hyperorality, stereotyped and perseverative behavior, progressive reduction of speech, and preserved spatial orientation differentiated 100% of FTD and AD subjects (Miller et al. 1997b). Items relating to affect and physical findings were not different in FTD versus AD. Loss of personal awareness, eating, perseverative behavior, and reduction of speech are the Lund-Manchester Research Criteria items that most clearly differentiate FTD from AD. Tables 24–1 and 24–2 compare and contrast the neuropsychiatric and neuropsychological differences of AD and FTD.

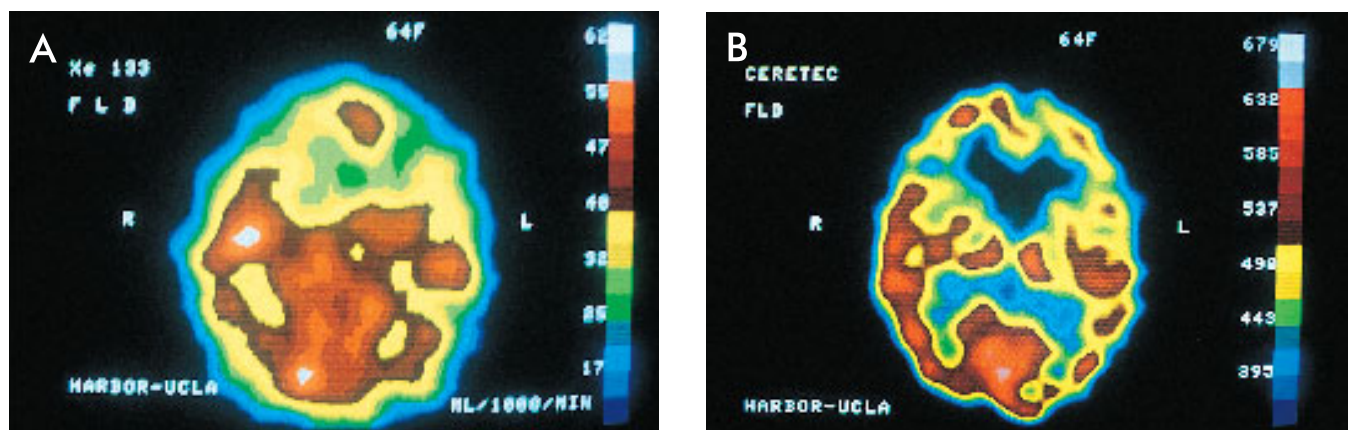

## Neuropathological Findings

All of the clinical entities described show neuropathological similarities. Brain weight is slightly to moderately reduced. Grossly, the brain has mild-to-severe frontal and/or frontal and anterotemporal atrophy. Neuronal loss, gliosis, and mild-to-moderate spongiform changes are found, primarily in the first three layers of the cortex. Gliosis is visualized with stains for glial acid fibrillary protein. Neuronal loss can be subtle, but disruption of neuronal cytoskeleton is seen, and there is dying back of neurons, which stain as periodic acid–Schiff (PAS)-positive spheroids (Zhou et al., in press). Plaques and tangles do not occur beyond what is seen in elderly individuals without FTD. Subcortical structures, such as the substantia nigra, are often abnormal. Severe degeneration of the substantia nigra was observed in 79% of patients with dementia lacking distinctive histology (Knopman et al. 1990), in 78% of patients with Pick's disease (Kosaka et al. 1991), and in three patients with dementia with motor neuron disease (Horoupian et al. 1984). Table 24–3 contrasts the pathology of AD versus FTD.

## Clinical and Pathological Features of Frontotemporal Dementia Subtypes

As is noted in the section on nosology, a variety of disorders can be considered clinical and pathological subtypes of FTD. These entities are described below.

**Pick's disease.** Pick first described the clinical and gross morphological features of his patients in 1892, but it took almost 20 years before Alzheimer noted the presence of cellular inclusions in Pick's original cases. Pick's disease

**FIGURE 24-1.** *Panel A:* Xenon-133 scan from a patient with early frontal lobe dementia (FLD). Note marked decreases in frontal perfusion. *Panel B:* A technetium-99m-labeled hexamethylpropyleneamine oxime (HMPAO) study from the same subject, showing marked frontal hypoperfusion with normal temporoparietal perfusion.

**FIGURE 24-2.** *Panel A:* Cerebral blood flow with xenon-133 in an elderly control subject. Cerebral blood flow is color coded to mL/100 g tissue per minute. Parietotemporal flow is normal. *Panel B:* Xenon-133 scan in a patient with Alzheimer's disease. Note markedly decreased perfusion to the temporoparietal cortex. *Panel C:* High-resolution scan of cerebral blood flow in an elderly control subject using technetium-99m-labeled hexamethylpropyleneamine oxime (HMPAO). The scan is color coded, and areas of yellow are 50%–62% of maximal cortical perfusion; areas of green are 40%–50%. Perfusion is symmetrical throughout the cortex. *Panel D:* HMPAO scan showing cerebral blood flow in a patient with Alzheimer's disease. Temporoparietal perfusion is approximately 50%–60% of normal (yellow color).

**TABLE 24-1. Psychiatric distinctions**

Diagnosis	Behavior	Affect	Apathy	Delusions	Compulsions	Eating
Alzheimer's disease	Socially correct	Normal	Mild	Simple	Mild	Weight loss
Frontotemporal dementia	Early disinhibition	Remote, bizarre	Severe	Bizarre	Severe	Weight gain

**TABLE 24-2. Neuropsychological features**

Diagnosis	Drawing	Memory	Executive	Generation	Anomia
Alzheimer's disease	Impaired	Impaired	Impaired	Impaired	Lexical
Frontotemporal dementia	Spared	Variable	Severely impaired	Severely impaired	Semantic (often)

**TABLE 24-3. Neuropathology features**

Diagnosis	Plaques	Neurofibrillary tangles	Gliosis	Abnormal genes	Neurochemistry
Alzheimer's disease	Yes	Yes	Proportional to neuronal loss	Amyloid precursor protein, presenilin 1 and 2 Apolipoprotein E4 Tau mutations	Presynaptic cholinergic and serotonergic
Frontotemporal dementia	No	No (except for familial tauopathy)	Out of proportion to neuronal loss		Postsynaptic cholinergic, presynaptic and postsynaptic serotonergic

accounts for 2%–3% of all degenerative dementias (Gustafson et al. 1990), but it is not possible to clinically distinguish patients with Pick's disease from patients with FTD without Pick's bodies. In the early stages, patients develop the Klüver-Bucy syndrome (Cummings and Duchon 1981), whereas in patients with AD this tends to occur in the later stages (Cummings and Benson 1992). As with the other FTDs, deterioration in personality in Pick's disease contrasts with relatively preserved visuospatial skills (Gustafson 1987). Also, language disturbances are common and may consist of semantic anomia, circumlocution, and verbal stereotypies with echolalia (Cummings and Duchon 1981; Miller et al. 1993a). Pick's disease can present as a highly selective language disturbance rather than as a dementia (Pick 1892; Wechsler et al. 1982), though this is more characteristic of the focal atrophies (Malamud and Boyd 1940; Mesulam 1982; Snowden et al. 1992). Neuropsychological tests show mainly frontal lobe dysfunction. These clinical, neuropsychological, and pathological findings are reflected in metabolic alterations revealed by PET (Kamo et al. 1987).

At autopsy, the brains of patients with Pick's disease show circumscribed atrophy of the frontal and/or temporal lobes. Microscopically there is neuronal loss, gliosis, and Pick's bodies, which are argentophilic cytoplasmic inclusions that fill inflated neurons (Pick's cells) (Corsellis 1976). These cells may be rare, and an extensive search may be necessary to achieve diagnosis. Asymmetric involvement of the frontotemporal lobes is seen in 70% of patients; 50% have more left-sided atrophy (Corsellis 1976; Cummings and Benson 1992). PET identifies reduced perfusion and metabolism in the frontal and temporal lobes (Kamo et al. 1987). However, tissue confirmation of Pick's bodies is needed for diagnosis, and functional imaging cannot distinguish patients with Pick's disease from those with FTD without Pick's bodies.

**Frontal lobe dementia of the non-Alzheimer type and dementia of the frontal type.** During the 1980s, studies performed by the Lund, Sweden, and Manchester, England, groups brought FTD into the modern era. In Lund, Brun, Gustafson, and Risberg carefully

characterized the clinical, perfusion, and pathological features of a large population with dementia. Of their first 150 patients, 20 showed non-AD pathology that affected the frontal and temporal regions. Hence the name “frontal lobe dementia of the non-Alzheimer type.” Four patients showed classical Pick’s disease whereas 16 showed frontal and temporally predominant gliosis, spongiosis, and neuronal loss without Pick’s bodies. Brun emphasized that the gliosis selectively involved the first three layers of cortex (Brun 1987).

Similarly, the Manchester group, led by Neary and Bowen, performed a biopsy study of patients with presenile dementia. Histology was performed immediately following biopsy so that a diagnosis was quickly obtained. Neary and colleagues (1988) noted the distinctive frontal clinical and imaging features of a subtype in whom biopsy showed gliosis, neuronal loss, and spongiosis. They chose the term “dementia of the frontal lobe type” to describe this population who shared the clinical and pathological features of the patients seen in Lund. In 1994, the Lund and Manchester groups (Brun et al. 1994) established research criteria for these conditions and replaced previous nomenclature with the term FTD.

**Dementia lacking distinctive histological features.** The categories “dementia of the frontal lobe type” (Neary et al. 1988), “frontal lobe dementia of the non-Alzheimer type” (Brun 1987), and “dementia lacking distinctive histological features” (Knopman et al. 1990) seem to be describing the same disorders. In the study by Knopman et al. (1990), the authors emphasized memory loss, prominent personality changes, and prominent dysphagia and dysarthria in later stages. Death of patients occurred within 7 years of onset of dementia. Fifty percent of patients had a positive family history of dementia, and cases of ALS were seen rarely in these families. It was difficult to distinguish these patients from those with classical Pick’s disease at autopsy.

**Progressive subcortical gliosis.** Neumann and Cohn (1967) described a “new disease entity” for which they coined the term *progressive subcortical gliosis*. Clinically, their patients showed personality changes including social impropriety, poor judgment, and perseveration. Memory impairment was common. One patient was unable to recognize family members and had paraphasias; another had childish behavior and paranoid delusions. Some developed muscle atrophy before death. Functional imaging studies were not performed, but clinically and pathologically these patients seemed similar to patients with FTD.

Pathologically, frontotemporal atrophy was seen. Also, neuronal loss with reactive astrocytosis occurred in

cortex, whereas rich gliosis was found in the subcortical areas. Ventral horns and substantia nigra showed abnormal gliosis. The presence of muscle atrophy and ventral horn gliosis in patients with progressive subcortical gliosis suggested a possible relationship between this disease and ALS. Our own most recent patient with this syndrome had a fulminant ALS associated with a progressive frontal syndrome. He resembled many of our patients with FTD on clinical and imaging features. A familial incidence has been found with progressive subcortical gliosis and linkage to chromosome 17 (Petersen et al. 1995). The prominent pathological feature of these patients is intense gliosis at the junction of six-layer cortex and white matter. However, because of the overlap between this entity and Pick’s disease, the original authors called it “Pick’s disease, type II” (Neumann 1949).

**Focal lobar atrophies.** Although awareness of an entity associated with focal degeneration of language areas dates back at least to Alajouanine’s description of the composer Ravel (Alajouanine 1948), it was Mesulam (1982) who first defined the entity of primary progressive aphasia. Mesulam described six patients with a progressive aphasia without signs of global dementia. Symptoms in five patients began with anomia, whereas symptoms in the sixth started with pure word deafness. Most progressed for years with language disturbance, while right-hemisphere functions and memory remained intact. Studies with both SPECT (Mesulam 1982; Snowden et al. 1992) and PET (Chawluk et al. 1986) demonstrated focal hypoperfusion in the left anterior hemisphere, whereas the right hemisphere showed mild or no hypoperfusion. Focal degeneration of the left anterior hemisphere can be genetically programmed, and Morris and colleagues (Lendon et al. 1998; Morris et al. 1984) have described a large family with this syndrome in whom linkage to chromosome 17 is present.

Although there are many reports on left frontotemporal lobar atrophies, only isolated reports exist concerning the behavioral and neuropsychological changes associated with right frontotemporal degeneration (Tyrrell et al. 1990). We described five patients with progressive right frontotemporal dysfunction, all of whom differed clinically and neuropsychologically from patients previously studied with left frontotemporal degeneration (Miller et al. 1993b). Our five patients exhibited dramatic changes in personality characterized by remote affect, severe behavioral disinhibition, agitation, hyperreligiosity, and impaired judgment. They showed profound disruption of social conduct. Also, they had difficulty recognizing familiar faces and voices, and, surprisingly, some had a semantic anomia. They had less language difficulty and

slightly more visuoconstructive problems than patients with left frontotemporal involvement.

Patients with progressive aphasia have been examined neuropathologically. In this population, the anatomical abnormalities typically are neuronal loss, gliosis, and atrophy localized primarily to the left temporal region, particularly the left-inferior and middle-temporal gyri. These findings mimic what is seen with FTD. We have seen similar changes in patients with right temporal atrophy.

**Amyotrophic lateral sclerosis.** Classically, lesions in ALS are localized to the upper and lower motor neurons. However, studies show that other areas of the cortex are often involved (Hudson 1991). Clinically, up to 15% of patients with ALS develop mental symptoms (Hudson 1981), and the cognitive changes often suggest frontal involvement (Hudson 1991; Mitsuyama 1984; Morita et al. 1987). Also, Klüver-Bucy syndrome has been described.

Patients with ALS show deficits in neuropsychological testing (Peavy et al. 1992). Although many patients are neuropsychologically normal, others show serious deficits in frontal systems tasks and memory. In vivo studies with PET, using [ $^{18}\text{F}$ ]fluoro-2-deoxyglucose, have shown generalized hypometabolism, most severe in the sensorimotor cortex and putamen (Dalakas et al. 1987; Hatazawa et al. 1988). Focal frontal and temporal hypometabolism was not reported. Similar patterns have been observed in ALS using SPECT (Figure 24-3). At autopsy, patients with ALS show nonspecific neuronal degeneration and gliosis (particularly in the upper cortical layers) and sponginess of the neuropil, most severely in the frontal and medial temporal regions (Horoupian et al. 1984).

**Secondary frontotemporal dementias.** Finally, there are diseases that cause frontal lobe dysfunction where the main pathology is not at the level of the frontal lobes. Several different mechanisms lead to secondary FTDs. One occurs in patients in whom the primary pathology occurs at the level of the basal ganglia, as in patients with Parkinson's disease, Huntington's disease, and Wilson's disease (Benson 1993). Because there are extensive connections between the basal ganglia and the frontal lobes, injury to the substantia nigra and neostriatum can cause frontal lobe-type dysfunction (Cummings 1993). These illnesses can usually be differentiated from primary FTD because a movement disorder is prominent. Also, the dementia with these diseases is characterized by marked awareness and concern and mental slowing, in marked contrast to the dementia associated with FTD.

A similar mechanism is associated with diseases of subfrontal white matter, which can disconnect the frontal lobes from their subcortical connections. This occurs in some types of vascular dementia such as Binswanger's disease, a few inherited metabolic diseases such as metachromatic leukodystrophy, and a variety of demyelinating illnesses such as multiple sclerosis. These patients can appear clinically similar to those with FTD, although MRI shows extensive white matter lesions not typically present with primary FTD.

With alcoholism, general paresis of the insane, some cases of Creutzfeldt-Jakob disease, and acquired immunodeficiency syndrome (AIDS) dementia, there is a primary attack on the frontal lobes. History, serological testing, and lumbar puncture should differentiate these patients from those with primary FTD. With some diseases, such as

**FIGURE 24-3.** *Panel A:* Xenon-133 scan of a patient with amyotrophic lateral sclerosis (ALS). Note mild frontal and temporal hypoperfusion. *Panel B:* Hexamethylpropyleneamine oxime (HMPAO) scan of the same patient, showing frontal and temporal hypoperfusion.

corticobasal degeneration, parkinsonian-ALS-dementia complex of Guam, Lewy body dementia, many cases of Creutzfeldt-Jakob disease, and AIDS dementia, both the frontal and the subcortical systems are involved. Patients with these diseases can be hard to differentiate from patients with advanced FTD in whom both the subcortical and the frontal lobes are dysfunctional.

## Treatment

There has been little effort to systematically assess treatment associated with FTD. However, we have had some success using selective serotonin reuptake inhibitors. Swartz and colleagues (1997) found that in more than one-half of subjects with FTD the eating disorder, compulsions, irritability, and depressed mood improved with these compounds. Anecdotally, we have found that some patients with FTD show greater irritability when given anticholinesterase compounds, although this has not been formally studied. To date, no therapy has been found that will slow progression or improve cognition.

## Summary

In this chapter, we outlined the clinical, genetic, imaging, and neuropathological characteristics of the two major cortical dementias: AD and FTD. As our knowledge of these conditions advances and as diagnostic tools are refined, improved diagnosis and a better understanding of pathogenesis will become possible. With this, better treatments will emerge.

# Hyperkinetic Movement Disorders

George R. Jackson, M.D., Ph.D.

Anthony E. Lang, M.D., F.R.C.P.

**M**ovement disorders constitute a spectrum of abnormalities that in broadest terms can be classified as either hypokinetic or hyperkinetic (Weiner and Lang 1989). *Hypokinetic* disorders are characterized by significant impairment in the initiation of movement (akinesia) and reduction in the amplitude and speed of movement (bradykinesia), as well as increased muscle tone (rigidity). Idiopathic Parkinson's disease is a prototypic akinetic-rigid syndrome (see Chapter 26 in this volume). In contrast, *hyperkinetic* disorders are characterized by excessive motor activity manifesting as involuntary movements (or dyskinesias). Common types of dyskinesias include tremor, chorea, dystonia, myoclonus, and tics.

Abnormal movements in elderly patients may occur in a wide variety of primary central nervous system disorders (e.g., neurodegenerative diseases). Alternatively, movement disorders in the elderly may be secondary to systemic processes, such as drug exposure, metabolic disturbances, vascular disease, or hypoxic-ischemic injury. A systematic approach to a patient presenting with abnormal move-

ments must include a careful history of the onset and course of illness as well as a detailed physical examination. Evaluation should include a remote and current drug history and documentation of family history. It is often necessary to review this information repeatedly or to seek additional details from other sources (e.g., other family members or physicians). When assessing a hyperkinetic movement disorder, the physician must first attempt to classify the nature of the dyskinesia. This "what is the dyskinesia?" step is a critical first component of the diagnostic approach to patients with movement disorders. It precedes the classic neurological questions of "where is the lesion?" and "what is the lesion?" Once the dyskinesia has been classified accurately using the definitions provided in the following sections, knowledge of the differential diagnosis of a particular dyskinesia guides the diagnostic evaluation and approach to treatment. Investigations will vary depending on clinical suspicion.

Many hyperkinetic movement disorders arise from dysfunction of the basal ganglia. Although the pathophysiology of hyperkinetic movement disorders, such as

Huntington's disease, often may be understood by examining the effects of known anatomical and neurochemical alterations on basal ganglia circuitry, in other instances, such as tics, examination of basal ganglia pathways sheds little light on pathophysiology. Moreover, in many cases, theories of basal ganglia dysfunction in movement disorders do not guide therapeutic interventions. For these reasons, this chapter does not summarize current theories of basal ganglia function and dysfunction in movement disorders. Interested readers are referred to several excellent reviews on this subject (Albin et al. 1989; Weiner and Lang 1989; Wichmann 1997). In the remainder of this chapter, we review the hyperkinetic movement disorders seen in older patients. The behavioral changes that commonly occur in these patients, either as a primary component of the disorder or secondary to the resulting disability, are highlighted.

## ■ Tremor

*Tremor* is defined as involuntary rhythmic oscillatory movement resulting from alternating or synchronous contraction of antagonist muscles. Tremor can be an exaggerated normal physiological process, an isolated monosymptomatic illness, or a component of a variety of neurological disorders. Usually, tremor is classified according to the circumstances in which it occurs. A rest tremor is seen with the body part in complete repose. Maintenance of a posture, such as extending the arms parallel to the floor, elicits a postural tremor. Kinetic tremor (or intention tremor) is seen during volitional movement. Other important descriptive qualities include the frequency, amplitude, and topographic distribution of the tremor (e.g., face or lower extremities).

Rest tremor is most commonly a sign of idiopathic Parkinson's disease or its drug-induced counterpart, but it sometimes may be seen in other conditions. Approximately 75% of patients with Parkinson's disease exhibit a 4- to 6-Hz rest tremor, which usually begins unilaterally in the upper or lower extremity. The well-recognized appearance of a "pill-rolling" tremor of the arm is characteristic of Parkinson's disease and results from rhythmic extension-flexion of the wrist, pronation-supination of the forearm, and grasping movements of the fingers. Many patients with Parkinson's disease also have an 8- to 12-Hz postural tremor of the arms that is clinically indistinguishable from essential tremor. (For further discussion of Parkinson's disease, see Chapter 26 in this volume.)

Unlike the close association between rest tremor and Parkinson's disease, postural and kinetic tremors occur in a wide range of disorders. In the elderly, pathological pos-

tural and kinetic tremors usually represent essential tremor or side effects of medications. Table 25-1 provides a summary of the various causes of tremor in elderly people.

In normal individuals, a low-amplitude, 10- to 12-Hz

**TABLE 25-1. Classification and differential diagnosis of tremor in elderly patients**

### Rest tremor

Parkinson's disease

Other parkinsonian syndromes (less commonly)

Midbrain ("rubral") tremor: the rest tremor is less prominent than the postural tremor, which is less prominent than the kinetic tremor

Essential tremor—only if severe: rest tremor is much less severe than the postural and kinetic tremors

### Postural tremor (typically with terminal accentuation)

Physiological tremor

Exaggerated physiological tremor

Stress, fatigue, and emotion

Endocrine: hypoglycemia, thyrotoxicosis, pheochromocytoma, and steroids

Drugs and toxins:  $\beta$  agonists, dopamine agonists, lithium, tricyclic antidepressants, neuroleptics, theophylline, caffeine, valproic acid, amphetamines, alcohol withdrawal, mercury, lead, arsenic, and others

Essential tremor

Primary writing tremor

With other central nervous system disorders

Parkinson's disease and other akinetic-rigid syndromes

Idiopathic dystonia, including focal dystonias

With peripheral neuropathy

Cerebellar tremor

### Kinetic tremor

Disease of cerebellar "outflow" (dentate nucleus and superior cerebellar peduncle): vascular, tumor, acquired hepatocerebral degeneration, drugs, toxins (e.g., mercury), multiple sclerosis, and others

### Miscellaneous rhythmical movement disorders

Psychogenic tremor

Orthostatic tremor

Rhythmical myoclonus (segmental myoclonus, such as palatal myoclonus and spinal myoclonus)

Asterixis

Clonus

Epilepsia partialis continua

*Source.* Adapted from Weiner and Lang 1989.

physiological tremor may be seen in the fingers when the arms are extended. This physiological tremor may be accentuated by a variety of emotional and metabolic factors such as stress, fatigue, thyrotoxicosis, or hypoglycemia. Accentuated physiological tremor may also be a result of treatment with a number of drugs, including caffeine, sympathomimetics, tricyclic antidepressants, and corticosteroids.

## Essential Tremor

Essential tremor is arguably the most common movement disorder. Its prevalence increases with advancing age. Essential tremor is thought to follow an autosomal dominant pattern of inheritance with variable expression. When a positive family history is elicited, the disorder is referred to as *familial tremor*. When it appears for the first time after age 65, it has been called *senile tremor*. Essential tremor is a slowly progressive disorder that usually begins as an 8- to 10-Hz postural tremor of the hands. The tongue, head, voice, trunk, and (less commonly) legs are involved. Typically, the tremor persists during action and worsens at the end point of movement (terminal accentuation). In more severe cases, tremor may also be present at rest. More severe forms of tremor with wider amplitude tend to be of lower frequency (4–6 Hz) and are more common in older individuals.

In many patients, the functional impact of essential tremor is minimal; hence, it is believed that only a small percentage of persons with the disorder seek medical attention. In others, however, the tremor interferes substantially with handwriting, eating, drinking, and fine manipulations and is a source of social embarrassment. As the disease progresses, increased tremor amplitude further compromises the performance of discrete movements. The prefix “benign” is often a misnomer, as essential tremor can be disabling (Koller et al. 1986). In some patients, notably those with prominent head tremor, embarrassment plays a major role in disability. Typically, stress and anxiety accentuate tremor and thus aggravate the problem, resulting in reactive depression in some individuals.

A clinical feature having both diagnostic and therapeutic significance is that most patients with essential tremor note dramatic reduction in tremor after ingesting alcohol. The judicious use of small amounts of alcohol before meals and important events is not contraindicated. Surprisingly, the risk of alcohol abuse among these patients is low (Koller 1983a).

For patients who require treatment, the two most effective drugs for essential tremor are primidone and propranolol or other  $\beta$ -adrenergic blockers (mainly those

with relatively selective peripheral  $\beta$ -adrenergic antagonist properties; e.g., metoprolol, nadolol, atenolol, or timolol). Acute vestibulocerebellar side effects—such as vertigo, ataxia, and nausea—are common in response to primidone, even when given in low doses (50–62.5 mg/day). These side effects may be more common in elderly patients and can be both disabling and protracted. A useful approach in elderly patients is to administer small doses of primidone elixir using a tuberculin syringe and incrementally adjust the dosage before beginning therapy with tablets. Many elderly patients cannot tolerate  $\beta$ -blockers because of cardiac or pulmonary disease. In patients with asthma, metoprolol may be preferable to propranolol because of relative cardiac selectivity (Koller and Biary 1984). A single daily dose of nadolol may be useful if patient compliance is a problem (Koller 1983c). Like  $\beta$ -blockers, alternative treatments such as alprazolam and phenobarbital also may not be well tolerated in the elderly (Huber and Paulson 1988). Other second-line drugs include clonazepam and carbonic anhydrase inhibitors (Busenbark et al. 1993; C. Thompson et al. 1984). Because of drug contraindications, intolerance, and poor efficacy, a significant number of elderly patients with essential tremor are left with persistent disability.

Patients with medically refractory, disabling tremor have been effectively treated with stereotactic thalamotomy (Goldman and Kelly 1992). More recently, high-frequency deep brain stimulation (DBS) of the ventral intermediate thalamic nucleus has proved to be effective in patients with severe essential and other types of tremor (Benabid et al. 1996; Hubble et al. 1996). This procedure is now widely available in major medical centers.

The physiological basis for essential tremor is incompletely understood, but the disorder is thought to be caused by an abnormal oscillation of a central nervous system “pacemaker” (the location of which is uncertain) that is influenced by peripheral reflex pathways. No neurotransmitter or structural abnormalities have yet been identified. Although linkage analysis of several kindreds has identified potential loci for essential tremor-related genes, none has yet been cloned (Gulcher et al. 1997; Higgins et al. 1997).

## Other Tremors

Primary writing tremor is induced almost exclusively by writing. It is characterized predominantly by pronation-supination movements of the forearm at 5–7 Hz. Because many such patients have an associated mild postural tremor, primary writing tremor may be related to essential tremor. However, the task specificity suggests that it may be a form of focal dystonia akin to dystonic “writer’s

cramp.” Botulinum toxin injection probably affords the best relief in this disorder (Wissel et al. 1996).

Patients with orthostatic tremor develop rapid rhythmic contractions of the legs and sometimes the buttocks within a few minutes of assuming a standing position (T. C. Britton et al. 1992; FitzGerald and Jankovic 1991; P. D. Thompson et al. 1986). Walking, sitting, or lying will cause the tremor to cease. Most patients respond to clonazepam, primidone, or propranolol.

Cerebellar disease most commonly causes slow, irregular tremor of the head and trunk (titubation) when the patient is upright. Cerebellar tremor of the limbs is typically absent at rest and during the initial stages of motion but becomes manifest through the course of and at the end of a trajectory. The term *intention tremor* has been used to describe the increase in tremor as the limb approaches a precise destination; this is not specific to cerebellar tremor, however, but is common to most forms of postural tremor.

Lesions in the midbrain involving the superior cerebellar peduncle and possibly the substantia nigra near the red nucleus result in midbrain or “rubral” tremor. This type of tremor is present at rest, increases with maintenance of posture, and increases still further with action. It is believed to result from interruption of the connections between cerebellar dentate nuclei and the thalamus. A lesion anywhere in this outflow pathway may cause such a tremor (thus the term *cerebellar outflow tremor*). Additional involvement of the dopaminergic nigrostriatal pathway may contribute to the tremor. Demyelinating lesions in multiple sclerosis are the most common cause of midbrain tremor overall, whereas posterior circulation stroke accounts for most cases in elderly patients. Other features of midbrain or diencephalic dysfunction typically accompany the tremor in this setting. Sometimes the onset of tremor may be delayed for weeks after a brain stem event (e.g., stroke or head injury). Often, medications are ineffective for this tremor type. Stereotactic thalamotomy or DBS may be useful in patients with severe debility; however, the disabling proximal component of the tremor is often resistant to this approach.

Numerous drugs can produce tremor (Table 25–1). As indicated above, often this is an accentuation of normal physiological tremor. Any patient who develops tremor acutely or subacutely after initiation of a new medication should be suspected of having a drug-induced tremor regardless of whether tremor is a recognized side effect. Some individuals may have a further predisposition to develop tremor from medications by virtue of underlying disorders such as essential tremor or subclinical Parkinson’s disease. Pronounced mixed postural and resting tremor may develop in patients with preexisting essential tremor

who are treated with neuroleptic drugs. A number of medications used in psychiatric practice are capable of causing tremor. Tricyclic antidepressants may accentuate physiological tremor; however, this rarely poses a management problem. Tremor is an extremely common side effect of lithium therapy, which occasionally requires treatment with  $\beta$ -blockers or primidone.

Neuroleptic agents may cause either a postural or a parkinsonian resting tremor. One variant of the latter is a tremor of the perinasal and oral region known as the *rabbit syndrome*. Neuroleptic-induced parkinsonian tremor typically subsides after drug withdrawal. Patients who require ongoing neuroleptic therapy and who have sufficiently bothersome or disabling tremor may be treated with anticholinergics or amantadine. However, because of the frequency of cognitive and psychiatric side effects, anticholinergics should be avoided in patients over age 65 and are contraindicated in patients with known cognitive disturbance. Other considerations include a change to a less potent neuroleptic or to an atypical agent such as clozapine.

## ■ Chorea

The term *chorea* is derived from the Greek word for dance. Choreic movements are brief, jerky, purposeless involuntary movements that occur in random sequence. They can involve the distal or proximal limbs, face, or trunk. The movements may be brisk and abrupt as in Sydenham’s chorea or more slow and flowing as in Huntington’s disease. Various causes of chorea in elderly patients are listed in Table 25–2. Because the types of chorea most frequently encountered in psychiatric practice include Huntington’s disease and tardive dyskinesia, these topics are emphasized in the following discussion.

### Huntington’s Disease

Huntington’s disease is a progressive, autosomal dominant disorder characterized by chorea, personality changes, and dementia. The prevalence of Huntington’s disease in North America ranges from 4 to 7 per 100,000 (Harper 1991). Symptoms usually appear insidiously in the fourth decade, although symptom onset as late as the tenth decade has been reported. Typically, the movement disorder and the cognitive and personality changes are present at the onset of the disease, although one may precede the other by a matter of years.

**Movement disorders.** Initially, involuntary movements most often involve the upper limbs and face with

**TABLE 25-2. Causes of chorea in elderly patients****Hereditary causes**

- Huntington's disease
- Benign hereditary chorea (typically childhood onset)
- Neuroacanthocytosis

**Other central nervous system degenerations**

- Olivopontocerebellar atrophy
- Machado-Joseph disease
- Kufs disease
- Dentatorubropallidolusian atrophy

**Aging-related causes**

- Spontaneous orofacial dyskinesias
- "Edentulous orodyskinesia"
- "Senile chorea" (probably several etiologies)

**Drug-induced causes**

- Neuroleptics, metoclopramide, flunarizine, cinnarizine, antiparkinsonian drugs, amphetamines, methylphenidate, tricyclic antidepressants, monoamine oxidase inhibitors, lithium, estrogens (including estrogen creams for atrophic vaginitis), steroids, antihistamines,  $\alpha$ -methyl dopa, anticonvulsants (phenytoin, ethosuximide, carbamazepine, and phenobarbital), benzodiazepines, digoxin, methadone, and toluene

**Metabolic causes**

- Hyperthyroidism
- Hypoparathyroidism
- Hypo- and hypernatremia, hypomagnesemia, hypocalcemia

Hypo- and hyperglycemia (latter may cause hemichorea or hemiballism)

Acquired hepatocerebral degeneration, Wilson's disease

**Infectious causes**

- Encephalitides
- Subacute bacterial endocarditis
- Creutzfeldt-Jakob disease

**Toxins**

Alcohol intoxication and withdrawal, anoxia, carbon monoxide, manganese, mercury, toluene, and thallium

**Immunological causes**

- Systemic lupus erythematosus
- Recurrence of Sydenham's chorea
- Primary anticardiolipin antibody syndrome

**Vascular causes**

- Infarctions usually involving striatum, subthalamic nucleus region
- Hemorrhage
- Arteriovenous malformation
- Polycythemia rubra vera
- Migraine

**Tumors**

**Trauma:** subdural hematoma

**Miscellaneous:** including paroxysmal choreoathetosis

*Source.* Adapted from Lang 1992a.

"fidgeting" of the hands, shrugging of the shoulders, grimacing of the face, or pursing of the lips. With time, more obvious and generalized choreic movements develop. Patients often try to incorporate these movements into normal purposeful acts, such as raising the hand to the head as if to smooth the hair; this incorporation of involuntary into seemingly voluntary movement is referred to as parkinsonia. Chorea may be aggravated by mental concentration, emotional stimuli, performance of complex motor tasks, or walking.

There is early impersistence of motor tasks such as the inability to sustain tongue protrusion or hand grip ("milkmaid grip"). Oculomotor disturbances are invariably present and include slowed pursuit and saccadic eye movements (Lasker and Zee 1997). Initially, patients may be unable to rapidly direct their gaze in a given direction (i.e., generate a saccade) without blinking the eyes or thrusting the head. Later, gaze palsies may be pronounced. Other prominent findings include decreased fine motor coordi-

nation, dysarthria, dysphagia, orolingual apraxia (inability to perform complex motor tasks such as licking the lips or sucking an imaginary straw), and ideomotor apraxia. The gait takes on a dancing, stuttering character, which may be associated with lateral swaying or decreased arm swing. As the disease progresses, postural stability becomes impaired and axial chorea may throw the patient off balance. Later, dystonia and rigidity often become superimposed on chorea. Involuntary movements may become so severe that routine activities of daily living are impossible. Importantly, apraxia and bradykinesia also contribute greatly to later motor disability.

**Neuropsychological and psychiatric features.**

Early mental disturbances in patients with Huntington's disease include personality and behavioral changes such as irritability, apathy, depression, decreased work performance, violence, impulsivity, and emotional lability (Morris 1995). Intellectual decline usually follows the per-

sonality changes. The neuropsychological profile characteristically includes a memory disturbance suggesting selective impairment of information retrieval with retention of the ability to register new information. Patients often have difficulty recalling information on command but are able to give the correct answer if provided categorical cues or a multiple-choice format. Other deficits in memory include loss of detailed recollections (equally severe across all decades of the patient's life). There is difficulty with organization, planning, and sequencing even when all the necessary information is available (Caine et al. 1978). Additional prominent abnormalities include visuospatial deficits, dyscalculia, impaired judgment, and ideomotor apraxia (the inability to perform previously learned tasks in the context of intact elementary motor function) (Brouwers et al. 1984; Cummings 1995). As the disease advances, there are more global intellectual deficits.

A wide range of psychiatric disturbances is seen in Huntington's disease. Thirty-eight percent of patients have an affective disorder. Depression is the most common psychiatric symptom and does not appear to be simply a reaction to fatal illness. Evidence for this is the fact that mood disorders are not randomly distributed but occur in subsets of families with Huntington's disease (Peyser and Folstein 1990). Impaired motivation and reinforcement of rewarding behavior may be caused by interruption of the anterior cingulate circuit by striatal dysfunction (Cummings 1993). Apathy and loss of spontaneity may result from impairment of the medial frontal–anterior cingulate subcortical circuit (Cummings 1993). Ten percent of patients develop mania. Psychosis is less common. Suicide accounts for 5.7% of deaths in patients with Huntington's disease, and 25% of all patients attempt suicide at least once (Farrer 1986). This tendency to suicide may be due to impulsivity related to dysfunction of the orbitofrontal circuit. Obsessive-compulsive symptoms such as handwashing may also be seen in patients with Huntington's disease (Cummings and Cunningham 1992).

**Course.** The duration of Huntington's disease from onset to death is typically 15–20 years. Death is often caused by pneumonia, trauma, or suicide. In 10% of patients, the disease begins before age 20. Juvenile-onset Huntington's disease (the so-called Westphal variant) usually presents as an akinetic-rigid disorder, occasionally with seizures. The predominant signs are bradykinesia, rigidity, dementia, and cerebellar disturbance, often with little or no chorea. This form of Huntington's disease may be more rapidly progressive and the duration of illness shorter than the adult-onset type. Occasionally the akinetic-rigid variant is seen in adults either de novo or developing after a choreic presentation.

Twenty-five percent of patients have late-onset Huntington's disease, which is usually defined as the onset of motor manifestations after age 50. One study of this population of patients (Myers et al. 1985) revealed that the average age at onset of chorea was 57.5 years and the average age at the time of diagnosis was 63 years. The clinical features are similar to those of the typical adult-onset variety, but the progression of motor signs is slower and the cognitive changes are less severe.

**Genetics.** Huntington's disease is inherited as an autosomal dominant trait with complete penetrance. Thus, all people who inherit the gene will develop symptoms of the disease if they do not die prematurely. The Huntington gene has been localized to the short arm of chromosome 4 (Gusella et al. 1983). It has been found to contain an expanded and unstable CAG trinucleotide repeat within exon 1 of a large gene, the protein product of which is called Huntington's disease (Huntington's Disease Collaborative Research Group 1993). The genetic "stutter" of trinucleotide repeats gives rise to elongated polyglutamine tracts within huntingtin. Normal alleles contain 34 or fewer CAG repeats, whereas repeats of 37–150 or more occur in affected individuals (Gusella et al. 1997). Patients with juvenile-onset disease show predominantly paternal inheritance of the expanded allele (Gusella and MacDonald 1995). A younger age at onset is associated with longer trinucleotide repeat lengths. Age at onset is correlated with repeat length; however, for any given repeat length, the age at onset may vary by 15 or more years, suggesting that factors other than repeat length alone determine the onset of symptoms (Gusella et al. 1997). It is not known whether such factors are genetic, environmental, or stochastic.

**Diagnosis.** A diagnosis of Huntington's disease can be made with confidence when a patient has dominantly inherited chorea and dementia with onset in adult life. Before the characterization of the genetic defect, the diagnosis was always clinical. There are no definite biochemical or radiological markers for Huntington's disease. Routine imaging demonstrates atrophy of the striatum (caudate nucleus and putamen), most easily appreciated as enlargement of the frontal horns of the lateral ventricles (Figure 25–1). In elderly patients this may be a less useful diagnostic feature unless it is very pronounced, given the normal reduction in brain mass with age and the occurrence of atrophy in other disorders that might be confused with Huntington's disease. [<sup>18</sup>F]fluorodeoxyglucose positron-emission tomography (PET) demonstrates striatal hypometabolism even before atrophy is seen on computed tomography (CT) or magnetic resonance imaging (MRI). However, this is a

nonspecific finding and may be seen in other disorders combining striatal degeneration and chorea (e.g., neuroacanthocytosis). The onset of symptoms may occur soon after the development of PET abnormalities in Huntington's disease; thus, this technique is of limited value in the evaluation of persons at risk for Huntington's disease.

Until 1993, the most sensitive method for detecting gene carriers had been genetic linkage analysis. It is now possible to evaluate the CAG repeat length in an individual patient. Repeat lengths of 40 or more are diagnostic of the disorder. There is a "gray area" of repeat lengths in the 36–39 unit range; that is, some but not all individuals with intermediate repeat lengths will live long enough to manifest symptoms of disease (Gusella et al. 1997). Predictive

testing is a problematic issue, because no effective treatment is currently available. A carefully designed counseling service is a necessary component of any pre-symptomatic or diagnostic testing program (International Huntington Association and the World Federation of Neurology Research Group on Huntington's Chorea 1994).

Difficulties in diagnosis often arise when the family history is negative. It may be necessary to interview several relatives on more than one occasion to be certain of the family history. Some families deny the presence of cognitive or psychiatric disease in other family members. Patients should be asked about extramarital conception. If the affected parent had late-onset Huntington's disease, the diagnosis may have been missed because the symptoms may have been so mild as to go unnoticed, or the parent may have died before clinically apparent symptoms developed. Furthermore, physicians may fail to consider the possibility of Huntington's disease in elderly patients, preferring to label the problem as "senile chorea." Spontaneous mutations have been described, in some instances in children of fathers with an "intermediate" repeat length. The true incidence of new mutations is not known. The availability of CAG repeat length analysis will now allow a definitive diagnosis in many patients with Huntington's disease who lack a clear family history.

The differential diagnosis of Huntington's disease in the elderly patient includes various degenerative, systemic, and drug-related conditions, including tardive dyskinesia (Table 25-2). One important source of confusion is the patient treated with neuroleptics for a psychiatric presentation of Huntington's disease. The subsequent development of a movement disorder may then be mistaken for a complication of the drug therapy rather than an important clue to the underlying neurological diagnosis. Knowledge of the clinical differences between the movement disorders of Huntington's disease and the abnormal movements typically seen in tardive dyskinesia may help to avoid this confusion (Table 25-3).

**Treatment.** Management of Huntington's disease requires a team approach involving a wide variety of medical, paramedical, and social services. Education of patients and their families about the implications of the disease is extremely important. Genetic, psychological, and social counseling is regularly required, and lay organizations such as the Huntington's Disease Society of America often assist greatly in these tasks.

Medical treatment is symptomatic. Drugs that block postsynaptic dopamine receptors (neuroleptics) or deplete presynaptic dopamine terminals (reserpine and tetra-

benazine) are the most useful in reducing chorea. The mechanism whereby antidopaminergic drugs decrease chorea is unknown. Neuroleptics may also help control emotional outbursts, paranoia, psychosis, and irritability sometimes seen in Huntington's disease. With respect to the movement disorder, these medications should be reserved for disabling dyskinesias because of the high incidence of serious side effects. Newer atypical agents such as clozapine may be of some use in selected patients, although the necessity of performing weekly complete blood counts (because of a risk of agranulocytosis) may limit its utility (Factor and Friedman 1997). Other atypical agents such as risperidone and olanzapine have been useful anecdotally; the risk of tardive side effects with these agents, though less

than with older neuroleptics, is not negligible. In younger patients, concern about the superimposition of tardive dyskinesia on the underlying choreic disorder encourages the use of dopamine-depleting agents rather than neuroleptics (Jankovic and Beach 1997; van Vugt et al. 1997). Reserpine is associated with problematic hypotension, which may limit its utility. Tetrabenazine, although not approved for use in the United States, can be obtained from England or Canada and may be of considerable utility. Sedation is common, however, and use of the medication does carry a long-term risk of parkinsonism. In elderly patients one might turn to neuroleptics more readily, because there may be less concern regarding long-term side effects. Despite the ability of dopamine antagonists to reduce chorea, mo-

tor disability may not be altered given other deficits, such as bradykinesia and apraxia, which may be worsened by these drugs.

Depression may be treated with conventional antidepressant agents, such as fluoxetine (Como et al. 1997). Sertraline may also be helpful in aggressive patients (Ranen et al. 1996b). Benzodiazepines are often helpful with anxiety. (See Chapter 34 in this volume for discussion of psychopharmacological agents in geriatric neuropsychiatric disorders.)

Akinetic-rigid patients occasionally benefit from antiparkinsonian medications such as carbidopa/levodopa or dopamine agonists; however, increasing chorea and psychiatric disturbances may ensue. Although clinical trials are under way of agents (such as antioxidants and coenzyme Q) that are intended to modify the course of the disease rather than treat it symptomatically, none of these agents has been demonstrated to be effective (Huntington Study Group 1998; Koroshetz et al. 1997; Ranen et al. 1996a). Recently, anecdotal reports have suggested a beneficial effect of fetal striatal transplants (Kopyov et al. 1998; Philpott et al. 1997). The efficacy and long-term outcome of this approach, however, remain to be proved. At present, it cannot be recommended.

## Other Chorea

**Spontaneous orofacial dyskinesia.** Spontaneous abnormal movements in the lingual-facial-buccal region occur in a variety of populations and are not exclusive to patients treated with neuroleptics. The prevalence of this disorder has been estimated as being 0.8% between the ages of 50 and 59, increasing to 7.8% between the ages of 70 and 79 (Klawans and Barr 1982). Spontaneous orodyskinesia may be more likely to develop in the context of underlying brain dysfunction such as in patients with schizophrenia or Down's syndrome (Dinan and Golden 1990; Waddington and Youssef 1990). The true incidence of the disorder, however, is difficult to ascertain because of difficulties in obtaining complete drug histories (Ticehurst 1990). Many patients described as having spontaneous orofacial dyskinesia actually have cranial dystonia or Meige's syndrome (discussed below) (Table 25-3).

**"Edentulous orodyskinesia" in elderly patients.** Elderly patients may develop orofacial dyskinesias following tooth extraction (Koller 1983b). This occurs in about 16% of patients, but only after a long period of edentulousness (average of 12 years). The movements are similar to those seen in tardive dyskinesia with stereotyped smacking and pursing of the lips and lateral

deviation of the tongue or jaw. However, the absence of vermicular movements of the tongue when inside the mouth and the lack of involuntary movements of the limbs or trunk help distinguish edentulous orodyskinesia from tardive dyskinesia. Most often, patients are unaware of these movements, and they never cause disability. Wearing dentures often diminishes or dampens the movements.

**"Senile chorea."** The uncommon condition called senile chorea is best considered a "syndrome" of late-onset generalized chorea (beginning after age 65) for which no underlying cause can be determined. There is no cognitive deterioration, nor is there a family history of psychiatric disturbance or chorea. Few cases with pathological documentation are available. The findings are not uniform, but they may resemble less severe degrees of the changes seen in Huntington's disease with degeneration of the caudate nucleus and putamen (Alcock 1936) or the putamen alone (J. H. Friedman and Ambler 1990). Senile chorea probably represents a heterogeneous group of disorders, which may inadvertently include late-onset Huntington's disease (J. W. Britton et al. 1995; Garcia Ruiz et al. 1997). Genotyping for CAG repeat length should aid in distinguishing late-onset, sporadic Huntington's disease from true senile chorea. Symptomatic treatment with dopamine-depleting agents or low-dose neuroleptics may be tried if necessary, as discussed above for Huntington's disease.

**Vascular chorea.** An important consideration when assessing chorea presenting in elderly patients is the potential role of multiple infarctions involving the basal ganglia, particularly the caudate nucleus, putamen, and subthalamic nucleus. This syndrome usually occurs in the setting of lacunar disease as a result of chronic hypertension. A wide range of other causes of cerebral infarction must also be considered. Vascular malformations also may give rise to chorea. Typically, vascular chorea is of abrupt onset and spares the face. The majority of patients recover within a few weeks of the vascular insult. Treatment with neuroleptics or dopamine-depleting agents may be tried. Although chorea due to systemic lupus erythematosus is usually a disorder of the young, it may also occur in older individuals, as may chorea due to the primary anticardiolipin syndrome (Asherson et al. 1987; Cervera et al. 1997; Lang et al. 1991). Here, the chorea is probably the result of vascular or immunologic processes. Treatment is directed toward control of the underlying disease.

Polycythemia rubra vera has been known to cause generalized chorea of acute, subacute, or gradual onset; indeed, chorea may be the presenting sign of polycythemia in up to two-thirds of cases (Bruyn and Padberg 1984).

Haloperidol or other antidopaminergic agents may diminish the chorea; however, the abnormal movements often improve after treatment of the underlying disorder by phlebotomy or treatment with phosphorus 32.

## Hemiballismus

The term *hemiballismus* describes involuntary, proximal, large-amplitude flailing or throwing movements that can be violent and potentially dangerous in severe cases. Hemiballismus is often classified as one extreme in the spectrum of chorea because of the clinical and pathological overlap between the two conditions. Many patients with hemiballismus have concomitant distal choreic movements. As patients with hemiballismus improve, they often go through a hemichoreic phase.

Most patients with hemiballismus have a lesion in the contralateral subthalamic nucleus, although lesions of the caudate nucleus, putamen, thalamus, and possibly even the cortex are able to induce similar movements (Dewey and Jankovic 1989; Ghika-Schmid et al. 1997; Lee and Marsden 1994; Shannon 1990; Vidakovic et al. 1994). Most hemiballismus is secondary to vascular insult in the form of either lacunar infarction or hemorrhage, typically presenting with sudden onset of the involuntary movements. Given the common causes, hemiballismus is most often a disorder of elderly individuals, particularly those with predisposing factors such as hypertension and diabetes. The diagnostic study of choice is brain MRI. Other possible causes include metastatic tumor, basilar meningitis, vascular malformations, infections (e.g., toxoplasmosis), drugs, and metabolic derangement (e.g., hyperglycemic non-ketotic states) (Glass et al. 1984; Lin and Chang 1994; Tamaoka et al. 1987).

Vascular hemiballismus usually resolves spontaneously after weeks or months, but it may occasionally be persistent. Given the severe disability caused by the pronounced abnormal movements, most patients require treatment with either neuroleptics or dopamine-depleting agents. Clozapine may be helpful in refractory cases (Stojanovic et al. 1997). Drug-resistant or persistent hemiballismus sometimes requires stereotactic thalamotomy.

## Tardive Dyskinesia

*Tardive dyskinesia* refers to a variety of persistent, involuntary movements caused by drugs that are dopamine receptor blocking agents (DRBAs). Neuroleptic antipsychotic drugs are the most common responsible agents. Medications less commonly recognized as DRBAs such as metoclopramide, promethazine, amoxapine, and per-

phenazine-amitriptyline (Etrafon) can also cause tardive dyskinesia. Other drugs such as antidepressants, antihistamines, and phenytoin may induce movements similar to those seen in tardive dyskinesia; however, such movements are not classified as tardive dyskinesia. Dopamine-depleting drugs such as reserpine, tetrabenazine, and  $\alpha$ -methylparatyrosine have not been shown to cause tardive dyskinesia.

Tardive dyskinesia usually begins insidiously after several years of therapy with a DRBA but can occur after only 3 months of exposure. Often, tardive dyskinesia also appears after a decrease in dosage or drug withdrawal. There is no definite period of time between stopping a DRBA and the onset of involuntary movements that excludes a diagnosis of tardive dyskinesia. However, it is widely accepted that the movement disorder must begin within 3 months of stopping the DRBA (Fahn 1992) for a diagnosis of tardive dyskinesia to be applied. In contrast to other neuroleptic-induced movement disorders—such as acute dystonic reactions, parkinsonism, and acute akathisia—the movements of tardive dyskinesia usually worsen when the offending agent is withdrawn and improve when the dose of the DRBA is increased.

Tardive dyskinesia is now considered a syndrome that includes several categories of abnormal involuntary movements (Table 25-4). The typical movements of tardive dyskinesia are choreic in speed and amplitude, but their stereotypical and almost rhythmic pattern distinguish them from the classic random, flowing choreic movements seen in Huntington's disease. Occasionally, a more typical choreic picture is seen. The involuntary movements usually reach maximal severity quickly after onset and then tend to stabilize.

The oral-buccal-lingual muscles tend to be involved earliest and most frequently in tardive dyskinesia. One early sign is a fine, vermicular movement of the tongue when inside the mouth. This may progress to horizontal tongue movements and later to rolling, twisting, or curling with pressing of the tongue against the cheek ("bon bon sign"). There may be brief or prolonged involuntary tongue protrusion ("fly catcher's tongue"). Jaw movements

include chewing, biting, teeth clenching, and lateral side-to-side movements. There may be pouting, pursing, smacking, or sucking movements of the lips, which sometimes have an audible component. The corners of the mouth may retract (“bridling”), or the cheeks may puff out intermittently. Despite these movements, speech and eating are often unaffected, as volitional activity of the affected muscles often dampens or alleviates the dyskinesia. The hands, feet, neck, and trunk may also be affected. Movements of the fingers may have a “piano-playing” appearance. There may be tapping motions of the feet, side-to-side oscillations of the foot at the ankle, or marching in place without the report of restlessness. Respiratory dyskinesia due to diaphragm and intercostal muscle involvement may produce an irregular respiratory pattern, periodic tachypnea, or grunting. The term *copulatory dyskinesia* colorfully describes a rocking, undulating movement of the pelvis sometimes encountered as a manifestation of tardive dyskinesia. Surprisingly, the gait is usually little affected.

Many patients seem unaware of even pronounced involuntary movements. However, a significant minority of patients are embarrassed and/or disabled by the dyskinesias because of interference with speech and swallowing, oral ulceration, or life-threatening respiratory involvement. Patients with both schizophrenia and tardive dyskinesia may have twice the mortality rate of patients with schizophrenia and no tardive dyskinesia, but the reasons for this are uncertain (Yagi et al. 1989; Youssef and Waddington 1987).

The movements described above refer to “classic” tardive dyskinesia, which should be distinguished from other subtypes of tardive dyskinesia such as tardive dystonia, tardive akathisia, and the withdrawal-emergent syndrome. Often, tardive dyskinesias represent combinations of different movement disorders, such as dystonia and chorea or dystonia and myoclonus (Cardoso and Jankovic 1997).

Unlike classic tardive dyskinesia, which occurs more frequently in elderly individuals, tardive dystonia is seen equally in all age groups. The prevalence of this condition among chronic psychiatric patients is approximately 2% (Yassa et al. 1986). Younger patients tend to have more generalized involvement, whereas older patients usually have a focal or segmental distribution. Retrocollis may be especially common in tardive dystonia, with more severe forms demonstrating opisthotonic posturing, often with the arms extended and pronated. A history of exposure to DRBAs, early facial and neck involvement, and concomitant signs of other tardive syndromes (e.g., classic tardive dyskinesia and tardive akathisia) can support a diagnosis of tardive

dystonia. Tardive dystonia is usually more disabling and more difficult to treat than classic tardive dyskinesia.

Patients taking neuroleptics often complain of inner restlessness or akathisia, usually involving the legs. Most often this is an early, dose-related complication referred to as *acute akathisia*, which occurs after initiating or increasing the dosage of a neuroleptic agent and resolves when the offending drug is stopped. In contrast, tardive akathisia is a persistent problem that results from long-term exposure to DRBAs and occurs in the context of a constant or decreasing drug dosage. Patients demonstrate a variety of “akathitic” movements, including rubbing the scalp, marching in place, crossing and uncrossing the legs, or rocking at the trunk. Moaning and shouting also may occur. As is true of the other tardive syndromes, tardive akathisia usually worsens on withdrawal of the DRBA and improves if the dose is increased. Like tardive dystonia, tardive akathisia can result in profound disability.

The withdrawal-emergent syndrome involves involuntary movements (usually choreic) that typically appear in children following the abrupt discontinuation of DRBAs. This is a self-limited disorder that usually disappears within 6–12 weeks of onset. Other tardive syndromes include myoclonus, tics, and possibly tremor, but they are much less common than those described above.

**Differential diagnosis.** The differential diagnosis of tardive dyskinesia is extensive, given the spectrum of movements seen in this condition (Table 25–5), and includes a variety of abnormal movements seen in elderly psychiatric populations. Manneristic movements such as rubbing, picking, or grimacing may also improve with administration of neuroleptic agents and may be mistaken for tardive dyskinesia. Patients with Huntington’s disease who have been receiving chronic neuroleptic therapy may develop superimposed tardive dyskinesia. Clinical points of distinction between Huntington’s disease and tardive dyskinesia are listed in Table 25–3.

**Epidemiology.** Estimates of the prevalence of tardive dyskinesia among patients receiving long-term neuroleptic therapy have ranged between 17% and 30% (Cardoso and Jankovic 1997; Kane and Smith 1982). Proven risk factors for the development of tardive dyskinesia include advanced age, female sex, and extended duration of treatment. The incidence of tardive dyskinesia in elderly patients may be four times higher than that in young adults. The incidence is higher in women. The risk of developing tardive dyskinesia increases with duration of DRBA treatment: the cumulative incidence is estimated to

be 5% after 1 year, 10% after 2 years, and 19% after 4 years (Khot et al. 1992). Other proposed but controversial risk factors include preexisting “organic brain dysfunction,” “negative features of schizophrenia,” and affective disorders (said to be a greater risk than schizophrenia).

**Pathophysiology.** Although tardive dyskinesia has been recognized for more than 30 years, its pathogenesis remains poorly understood. The most commonly proposed mechanism is supersensitivity of postsynaptic striatal dopamine receptors as a consequence of chemical denervation caused by long-term use of DRBAs (Egan et al. 1997). Supersensitive striatal neurons may then respond abnormally to the presence of dopamine and produce the movements of tardive dyskinesia. The discontinuation of DRBAs would be expected to facilitate more interaction between dopamine and supersensitive receptors, leading to worsening of symptoms. Increasing the dosage of the offending drug would increase receptor blockade and improve (or mask) symptoms. The appearance of tardive dyskinesia during ongoing neuroleptic therapy suggests that competitive receptor blockade can sometimes be overcome by endogenous dopamine; the latter may be increased through enhanced activity of presynaptic nigrostriatal neurons responding to blockade of the postsynaptic receptors. Most neuroleptic agents are antagonists of the D<sub>2</sub> receptor. The atypical neuroleptic clozapine is a D<sub>4</sub> agonist, which is believed to explain its lack of association with tardive dyskinesias. Other newer atypical DRBAs show varying degrees of selectivity for other dopamine receptors (Baldessarini and Frankenburg 1991). The postsynaptic receptor hypersensitivity hypothesis has a number of limitations but is still useful in attempting to rationalize therapy for tardive dyskinesia.

**Prevention.** Given the iatrogenic nature of tardive dyskinesia, prevention should be emphasized. The indications for long-term antipsychotic medication should be delineated clearly and reevaluated regularly. Patients requiring ongoing neuroleptic therapy should be maintained on the minimal dose needed for a therapeutic effect. Patients should be evaluated regularly for signs of tardive dyskinesia. Neuroleptics should be avoided in psychiatric conditions for which other categories of drugs may be effective. Antiemetics such as metoclopramide should not be given for maintenance therapy unless other drugs have failed. The use of anticholinergic agents in addition to neuroleptics should be minimized because they may aggravate movements of tardive dyskinesia and are thought to increase the likelihood of its developing, although this remains to be proved. The former practice of using intermittent neuroleptic therapy, or “drug holidays,” in hopes of determining whether early tardive dyskinesia has developed but is being masked by ongoing treatment is no longer recommended, given the clinical impression that drug holidays may be associated with an increased risk of tardive dyskinesia (Jeste et al. 1979).

**Treatment.** Once the diagnosis of tardive dyskinesia is established, the offending agent should be gradually withdrawn if the psychiatric state allows (Figure 25–2). Anticholinergic and other antiparkinsonian medications should be discontinued. In patients who must continue receiving neuroleptic therapy, the movements of tardive dyskinesia usually remain static but may gradually improve or even remit (Casey et al. 1986; Jeste et al. 1983; Koshino et al. 1991). During the drug-withdrawal phase, involuntary movements will often worsen transiently over weeks, and it may be necessary to add a benzodiazepine or phenobarbital to ease the patient’s discomfort and anxiety. Between one-quarter and one-half of patients will improve within 1 year of drug withdrawal, but others may require up to 5 years (Klawans et al. 1984). Sometimes tardive dyskinesia may be permanent. The severity of the movements does not predict outcome after drug withdrawal. The chance of remission may be greater if DRBAs are discontinued soon after the onset of symptoms. Elderly patients have less chance for spontaneous remission once drugs are discontinued.

Patients requiring long-term neuroleptic treatment should be considered for conversion to a novel antipsychotic such as clozapine, olanzapine, quetiapine, or risperidone (Casey 1998; Factor and Friedman 1997; Peacock et al. 1996; Silberbauer 1998; Tollefson et al. 1997). The risk of developing tardive dyskinesia with other atypical agents such as risperidone and olanzapine is lower than

**FIGURE 25-2.** Approach to the management of tardive dyskinesia. DRBAs = dopamine receptor blocking agents; ECT = electroconvulsive therapy.

Source. Adapted from Weiner and Lang 1989.

with older agents but is not negligible.

For patients with disabling classic tardive dyskinesia, dopamine antagonists offer the most effective therapy for suppressing abnormal movements. Treatment with DRBAs, however, significantly decreases the chance of remission. Presynaptic depleting agents such as reserpine and tetrabenazine may be very effective in suppressing tardive dyskinesia, but these agents may not be well tolerated because of secondary parkinsonism, akathisia, and depression. Therapeutic trials of GABA agonists (clonazepam, valproic acid, diazepam, and baclofen), noradrenergic antagonists (propranolol and clonidine), and cholinergic agonists (lecithin and choline chloride) may also be helpful, but these drugs are rarely as effective as treatment with dopamine antagonists. Second-line agents include vitamin E, buspirone, and calcium channel blockers.

Whereas younger patients with tardive dystonia may benefit from anticholinergic agents such as trihexyphenidyl and ethopropazine, older patients are more likely to develop memory loss and confusion, and thus these drugs are relatively contraindicated in elderly patients. Dopamine antagonists—especially dopamine-depleting drugs, but sometimes even DRBAs—have the greatest likelihood of therapeutic success in disabling tardive dystonia, and some patients have been helped by anticholinergic therapy. Dopamine-depleting drugs alone or in combination with other agents are helpful in more than 50% of patients (Kang et al. 1986). Atypical neuroleptics have been effective in some cases (Yoshida et al. 1998). Botulinum toxin injection may be extremely effective in selected patients with prominent focal involvement of cranial and cervical musculature.

In contrast to acute akathisia, tardive akathisia usually does not respond to  $\beta$ -blockers, antiparkinsonian agents (e.g., anticholinergics and amantadine), or benzodiazepines. Management of this disabling tardive variant is difficult and usually involves dopamine-depleting agents or receptor blockers. Opioids may be helpful in some cases.

## ■ Dystonia

Dystonia is characterized by abnormal involuntary twisting movements that tend to be sustained and can result in abnormal postures. Some dystonic movements are slow and writhing and, when they occur distally, may be referred to as *athetosis*. Dystonic movements also may be quite rapid and resemble the lightning-like jerks of myoclonus. There may be superimposed rhythmic movements that are especially prominent when the patient tries to actively resist the

dystonia (sometimes referred to as *dystonic tremor*). Dystonic movements frequently occur only during specific actions (e.g., writer's cramp). The movements are often increased by stress and improve with relaxation. Patients often use a variety of sensory tricks or antagonistic gestures to decrease the severity of the movements. Spontaneous remissions may occur in some forms of idiopathic dystonia, especially torticollis. Failure to recognize these unusual features has commonly resulted in dystonia being misdiagnosed as hysteria.

Dystonia is often classified by distribution, age at onset, and etiology. When a single body part is affected it is called *focal dystonia*. Involvement of two or more contiguous parts is called *segmental dystonia*, whereas it is called *multifocal dystonia* when distribution is not contiguous. The term *generalized dystonia* indicates involvement of one or both legs, the trunk, and some other body part. *Hemidystonia* is the involvement of one side of the body.

Dystonia beginning in adulthood typically affects the neck, face, or arm. Involuntary movements tend to remain limited to one or a small number of contiguous regions (e.g., face and neck). This is unlike dystonia of childhood onset, in which signs usually begin in the legs and frequently generalize.

With respect to etiology, dystonia may be idiopathic or secondary to other disorders (Table 25–6). The age at onset and the distribution of the dystonia are often helpful in determining the cause. For example, in adulthood, generalized involvement or onset in the legs suggests that the dystonia is secondary to some underlying condition, whereas isolated focal or segmental dystonia is usually idiopathic. Involvement of one side of the body (hemidystonia) is often associated with a contralateral basal ganglia lesion. The nature of the dystonic movements also may assist in diagnosis. For example, as mentioned above, early in the course of dystonia, patients may exhibit the abnormal movements only when performing specific actions. This feature is particularly common in idiopathic dystonia. When a patient demonstrates constant abnormal posturing of a limb early in the disease (i.e., dystonia at rest), this is suggestive of secondary cause.

## Idiopathic Dystonia

Idiopathic torsion dystonia typically begins in childhood and often leads to severe disability by age 20. Occasional members of families with idiopathic torsion dystonia have onset delayed until later adulthood. The inheritance of idiopathic torsion dystonia seen in Ashkenazi Jewish and non-Jewish populations is autosomal dominant with variable penetrance. Linkage studies have localized the genes

for idiopathic torsion dystonia in Jewish and some non-Jewish families to chromosome 9 (Ozelius et al. 1989). More recently, the DYT1 gene has been cloned and has been shown to encode an ATP-binding protein (Ozelius et al. 1997).

**Focal dystonias.** Idiopathic adult-onset focal dystonia is much more common than idiopathic torsion

dystonia (Dauer et al. 1998). Marsden (1976) provided compelling arguments in favor of classifying these disorders as variants of idiopathic torsion dystonia. However, efforts to link focal dystonia to the DYT1 mutation have been unproductive to this point (Dauer et al. 1998).

The most common forms of idiopathic adult-onset focal dystonia are spasmodic torticollis (cervical dystonia), cranial dystonia, including blepharospasm and oromandibular dystonia, spasmodic dysphonia (laryngeal dystonia), and dystonia of the upper limb most often manifested as writer's cramp.

*Spasmodic torticollis* is the most common type of adult-onset focal dystonia (Dauer et al. 1998). It usually begins in the fourth or fifth decade and is more common in women. Involuntary activity of neck muscles causes abnormal postures and movements of the head. The movements may be sustained or may appear as twisting, shaking, or turning of the head. Commonly the head is turned to one side (torticollis) or is tilted with the ear toward the shoulder (laterocollis). Less often there is excessive head flexion (anterocollis) or extension (retrocollis). The continuous muscle contraction may lead to muscle hypertrophy, frequently evident in the sternocleidomastoid muscle, and there may be associated shoulder elevation. Neck discomfort and pain are common (Chan et al. 1991). Although many patients initially report an involuntary pulling of the head in one direction, some are unaware of the abnormal head posture until a family member draws it to their attention. Up to 50% of patients will have additional dystonic features, usually in the face or arm. Associated postural tremor of the hands is common (Dauer et al. 1998).

Many patients use sensory tricks (*geste antagoniste*) to decrease the severity of the dystonic movements. Resting the head against a high-back chair, holding the back of the neck, or lightly touching the cheek may return the head to the normal position. Activities such as walking, writing, and combing the hair often aggravate the symptoms.

Symptoms usually increase during the first 5 years. Partial or full remission occurs in up to one-fifth of patients, but this is almost always transient (A. Friedman and Fahn 1986; Jahanshahi et al. 1990). Symptoms may be mild, but most patients experience some degree of disability related to pain, abnormal head posture, and embarrassment. Patients with long-standing symptoms occasionally develop cervical root or cord compression. This complication may be more likely in elderly patients, who have a higher incidence of underlying cervical spondylosis.

Focal or segmental dystonia involving cranial muscles is called *cranial dystonia*. The usual age at onset is the sixth decade, and women are more commonly affected than are men. The most common component of cranial dystonia is

blepharospasm, characterized by involuntary, forced eye closure caused by excessive contraction of the orbicularis oculi muscles (Grandas et al. 1988). The disorder usually begins with an increase in blink rate, which gradually progresses to more forceful closure of both eyelids. Aggravating factors include talking, watching television, reading, and exposure to bright lights. Tricks such as rubbing or lightly touching the eye, yawning or opening the mouth, or extending the neck may interrupt the eyelid closure. Blepharospasm may eventually result in functional blindness despite normal visual acuity.

Another component of cranial dystonia is oromandibular dystonia, featuring involuntary spasms of lower cranial muscles that cause mouth opening, jaw clenching, platysma contraction, tongue muscle contractions and protrusion, and contractions of the soft palate. There may be associated grunting, throat clearing, and inspiratory noises. This type of dystonia is usually seen in combination with blepharospasm as Meige's syndrome, or as spasmodic dysphonia (see below), but it may occur in isolation (Tolosa and Marti 1988). In contrast to classic tardive dyskinesia (for which oromandibular dystonia is commonly mistaken), the movements of oromandibular dystonia are typically brought out or aggravated by use of the involved muscles, such as in talking or chewing (Table 25-3). Injuries of the tongue, lips, and teeth are common. Touching the finger to the lips or teeth may lessen the spasms.

Involvement of laryngeal muscles is known as *spasmodic dysphonia*. Most patients have a voice disturbance due to hyperadduction of the vocal cords (adductor spasmodic dysphonia) (Blitzer et al. 1988). The voice is strained, tight, hoarse, and often tremulous. The less common hyperabduction variety (abductor spasmodic dysphonia) results in breathy phonation and sudden drops in pitch.

*Writer's cramp* is the most common form of task-specific focal limb dystonia (P. D. Thompson 1993). Typically, the fingers and wrist flex excessively, causing the hand to tightly grasp the pen and press unnecessarily hard on the paper. Alternatively, the fingers may involuntarily extend or splay, making it difficult to hold the pen. Tremor or myoclonic jerks also may occur while writing. Initially, only writing may be affected (simple writer's cramp). Later, other manual tasks also may be impaired (dystonic writer's cramp). There are a wide variety of other "occupational palsies" or task-specific dystonias (Rosenbaum and Jankovic 1988). As in the case of writer's cramp, these typically begin in mid-adult life and subsequently persist or progress. Like all other forms of dystonia, these disorders are commonly misdiagnosed as being due to anxiety or "nerves." Both the chronic disability caused by the focal dystonia and the frequent mislabeling as a psychological

disorder often result in emotional upset and reactive depression.

**Pathophysiology.** Little is known of the etiology or pathophysiology of idiopathic dystonia. Electrophysiological studies suggest disturbances of inhibitory mechanisms in the brainstem and spinal cord (Hallett 1998; Marsden and Quinn 1990). These changes may be secondary to aberrant suprasegmental influences, for example, originating from the basal ganglia. Routine histopathology studies have failed to demonstrate consistent abnormalities. Study of secondary dystonias may provide further clues to the origin and nature of the abnormalities in idiopathic dystonia.

## Secondary Dystonia

**Drug-induced dystonia.** Levodopa-induced dystonia in Parkinson's disease is probably the most common form of drug-induced dystonia. Other important agents that can cause dystonia include DRBAs and, less commonly, anticonvulsants, selective serotonin reuptake inhibitors, antimalarial agents, and other miscellaneous drugs (Lang 1992b; Leo 1996). With respect to neuroleptics (antipsychotics and antiemetics such as metoclopramide), these drugs may cause short-lived dystonia very early in their course (acute dystonic reactions) or prolonged dystonia usually after long-term use (tardive dystonia). Unlike tardive dystonia, which has no age preference, and tardive dyskinesia and drug-induced parkinsonism, which are more common in elderly patients, neuroleptic-induced acute dystonia is more common in younger patients and indeed rarely develops in elderly patients. It may be more common in men and is more likely to occur with higher-potency neuroleptics. Although it is rare, acute dystonia has been reported with clozapine (Kastrup et al. 1994; Thomas et al. 1994). Dystonic reactions usually develop within the first 5 days of starting a neuroleptic, most often occurring on day 2 (Casey 1992). Patients may develop a sensation of thickness of the tongue, involuntary opening or closing of the mouth, facial grimacing, tongue protrusion, tightness in the throat, torticollis, retrocollis, oculogyric crisis (rolling of the eyes upward or off to the side), or laryngopharyngeal spasms. Limb or truncal spasm may result in bizarre posturing.

The pathophysiology of acute dystonia may involve an idiosyncratic response to D<sub>2</sub> receptor antagonists, although this is controversial (Casey 1994). Treatment consists of parenteral administration of anticholinergic or antihistaminic agents followed by oral anticholinergics for 1-2 days.

**Miscellaneous secondary dystonias.** In childhood a wide variety of storage diseases and neurometabolic disorders can cause dystonia. All children presenting with dystonia require a trial of levodopa to exclude the diagnosis of dopa-responsive dystonia. This disorder is caused in many instances by mutations in the gene encoding GTP cyclohydrolase, which is necessary for synthesis of tetrahydrobiopterin, a cofactor for tyrosine hydroxylase (Ichinose et al. 1994; Tamaru et al. 1998). Adults presenting with this disorder typically demonstrate features of Parkinson's disease rather than dystonia. Wilson's disease is an extremely important consideration; however, it rarely if ever presents de novo after age 45.

Dystonia can be seen after various acute brain insults such as stroke (Lee and Marsden 1994; Marsden et al. 1985) or head trauma (Krauss et al. 1996; Lee et al. 1994). The dystonia secondary to stroke usually occurs weeks or even years after the initial insult. The involuntary movements often develop as hemiparesis resolves. Lesions resulting in hemidystonia occur most often in the contralateral putamen, thalamus, caudate nucleus, and globus pallidus. Occasionally, blepharospasm has been associated with lesions in the brainstem, thalamus, or basal ganglia (Jankovic 1986).

Many of the secondary dystonias due to environmental causes, such as encephalitis and exposure to toxins, have stabilization of symptoms once the destructive process is completed. However, for reasons that are not clearly known, the symptoms of a static encephalopathy, including dystonia, choreoathetosis, myoclonus, and even pyramidal tract deficits, may progress in later adult life (Scott and Jankovic 1996).

There is increasing evidence that peripheral trauma may be associated with various forms of dystonia (Fletcher et al. 1991; Jankovic 1994). Post-traumatic dystonia tends to have a rapid onset after the inciting injury. In some instances, there may be a genetic predisposition to idiopathic dystonia, although to date this has not been proved. Sometimes a seemingly inconsequential injury can result in severe, fixed dystonic postures with features of reflex sympathetic dystrophy.

Dystonia is common to a variety of neurodegenerative diseases. It is common in Parkinson's disease both as a manifestation of the disorder and as a complication of therapy with dopamine agonists (e.g., levodopa, bromocriptine, pergolide, and newer agents such as pramipexole and ropinirole). Patients often develop transient dystonia as their medications are "wearing off," in the fully developed "off" period, on awakening in the morning, or as a peak-of-dose effect (Poewe et al. 1988). Patients with progressive supranuclear palsy usually have pronounced neck

and trunk rigidity, sometimes with nuchal extension, which has been referred to as *axial dystonia*. There may be associated dystonic posturing of the limbs, sometimes in a hemidystonic pattern (Barclay and Lang 1997). Cortical-basal ganglionic degeneration causes an akinetic-rigid syndrome with apraxia, cortical sensory deficit, action tremor, myoclonus, and frequent limb dystonia (Rinne et al. 1994). Multiple system atrophy, which includes striatonigral degeneration, Shy-Drager syndrome, and olivopontocerebellar atrophy, may also manifest various forms of dystonia, including excessive neck flexion (or anterocollis) (Wenning et al. 1994). An occasional feature of multiple system atrophy is laryngeal stridor, possibly secondary to vocal cord paralysis (Isozaki et al. 1996) or even laryngeal dystonia (Marion et al. 1992). Dystonia may be a prominent feature of Machado-Joseph disease, a dominant spinocerebellar ataxia, which, like Huntington's disease, is associated with expansion of unstable CAG repeats (Schols et al. 1996).

Psychogenic dystonia is uncommon, but when it does occur it can be severe enough to cause permanent contractures. Clinical clues that suggest psychogenic dystonia include "giving way" weakness, nondermatomal sensory loss, fixed postures, absence of sensory tricks, multiple somatizations, and especially inconsistency and incongruity of the abnormal movements (Fahn and Williams 1988; Lang 1995).

## Treatment

Dystonia has traditionally been one of the most difficult movement disorders to manage. Drug therapy is often unrewarding. The most effective drugs have a high incidence of side effects, especially in elderly patients. High doses of anticholinergic drugs (e.g., trihexyphenidyl, ethopropazine, and benztropine) may be at least partially effective in up to 50% of patients. Adults frequently experience intolerable side effects secondary to both peripheral and central anticholinergic effects. Peripheral side effects such as blurred vision and constipation may be lessened by the use of concomitant pilocarpine eye drops and oral bethanechol or pyridostigmine. However, central side effects including memory loss and confusion remain a major limiting factor, especially in older patients. Tricyclic antidepressants, benzodiazepines, carbamazepine, and baclofen may also be helpful. Dopamine antagonists, particularly clozapine, may be of some benefit. Tetrabenazine may also be useful, particularly in tardive dystonia.

Botulinum toxin injection has revolutionized the therapy of focal dystonia, particularly blepharospasm, spasmodic torticollis, spasmodic dysphonia, and oroman-

dibular dystonia (Jankovic and Brin 1991). The toxin acts presynaptically at nerve terminals to decrease the amount of acetylcholine released into the neuromuscular junction. Chemical denervation of the muscle results in weakness and wasting. The duration of benefit is usually 3–4 months. Side effects are mainly related to excessive weakness of injected muscles and to spread of the toxin locally to other areas (e.g., causing dysphagia in patients treated for cervical dystonia).

## ■ Myoclonus

*Myoclonus* refers to sudden, brief, shock-like involuntary movements that are usually caused by active muscle contraction (positive myoclonus) but can also be caused by inhibition of ongoing muscle activity (negative myoclonus, including asterixis) (Caviness 1996). Myoclonus may be focal, multifocal, segmental (involving two or more contiguous regions), or generalized. There is a wide clinical spectrum of myoclonic movements (Obeso et al. 1993). They may be single, rare jerks or constant repetitive contractions. The amplitude may vary from a mild twitch that fails to move a joint to a gross jerk that moves the entire body. The pattern is usually irregular but sometimes may be rhythmic, giving a superficial appearance of tremor. Myoclonus may occur spontaneously at rest or on attempting movement (action myoclonus). Myoclonus is frequently triggered (stimulus sensitive) by a variety of stimuli such as sudden noise, light, visual threat, soft touch, pinprick, or muscle stretch.

Myoclonus can originate from a variety of locations in the central nervous system (Shibasaki 1995). Electrophysiological studies, including back-average recording of electroencephalographic (EEG) potentials, evoked potentials, long-latency reflex recordings, and multichannel electromyographic (EMG) assessment, are capable of separating myoclonus of cortical and subcortical (reticular) origin. Less often, myoclonus originates at a segmental (brainstem or spinal) level, in which case the movements are often rhythmical. Rarely, myoclonic movements are caused by lesions in the peripheral nervous system. Clinically, it is sometimes difficult to distinguish myoclonus from tics. Unlike tics, myoclonus cannot be willfully controlled nor is it associated with a conscious urge to move or with relief once the movement has been completed. Myoclonic movements are usually of shorter duration and less patterned than tics and are typically increased rather than diminished when the patient performs a motor act.

Causes of myoclonus in the elderly may include idio-

pathic disorders such as physiological myoclonus, nocturnal myoclonus, essential myoclonus, and startle syndromes. More commonly, however, myoclonus in elderly patients is secondary to metabolic disorders, infections, drug administration, hypoxia, and degenerative diseases (Table 25–7). In earlier life, myoclonus is a common feature of idiopathic seizure disorders (epileptic myoclonus), and it may be a feature of progressive encephalopathies associated with seizures such as Lafora's disease (i.e., progressive myoclonic epilepsies).

## Idiopathic Myoclonus

**Physiological myoclonus.** Physiological myoclonus occurs in healthy individuals and is often worsened by fatigue or stress. Hiccups and the jerking that most people experience on falling asleep (sleep starts or hypnic jerks) are other forms of myoclonus seen in healthy individuals.

**Nocturnal myoclonus.** Periodic movements in sleep are stereotyped, repetitive movements of the legs that appear during stages 1 and 2 of sleep (Silber 1997; Wetter and Pollmacher 1997). Typically, there is myoclonic jerking of one or both legs followed by tonic flexion at the knee and hip, dorsiflexion at the ankle, and extension of the big toe. The duration of the movements may be as long as 5 seconds, implying that they are not truly myoclonic in nature; they occur at regular intervals, usually every 20–40 seconds. The prevalence of periodic movements in sleep appears to increase with age, being present in 29% of patients over age 50 (Lugaresi 1986).

Restless legs syndrome consists of nighttime unpleasant paresthesia and restlessness of the legs. These symptoms are relieved or lessened by activity, and patients may demonstrate a variety of secondary purposeful movements such as stretching, rubbing the legs, wiggling the ankles, or arising and pacing. Some patients also have myoclonic or dystonic involuntary movements in the legs while awake, and periodic movements in sleep are almost universal (Walters and Hening 1987). The symptoms interfere with sleep and, in fact, restless legs syndrome is the fourth leading cause of insomnia after psychiatric disorders, drug abuse, and sleep apneas (Coleman 1982). Restless legs syndrome can develop at any age, but symptoms may become more severe in old age. Most cases are idiopathic, although strong associations exist with iron deficiency anemia, rheumatoid arthritis, and uremia. When no cause is apparent, restless legs syndrome may be inherited as an autosomal dominant trait. Neuroleptic treatment can exacerbate the symptoms of restless legs syndrome. Peripheral neuropathies may cause similar symptoms. Both periodic

- Anxiety induced

**Essential myoclonus****Secondary myoclonus**

## Metabolic causes

- Hepatic failure
- Renal failure
- Dialysis syndrome
- Hyponatremia
- Hypoglycemia
- Nonketotic hyperglycemia

## Viral encephalopathies

- Herpes simplex encephalitis
- Arbovirus encephalitis
- Encephalitis lethargica
- Postinfectious encephalomyelitis

## Drugs and toxins

- Bismuth
- Heavy metal poisons
- Methyl bromide, DDT
- Drugs: tricyclic antidepressants, levodopa, monoamine oxidase inhibitors, antibiotics, and lithium

## Physical encephalopathies

- Postanoxic (Lance-Adams syndrome)
- Posttraumatic
- Heat stroke
- Electric shock
- Decompression injury

## Dementing and degenerative diseases

- Creutzfeldt-Jakob disease
- Alzheimer's disease
- Cortical-basal ganglionic degeneration
- Parkinson's disease
- Huntington's disease
- Multiple system atrophy
- Pallidal degenerations

## Focal central nervous system damage

- Poststroke
- Olivodentate lesions (palatal myoclonus)
- Spinal cord lesions (segmental/spinal myoclonus)
- Tumor
- Trauma
- Following thalamotomy (often unilateral asterixis)

Source. Adapted from Fahn et al. 1986.

movements in sleep and restless legs syndrome respond to benzodiazepines, including clonazepam and nitrazepam; dopamine agonists such as levodopa, pergolide, and pramipexole; or  $\mu$ -receptor opiate agonists such as codeine or propoxyphene (Kaplan et al. 1993; Winkelmann et al. 1998).

**Essential myoclonus.** Essential myoclonus is an idiopathic disorder that is often inherited in an autosomal dominant pattern (Quinn 1996). Symptoms typically begin in childhood or early adult years and persist with a variable course over the remainder of the patient's life. Disability may be pronounced. Some patients also demonstrate a postural tremor, and others have features of focal or segmental dystonia. Whether these features are all manifestations of the same genotype or whether "essential myoclonus" represents several different genetic diseases remains to be determined (Bressman and Fahn 1986). Some patients experience a pronounced beneficial response with alcohol, and this has led to problematic alcohol abuse (Quinn 1996).

**Startle syndromes.** The startle syndromes represent exaggerations of the normal human alerting reaction (startle). There is excessive motor response to unexpected auditory or visual stimuli. Typically, this consists of a blink, contortion of the face, and flexion of the neck, trunk, and arms. Sometimes the condition is inherited in autosomal dominant fashion (hyperreflexia) and may be associated with a mutation in the  $\alpha_1$ -glycine receptor subunit (Shiang et al. 1993), but in rare cases it may result from acquired brain stem pathology such as anoxia, hemorrhage, or sarcoidosis (Brown et al. 1991b). Clonazepam is currently the treatment of choice.

**Secondary Myoclonus****Myoclonus secondary to metabolic disturbances.**

Myoclonus may result from a wide range of metabolic disturbances, including severe hepatic failure, hyponatremia, hypoglycemia, and nonketotic hyperglycemia. The myoclonus commonly seen in uremia involves the face and upper extremities and is often aggravated by auditory or tactile stimuli. A significant number of patients with metabolic derangements will demonstrate asterixis. These brief lapses in postural tone (negative myoclonus) can be demonstrated by attempting to hold the wrist actively extended or the foot dorsiflexed. Toxic levels of anticonvulsants, especially phenytoin, may cause asterixis as well as typical myoclonus. Unilateral asterixis may be caused by focal central nervous system lesions, which often involve the thalamus (Young and Shahani 1986).

**Myoclonus secondary to infections or tumors.** Multifocal or generalized myoclonus may be seen in patients with systemic infections, acute encephalitis, or postinfectious encephalomyelitis. Myoclonus may be accompanied by opsoclonus (dancing eye movements) as a paraneoplastic syndrome. In adults, this may accompany gynecological tumors and has been associated with the Ri antineuronal antibody (Dropcho 1998).

**Myoclonus secondary to drug administration.** A wide variety of medications may cause myoclonus. Most often this occurs in the context of an acute toxic encephalopathy. For example, antibiotics, especially the penicillins and cephalosporins, can cause isolated myoclonus or more severe toxic encephalopathy with seizures, especially if given to patients with compromised renal function. A number of other drugs may cause myoclonus even in the absence of other features of toxicity; these include tricyclic antidepressants, levodopa, dopamine agonists, monoamine oxidase inhibitors, and lithium. In psychiatric practice, myoclonus occurs in up to 40% of patients taking tricyclic antidepressants (Garvey and Tollefson 1987).

**Postanoxic myoclonus.** Postanoxic myoclonus usually results from cardiac arrest, respiratory failure, or an anesthetic accident. Pronounced myoclonus in a patient with one of these conditions usually indicates a severe anoxic encephalopathy with poor prognosis. A unique syndrome of action myoclonus (Lance-Adams syndrome) occurs in a minority of patients surviving severe cerebral anoxia. As the patient awakens from coma, action-induced myoclonic jerks emerge, as do lapses in posture (negative myoclonus), which frequently result in falling. In more severely affected individuals, myoclonus interferes with all voluntary movement, including speech and swallowing. Additional cognitive and behavioral disturbances may accompany the myoclonus depending on the extent of anoxic cerebral damage.

The pathophysiology of postanoxic action myoclonus is strongly associated with dysfunction of brainstem serotonin pathways. The major metabolite of serotonin, 5-hydroxyindoleacetic acid, is typically reduced in the cerebrospinal fluid of these patients. Agents that increase serotonin activity, such as the serotonin precursor L-5-hydroxytryptophan (L5HTP) given with carbidopa are often markedly effective in reducing myoclonus. However, L-5HTP may cause a variety of side effects and is not readily available. For these reasons, the treatments of choice are valproic acid and/or clonazepam, agents that can also result in a striking reduction in the severity of the myoclonus.

**Myoclonus related to dementing and neurodegenerative diseases.** Myoclonus is a prominent feature of Creutzfeldt-Jakob disease (see Chapter 23 in this volume), a disorder that causes subacute onset of dementia and personality change. Myoclonus may begin in the face or limbs, but it later becomes more generalized as the disease progresses. Although present at rest, the myoclonus can often be triggered by loud noise. The EEG often shows periodic sharp discharges, occurring approximately once per second. The myoclonic jerks are sometimes time locked to these abnormal EEG discharges.

Myoclonus is present in 10% or more of patients with Alzheimer's disease. It can occur at any time in the course of the illness but is often a late manifestation (Hauser et al. 1986). Focal, stimulus-sensitive myoclonus is a common feature of cortical-basal ganglionic degeneration and multiple system atrophy, including striatonigral degeneration, Shy-Drager syndrome, and olivopontocerebellar degeneration. In Parkinson's disease, myoclonus rarely occurs as an early feature. Most often it develops as a late-stage side effect of levodopa, especially in patients with psychiatric complications and concomitant dementia.

## Segmental Myoclonus

Palatal myoclonus is characterized by unilateral or bilateral 1.5- to 3-Hz rhythmic (thus the more appropriate designation as a "tremor") movements of the soft palate (Deuschl et al. 1994). Synchronous movements of adjacent muscles of the face and neck frequently accompany the palatal activity. In most patients, a definitive cause can be identified, and these patients are said to have symptomatic palatal tremor. The most common cause of symptomatic palatal tremor is stroke affecting the brainstem and cerebellum (Deuschl et al. 1990). The palatal tremor usually develops after a delay of up to 10 months after the initial stroke and persists as a permanent sequela.

Patients do not typically complain of the involuntary palatal movements, but rather they are more bothered by limb, gait, and oculomotor disturbances from the underlying infarction. MRI often shows a hyperintense signal in the inferior olive (Pierot et al. 1992). Pathological examination shows vacuolar hypertrophic transsynaptic degeneration of the inferior olive with a lesion involving the connection between the cerebellar dentate nucleus (via the superior cerebellar peduncle) and the central tegmental tract to the contralateral inferior olive. When the lesion is unilateral, the olivary hypertrophy is on the side opposite the myoclonus.

One-quarter of patients with palatal tremor (myoclonus) have no underlying cause identified (Deuschl et al.

1990). These patients are considered to have essential palatal tremor, which typically occurs in young adulthood and presents with a clicking sound in the ear that can often also be heard by the examiner. The cause of the ear click is probably the sudden opening and closing of the eustachian tube as a result of intermittent contraction of the tensor veli palatini muscle.

Palatal myoclonus is typically resistant to pharmacological therapy, although occasional patients will respond to drugs such as clonazepam or anticholinergics. Bothering ear click may be reduced by focal injections of botulinum toxin into the tensor veli palatini muscle (Deuschl et al. 1991).

Spinal myoclonus is also usually slow and rhythmic, involving the muscles of several spinal segments and resulting in movements of one or more limbs and/or trunk. Lesions in the spinal cord that may give rise to myoclonus include infection, demyelination, tumor, degenerative disease, and cervical myelopathy (Jankovic and Pardo 1986). Another rare form of spinal myoclonus is thought to originate in slowly conducting propriospinal pathways. Propriospinal myoclonus includes spontaneous and stimulus-sensitive nonrhythmic axial jerks causing symmetric flexion of the neck, trunk, hips, and knees (Brown et al. 1991a).

## Hemifacial Spasm

Hemifacial spasm typically begins in adulthood and is more common in women. It begins as brief twitches around the eye that gradually increase in severity and may evolve to sustained contractions lasting many seconds to minutes. The movements may remain isolated to the orbicularis oculi or may spread to other ipsilateral facial muscles. The movements cannot be voluntarily suppressed and tend to persist in sleep. In most instances it is thought that hemifacial spasm is caused by mechanical compression of the facial nerve at the nerve root exit zone by an aberrant blood vessel (less commonly by a tumor, aneurysm, or other compressive lesion). Although surgical decompression of the facial nerve can be curative (Jannetta et al. 1977), botulinum toxin injection is extremely effective in reducing the involuntary movements and is the treatment of choice (Jankovic and Brin 1991).

## Tics

Tics are intermittent, repetitive, stereotyped abnormal movements (motor tics) or sounds (vocal tics) that vary in intensity and are repeated at irregular intervals. Tics en-

compass an extremely broad range of movements and sounds. Although most tics are abrupt and brief, some tics may be slower in onset and prolonged (dystonic tics). Motor and vocal tics may be further classified as simple or complex. Simple motor tics involve one group of muscles and include eye blinking, shoulder shrugging, or facial grimacing. Complex motor tics are coordinated sequences of movement such as touching, hitting, jumping, or copropraxia (obscene gestures). Simple vocal tics are inarticulate noises or sounds, including throat clearing, sniffing, and grunting. Complex phonic tics involve saying words and include echolalia (repetition of others), palilalia (repetition of self), and coprolalia (swearing). Patients usually experience an inner urge to perform the movement that is temporarily relieved by the execution of the movement. More than most other movement disorders, tics can be suppressed for prolonged periods of time and are decreased by distraction or concentration on complex mental or motor tasks.

Tics are most commonly idiopathic but may result from a variety of other conditions such as encephalitis, head injury, stroke, and drug administration (Table 25–8). Tics usually begin in childhood either as a simple transient motor tic or as part of the spectrum of manifestations of Gilles de la Tourette syndrome (Tourette syndrome). Many patients with Tourette syndrome remit in adolescence, but for the remainder the syndrome is a lifelong disorder. Tourette syndrome is probably inherited in an autosomal dominant pattern, with incomplete penetrance and sex-related expression. A close association exists with obsessive-compulsive disorder; indeed, behavioral mani-

**TABLE 25–8. Causes of tics in elderly patients**

Mental retardation syndromes: including chromosomal abnormalities
Postrheumatic chorea (probably not seen in the elderly)

festations in the absence of motor tics may be a variant.

Unfortunately, there is limited information regarding the course of Tourette syndrome as patients reach the geriatric age period. Interestingly, the first well-described patient with Tourette syndrome reported by Itard in 1825 (included in Gilles de la Tourette's first paper) was 85 years old (Bruun 1988). The results of studies including elderly patients with Tourette syndrome indicate that most patients improve with maturity (except for occasional worsening in the fourth decade) and that when symptoms persist beyond age 50 they are typically mild (Bruun 1988; Burd et al. 1986). On the other hand, we have seen one patient with lifelong multiple simple motor tics who at the age of 72 developed the complex vocal tic of shouting the names of friends and 2 years later developed echolalia and coprolalia (Lang et al. 1983). Additional studies are required to understand the effects of aging on the course of tics. Further complicating this issue is the rare occurrence of idiopathic adult-onset tics. Epidemiological and clinical aspects of tics beginning in mid to late adult life have yet to be formally studied. The relationship between adult-onset tics and the more common childhood-onset tics, including Tourette syndrome, is unknown at present.

In the treatment of tics, the goal should be satisfactory alleviation rather than complete elimination of motor manifestations. In mild cases, treatment with clonidine may suffice. Neuroleptics (most commonly haloperidol) may then be tried if this is unsuccessful. Other medications that have been reported in tic treatment include tetrabenazine and clonazepam. Botulinum toxin injection may be helpful in cases of painful dystonic tics. Compulsive symptoms that accompany tics may be treated with serotonin selective reuptake inhibitors such as fluoxetine.

## Summary

The hyperkinetic movement disorders include tremor, chorea, dystonia, myoclonus, and tics. A wide variety of these dyskinesias begin in late life or have a course affected in some manner by the aging process. The idiopathic focal dystonias, including spasmodic torticollis, cranial dystonia, and writer's cramp, begin in mid to late life and can result in significant disability. Neurodegenerative disorders such as multiple system atrophy, progressive supranuclear palsy, cortical basal ganglionic degeneration, Alzheimer's disease, and Creutzfeldt-Jakob disease all may be associated with variable degrees of dystonia, myoclonus, or tremor. Patients with Parkinson's disease who have been receiving long-term levodopa therapy often develop prominent choreiform and dystonic movements.

Aging is associated with an increased risk of

cerebrovascular disease, which can sometimes result in "cerebellar outflow tremor," chorea (including hemiballismus), delayed dystonia, palatal myoclonus, and occasionally asterixis. Elderly patients have a greater chance of developing tardive dyskinesia when exposed to neuroleptics and appear to have less potential for improvement after discontinuation of these drugs than do younger patients. The incidence of periodic movements in sleep and "spontaneous orofacial dyskinesia" also increases with advancing age. Some disorders, such as essential tremor, may worsen with age. Conversely, there are examples in which advanced age appears to be an attenuating factor in the expression of hyperkinetic disorders. The incidence of neuroleptic-induced acute dystonic reactions decreases with age, and these reactions rarely occur in the elderly. Tics appear to lessen in severity after the third decade.

Treatment of hyperkinetic movements in older patients is often limited by medical contraindications or poor drug tolerance. An informed trial-and-error sequential use of several different medications may be necessary in disabled patients. Botulinum toxin has revolutionized the treatment of dystonia. Neuroleptics might be used more readily in elderly patients for the management of choreiform disorders, as there is less concern about long-term sequelae such as tardive dyskinesia; however, this possibility should remain a concern, as should the greater risk of disabling drug-induced parkinsonism.

In summary, an elderly patient with a movement disorder may pose a diagnostic and therapeutic challenge for the clinician. The important first step is the classification of the dyskinesia, which then focuses the diagnostic considerations and guides the approach to treatment.

# Parkinson's Disease and Parkinsonism

Alexander I. Tröster, Ph.D.

Julie A. Fields

William C. Koller, M.D., Ph.D.

James Parkinson (1817), in his treatise of the disease now bearing his name, considered the senses and intellect to be spared in Parkinson's disease (PD), but alterations of mental function have been recognized since the late 1800s (Charcot 1878). These alterations may take the form of cognitive dysfunction, clinical psychiatric illness, sleep disturbance, or any combination thereof. The alterations are commonly encountered by clinicians who manage this illness or provide general medical care. In PD, the diagnosis of cognitive and behavioral disturbances, such as dementia and depression, is usually based on *Diagnostic and Statistical Manual of Mental Disorders* (American Psychiatric Association 1994) criteria. The appropriateness of these criteria to PD remains debated, and the criteria provide no guidance in the diagnosis of circumscribed cognitive impairments in PD without dementia. The establishment of specific diagnostic guidelines would facilitate recognition of, and reinforce the cause-and-effect relationship be-

tween, these abnormalities of mental function and PD.

In this chapter, our goal is to provide a description of the various neurobehavioral changes encountered in PD. In doing so, we emphasize the clinical features and discuss the proposed pathogenetic mechanisms and treatment options currently available.

## ■ Clinical Features

The four cardinal signs of parkinsonism are tremor, bradykinesia, rigidity, and postural abnormalities (including disturbance of balance). However, the clinical onset may be heralded by nonspecific symptoms such as generalized fatigue; muscle tightness, aching, or cramping; focal dystonias; decreased manual dexterity; restlessness; sensory symptoms (e.g., extremity pain or paresthesias); and psychiatric complaints (e.g., anxiety and/or depression). Complaints may also be related to autonomic nervous sys-

tem dysfunction such as postural hypotension, constipation, and/or paroxysmal sweating.

## ■ Epidemiology

Two measures are used to express the frequency with which a given disease occurs. Prevalence refers to the total number of cases present within a population at a given time. Incidence refers to the number of new cases that occur within a given time, usually per year, in a given population. Prevalence rates are sensitive to factors related to disease survival. For example, a slowly progressive disease such as PD will have a much higher prevalence than another disease with comparable incidence but a short survival time. Consequently, incidence is considered a more accurate measure of disease frequency. Unfortunately, incidence rates are more difficult to establish, and the majority of epidemiological studies of PD have examined its prevalence.

The first comprehensive study (Kurland 1958), a community-based study in Rochester, Minnesota, recognized persons receiving medical attention for PD and found a 187/100,000 prevalence and a 20/100,000 annual incidence. Prevalences found by community-based studies worldwide have varied from 31 to 347 per 100,000 (Table 26–1).

A number of risk factors for the development of PD have been investigated. Among demographic factors, increasing age has been the most consistently identified risk factor. Onset of PD before the fifth decade is rare, and age-specific prevalence is highest for the seventh and eighth decades (Tanner et al. 1997). Gender and race may be other risk factors: PD is almost twice as common in men as in women; its prevalence may be higher among whites than among blacks (Schoenberg et al. 1985), but this

finding remains controversial.

Several putative environmental risk factors (e.g., toxins) have also been identified. The most striking example of toxins causing parkinsonism (Table 26–2) is 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which produces clinical and cognitive changes closely resembling those of idiopathic PD (Langston et al. 1983; Stern and Langston 1985). Other neurotoxins cause more widespread injury resulting in parkinsonism and a constellation of other clinical findings (Goetz 1985). Several other factors, probably by virtue of involving toxicant exposure, have been linked to a heightened prevalence of PD: residence in industrialized nations (Aquiloni and Hartvig 1986); farming (Gorell et al. 1998) and residence in rural areas with exposure to well water, herbicides, or pesticides (Hubble et al. 1993; Koller et al. 1990; Tanner et al. 1987); and employment in chemical, wood pulp, and steel-manufacturing industries (Tanner 1989).

Genetic factors do not appear to play a primary role in the pathogenesis of PD. Studies of several large family kindreds suggested an autosomal-dominant inheritance mechanism in atypical PD (e.g., Golbe et al. 1990a, 1993; Waters and Miller 1994), but only rarely in typical PD (Wszolek et al. 1995). Interpretation of some of these studies is complicated by possible intermarriage in preceding generations (which may result in a spurious autosomal-dominant inheritance pattern) and by disease ascertainment methods (Wszolek et al. 1996). A significantly greater concordance of PD in monozygotic than dizygotic twins, which would support a genetic basis for the disease, also has not been found (e.g., Marsden 1987; Ward et al. 1983).

Genetic factors may, however, predispose to PD. Such a genetic predisposition, together with environmental fac-

**TABLE 26–1. Estimated prevalence of Parkinson's disease in community-based studies**

1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP)	Tumor
<b>Pharmacological causes of parkinsonism</b>	Trauma
Neuroleptics	Subdural hematoma
Phenothiazines	Syringomesencephalia
Butyrophenones (e.g., haloperidol)	<b>Metabolic causes of parkinsonism</b>
Thioxanthenes (e.g., thiothixene)	Hypoparathyroidism and basal ganglia calcification
Benzamides (e.g., metoclopramide)	Chronic hepatocerebral degeneration
Reserpine, tetrabenazine	<b>Hereditary diseases of the nervous system associated with parkinsonism</b>
Miscellaneous agents	Wilson's disease
α-Methyl dopa	Huntington's disease
Lithium	Disorder with diffuse pathology
<b>Multiple system atrophies with parkinsonian features</b>	Spinocerebellonigral degeneration
Striatonigral degeneration	Parkinsonism with ataxia and neuropathy
Progressive supranuclear palsy	Parkinsonism with alveolar hypoventilation
Olivopontocerebellar degeneration	<b>Psychogenic disorders</b>
Shy-Drager syndrome	Factitious disorder
<b>Other degenerative diseases of the nervous system with parkinsonian features</b>	Somatoform disorder
Primary pallidal atrophy	Malingering
Idiopathic dystonia-parkinsonism	
Corticobasal ganglionic degeneration	

tors, may lead to the appearance of the clinical syndrome (Barbeau and Pourcher 1982). For instance, individuals with defective xenobiotic-metabolizing enzymes (e.g., CYP2D6, a subfamily of the cytochrome P450 enzymes) may be at greater risk for PD when exposed to toxins usually broken down by these enzymes, but the relationship between CYP2D6 alleles and PD remains unclear (Tanner et al. 1997).

Several factors have been suggested to protect against PD, including smoking (e.g., Grandinetti et al. 1994) and ingesting of foods rich in antioxidant vitamins (Golbe et al. 1990b; Li et al. 1982).

## ■ Differential Diagnosis

The differential diagnosis includes any disorder manifesting parkinsonism (Table 26-2), a syndrome that may result

from a variety of etiologies. PD is thought to have a long prodromal phase (Koller and Montgomery 1997), and no set of universally accepted diagnostic criteria for early PD exists. Research criteria (Table 26-3) and probabilistic criteria (Table 26-4) are commonly employed, and various exclusionary criteria (Table 26-5) have been proposed to enhance diagnostic accuracy. Probability criteria based on inclusionary and exclusionary features were recently proposed by Gelb et al. (1999), but, like other criteria, their utility remains to be evaluated. Clinical diagnostic accuracy defined on the basis of postmortem neuropathological examination is approximately 75% (Hughes et al. 1992; Rajput et al. 1991).

The group of disorders designated multiple system atrophies (also known as parkinsonism-plus syndromes) share parkinsonian features with PD, but manifest additional findings (e.g., supranuclear ophthalmoplegia in progressive supranuclear palsy and dysautonomia in

**TABLE 26-3. Research criteria for probable Parkinson's disease**

1. Evidence of disease progression
2. Presence of at least two of the three cardinal features of parkinsonism:
  - a. Tremor
  - b. Rigidity
  - c. Bradykinesia
3. Presence of at least two of the following:
  - a. Marked response to levodopa (functional improvement or dyskinesia)
  - b. Asymmetry of signs
  - c. Asymmetry at onset
4. Absence of clinical features of alternative diagnosis
5. Absence of etiology known to cause similar features

*Source.* Reprinted with permission from Koller WC, Montgomery EB: "Issues in the Early Diagnosis of Parkinson's Disease." *Neurology* 49 (suppl 1): S10-S25, 1997. Copyright 1997 Lippincott Williams & Wilkins.

Shy-Drager syndrome). Early in their courses, these disorders may be difficult to distinguish from PD. One useful characteristic in this regard is their poor responsiveness to levodopa or dopamine agonists. Parkinsonian signs and symptoms may also be of psychogenic origin. In these instances, it becomes important to determine whether the signs are a manifestation of malingering, a somatoform disorder, or a factitious disorder (Koller et al. 1998a).

## Treatment

Treatment goals should be individualized for each patient. A treatment algorithm for PD is presented in Figure 26-1. Patient and family education is important for the patient newly diagnosed with PD (Figure 26-2), and patients should be encouraged to contact a PD support group.

## Pharmacotherapy

**Levodopa.** Levodopa has been the mainstay of drug therapy for the motor manifestations of the disease. Its absorption is highly variable in the proximal small intestine, with competition for transport from amino acid components of ingested protein (Riley and Lang 1988). It is decarboxylated to dopamine in the gut and liver and, after crossing the blood-brain barrier, in the brain by the surviving dopaminergic neurons and by decarboxylase-containing serotonergic and adrenergic neurons (Melamed et al. 1980).

**TABLE 26-4. Probabilistic classification scheme for the diagnosis of Parkinson's disease**

### Clinically possible

The presence of any one of the salient features:

- Tremor
- Rigidity
- Bradykinesia

Impairment of postural reflexes is not included because it is too nonspecific. The tremor must be of recent onset but may be postural or resting.

### Clinically probable

A combination of any two of the cardinal features:

- Resting tremor
- Rigidity
- Bradykinesia
- Impaired postural reflexes

Alternatively, asymmetrical resting tremor, asymmetrical rigidity, or asymmetrical bradykinesia is sufficient.

### Clinically definite

Any combination of three of the cardinal features (above).

Alternatively sufficient are two of these features, with one of the first three displaying asymmetry.

*Source.* Reprinted with permission from Koller WC, Montgomery EB: "Issues in the Early Diagnosis of Parkinson's Disease." *Neurology* 49 (suppl 1): S10-S25, 1997. Copyright 1997 Lippincott Williams & Wilkins.

The initiation of levodopa therapy, most often when PD has begun to interfere with activities of daily living, usually results in dramatic improvement in motor symptoms. The absence of a therapeutic effect at high doses necessitates reappraisal of the diagnosis. Bradykinesia and rigidity respond best. Tremor may improve somewhat, but usually there is no improvement in postural stability, mental state, or autonomic nervous system dysfunction.

Levodopa is combined with a peripheral dopa decarboxylase inhibitor (carbidopa in the United States, benserazide in Europe) to counteract the adverse effects of peripherally produced dopamine (e.g., nausea, vomiting, and postural hypotension). Domperidone, a peripheral dopamine antagonist not yet available in the United States, may also be used to treat levodopa-associated nausea (Olanow and Koller 1998). Most patients are started at a dose of one tablet of Sinemet 25/100 (25 mg carbidopa and 100 mg levodopa) thrice daily, 30 minutes before or 1 hour after meals. The subsequent dosage is adjusted to obtain an optimal motor response.

A long-acting preparation, Sinemet CR (controlled-release) 50/200, is a slowly eroding tablet that is absorbed

**TABLE 26–5.** Proposed exclusion criteria for the diagnosis of Parkinson's disease

Suggested exclusion criteria	Author		
	Gibb 1988	Koller 1992	Quinn 1994
More than one affected relative	X		
Remitting course	X	X	
History of definite encephalitis lethargica	X	X	
Oculogyric crises	X	X	
Neuroleptic therapy within the previous year	X	X	
Supranuclear down or lateral gaze palsy	X	X	
Cerebellar signs	X	X	
Autonomic neuropathy	X		
Alzheimer-type dementia from onset of symptoms	X	X	
Pyramidal signs not explained by discrete strokes	X	X	
Cerebrovascular disease <sup>a</sup>	X		
Abrupt onset of symptoms		X	
Stepwise progression		X	
Lower motor neuron signs		X	
Severe autonomic failure causing repeated syncope		X	
Postural instability, with falling, early in disease course		X	
Rapid disease progression			X
Permanently wheelchair-bound despite therapy			X
Irregular jerk tremor			X
Marked dysarthria			X
Marked dysphagia			X
Disproportionate antecollis			X
Cold, dusky hands (Raynaud's phenomenon)			X

<sup>a</sup>Implied by ataxic gait, stroke at onset, incontinence in first year, or early severe dementia; or two of the following: hypertension, emotional incontinence, spastic gait.

over a more protracted period of time. Its onset of effect is slower than that of standard Sinemet, but it has been shown to decrease "off" time (return of symptoms as a result of subtherapeutic drug effects), early morning dystonia, and nocturnal disturbances. Sinemet and Sinemet CR may be given separately or in combination based on the desired clinical effect.

Dyskinesias are prominent among the adverse effects caused by levodopa. Choreic movements are most common, and dyskinesias may interfere with speech, swallowing, respiration, and balance (Tanner 1986). Dyskinesias are dose-related and may improve by lowering the dose, although this may exacerbate the parkinsonism. In addition, motor fluctuations (e.g., early morning akinesia), "wearing-off," and "on-off" phenomena are more severe in patients treated with levodopa. Smaller and multiple doses may improve this end-of-dose deterioration. The

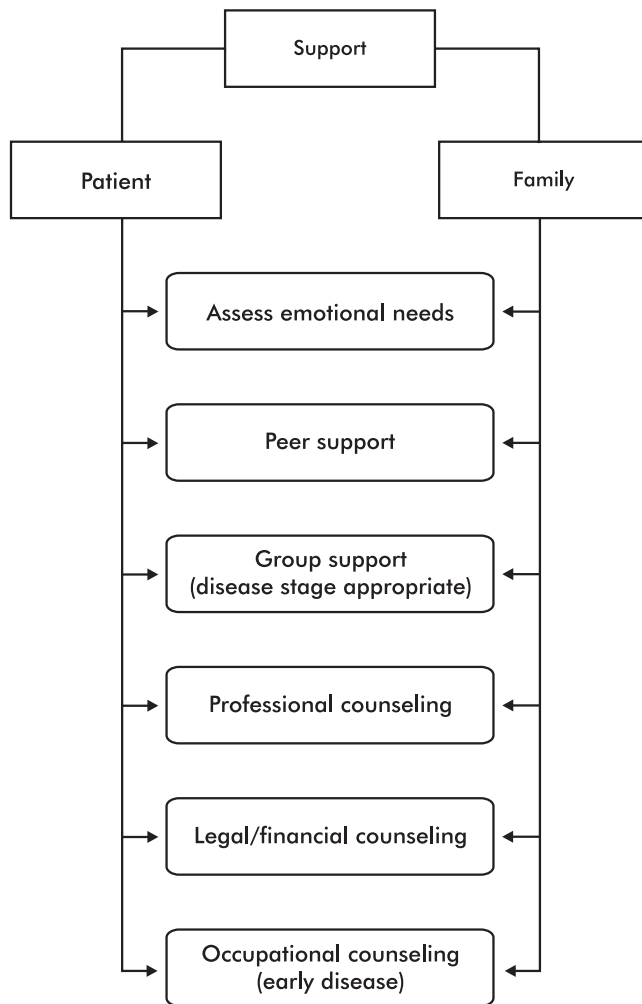

neurobehavioral complications of levodopa therapy are discussed later in this chapter.

The natural history of PD includes gradual deterioration of speech and posture and gait abnormalities. Levodopa does little to affect progression to disability in this regard. However, its efficacy may continue for rigidity, bradykinesia, tremor, and micrographia after many years of levodopa therapy (Klawans 1986), and levodopa has reduced premature mortality in patients with PD (Curtis et al. 1984).

**Selegiline and neuroprotection.** Because oxidant stress might play a role in the pathogenesis of PD, selegiline (L-deprenyl, Eldepryl), a monoamine oxidase-B (MAO-B) inhibitor, might exert a neuroprotective effect by reducing stress associated with MAO-B oxidation of dopamine. Selegiline has been shown to delay evolution of

disability requiring symptomatic therapy and to slow disease progression (Parkinson Study Group 1989, 1993). A report that selegiline plus levodopa treatment was associated with significantly higher mortality than was levodopa treatment alone (Parkinson's Disease Research Group in the United Kingdom 1995) has eluded replication and been criticized on methodological grounds (Olanow et al. 1996). Lazabemide, another selective and reversible MAO-B inhibitor, may affect PD progression in a manner similar to selegiline (Parkinson Study Group 1996).

**Anticholinergic drugs and tremor.** Anticholinergics (e.g., benztropine and trihexyphenidyl) and

amantadine (which acts as an anticholinergic and stimulates dopamine release) may be beneficial when tremor is a major problem. Because of their adverse effects (especially cognitive changes), they are best avoided in patients older than 70 years.

**Dopamine agonists.** The action of these agonists on various receptors is shown in Table 26-6. Bromocriptine and pergolide, both ergot derivatives, have traditionally been used in combination with levodopa once motor fluctuations emerge. They are started in small, once-daily (bedtime) doses to minimize the occurrence of orthostatic hypotension. The dosage may be gradually increased until the desired therapeutic benefit is realized. Dopamine agonists are also being evaluated as an initial monotherapy for PD. Used in this fashion, they are less likely than levodopa to lead to motor fluctuations and dyskinesias, but such monotherapy conveys adequate benefit for more than 3 years in only approximately 30% of patients (Poewe 1998).

Two relatively new, non-ergoline dopamine agonists (pramipexole and ropinirole) are anticipated to have fewer side effects than the ergot-derived dopamine agonists, but there is limited clinical experience with these agents. Ropinirole monotherapy was well tolerated and improved motor function in early PD (Adler et al. 1997) and effectiveness persisted at least 3 years in one study (Korczyn et al. 1999). As an adjunct to levodopa, ropinirole permitted reductions in levodopa dosage without loss of function (Brooks et al. 1995). Pramipexole also improved motor function in early PD, and, when given with levodopa or other antiparkinsonian medications in advanced PD, it reduced motor fluctuations, yielded further motor improvements, and permitted a decrease in levodopa dosage (Lieberman et al. 1997; Parkinson Study Group 1997; Pinter et al. 1999). It is hypothesized that early use of dopamine agonist may also exert a neuroprotective effect (Olanow 1997).

**Catechol-O-methyltransferase inhibitors.** Because peripheral degradation of levodopa by catechol-O-methyltransferase (COMT) is linked to motor fluctuations and dyskinesias, COMT inhibition is thought to be one means of extending the therapeutic effect of levodopa. Entacapone (a new, peripheral COMT inhibitor) and tolcapone (a peripheral and central COMT inhibitor), when used as an adjunct to levodopa, reduce motor fluctuations and "off" time (Martínez-Martín and O'Brien 1998; Rinne et al. 1998). Improvements in activities of daily living, motor function, and quality of life were observed in a randomized, double-blind, placebo-controlled study of stable patients with PD, taking 100 mg or 200 mg

tolcapone three times per day, and these improvements were maintained at 12-month follow-up (Waters et al. 1997). In patients with “wearing-off” phenomena, treatment with 100 mg or 200 mg tolcapone three times daily was associated with significant reductions in “off” time and increases in “on” time (Baas et al. 1997; Rajput et al. 1997). In both studies the development or worsening of dyskinesias, often within the first 30 days of treatment, was the most frequent complication (in up to 62% of patients). Although peripheral COMT inhibitors are a promising adjunct to levodopa therapy, the effects of both their early and long-term use remain to be documented.

### Stereotactic and Functional Neurosurgery

Stereotactic surgery for PD (particularly thalamotomy) reached its height in the 1950s and 1960s but declined rapidly after the introduction of levodopa in 1968 (Wilkinson and Tröster 1998). Acknowledgment of the limitations of pharmacotherapy, together with advances in neurophysiology, radiology, and stereotaxy, led to a resurgence of the surgical treatment of movement disorders (Goetz and Diederich 1996; Koller et al. 1998b). Laitinen and colleagues’ (1992) rediscovery of Leksell’s pallidotomy brought about a renaissance in ablative surgery. Alternative treatments, such as chronic deep brain stimulation and neural transplantation, were also further developed and refined. Surgical intervention may be considered in patients who no longer derive significant benefit from levodopa and/or dopamine agonists or who develop intolerable side effects from these medications. Patients with dementia or major affective disorder are typically not considered surgical candidates.

**Ablative surgery.** Unilateral thalamotomy is effective for severe tremor, especially if there is an action component. Burchiel (1995) estimated that significant changes

in memory and language functions may occur in up to 31% of cases (in 60% of bilateral and in 31% of unilateral thalamotomy cases). Outcomes in early and more recent thalamotomy series are difficult to compare, but, in the largest, most recently reported series, no significant neurobehavioral morbidity was observed (Lund-Johansen et al. 1996).

Modern unilateral pallidotomy has been reported to alleviate all parkinsonian motor signs, predominantly on the side contralateral to surgery, and dyskinesias bilaterally (Kishore et al. 1997; Lang et al. 1997; Laitinen 1995). Long-term effects of pallidotomy remain to be adequately evaluated. In one study, contralateral parkinsonian signs remained improved at 2-year follow-up, but improvements in gait, balance, and ipsilateral dyskinesia were more short lived (Lang et al. 1997). Another study reported that overall motor function and dyskinesias remained improved for up to 4 years (Fazzini et al. 1997). Significant improvements in quality of life have been observed after pallidotomy, at least in the short term (Baron et al. 1996; Scott et al. 1998; Tröster et al. 1998b). Some patients experience typically mild and transient cognitive morbidity, most often affecting verbal fluency, learning and memory, and executive functions (Baron et al. 1996; Cahn et al. 1998; Scott et al. 1998; Trépanier et al. 1998; Uitti et al. 1997). Patients with mild or incipient dementia before surgery appear at greater risk for more severe and permanent cognitive declines (Alterman et al. 1997; Lang et al. 1997). Depression (Lang et al. 1997; Sutton et al. 1995), psychosis (Friedman et al. 1996; Johansson et al. 1997), euphoria (Narabayashi et al. 1997), a “reduction in motivation” (Samuel et al. 1998), and perseveration, impulsivity, lability, unawareness of deficits, and poor social judgment (Trépanier et al. 1998) have been observed after unilateral pallidotomy, but the frequency, persistence, and etiology of these disturbances remain to be established. Bilateral pallidotomy has been associated with marked cognitive im-

pairment (Gálvez-Jiménez et al. 1996), but Scott et al. (1998) reported generalized cognitive impairment in only one of eight cases.

**Deep brain stimulation.** Deep brain stimulation (DBS) involves stereotactic placement of a typically quadripolar electrode within the ventral intermediate nucleus of the thalamus, the internal globus pallidus, or the subthalamic nuclei. The electrode is connected subcutaneously to a programmable pulse generator, implanted in the subclavicular region, via an extension lead. In cases of bilateral DBS, two independently programmable stimulators are implanted. At this time, only unilateral thalamic DBS is an approved treatment in the United States.

Relative to ablative procedures, DBS has both advantages and disadvantages (Pollak et al. 1998). Potential disadvantages include cost, need for replacement of the battery, need for additional visits to adjust the stimulator settings, infection, discomfort, and device failure. Advantages include the adaptability over time and reversibility of DBS, and consequently the minimization of morbidity. DBS is less likely than a permanent lesion to compromise potential benefit from future medical therapies. Adaptability of thalamic DBS may obviate the need for reoperation as is occasionally necessary after unsatisfactory thalamotomy (Tasker 1997).

DSS of the various targets differentially affects parkinsonian signs and symptoms (Table 26-7). Thalamic DBS has been shown effective in controlling tremor and improving disability (Benabid et al. 1996; Koller et al.

**TABLE 26-7. Estimated effects of stimulating subthalamic nucleus (STN), globus pallidus internus (Gpi), and ventral intermediate nucleus (Vim) on the main symptoms of PD**

	STN	Gpi	Vim
Tremor	+++	++	+++
Akinesia	+++	+(+)	0
Rigidity	+++	++	+
Dyskinesia	0/- (short-term) ++ (long-term)	+++	+(++VL)
Off-period dystonia	+++	++	0/-

+ = mildly effective; ++ = moderately effective; +++ = greatly effective; 0/- = may be deleterious; VL = ventrolateral thalamus.

1997; Tasker 1997). Pallidal DBS appears to alleviate akinesia, rigidity, and dyskinesia, but the effect on tremor and gait appears less reliable (Gross et al. 1997; Siegfried and Wellis 1997). Subthalamic DBS reportedly alleviates akinesia, rigidity, tremor, dyskinesias, and gait and balance disturbances (Pollak et al. 1998).

Unilateral thalamic (Caparros-Lefebvre et al. 1992; Tröster et al. 1997a) and pallidal DBS (Tröster et al. 1997b) appear relatively safe from the standpoint of cognitive morbidity, although decrements in verbal fluency are occasionally observed (see Fields and Tröster, in press). It has been anecdotally reported that subthalamic DBS entails no neuropsychological morbidity except "for those with poor presurgical neuropsychological performance" (Pollak et al. 1998), although another study (Kumar et al. 1999) reported mild memory and/or personality changes in some patients after subthalamic DBS. Given concerns about cognitive morbidity after bilateral ablative procedures, the safety of bilateral pallidal DBS (Fields et al., in press; Ghika et al. 1998) is noteworthy. The cognitive effects of stimulation, rather than of the combined effects of electrode implantation and stimulation, have been evaluated in only one case (Tröster et al. 1998c). DBS in PD tends to be associated with improvements in quality of life and mood state (Straits-Tröster et al., in press; Vingerhoets et al. 1999). Psychiatric morbidity has not been formally studied in DBS.

**Transplantation.** The intrastriatal implantation of autologous adrenal medullary tissue, despite its early promise (Goetz et al. 1989), has been virtually abandoned given the lack of lasting benefit and considerable morbidity and mortality. Psychiatric morbidity was considerable in a multicenter study (22% by 2-year follow-up) (Goetz et al. 1991), and complications such as confusion, hallucinations, delusions, depression, hypomania, and somnolence were reported in several other studies (Stebbins and Tanner 1992), especially after open as opposed to stereotactic procedures (Rehncrona 1997). The few studies formally evaluating cognition after adrenal tissue implantation did not find significant morbidity (Goetz et al. 1990; Ostrosky-Solis et al. 1988).

More recently, intrastriatal grafting of fetal mesencephalic tissue has been attempted. Although studies' variable outcomes are difficult to compare given methodological differences (e.g., surgical approach, number and site of grafts), a recent report indicated continued clinical benefit in 7 of 10 patients 5 years after unilateral grafting (López-Lozano et al. 1997). Graft viability, as indexed by positron-emission tomography (PET)-imaged increases in fluorine-18-labeled dopa uptake, appears a robust predictor of clinical benefit (Hagell et al. 1999; Rehncrona 1997).

Neurobehavioral outcomes after fetal tissue grafting are inadequately documented. Transient, perioperative psychiatric disturbances such as depression, paranoia, and hallucinations have been reported after open operations (Madrazo et al. 1990; Molina et al. 1991), but not after stereotactic procedures (Price et al. 1995). Sass et al. (1995) reported improvements in verbal memory in three patients 12 and 24 months after grafting, but these improvements were not maintained 36 months after surgery. Among five patients evaluated neuropsychologically before and 12 months after unilateral grafting, one patient demonstrated significant cognitive decline whereas two patients improved (Leroy et al. 1996).

Several other treatment approaches—for example, xenografts, intraventricular delivery of neurotrophic factors, and gene therapy—are currently under study (see Lang and Lozano 1998).

## ■ Cognitive Impairment in Early Parkinson's Disease

Parkinson's disease, even early in its course, is often accompanied by mild cognitive disturbances and affective disorders such as depression. Although the prevalence of cognitive impairment without dementia is difficult to ascertain given the lack of specific criteria, a review of 20 studies of treated and untreated patients with PD without dementia estimated the prevalence at 19% (range 17%–53%) (Lieberman 1998). Dementia is almost never evident in the earliest disease stage. A dementia preceding or accompanying the evolution of the motor signs of PD raises the suspicion that the dementia is related to another condition, for example, Alzheimer's disease (AD) or depression.

When cognitive impairment is present in early PD, it is typically mild and circumscribed, most often affecting executive functions (e.g., planning, reasoning, abstraction, conceptualization, cognitive flexibility), visuo-perceptual functions, and memory (Bondi and Tröster 1997). Bradyphrenia, a slowing of thought and information processing speed, is also observable early in the disease and has been linked to noradrenergic changes (Mayeux et al. 1987).

Executive deficits have been ascribed to frontal lobe dysfunction secondary to cortical-striatal-thalamic-cortical circuit pathophysiology and are most apparent on tasks requiring spontaneous, self-directed strategy formulation and deployment (Taylor and Saint-Cyr 1995).

The existence of a pure, primary impairment of visuo-perceptual processes remains controversial. Although visuo-perceptual impairments have been frequently ob-

served in early PD, even when tasks' motor demands are minimized (Huber et al. 1986; Taylor et al. 1986), it has been argued that some instances of visuospatial impairment may reflect deficient motor speed and dexterity, spatial memory, and shift of mental set from one orientation to another and/or executive dysfunction (e.g., Bondi et al. 1993; Brown and Marsden 1986).

The memory impairment of PD is characterized predominantly by retrieval deficits, as evident from patients' disproportionately better performance on recognition than recall tests (Beatty et al. 1989; Pillon et al. 1993). The memory deficits in early PD have also been ascribed to frontal lobe dysfunction (Taylor et al. 1986, 1990a, 1990b), although it is unlikely that frontal lobe dysfunction is the sole determinant of memory impairment (Tröster and Fields 1995). Unlike the ability to learn new information, remote memory content is typically spared in early PD (Freedman et al. 1984; Leplow et al. 1997; Sagar et al. 1988; but see Venneri et al. 1997).

Performance on simple attention tasks such as digit span is often preserved. Impairments are readily observed on more complex tasks involving working memory (Gabrieli et al. 1996).

Language functions such as repetition, comprehension, and word knowledge are typically preserved (Cummings et al. 1988; Lewis et al. 1998; Tröster et al. 1996a). Patients with early PD may demonstrate subtle reductions in the syntactic complexity of spontaneous speech (Illes 1989; Lieberman et al. 1990) and difficulty in comprehension of syntax (Grossman et al. 1992; Lieberman et al. 1992). Visual confrontation naming, typically preserved, may be impaired (Globus et al. 1985; Levin et al. 1989). Some studies have observed mild impairments on verbal fluency tasks requiring oral generation of words belonging to a given semantic category or beginning with a given letter of the alphabet (Lewis et al. 1998; Troyer et al. 1998). These verbal fluency impairments probably reflect difficulties with the initiation and maintenance of systematic word retrieval strategies and are attributed to frontostriatal dysfunction. The presence of verbal fluency impairments in the earliest stages of PD may be a strong predictor of the subsequent development of dementia (Jacobs et al. 1995; Mahieux et al. 1998).

## ■ Dementia in Parkinson's Disease

### Epidemiology

Reported prevalence rates range from 8% (Taylor et al. 1985) to 81% (Martin et al. 1973). Sampling and case defi-

nition and ascertainment methods differ across studies. As Cummings (1988a) pointed out, studies employing nonstandardized clinical examinations report the lowest prevalence rates of dementia, whereas studies employing formal neuropsychological evaluation report the highest rates. Commonly accepted prevalence estimates range from 20% to 40% (Mohr et al. 1995). Incidence of dementia in PD has rarely been reported. Mayeux et al. (1990) reported an incidence of 69 per 1,000 person-years, whereas Biggins et al. (1992) reported one of 48 per 1,000.

A genetic predisposition to the dementia of PD has been proposed. The risk of dementia among the first-degree relatives of patients with PD with dementia is sixfold greater than that in relatives of patients with PD without dementia (Marder et al. 1990). A familial association between PD and AD has been reported; first-degree relatives with AD had a threefold risk of PD, suggesting a common genetic etiology (Hofman et al. 1989). However, the risk factors most often associated with AD are not found in patients with PD with dementia. For example, the apolipoprotein E e4 allele is associated with an increased risk of AD, but dementia in PD appears not to be related to apolipoprotein E genotype (Koller et al. 1995; Marder et al. 1994).

Putative risk factors for the development of dementia in PD include increasing age (Stern et al. 1993a), older age at disease onset (Glatt et al. 1996; Lieberman et al. 1979), low socioeconomic status and education (Glatt et al. 1996; Salganik and Korczyn 1990), greater severity of extrapyramidal signs (Marder et al. 1995) (although the specific extrapyramidal signs associated with dementia remain to be specified), susceptibility to psychosis or confusion in response to levodopa (Stern et al. 1993a), and depression (Marder et al. 1995; Stern et al. 1993a).

### Diagnostic Criteria and Definitions of Dementia in Parkinson's Disease

Diagnostic criteria for dementia have been defined in the DSMs. In DSM-IV, the most recent edition of this work, dementia as a result of PD is classified under Dementia Due to Other General Medical Conditions (Table 26-8). These criteria remain subject to the concerns and criticisms leveled against earlier versions of DSM. One criterion for the diagnosis of dementia in PD is that the required decline in occupational or social functioning is *caused* by cognitive deficits. A modification of this criterion has been recommended (Brown and Marsden 1984; McCarthy et al. 1985) because it is difficult to determine the extent to which functional impairment in PD reflects motor disability as opposed to cognitive decline. It has also been sug-

gested that because of performance expectations, especially in the workplace, dementia in men may be recognized sooner than that in women homemakers (Rajput et al. 1990).

DSM criteria for dementia require the presence of a memory impairment. Because bradyphrenia and impairments in executive and visuo-perceptual functions may precede significant memory impairment, it is possible that a patient without memory impairment, but functional impairment comparable to that of a patient with dementia, would not meet DSM criteria for dementia. Another unresolved issue is whether the required memory impairment must be a *primary* memory impairment. As noted earlier, subtle encoding and retrieval strategy deficiencies, attributed to frontal or executive dysfunction, are observed in early PD. It is unclear whether such changes in memory *processes* should be classified as memory or executive dysfunction when the diagnostic possibility of dementia arises.

Cummings and Benson (1992) proposed alternate criteria for dementia. These criteria define dementia as an acquired, persistent impairment in at least three of five domains: 1) language, 2) memory, 3) complex cognition (executive functions), 4) visuospatial functions, and 5) personality or emotion. Occupational and social functioning

**TABLE 26-8. DSM-IV criteria for dementia as a result of Parkinson's disease**

- 
- A. The development of multiple cognitive deficits manifested by both
1. Memory impairment (impaired ability to learn new information or to recall previously learned information)
  2. One (or more) of the following cognitive disturbances:
    - a. Aphasia (language disturbance)
    - b. Apraxia (impaired ability to carry out motor activities despite intact motor function)
    - c. Agnosia (failure to recognize or identify objects despite intact sensory function)
    - d. Disturbance in executive functioning (e.g., planning, organizing, sequencing, abstracting)
- B. The cognitive deficits in criteria A1 and A2 both cause significant impairment in social or occupational functioning and represent a significant decline from a previous level of functioning.
- C. There is evidence from the history, physical examination, or laboratory findings that the disturbance is the direct physiological consequence of Parkinson's disease.
- D. The deficits do not occur exclusively during the course of a delirium.
-

need *not* be affected. These criteria are more liberal than those in DSM, and it is possible that a patient with relatively mild cognitive impairments would meet the Cummings and Benson but not the DSM criteria for dementia (McPherson and Cummings 1996). The possibly differential validity of DSM and Cummings and Benson criteria remains to be addressed.

## Neuropathology

PD is characterized by the loss of pigmented neurons from the pars compacta of the substantia nigra, reactive gliosis at sites of cell loss, and the appearance of Lewy bodies in the substantia nigra, locus ceruleus, ventral tegmental area, nucleus basalis of Meynert, thalamus, dorsal raphe nuclei, cerebral cortex, and autonomic nervous system. The mechanism of Lewy body formation is unknown but is thought to be related to a disruption of neurofilament metabolism, perhaps in reaction to cell stress (Esiri and McShane 1997).

Neuronal loss in the substantia nigra pars compacta is associated with decreased levels of dopamine and its metabolites in the substantia nigra, caudate, putamen, globus pallidus, and nucleus accumbens. This neuronal loss, together with that in the ventral tegmental area, is also associated with reductions in dopamine in mesocortical projection sites such as entorhinal, hippocampal, cingulate, and frontal cortices. Ventral tegmental neuronal degeneration is associated with reduction of dopamine in mesolimbic projection areas (e.g., nucleus accumbens, hypothalamus, amygdaloid nucleus). Reductions in norepinephrine and serotonin concentrations are linked to neuronal loss in the locus ceruleus and dorsal raphe nuclei, respectively.

It is likely that there are several dementia syndromes in PD (Cummings 1988b). From a neurochemical perspective, dementia may be related to either dopaminergic or combined dopaminergic and cholinergic deficits (McPherson and Cummings, 1996). Alternatively, dementia might occur when damage of both the basal ganglia and several mutually interactive ascending neuronal pathways (including serotonergic, cholinergic, dopaminergic, and noradrenergic) reaches the threshold for expression of severe cognitive impairment (Dubois and Pillon 1998).

The most common cause of dementia in PD appears to be coexistent AD (Esiri and McShane 1997). Up to 35% of patients with PD with dementia have been found at autopsy to have the neuropathological hallmarks (neuritic plaques, neurofibrillary tangles, and granulovacuolar degeneration) of AD (Boller et al. 1980; Gaspar and Gray 1984; Hughes et al. 1993). However, AD does not account for all, or even the majority of, cases of dementia in PD. Some in-

vestigators (e.g., Ball 1984; Perry et al. 1983) have reported only an infrequent association between PD and AD, and dementia has been present in patients without cortical pathology (Xuereb et al. 1990). The observations that frontal cognitive deficits (Dubois et al. 1990) and severity of dementia (Nakano and Hirano 1984; Perry et al. 1985) are related to cholinergic abnormalities and that neuronal loss in the nucleus basalis of patients with PD with dementia is usually more severe than in those without dementia (Whitehouse et al. 1983) are mitigated by the observation that dementia in PD may occur in the absence of both Alzheimer-type changes and atrophy of the nucleus basalis (Helig et al. 1985). The role of AD in the dementia of PD is further clouded by the description of another neuropathological entity, namely dementia with Lewy bodies, and the recent observation that severity of dementia in patients with PD without AD changes was related to density of Lewy neurites in the hippocampal CA2 cell field (Churchyard and Lees 1997).

## Dementia With Lewy Bodies

Kosaka et al. (1980) introduced the notion of a spectrum of Lewy body diseases, and they described a new clinicopathological entity characterized by Lewy bodies present not only in brainstem neurons but distributed throughout the cerebral cortex. The spectrum of Lewy body diseases includes several variants (Lennox and Lowe 1997): a cortical Lewy body variant characterized by cortical and brainstem Lewy bodies in the absence of plaques or tangles (most closely resembling what has been termed “pure” Lewy body disease); variants of cortical Lewy body disease with plaques and tangles (resembling cortical Lewy body disease with AD) or with only plaques; and a brainstem Lewy body disease variant (in which very few cortical Lewy bodies are seen), corresponding closely with the clinical correlate of PD. Lennox and Lowe (1997) define “Alzheimer’s disease and Parkinson’s disease” as an entity meeting pathological criteria for AD with the additional feature of brainstem but not cortical Lewy bodies. It remains debated whether dementia with Lewy bodies (DLB) is a distinct disease entity, a form of AD, or a form of PD. Proposed clinical criteria and neuropathological features of DLB (Table 26–9) will likely facilitate research to clarify this issue.

The clinical picture of DLB is heterogeneous. Kosaka (1990) noted that a dementia, often with cortical features (e.g., aphasia, apraxia), was the presenting syndrome in more than half the cases. Other cases may present initially with psychiatric disorders or extrapyramidal signs. Psychosis is estimated to occur in 60% of cases (Morris et al. 1998). Hallucinations (visual more often than auditory)

**TABLE 26–9. Consensus criteria for the clinical diagnosis of probable and possible dementia with Lewy bodies (DLB) and pathological features associated with disease of DLB**

#### Diagnostic criteria

1. The central feature required for a diagnosis of DLB is progressive cognitive decline of sufficient magnitude to interfere with normal social or occupational function. Prominent or persistent memory impairment may not necessarily occur in the early stages, but is usually evident with progression. Deficits on tests of attention and of frontosubcortical skills and visuospatial ability may be especially prominent.
2. Two of the following core features are essential for a diagnosis of probable DLB, and one is essential for possible DLB:
  - a. Fluctuating cognition with pronounced variations in attention and alertness
  - b. Recurrent visual hallucinations that are typically well formed and detailed
  - c. Spontaneous motor features of parkinsonism
3. Features supportive of the diagnosis are
  - a. Repeated falls
  - b. Syncope
  - c. Transient loss of consciousness
  - d. Neuroleptic sensitivity
  - e. Systematized delusions
  - f. Hallucinations in nonvisual modalities
4. A diagnosis of DLB is less likely in the presence of
  - a. Stroke disease, evident as focal neurological signs or on brain imaging
  - b. Evidence on physical examination and investigation of any physical illness or other brain disorder sufficient to account for the clinical picture

#### Pathological features

Essential for diagnosis of DLB

Lewy bodies

Associated but not essential

- a. Lewy-related neurites
- b. Plaques (all morphological types)
- c. Neurofibrillary tangles
- d. Regional neuronal loss, especially brainstem (substantia nigra and locus ceruleus) and nucleus basalis of Meynert
- e. Microvacuolation (spongiform change) and synapse loss
- f. Neurochemical abnormalities and neurotransmitter deficits

have been estimated to occur in 20%–80% of cases (Morris et al. 1998), and more often in DLB than AD, but as frequently as in PD (Klatka et al. 1996). The estimated prevalence of delusions (often persecutory in nature) in DLB ranges between 20% and 80%. Delusions in DLB were found in one study to be as common as those found in AD, but more common than those found in PD (Klatka et al. 1996). Morris et al. (1998) recommended that nonpharmacological approaches to treating psychosis be used first, given the potential increased morbidity and mortality associated with use of conventional antipsychotics in DLB. When pharmacological intervention is necessary, the newer atypical antipsychotics (e.g., clozapine or risperidone) were recommended, although these are prescribed in lower than typical doses. Affective disturbances are common in DLB, and prevalence of depression has been estimated to be about 40% (Klatka et al. 1996; Weiner et al. 1996).

The dementia of DLB is characterized by pronounced impairments in attention, visuospatial and visuoconstructive functions, psychomotor speed, and memory retrieval (Salmon and Galasko 1996). When compared with AD, DLB involves more marked impairments in visuospatial, visuoconstructive, and attentional functions, and in lexical verbal fluency (Hansen et al. 1990; Salmon et al. 1996). When DLB is characterized by additional AD pathology, the dementia resembles a superimposition of the cognitive deficits of AD and PD (Salmon and Galasko 1996), although the memory deficit may be more pronounced in AD than DLB with AD pathology (Connor et al. 1998).

#### Clinical Features of Dementia in Parkinson's Disease: Cortical Versus Subcortical

Dementia is an acquired clinical syndrome, not a single entity or outcome. It may result from a number of etiologies and present in various forms depending on underlying neuropathology and which cognitive functions are most affected. Neuropsychological deficits have not been found to develop in a uniform manner during the progression of PD (Huber et al. 1989c).

Dementia syndromes have been subdivided on the basis of neurobehavioral deficits into two categories: cortical and subcortical (Cummings 1986). The prototypical cortical dementia is AD. Examples of subcortical dementia occur in PD, Huntington's disease, and progressive supranuclear palsy. Criticized because cortical and subcortical pathology eventually becomes evident in all dementias and because the features of dementias within a

given class vary, the cortical-subcortical classification nonetheless serves as a useful clinical shorthand for describing cognitive and behavioral deficits early in the course of dementias. A comparison of the features of cortical and subcortical dementias is presented in Table 26–10. Such differences in the features between cortical and subcortical dementias are observable even on cognitive screening examinations such as the Dementia Rating Scale (Paolo et al. 1995).

**Attention.** Performance on digit span is generally preserved in patients with PD with dementia (Huber et al. 1986, 1989b; Pillon et al. 1986). Performance on tasks requiring the self-allocation of attentional resources is impaired (Brown and Marsden 1988; Wright et al. 1990), and, as the disease progresses, patients may have difficulty performing tasks even when external cues are provided (Yamada et al. 1990).

**Memory.** The memory deficits of PD, although variable in quality (Filoteo et al. 1997), are not as pervasive as those in AD. The diminished ability to learn and remember new information is characterized by predominantly a retrieval deficit, as evident from relatively preserved recogni-

tion, as opposed to free recall, and the ability to benefit from cuing. There may also be an increased reliance on serial encoding (remembering words in the order presented) and diminished semantic encoding (remembering words in clusters according to the semantic category to which they belong) (Buytenhuijs et al. 1994).

Spared early in the disease, remote memory becomes affected in PD with dementia (Freedman et al. 1984; Huber et al. 1986). However, the impairment is milder in PD than in AD. Furthermore, unlike in AD, in which the retrograde amnesia is characterized by a temporal gradient with relative preservation of memories of more distant than recent events, the remote memory impairment in PD with dementia is equally severe across previous decades of life.

Nondeclarative memory refers to “knowing how” and a form of remembering that can be expressed only through the performance of task operations. Performance on nondeclarative memory tasks appears task dependent. Early in PD, patients show intact priming (facilitation in processing a previously presented stimulus). Impairments in the learning of new motor, perceptual, and cognitive skills may or may not be evident (Ferraro et al. 1993; Heindel et al. 1989; Huberman et al. 1994; Knowlton et al.

**TABLE 26–10. Comparison of cortical and subcortical types of dementia**

Feature	Cortical dementia	Subcortical dementia
Language	Aphasia	Relatively preserved
Memory functions		
Recall	Impaired	Impaired
Recognition cues	Ineffective	Effective
Encoding	Ineffective	Effective or mildly impaired
Priming	Absent	Present
Procedural	Intact	Impaired
Visuoperception	Severe impairment	Mild impairment
Calculation	Acalculia	Relatively preserved
Executive/frontal systems function	Proportionate to overall intellectual impairment	Affected greater than overall impairment
Speed of information processing	Normal	Slowed
Personality and mood	No insight; unconcerned; depression infrequent	Insight; apathetic; depression frequent
Motor functions		
Speech	Normal articulation until late	Dysarthria early
Motor speed	Normal until late	Slowed
Posture	Normal until late	Stooped, rigid
Gait	Normal until late	Abnormal
Coordination	Normal until late	Abnormal
Adventitious movements	Absent except for myoclonus late in course	Chorea, tremor, dystonia, and tics

Source. Adapted from Ross et al. 1992.

1996). In contrast, patients with dementia typically perform poorly on nondeclarative memory tasks (Heindel et al. 1989).

**Language.** AD involves early difficulties with word finding as evident from poor performance on tests of lexical and semantic verbal fluency and visual confrontation naming. Spontaneous speech is characterized by circumlocutions and occasional paraphasias. The language impairments in AD progress to resemble a transcortical sensory aphasia (dysnomia, paraphasias, impaired written and auditory comprehension, and aphasic dysgraphia). Speech remains fluent, with relatively intact repetition and ability to read aloud (Cummings and Benson 1983).

Speech in PD is marked by hypophonia and dysarthria, with rare paraphasic errors. Mild impairments of word generation and retrieval early in PD are believed to be consistent with frontal lobe dysfunction (Matison et al. 1982). In PD with dementia, performance on lexical and semantic verbal fluency tasks is as poor as in AD (Tröster et al. 1998a), or even worse (Stern et al. 1993b). The visual confrontation naming impairment is less pronounced than that in AD (Tröster et al. 1996b, 1998a). Comprehension and writing (limited by motor impairments) are relatively preserved in PD.

**Visuospatial functions.** Impaired visuospatial and visuoconstructive abilities are characteristic of AD. Similar deficits have been found consistently in patients with PD with dementia relative to patients with PD without dementia and psychiatrically healthy control subjects, even when tasks minimize or eliminate motor demands (Globus et al. 1985; Huber et al. 1989b; Pillon et al. 1986). The results of studies comparing the abilities of groups with PD and AD are not conclusive. Huber et al. (1986) found that patients with AD outperformed patients with PD with dementia on Raven's Progressive Matrices (a test of spatial reasoning) (Raven 1958). In contrast, patients with PD performed better at Block Design than did the group with AD, suggesting more severe involvement of frontal systems in PD and more severe posterior hemispheric changes in AD. Visuospatial impairments do not improve with dopamine replacement and do not vary during "on" and "off" periods. If the dopamine deficit plays a role in these abnormalities, it must be in conjunction with other neurochemical or pathological processes (Pillon and Dubois 1989).

**Executive functions.** Executive functions depend critically on the integrity of the frontal lobes and their thalamostriatal connections, especially the dorsolateral circuit (Mega and Cummings 1994). Frontal lobe dysfunction

in PD most likely results from the deficit of dopamine within the basal ganglia (Taylor et al. 1990b), although cholinergic dysfunction secondary to neuronal loss in the septal and basal nuclei has also been implicated (Dubois et al. 1990).

Executive deficits are especially notable on tasks requiring the self-initiated or internally guided planning and execution of information processing strategies. Poor performance of tasks that require coordination of mental and motor functions (e.g., resulting in frequent falling or poor operation of an automobile) has also been attributed to the disturbance of frontal-subcortical pathways. The loss of these abilities may be conditioned by visuospatial deficits leading to the defective planning and execution of strategies to accomplish a task (e.g., turning a corner while walking or driving) (Marsden 1982). This gives rise to the hypothesis that the basal ganglia serve as a subcognitive, internal navigational system that places limits on the options available to efficiently solve a problem (Robertson and Flowers 1990; Taylor et al. 1990b).

**Affect.** Disorders of mood are more extensively discussed below. In contrast to AD, depression is much more frequently seen in PD dementia. It is considered an important feature that distinguishes subcortical from cortical syndromes.

## Neuroimaging

**Structural neuroimaging.** Brain-imaging studies often accompany the workup of the patient manifesting a dementia syndrome. These studies are most useful in eliminating the possibility of dementia secondary to a structural brain abnormality, such as a space-occupying lesion (tumor or vascular malformation) or hydrocephalus. The contribution of these studies to the evaluation of dementia secondary to other types of brain disease is less clear.

Cerebral atrophy is the most frequent finding of brain-imaging studies in neurodegenerative disorders. Computed tomography (CT) studies attempting to relate nonspecific measures of atrophy (e.g., ventricular enlargement or size of the sulci) with the severity of dementia, determined by less than rigorous neuropsychological criteria, have yielded conflicting results (deLeon and Ferris 1980; Wilson et al. 1982). Even when it was demonstrated that greater atrophy was present in patients with dementia, significant overlap was shown with the control groups.

Subsequent studies relating specific neuropsychological test results to measures of structural brain changes (from CT) (Inzelberg et al. 1987; Lichter et al. 1988) also failed to demonstrate strong relationships between mea-

tures of cortical atrophy and dementia. However, findings suggesting subcortical atrophy (e.g., increase in intercaudate distance or ventricular enlargement) or frontal atrophy (e.g., increased width of the anterior interhemispheric fissure) were associated with the presence of cognitive dysfunction (Inzelberg et al. 1987; Starkstein and Leiguarda 1993).

Magnetic resonance imaging (MRI) provides more precise visualization of brain abnormalities including cerebral cortical loss, ventricular enlargement, and changes in the periventricular white matter. Despite this enhanced sensitivity, the correlation of MRI abnormalities and dementia in patients with PD parallels that of the CT studies (Huber et al. 1989a). Cerebral cortical atrophy correlates poorly with dementia. Findings consistent with subcortical atrophy (e.g., ventricular enlargement and increase in intercaudate width) were associated with cognitive impairment (Inzelberg et al. 1987; Korczyn et al. 1986; Lichter et al. 1988). Laakso et al. (1996) observed hippocampal atrophy in patients with PD both with and without dementia, and this atrophy might relate to memory impairment.

**Functional neuroimaging.** Functional neuroimaging studies in PD have utilized both single photon emission computed tomography (SPECT) and PET. SPECT studies of resting cerebral blood flow in PD with dementia have revealed frontotemporoparietal decreases (Sawada et al. 1992). Estimates of oxygen and glucose metabolism via the utilization of oxygen-15 ( $^{15}\text{O}_2$ ) or  $^{18}\text{F}$ -2-fluoro-2-deoxyglucose ( $^{18}\text{FDG}$ ) are measurable by PET. Cerebral metabolism in patients with PD (without dementia) is decreased globally (especially in the frontal lobes) (Brooks and Frackowiak 1989) and related to psychometric test performance (Kuhl et al. 1984; Peppard et al. 1988). These findings would be consistent with the current concept that cognitive deficits in early PD are most likely symptomatic of frontal lobe dysfunction. However,  $^{18}\text{FDG}$  PET studies in PD with dementia have generally revealed changes closely paralleling those in AD, that is, decreased glucose utilization in the posterior parietal and temporal areas (Otsuka et al. 1991; Wolfson et al. 1985). It is thus unclear whether metabolic changes in PD dementia reflect AD, DLB, or some other degenerative process (Brooks 1997).

In addition to providing measures of blood flow and metabolism during the resting state, PET has been used to demonstrate changes in cerebral blood flow and metabolism in response to activation with motor and cognitive tasks. Owen et al. (1998) recently demonstrated the importance of neostriatal outflow to frontal cortex in working memory and planning tasks, observing diminished internal

globus pallidus activation in PD during performance of these cognitive tasks. Motor activation studies have shown reduced lentiform nucleus (putamen and globus pallidus), anterior cingulate, supplementary motor area, and dorso-lateral prefrontal cortex activation in PD when the patient is operating a joystick or extending the index finger (Brooks 1997). Activation studies in PD with dementia have not been carried out, but cognitive activation PET provides one avenue for exploring cerebral correlates of specific cognitive impairments.

PET also provides images that measure the binding of positron-emitting radiopharmaceuticals to specific neurochemical receptors. Numerous tracers are now available to study dopamine transport, storage, uptake, and binding. Initial studies suggest that such functional imaging is useful in detecting disease early, tracking PD progression, and evaluating graft survival (Brooks 1997). Studies have yet to take advantage of these techniques to demonstrate the role of dopaminergic abnormalities in neurobehavioral changes in PD.

## Treatment of Dementia

The drugs piracetam and phosphatidylserine (both nootropics) have been the subjects of controlled clinical trials in the treatment of dementia in PD. Neither resulted in improvement of cognition (Fünfgeld et al. 1989; Sano et al. 1990). Selegiline appears to have no effect on cognition in early PD (Kieburz et al. 1994). Other studies of the effects of selegiline on cognition are difficult to interpret, given the small numbers of patients studied and study differences in patient characteristics and assessment. One study reported that a dose of 5 mg selegiline twice per day was associated with modest improvements on the Mini-Mental State Exam (Folstein et al. 1975) in PD with dementia (Tarczy and Szirmai 1995). Cholinomimetics such as tacrine, which may be beneficial in AD, have not been used in controlled clinical trials, perhaps because they might exacerbate parkinsonism (Ott and Lannon 1992). Lieberman (1998) indicated that trials of donepezil (5 to 10 mg/day) or exelon (6–12 mg/day) may be useful in some patients but that such treatment can be accompanied by agitation and worsening of tremor.

## ■ Disease-Related Psychiatric Conditions

The psychiatric manifestations of PD may be as, or more, disabling than the motor dysfunction and may occur as a result of the disease itself or as a complication of

pharmacotherapy for the motor symptoms of the disease. The specific disease-related syndromes are discussed below. Treatment-related syndromes are discussed in a subsequent section.

## Depression

**General considerations.** Parkinson's original description characterized his patients as manifesting melancholy and appearing dejected. Subsequent studies found a wide ranging prevalence of depression (7%–90%) in PD, with the most commonly accepted prevalence being about 40% (Cummings 1992). Approximately 50% of patients become depressed at some time during the disease (Dooneief et al. 1992; Mayeux 1982), and depression is present in up to one-third of patients at the time of their diagnosis (Santamaria et al. 1986). Recent studies (Hantz et al. 1994; Tandberg et al. 1996) suggest that minor depression, or dysthymia, might be more common than major depression in PD, but other studies indicate that approximately half the patients have a dysthymia and the other half have a major depression (Davous et al. 1995; Starkstein et al. 1990).

Both dysthymia and major depression deemed to be a feature of PD itself are defined in DSM-IV under the criteria for mood disorders due to a general medical condition (Table 26–11). These criteria make it clear that a mood disorder due to PD must be differentiated from an adjustment reaction. Although some patients develop depression in reaction to having PD and limitations in activities of daily living (e.g., Gotham et al. 1986), the diagnosis of an adjustment reaction in PD is rare. Numerous findings can be cited to support both a “reactive” and an “endogenous” basis for the depression in PD, but, as Brown and Jahanshahi (1995) pointed out, the debate about reactive versus endogenous depression in PD has become a sterile issue. They view the distinction as overly simplistic, and one that needs to be replaced by an interactionistic perspective.

**Depression and cognitive impairment.** Depression in patients without PD is associated with cognitive deficits, particularly in the encoding and retrieval of information from memory (Zakzanis et al. 1998). Not surprisingly, depression also affects cognition and memory in PD. Given that depression is a risk factor for dementia in PD (Stern et al. 1993a), that depression exacerbates cognitive impairment in PD (Kuzis et al. 1997; Tröster et al. 1995a, 1995b) when the depression is sufficiently severe (Boller et al. 1998), and that depression is associated with more rapid declines over time in cognition and ability to successfully perform activities of daily living (Starkstein et al. 1992), it is

**TABLE 26–11. DSM-IV diagnostic criteria for mood disorder as a result of Parkinson's disease**

- 
- A. A prominent and persistent disturbance in mood predominates in the clinical picture and is characterized by either (or both) of the following:
    1. Depressed mood or markedly diminished interest or pleasure in all, or almost all, activities
    2. Elevated, expansive, or irritable mood
  - B. Evidence from the history, physical examination, or laboratory findings suggests that the disturbance is the direct physiological consequence of Parkinson's disease.
  - C. The disturbance is not better accounted for by another mental disorder (e.g., adjustment disorder with depressed mood in response to the stress of having Parkinson's disease).
  - D. The disturbance does not occur exclusively during the course of a delirium.
  - E. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify types:*

**With depressive features:** if the predominant mood is depressed, but the full criteria are not met for a major depressive episode

**With major depressive-like episode:** if the full criteria are met (except for criterion D) for a major depressive episode

**With manic features:** if the predominant mood is elevated, euphoric, or irritable

**With mixed features:** if the symptoms of both mania and depression are present but neither predominates

---

important to determine whether a dementia in PD is related to depression. Prompt treatment of depression is essential to enhance the patient's quality of life (Valldeoriola et al. 1997): treatment of depression may retard the rate of cognitive decline (Starkstein et al. 1992) and ameliorate depression-related functional decline (Cole et al. 1996). Unfortunately, no studies have examined the extent to which cognition and function improve with treatment of depression and whether such gains would be observed in patients with a depressive dementia or a depression overlaid on another dementia.

**Pathophysiology.** Serotonergic pathophysiology has been more consistently linked to depression in PD than have dopaminergic and noradrenergic abnormalities. Several findings implicate serotonergic abnormalities in depression in PD. Studies of the cerebrospinal fluid of pa-

tients with PD with depression have shown decreased concentrations of the serotonin metabolite 5-hydroxyindoleacetic acid (5-HIAA) (Kostic et al. 1987; Mayeux et al. 1984). Furthermore, depression improves following administration of 5-hydroxytryptophan (5-HTP), the precursor of serotonin, and concomitant increases in cerebrospinal fluid 5-HIAA (Mayeux et al. 1988; McCance-Katz et al. 1992). The brain content of serotonin at autopsy in patients with PD is reduced, and the raphe nuclei have a reduced ability to decarboxylate amino acids in PD.

A dopaminergic role in depression in PD is suggested by the finding of pronounced dopaminergic cell loss in the ventral tegmentum of patients with PD who are depressed (Torack and Morris 1988). Dose-related elevations in mood and reductions in anxiety were found in a placebo-controlled study of acute levodopa infusion in patients with motor fluctuations (Maricle et al. 1995), and this response is less pronounced in early PD (Maricle et al. 1998), presumably when dopaminergic depletion is not as pronounced as that in patients with motor fluctuations. The observation that chronic treatment with dopaminergic agents does not alleviate depression (but see Miyoshi et al. 1996) does not entirely discount a dopaminergic role in depression. Dopaminergic drugs may have a greater impact on the nigrostriatal than the mesolimbic system, which is more likely to be involved in depression. Indeed, in response to methylphenidate infusion, thought to activate the mesolimbic system, patients with PD who are depressed showed a much lesser euphoric response than patients with PD who are not depressed (Cantello et al. 1989). Evidence linking noradrenergic changes to depression in PD is generally based on the response of depression to tricyclics (Fields et al. 1998).

Functional neuroimaging studies have highlighted the involvement of frontosubcortical systems, and especially the paralimbic pathways linking frontal and temporal cortices and striatum, in depression in PD. Depression in PD has been associated with hypometabolism in the inferior orbital and anterior temporal cortex (Mayberg et al. 1990) and in the medial frontal and anterior cingulate cortex (Ring et al. 1994). Medial prefrontal blood flow abnormalities are also seen in patients without PD who are depressed, and they are more strongly related to cognitive dysfunction than to mood (Bench et al. 1993; Dolan et al. 1994). Dorsolateral and medial prefrontal regional cerebral blood flow (rCBF) normalization occurs with remission of depression (Bench et al. 1995), but it is unknown if cognitive dysfunction improves and if similar changes would be seen in patients with PD with depression. It is of interest that frontal dysfunction indexed by cognitive screening and

psychophysiological methods may be a harbinger of poor or delayed response to antidepressant treatment in the elderly (Kalayam and Alexopoulos 1999). Whether frontal dysfunction in PD might be related to treatment response remains to be investigated.

**Clinical features.** Among patients with PD and depression, approximately half have a major affective disorder and the other half have a dysthymia. Major depression and dysthymia differ in that the former is characterized by periods of depression separated by intervals with normal affect; the latter is a chronic condition with more mild mood changes. The depression is usually mild to moderate; very infrequently it is severe. Several features of depression in PD distinguish it from idiopathic depression (Meyerson et al. 1997): comorbid anxiety and panic, a relative lack of self-reproach and guilt, and a low suicide rate.

Clinical features of PD have been only inconsistently related to depression. Tentative evidence suggests that patients with an early disease onset age, with rapid disease progression, and in the early and advanced stages of the disease are more likely to be depressed (Brown and Jahanshahi 1995). There does not appear to be a linear or parallel relationship between depression and disease severity or between depression and disability. Cummings (1992) proposed that membership in patient groups with or without depression remains relatively stable over time, suggesting the possibility that there are two distinct disease types.

**Treatment: pharmacotherapy.** Before discussing specific drug therapy for depression in PD, we consider the effects of antiparkinsonian medication on mood. Levodopa therapy has been found to transiently improve mood, but this effect is rarely sustained (Shaw et al. 1980), and levodopa is not effective as an antidepressant (Mindham et al. 1976; Taylor and Saint-Cyr 1990). In addition, because of its effects on serotonin metabolism, levodopa may predispose to depression (Anderson and Aabro 1980). Pergolide does not ameliorate depression (Factor et al. 1995). Several other antiparkinsonian agents do, however, appear to improve mood in some cases. Bromocriptine (Jouvent et al. 1983; Sitland-Marken et al. 1990), anticholinergic drugs (e.g., trihexyphenidyl) (Kaspar et al. 1981), amantadine (Bavazzano and Guarducci 1980), and selegiline (Allain et al. 1993; Baronti et al. 1992; Eisler et al. 1981; Parkinson Study Group 1989) had beneficial effects on mood in some studies. It remains unknown if these agents are also useful in treating major depression. Should levodopa exacerbate the symptoms of depression, either lowering the dosage or combining it with one of the above agents may be effective in treating motor

and depressive symptoms (Silver and Yudofsky 1992). The effects on mood of the newer dopamine agonists and COMT inhibitors remain to be documented.

Tom and Cummings (1998) provided an algorithm (Figure 26–3) for the treatment of depression in PD. A listing of some commonly used antidepressants and their neurotransmitter actions appears in Table 26–12. Few methodologically rigorous, controlled clinical trials of antidepressants in PD (Klaasen et al. 1995) have been performed. Among the 12 trials these authors defined as methodologically adequate, positive outcomes were reported for selegiline (10 mg/day), nortriptyline (100 mg/day), desipramine (100 mg/day), imipramine (30–75 mg in patients older than 55 years; 50–100 mg in patients younger than 55), and bupropion (maximum 450 mg).

The side-effect profiles of some commonly used antidepressants are detailed in Table 26–13. Because of the side effects, these medications require caution in their administration. Patients with PD are particularly sensitive to certain of these effects. Many experience orthostatic hypotension that may be exacerbated by drugs, resulting in syncope with injury (e.g., fractures and lacerations). Nortriptyline is less likely to cause postural hypotension than is imipramine (Roose and Glassman 1981). The anticholinergic effects of some agents may cause confusion and worsen preexisting cognitive problems. Among the heterocyclic antidepressants, desipramine and nortriptyline are less likely than amitriptyline to cause these effects. Trazodone and selective serotonin reuptake inhibitors (e.g., fluoxetine and sertraline) have no significant anticholinergic effects.

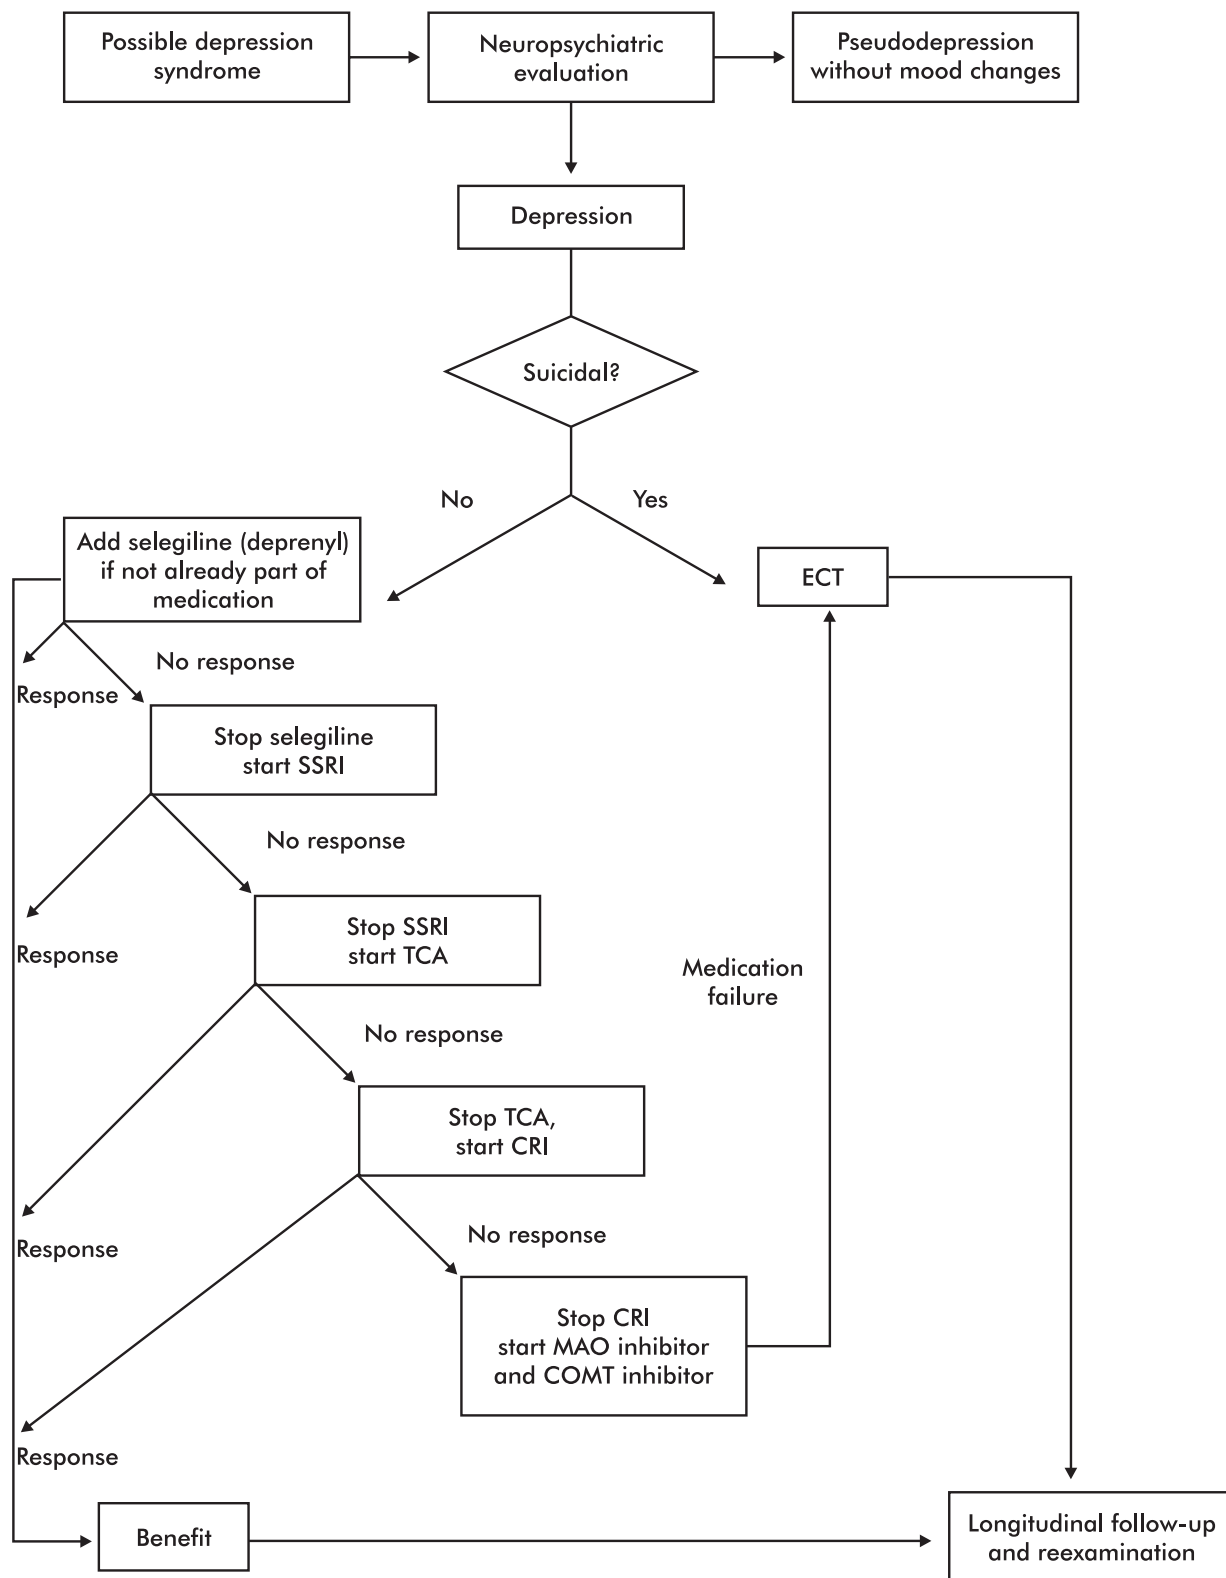

Several antidepressant agents, via different actions, are known to cause parkinsonian symptoms. These agents include amoxapine (which is metabolized to loxapine) (Thornton and Stahl 1984), fluoxetine (Bouchard et al. 1989), and phenelzine (Gillman and Sandy 1986; Waldmeier and Delini-Stula 1979). Fluoxetine has a known dopamine-antagonistic activity (Brod 1989). Steur (1993) reported a transient increase in parkinsonian signs and symptoms in four patients with PD taking fluoxetine (20 mg/day). On the other hand, Caley and Friedman (1982) reported no exacerbation of parkinsonian symptoms in 20 patients with PD with depression receiving up to 40 mg/day of fluoxetine. An additional three patients experienced mild worsening of symptoms. This antidepressant should be administered with caution to patients with PD. Bupropion is mildly dopaminergic and may induce dyskinesias or hallucinations.

Drugs that may offer specific advantages include selegiline, which, when given at dosages selective for MAO-B receptor activity, may improve mood (Parkinson

Study Group 1989). Caution has been advised in using selegiline together with tricyclic antidepressants or selective serotonin reuptake inhibitors. Such combinations may give rise to “serotonin syndrome,” the symptoms of which overlap with those of malignant neuroleptic syndrome and include tremor, agitation, restlessness, reduced consciousness, and hyperpyrexia. Nonetheless, Richard et al. (1997), based on a survey of investigators, concluded that adverse reactions to combinations of selegiline and antidepressants were rare. They concluded that, among 4,568 patients treated with selegiline and an antidepressant, 0.24% experienced symptoms consistent with a possible serotonin syndrome, and only 0.04% had serious adverse events. Trazodone and fluoxetine, by virtue of negligible anticholinergic properties, have little adverse effect on cognition. Sertraline and fluvoxamine have not been adequately evaluated in PD. An open-label pilot study found depression in PD to respond to sertraline (25 mg/day for 1 week, then 50 mg/day) (Hauser and Zesiewicz 1997). One case report supports the efficacy of fluvoxamine in treating depression in PD (McCance-Katz et al. 1992).

No long-term studies of antidepressant therapy in patients with PD have been conducted, although one study of 21 patients found that depression remitted in only four of these cases after a 2.5-year follow-up (Mayeux et al. 1988). Given the absence of long-term treatment studies, general principles of antidepressant drug therapy are applicable. Tom and Cummings (1998) suggest that an adequate trial should last at least 6 weeks. The drug should be titrated to the dose necessary (within the recommended guidelines) to achieve a satisfactory antidepressant effect in the absence of intolerable side effects. Once an adequate effect is achieved, therapy should be continued for at least 6 months before the medication is gradually tapered.

Plasma levels are not required for the management of patients receiving antidepressant therapy. Guidelines were developed by the American Psychiatric Association Task Force on the Use of Laboratory Tests in Psychiatry (1985) to determine optimal plasma levels in patients with major depression (excluding patients with neurodegenerative disorders, such as PD). An optimal trial of the medication is assumed when plasma levels fall within the guidelines. It is not known if the results of these determinations are applicable to more complicated clinical settings (i.e., in the setting of a documented brain disorder). Levels of imipramine and its desmethyl metabolite, desipramine, should be greater than 200–250 ng/mL; levels of desipramine, greater than 125 ng/mL; and a level of nortriptyline, between 50 and 150 ng/mL. Levels should be drawn 10–14 hours after the last dose.

**FIGURE 26-3.** Algorithm for treatment of depression in Parkinson's disease (PD). COMT = catechol-*O*-methyltransferase; CRI = combined reuptake inhibitor; ECT = electroconvulsive therapy; MAO = monoamine oxidase; SSRI = selective serotonin (5-hydroxytryptamine; 5-HT) reuptake inhibitor; TCA = tricyclic antidepressant. **TABLE 26–12.** Neurotransmitter effects of selected antidepressants

Agent (trade name)	Serotonin	Norepinephrine	Dopamine
Amitriptyline (Elavil)	++	+	0
Bupropion (Wellbutrin)	0	+	+ <sup>a</sup>
Desipramine (Norpramin)	+	+++	+/-
Fluoxetine (Prozac)	+++	0	+/- <sup>b</sup>
Nefazodone (Serzone)	++ <sup>c</sup>	+/-	0
Nortriptyline (Pamelor)	+	++	0
Sertraline (Zoloft)	+++	0	+/- <sup>b</sup>
Venlafaxine (Effexor)	+++	++	+ <sup>a</sup>

*Note.* Values are approximations, derived from in vivo, in vitro, and clinical studies. +++ = marked effects; ++ = moderate effects; + = modest effects; +/- = minimal effects; 0 = virtually no effects.

<sup>a</sup>Dopaminergic effects probably significant only at higher doses.

<sup>b</sup>Selective serotonin reuptake inhibitors (SSRIs) have variable effects on dopamine, perhaps decreasing dopamine in some brain regions. However, sertraline has substantial dopamine reuptake inhibition compared with the other SSRIs, and this may have implications for its apparently beneficial effects on cognitive function in some patients.

<sup>c</sup>Nefazodone antagonizes the 5-HT<sub>2</sub> receptor but shows modest blockade of 5-HT reuptake.

**Treatment: electroconvulsive therapy.** Electroconvulsive therapy (ECT) has been shown to be effective in the treatment of psychiatric disorders, especially depression (Brandon et al. 1984; Faber and Trimble 1991; Gregory et al. 1985). In controlled comparisons with antidepressant medications, ECT has been demonstrated to be superior (Abrams 1988). Dating back to the 1950s (Lebensohn and Jenkins 1975; Savitsky and Karliner 1953; Shapiro and Goldberg 1957), ECT has been observed to also benefit the tremor and motor symptoms of patients with PD who are undergoing the procedure for depression, as well as to improve parkinsonism secondary to neuroleptic medications (Goswami et al. 1989). Furthermore, ECT improved the motor symptoms of patients with PD without psychiatric illness in five of six reports (in 22 of 34 patients) (Faber and Trimble 1991).

Several studies (Andersen et al. 1987; Douyon et al. 1989; Zervas and Fink 1991) have reported ECT to be effective in relieving depression and transiently improving the motor symptoms of PD. The total number of patients studied is, however, small: Faber and Trimble (1991) noted that between 1975 and 1991 there had been a total of 21 reports detailing ECT in 44 patients with PD and psychiatric morbidity. A recent retrospective study of 25 patients with

PD and one or more of major depression with psychosis (4), major depression without psychosis (15), unspecified anxiety disorder (2), dementia (6), or unspecified other disorders (12) found improvements in mental state, depression, and anxiety (Moellentine et al. 1998). Transient improvement in 14 of the 25 patients' parkinsonian symptoms was found.

The primary indication for ECT in PD is in the treatment of depression, especially when antidepressant medications are ineffective or when side effects make them intolerable. The latter may include impairment of cognition, glaucoma, ileus, heart conduction block, or urinary retention. In addition, ECT may be preferable in life-threatening situations requiring a more rapid response (e.g., suicidal depression or malnutrition secondary to apathy and psychomotor retardation).

Other psychiatric uses of ECT include the treatment of mania (Small and Millstein 1986), which is uncommon in patients with PD. Roth et al. (1988) reported improvement in both motor and affective signs in a patient with PD with mania treated with ECT. ECT has been used effectively in the treatment of psychosis induced by dopaminergic therapy (see section on Drug-Related Psychiatric Conditions below).

**TABLE 26-13. Side-effect profiles of selected antidepressants**

Drug (trade name)	Anticholinergic (blurry vision, dry mouth, constipation)	Sedation/ drowsiness	Insomnia/ agitation	Orthostatic hypotension	Cardiac arrhythmia	Gastrointestinal distress/diarrhea	Weight gain
Amitriptyline (Elavil)	4	4	½	4	3	½	4
Bupropion (Wellbutrin)	0	½	2	0	½	1	0
Desipramine (Norpramin)	1	1	1	2	3	½	1
Doxepin (Sinequan)	3	4	½	3	2	½	3
Fluoxetine (Prozac)	0	½	2	0	½	3	0 <sup>a</sup>
Imipramine (Tofranil)	3	3	1	4	3	1	3
Nefazodone (Serzone)	½	½	0	2	½	2	½
Nortriptyline (Pamelor)	1	2	½	1	2	½	2
Paroxetine (Paxil)	½	½	1	0	½	3	0 <sup>a</sup>
Sertraline (Zoloft)	0	½	1	0	½	3	0 <sup>a</sup>
Venlafaxine (Effexor)	½	½	2	0	½	3	0

*Note.* All values are rough guidelines and may vary according to dose, duration of treatment, and age of patient. 4 = high; 3 = moderately high; 2 = significant; 1 = modest; ½ = minimal; 0 = virtually none.

<sup>a</sup>Despite published data showing little or no weight gain with the selective serotonin reuptake inhibitors (SSRIs), clinical experience has shown that some patients, often after an initial period of weight loss, may gain substantial weight with fluoxetine, paroxetine, and perhaps other SSRIs.

*Source.* Adapted from Pies 1998.

Included with the risks of ECT are those attendant with the induction of and recovery from anesthesia. Psychotropic drugs are discontinued before ECT, and levodopa dosage should be reduced. The latter is required to minimize the occurrence of dyskinesias and post-treatment delirium, which may result from increased dopamine sensitivity. The cardiovascular risks of ECT are small (Kramer 1985), with a mortality of one death per 50,000 treatments. Neither permanent electroencephalographic changes nor subsequent spontaneous seizures follow ECT. Postictal confusion is common for up to 30 minutes after the procedure. In comparison to a control group of patients without PD undergoing ECT, patients with PD had a higher rate of complications (56% vs. 12% in the control group) (Moellentine et al. 1998). The most common complication was an intertreatment delirium (52%). Indeed, two other studies suggested that patients with PD may be at greater risk for prolonged delirium than other patients receiving ECT (Douyon et al. 1989; Figiel et al. 1991), suggesting that pathological changes in the basal ganglia may play a role in the pathogenesis of this mental status abnormality. Moellentine et al. (1998) also found that length of hospitalization was longer for the PD than the control group. Bilateral electrode placement results in some degree of memory impairment for at least 6 months (Weiner et al. 1986). However, unilateral electrode placement with brief pulse stimulation produces a memory disturbance no greater in ECT-treated patients than in antidepressant-treated control subjects.

ECT is safe and effective in patients with dementia in general (Tsuang et al. 1979). Moellentine et al. (1998) observed no relationship between dementia and the occurrence of prolonged delirium in PD and an increase in Mini-Mental State Exam scores after ECT in both the patient and control groups.

## Mania

Manic behavior (occurring in 1%–5% of patients with PD) is rarely a manifestation of bipolar illness in PD; it is associated with levodopa therapy (Celesia and Barr 1970) and dementia. Hyperactivity may also occur as a manifestation of a schizophrenic-like disorder that has been described rarely in PD (Crow et al. 1976). Management is difficult because of the likelihood of the exacerbation of manic symptoms by levodopa and the risk of increasing extrapyramidal symptoms (e.g., tardive dyskinesia) by lithium.

## Anxiety Disorders

Anxiety disorders such as generalized anxiety, panic, and social phobia occur in up to 40% of patients with PD, fre-

quently with comorbid depression (Richard et al. 1996). Optimal treatments have not been established, but some guidelines are provided below and by Lieberman's (1998) algorithm (Figure 26–4).

**Generalized anxiety disorder.** Generalized anxiety is a frequent finding in patients with PD. Stein et al. (1990) found the disorder in 38% of patients with PD and with no relationship to their degree of motor disability or treatment with levodopa. Symptoms of anxiety or panic may also coexist with depression (Henderson et al. 1992; Schiffer et al. 1988; Starkstein et al. 1993).

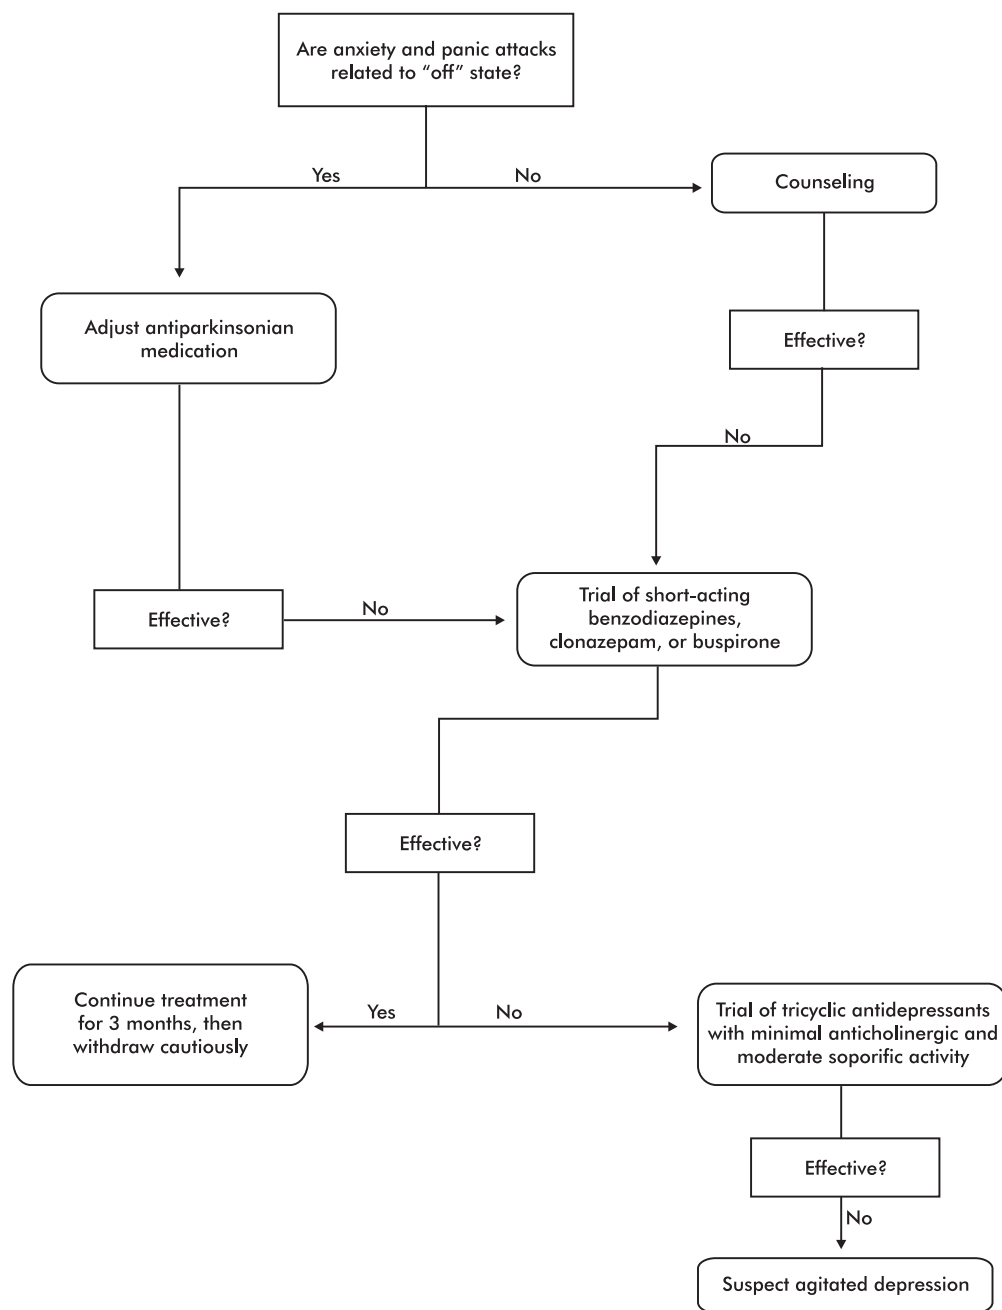

Benzodiazepines are effective in the treatment of anxiety. In addition, they may be used in conjunction with antidepressants and are effective in counteracting the not infrequent occurrence of stimulant effects by small, initial doses of antidepressants (e.g., in the treatment of panic disorder). Buspirone, a nonbenzodiazepine with both anxiolytic and antidepressant properties, may be administered in conjunction with antidepressant drugs to treat coexistent anxiety (Fabre 1990). However, in a double-blind placebo-controlled crossover study of 16 patients with PD, buspirone in doses of 10–100 mg/day had no effect on anxiety, depression scales, or extrapyramidal symptoms (Ludwig et al. 1986).

**Panic.** Among 131 levodopa-treated patients with PD, Vázquez et al. (1993) found 24% to have recurrent panic attacks, with 90% of the attacks occurring during the “off” state. In cases with panic related to the “off” state, management of motor fluctuations is indicated. Panic disorder may be effectively treated with the heterocyclic antidepressants nortriptyline, desipramine, and imipramine or with fluoxetine (Silver and Yudofsky 1988).

**Phobic disorder.** Phobic disorders are characterized by irrational fear (fully defined by DSM-IV), such as fear of crowded places. Initially, fear manifested by patients with PD may be justified (e.g., fear of falling because of impaired postural reflexes), but later it may be exaggerated to include situations in which it is not reasonable. This disorder rarely begins before the onset of PD.

**Obsessive-compulsive disorder.** Obsessive-compulsive symptomatology (OCS) has been linked to dysfunction of the basal ganglia. OCS is sometimes present in disorders involving the basal ganglia (e.g., Gilles de la Tourette's syndrome, Huntington's disease, and Sydenham's chorea) and has been observed in postencephalitic parkinsonism. It has also been associated with lateralized brain abnormalities in both left and right hemispheres.

**FIGURE 26-4.** Algorithm for treatment of anxiety in Parkinson’s disease. Reprinted with permission from Lieberman A: “Managing the Neuropsychiatric Symptoms of Parkinson’s Disease.” *Neurology* 50 (suppl 6):S33–S38, 1998. Copyright 1998 Lippincott Williams & Wilkins.

Tomer et al. (1993), using the Leyton Obsessional Inventory (Cooper 1970), studied the relationship between OCS and the lateralization of motor symptoms in 30 patients with idiopathic PD. The severity of left-sided motor dysfunction was found to be a reliable predictor of the overall severity of OCS. The variables that most significantly correlated with left-sided motor impairment were overconscientiousness, repetition, disturbing thoughts,

and obsessions with cleanliness. This may reflect a relatively greater deficiency of dopamine in the right basal ganglia of patients with PD manifesting OCS.

**Psychosis**

Symptoms of psychosis occur in up to 40% of patients with PD (Peyser et al. 1998). Based on their literature review,

Peyser et al. (1998) identified six types of psychotic disorders in PD: 1) hallucinations with preserved insight (usually in the context of dopaminergic treatment); 2) medication-induced psychoses (delusions, hallucinations, and/or thought disorder) without clouding of consciousness but partial or total loss of insight; 3) delirium (usually provoked by dopaminergic treatment or another medical condition); 4) schizophrenia-like psychoses not related to medications; 5) schizophrenia predating PD; and 6) other psychoses (including psychotic depression and mania). Many of the psychoses in PD not related to medical treatment have been the subject of case reports, and it is evident that most of the studies reveal psychotic disorders to usually occur with dopaminergic treatments or in the context of dementia. Recent studies indicate psychotic symptoms to be common in DLB, even in the absence of medications (Morris et al. 1998). No convincing association has been found between PD and psychosis (i.e., schizophrenia).

## ■ Drug-Related Psychiatric Conditions

Virtually every drug used in the treatment of PD can produce clinically significant psychiatric symptoms (for review, see Young et al. 1997). Included are the anticholinergics, amantadine, selegiline, levodopa, MAO-B inhibitors, and dopamine receptor agonists. These adverse effects significantly limit the efficacy of antiparkinsonian medication in some patients. Data reported in some studies regarding the incidence of certain effects (e.g., hallucinations, delusions, and delirium) may be inaccurate (i.e., underestimates) because of imprecise psychiatric interviewing techniques, the reluctance of patients and families to relate these disturbing events, and failure to distinguish the exact nature of the adverse effect.

### Hallucinations

Visual hallucinations are the most common medication-induced side effect (tactile and auditory hallucinations are rare) and may occur with the use of any antiparkinsonian medication. The overall incidence is estimated to be about 20% and is greatest with the use of dopaminergic agents (Goetz et al. 1982). It is thought that bromocriptine has a greater potential to cause psychiatric side effects than levodopa.

Hallucinations most frequently occur in the absence of delirium, at night, and most often they involve seeing formed objects (e.g., people or animals) (Sanchez-Ramos et al. 1996). Sleep disturbances may also be present. Increasing age, a history of multiple-drug therapy, a premorbid history of psychiatric illness, and the use of

anticholinergic medications have been found to be predictors for the occurrence of hallucinations (Glantz et al. 1986; Tanner et al. 1983).

Hallucinatory syndromes differ depending on the offending agent. Anticholinergic drugs are more likely to produce hallucinations that are threatening, be combined with tactile or auditory components, and be accompanied by delirium (Goetz et al. 1982). Patients usually respond to decreasing the dosage of the causative agent(s). A few patients with PD experience benign hallucinations: vivid, nonthreatening visual hallucinations in the absence of delirium or other cognitive impairment, with insight remaining intact. Dosage reduction, if possible, is usually effective in lessening or eliminating hallucinations. An algorithm for the treatment of hallucinations and delirium (Olanow and Koller 1998) is presented in Figure 26-5.

### Delusions

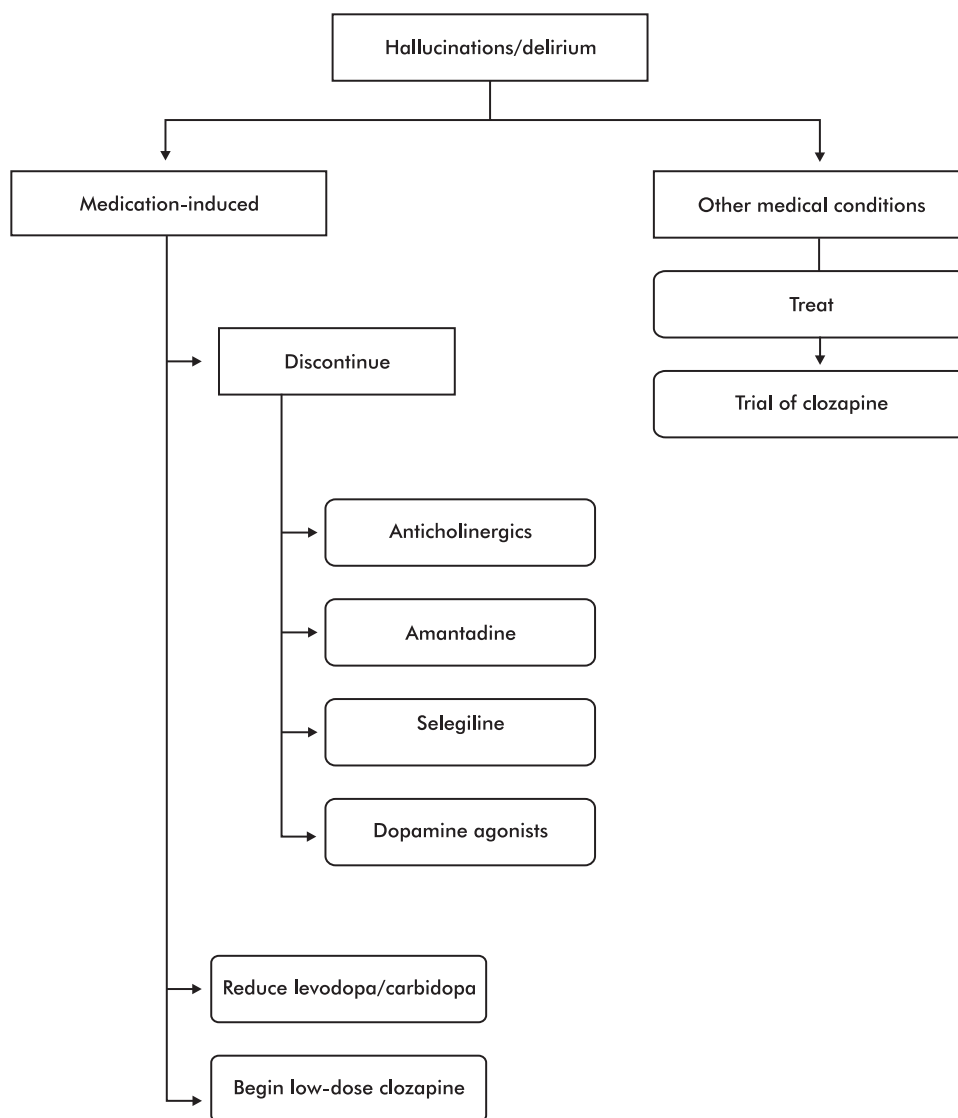

Delusions (false beliefs based on faulty inference, held despite evidence to the contrary, and ordinarily not accepted by members of a person's culture or subculture) have been reported with all types of antiparkinsonian medication. The reported incidence ranges from 3% to 30% (but may be higher if more scrupulously sought), and it is greater at higher doses.

If caused by levodopa, delusions may often be predicted by the occurrence of dreams and/or visual hallucinations (Klawans 1978). Delusions may occur in the setting of a clear or clouded sensorium (Moskovitz et al. 1978) and are typically of the paranoid type but may be self-persecutory. A case of amantadine-induced Othello syndrome (pathological jealousy) has also been described (McNamara and Durso 1991). Older patients with dementia are particularly susceptible (Fischer et al. 1990), and delusions are rarely associated with a schizophrenic-like thought disorder (Beardsley and Puletti 1971).

Management of delusions includes withdrawal of anticholinergic agents and amantadine and reduction of the dosage of levodopa or other dopaminergic drugs.

### Treatment of Drug-Induced Psychoses

Drug-induced psychoses resulting from antiparkinsonian medications have been successfully treated using neuroleptic medications. They are limited by their tendencies to produce extrapyramidal symptoms and, thus, worsen the parkinsonism. Low dosages of molindone, thioridazine, perphenazine, and haloperidol may be administered with caution to alleviate symptoms (Hale and Bellizzi 1980). However, in our experience, a successful

**FIGURE 26-5.** Algorithm for treatment of hallucinations/delirium in Parkinson's disease.

*Source.* Reprinted with permission from Olanow CW, Koller WC: "An Algorithm (Decision Tree) for the Management of Parkinson's Disease: Treatment Guidelines." *Neurology* 50 (suppl 3):S1-S57, 1998. Copyright 1998 Lippincott Williams & Wilkins.

result is rarely achieved because of exacerbation of the parkinsonian features with these drugs. In addition, L-tryptophan has been reported to reduce paranoid delusions in a few patients (Miller and Nieburg 1974).

Several newer, atypical antipsychotics, thought to produce fewer extrapyramidal side effects, have been evaluated in the treatment of psychotic symptoms (including delusions) in PD. The neurotransmitter receptor antagonism profile and the side-effect profile of some of these agents are presented in Tables 26-14 and 26-15, respectively.

Clozapine has been used successfully in the treatment of drug-induced psychosis. Auzou et al. (1996), in their review of studies detailing clozapine treatment in more than

200 patients, concluded that good results were obtained in 90% of patients without worsening of extrapyramidal symptoms. Indeed, some researchers have observed improvements in one or more of tremor, gait disorder, rigidity, bradykinesia, and dyskinesia with clozapine treatment (Bennett et al. 1994; Durif et al. 1997; Friedman and Lannon 1989, 1990; Friedman et al. 1997; Parkinson Study Group 1999). Clozapine may cause bone marrow suppression, and hematological monitoring (i.e., weekly complete blood counts) is required. However, one study (Ruggieri et al. 1997) reported no cases of agranulocytosis in 36 patients with PD who were treated for 12 months with a mean dosage of  $10.59 \pm 6.48$  mg/day. In the Parkinson Study Group

**TABLE 26–14. Relative receptor antagonism of atypical antipsychotic agents (trade names in parentheses)**

Receptor	Risperidone (Risperdal)	Clozapine (Clozaril)	Olanzapine (Zyprexa)	Quetiapine (Seroquel)	Sertindole (SerLect)
D <sub>2</sub>	1	+/-	½	+/-	4
5-HT <sub>2A</sub>	3	2	1	+/-	4
M <sub>1</sub> (muscarinic cholinergic)	+/-	3	4	1	+/-
H <sub>1</sub> (histaminic)	½	4	2	1	+/-
α <sub>1</sub> -adrenergic	2	1	½	½	4

*Note.* Data are semiquantitative comparisons of in vitro affinities for a given receptor. Values should not be compared “vertically”; for example, a “4” on D<sub>2</sub> antagonism may not be quantitatively equivalent to a “4” on α<sub>2</sub> antagonism in the same column. In vitro affinities do not always correspond with clinical effects. 4 = marked; 3 = substantial; 2 = moderate; 1 to ½ = slight; +/- = minimal; 5-HT = 5-hydroxytryptamine.

(1999) study, only one patient treated with clozapine developed leukopenia. Clozapine has been associated with an increased risk of seizures, but the risk in patients with PD appears to be less than 1% (Factor et al. 1995).

Given its anticholinergic properties, clozapine must be used with caution in patients with dementia, who may be at increased risk for confusion (Factor et al. 1994). Indeed, lower dosages of clozapine are used in patients with PD than in patients with schizophrenia (Musser and Akil 1996). Factor et al. (1995) recommended a starting dose of 6.25–12.5 mg/day or every other day, which is increased by 12.5 mg every 4–7 days until symptoms are controlled.

Other new atypical antipsychotics have been studied in too few patients with PD to permit compelling conclusions about these agents' efficacy and safety in this disease. Nonetheless, some of these agents do show promise. Risperidone has been found to be effective and safe in some patients with PD (Ford et al. 1994; Meco et al. 1997; Rich et al. 1995), although motor symptoms may be exacerbated at higher doses. A recent study of 9 patients with PD and dementia found the drug to be effective and well tolerated without exacerbating motor symptoms or cognitive impairment (Workman et al. 1997). An initial study indicated that olanzapine (1–15 mg/day) was effective and well tolerated in 15 patients with PD without dementia with drug-induced psychoses (Wolters et al. 1996). Olanzapine may also be effective in PD patients with dementia (Aarsland et al. 1999). Quetiapine has been evaluated in only two cases with PD (Parsa and Bastani 1998). Remoxipride may be effective in controlling psychosis in PD (Lang et al. 1995; Mendis et al. 1994), but higher doses (mean 161 mg/day) may worsen parkinsonism in a significant percentage of patients. Zotepine (not available in the United States) failed to improve psychosis without worsening motor symptoms in two studies (Arnold et al. 1994; Spieker et al. 1995). New serotonin antagonists such as ondansetron (Zoldan et al. 1995) and mianserin (Ikeguchi and Kuroda 1995) have also had inadequate evaluation in PD. Although efficacy data are encouraging, the cost of ondansetron may be prohibitive.

### **Confusion/Delirium/Cognitive Impairment**

The terms confusion and delirium are often used interchangeably and refer to a syndrome consisting of an altered state of consciousness, incoherent speech, altered psychomotor activity, memory impairment, and sudden onset and rapid fluctuation. Mild forms may go unrecognized. This syndrome has been noted to complicate all forms of antiparkinsonian therapy with a prevalence of 5%–25% and seems to be more frequent among

higher-potency ergot derivatives (e.g., bromocriptine and pergolide). Confusional states are likely to be induced by anticholinergic agents, especially in those patients with preexisting cognitive impairment (Saint-Cyr et al. 1993). One algorithm for treatment of cognitive impairment is presented in Figure 26–6. Agitation may occur with or without delirium. An algorithm for treatment of agitation is presented in Figure 26–7.

### **Depression**

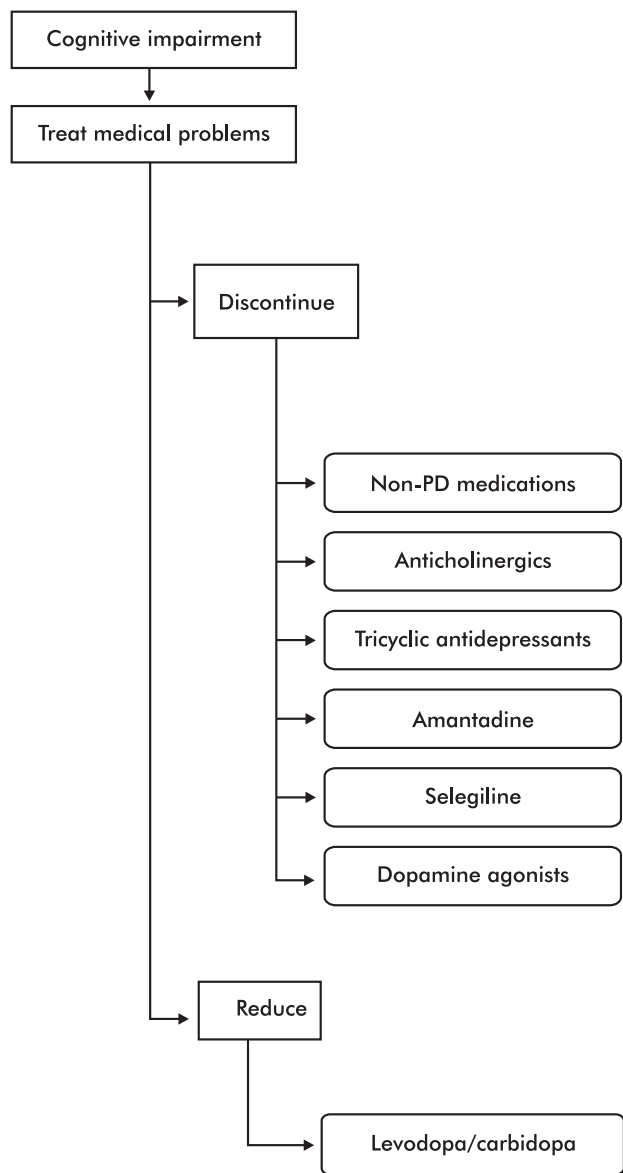

Table 26–16 lists DSM-IV criteria for substance-induced mood disorders. Despite its mood-elevating effects in some patients with PD, levodopa has also been implicated in causing depression. Huber et al. (1988) found that patients with PD and depression had taken the drug for longer periods and were receiving significantly higher dosages than were patients with PD without depression. However, the prevalence range of depressive symptoms in patients with PD treated with levodopa compared with those untreated is approximately the same, ranging from 2% to 50%. Levodopa may affect the appearance of depressive symptoms but not make them more prevalent. Treatment of depression in the setting of levodopa therapy is by the conventional use of antidepressants and ECT.

### **Mania**

Levodopa has the capability of mood elevation along a spectrum from a simple feeling of well-being to full-blown episodes of mania (elation, grandiosity, pressured speech, racing thoughts, hyperactivity, reduced requirement for sleep, increased libido, and risk-taking behavior) (Celesia and Barr 1970; Ryback and Schwab 1971). Pergolide has also been reported to cause mania (Lang and Quinn 1982). In patients with PD with a *premorbid* history of mania, hypomania has resulted from levodopa and bromocriptine therapy (Goodwin 1971; Jouvent et al. 1983). It usually subsides with dosage reduction.

### **Anxiety**

Symptoms of anxiety and panic (e.g., apprehension, irritability, nervousness, feelings of impending doom, palpitations, and hyperventilation) have been attributed to levodopa therapy, especially when occurring in patients not so predisposed before the onset of PD (Celesia and Barr 1970). Those with similar prior symptomatology have reported worsening of their anxiety syndromes (Rondot et al. 1984). Pergolide and selegiline (in combination with levodopa) therapies have also been associated with a significant incidence of anxiety (Lang and Quinn 1982; Yahr et al. 1983). Anxiety occurs in approximately two-thirds of

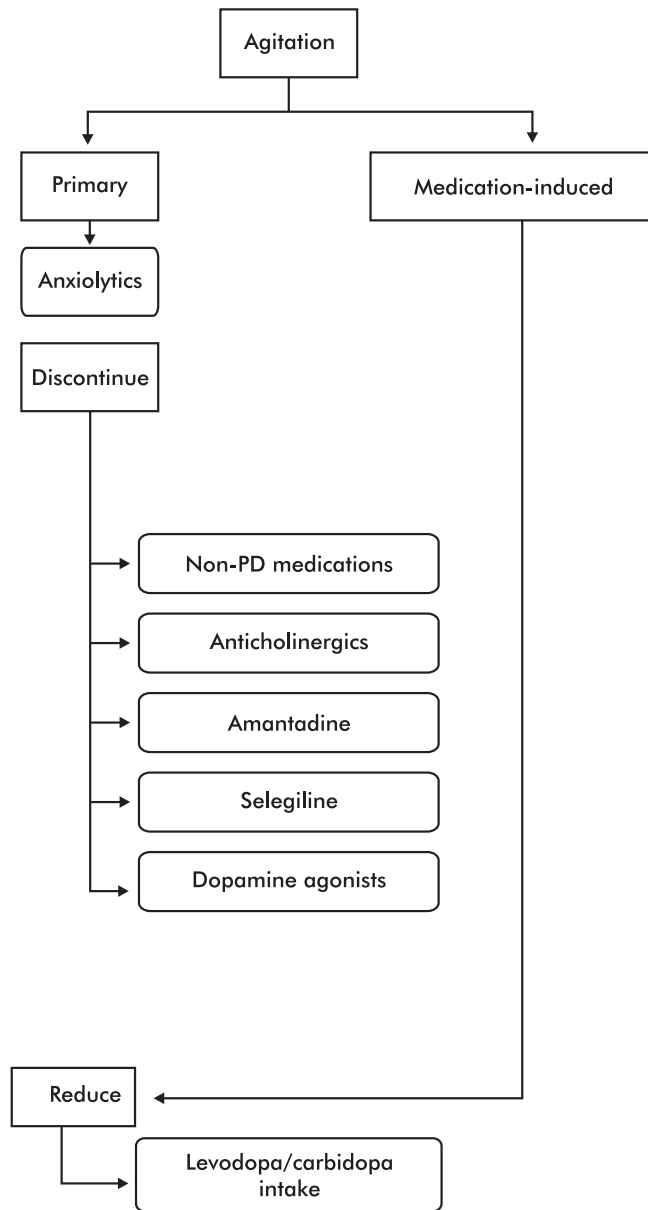

**FIGURE 26-6.** Algorithm for treatment of cognitive impairment in Parkinson's disease (PD).

patients with motor fluctuations, especially in the "off" state (Nissenbaum et al. 1987). Treatment is by adjustment (usually reduction) of the agent and use of anxiolytic agents (e.g., benzodiazepines).

**Altered Sexual Behavior**

Increased libido, resulting from antiparkinsonian therapy, may occur in conjunction with or in the absence of a manic

**FIGURE 26-7.** Algorithm for treatment of agitation in Parkinson's disease (PD).  
 Source. Reprinted with permission from Olanow CW, Koller WC: "An Algorithm (Decision Tree) for the Management of Parkinson's Disease: Treatment Guidelines." *Neurology* 50 (suppl 3):S1-S57, 1998. Copyright 1998 Lippincott Williams & Wilkins.

syndrome. Its expression may range from a renewed sexual interest with increased potency to a pathological state (i.e., hypersexuality). Increases in libido in case series reports range from 1% to 10% but may be more frequent. Hypersexuality may be manifested by increased masturbation or sexual intercourse. Males are predominantly

**TABLE 26–16. DSM-IV diagnostic criteria for substance-induced mood disorder**

- A. A prominent and persistent disturbance in mood predominates in the clinical picture and is characterized by either (or both) of the following:
1. Depressed mood or markedly diminished interest or pleasure in all, or almost all, activities
  2. Elevated, expansive, or irritable mood
- B. There is evidence from the history, physical examination, or laboratory findings of either items 1 or 2:
1. The symptoms in criterion A developed during, or within a month of, substance intoxication or withdrawal
  2. Medication use is etiologically related to the disturbance
- C. The disturbance is not better accounted for by a mood disorder that is not substance-induced. Evidence that the symptoms are better accounted for by a mood disorder that is not substance-induced might include the following: the symptoms precede the onset of the substance use (or medication use); the symptoms persist for a substantial period of time (e.g., about a month) after the cessation of acute withdrawal or severe intoxication or are substantially in excess of what would be expected, given the type or amount of the substance used or the duration of use; or other evidence suggests the existence of an independent non-substance-induced mood disorder (e.g., a history of recurrent major depressive episodes).
- D. The disturbance does not occur exclusively during the course of a delirium.
- E. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify types:*

**With depressive features:** if the predominant mood is depressed

**With manic features:** if the predominant mood is elevated, euphoric, or irritable

**With mixed features:** if symptoms of both mania and depression are present and neither predominates

affected, and levodopa is the most common causative agent (Harvey 1988; Vogel and Schifter 1983). The behavior has also been reported with pergolide (Quinn et al. 1984). Sexually deviant behavior has been reported in patients with PD both with and without a history but is more likely in those with a predisposition. Paraphiliac disorders that have been reported include sexual masochism, pedophilia, voyeurism, sadomasochistic fantasies, and exhibitionism.

## Sleep Disturbances

Sleep disturbances are more likely in patients with PD with drug-related psychiatric conditions, although sleep disturbance can be a manifestation of PD itself, depression, pain, nightmares, and dyskinesias (Olanow and Koller 1998). Vivid dreams and nightmares complicate both levodopa and pergolide treatment (Lang and Quinn 1982). Sleep studies in patients with PD have found diminished stage III and IV sleep, with multiple arousals and awakenings (Emser et al. 1988). Hypnotic agents (e.g., chloral hydrate or benzodiazepines) and antidepressants (if the sleep disorder is related to depression) may be effective.

## Summary

Cognitive and psychiatric disorders are important aspects of the clinical syndrome resulting from PD. Although the motor symptoms often receive the majority of attention, deterioration of the mental state is not uncommon and virtually inevitable if the disease is long-standing. Behavioral disturbances may result from the disease itself and from medical and surgical treatments used to improve motor function.

Following recognition of changes in the mental state, it is necessary to distinguish those who may be more likely to respond to treatment (e.g., patients with depression and drug-induced psychosis) from those who will not (e.g., patients with dementia and bradyphrenia). This determination will be facilitated when specific diagnostic guidelines are formulated that take into account both the behavioral and the motor manifestations of PD. For the neuropsychiatric manifestations, effective therapies (e.g., drug and ECT) are available and may significantly improve the quality of life of the patient with PD.

# Stroke

Sergio E. Starkstein, M.D., Ph.D.

Robert G. Robinson, M.D.

Cerebrovascular disease is one of the most common life-threatening problems among the elderly population in the United States, and it ranks as the third leading cause of death (behind only heart disease and cancer) in patients over age 50. The prevalence of stroke increases steadily with age, rising from 10/100,000 for those under age 35 to 5,970/100,000 for those over age 75 (Wolf et al. 1984). The National Survey of Stroke estimated that there will be 500,000 new cases of stroke each year (Walker et al. 1981). During the past 10 years, however, there has been a steady decline in the incidence of stroke, which most investigators have attributed to the improved control of hypertension (Hachinski and Norris 1985; Wolf et al. 1984). Nevertheless, 75% of stroke survivors are left with physical or intellectual impairments of sufficient severity to limit their vocational capacity (Hachinski and Norris 1985).

The psychiatric complications of stroke lesions, although recognized for more than 100 years (Kraepelin 1921), have never received the attention that has been devoted to poststroke motor deficits, language problems, or intellectual disturbances. This relative neglect of emo-

tional impairments following stroke is difficult to understand for several reasons. First, psychiatric complications of stroke, such as depression or apathy, have a high prevalence (Robinson et al. 1983; Starkstein et al. 1993a). Second, these behavioral disorders have been shown to significantly impair the physical recovery (Parikh et al. 1990) and to increase the long-term mortality (Morris et al. 1993) of stroke patients. Everson et al. (1998) examined the association between depression symptoms and stroke mortality in a prospective study of behavioral, social, and psychological factors related to health and mortality in a community sample. They confirmed a significant relationship between depressive symptoms and stroke mortality. Third, clinicopathological correlations derived from the study of stroke lesions may constitute a valuable model for illuminating the mechanisms of psychiatric disorders in patients without known neuropathological disorders (i.e., functional disorders).

In this chapter, we briefly review the classification and nature of cerebrovascular disease and then discuss the most frequent emotional-behavioral sequelae of stroke lesions. Some of these psychiatric complications of stroke, such as depression, have been the focus of intense research,

whereas other complications, such as anxiety or emotional lability, have not been characterized as well.

## ■ Cerebrovascular Disease

### Classification

One obvious way of classifying cerebrovascular disease is based on the cause of the anatomic-pathological process within the blood vessels that perfuse the central nervous system. Such a classification would include infectious, connective tissue, neoplastic, hematologic, pharmacological, and traumatic causes. Alternatively, the classification of cerebrovascular disease may be based on the mechanisms of these different pathological processes, such as the interactive effects of systemic hypertension and atherosclerosis on the resilience of large arteries, the integrity of vessel lumens, and the production of end-organ ischemia; developmental abnormalities leading to the formation of aneurysmal dilations or weakness of the arterial wall; or the effect of cardiac arrhythmias on the propagation of emboli.

The most pragmatic way of classifying cerebrovascular disease, however, is categorizing disorders based on the way in which parenchymal changes in the brain do or do not occur (Starkstein and Robinson 1992). The first of these, ischemia, may occur with or without parenchymal infarction. Ischemic disorders include transient ischemic attacks, which may not produce parenchymal changes, and infarctions, which do produce parenchymal lesions. The causes of infarctions include atherosclerotic thrombosis, cerebral embolism, lacunae, and others, such as arteritis and fibromuscular dysplasia. The other cause of parenchymal changes is hemorrhage. Hemorrhages may cause direct parenchymal damage by extravasation of blood into the surrounding brain tissue, as in intracerebral hematoma, or indirect parenchymal damage by hemorrhage into the ventricles, subarachnoid space, extradural space, or subdural regions.

There are five major categories of cerebrovascular disease that produce focal parenchymal lesions: atherosclerotic thrombosis, cerebral embolism, lacunae, intracranial hemorrhage, and vascular malformations, such as aneurysms and arteriovenous malformations. Ischemic infarcts constitute the most prevalent type of stroke, and the ratio of infarcts to hemorrhages is about 5:1; atherosclerotic thrombosis and cerebral embolism account for about one-third of all strokes (Caplan and Stein 1986).

### Atherosclerotic Thrombosis

Atherosclerotic thrombosis is often a result of a dynamic interaction between hypertension and atherosclerotic deposition of hyaline-lipid material in the walls of peripheral, coronary, and cerebral arteries. Hypertension is the most important risk factor for thrombotic stroke; other factors such as hyperlipidemia, diabetes mellitus, smoking, and obesity are of less importance. Atheromatous plaques tend to propagate at the bifurcation of the internal carotid artery or the carotid sinus, the “top” of the basilar artery, the posterior cerebral arteries at the midbrain level, and the anterior cerebral arteries as they curve over the corpus callosum. These plaques may lead to stenosis of one or more of these cerebral arteries or to complete occlusion.

Transient ischemic attacks, defined as periods of transient focal ischemia associated with reversible neurological deficits within a few hours, are usually produced by a thrombotic process. Most commonly, transient ischemic attacks have a duration of 2–15 minutes, with a range from a few seconds to up to 12–24 hours. Whereas the neurological examination between episodes of transient ischemic attacks is entirely normal, permanent neurological deficits (i.e., those lasting more than 24 hours) indicate that infarction has occurred.

### Cerebral Embolism

Cerebral embolism, which accounts for approximately one-third of all strokes, is usually caused by a fragment breaking away from a thrombus within the heart and traveling up the carotid artery. The embolism may also originate from an atheromatous plaque within the lumen of the carotid sinus or from the distal end of a thrombus within the internal carotid artery, or less frequently it may represent a fat, tumor, or air embolus within the internal carotid artery. The causes of thrombus formation within the heart include cardiac arrhythmias, congenital heart disease, infectious processes, valve prostheses, postsurgical complications, and myocardial infarction with mural thrombus. Of all strokes, those caused by cerebral embolism develop most rapidly. A large embolus may occlude the internal carotid artery or the stem of the middle cerebral artery, producing a severe hemiplegia. More often, however, the embolus is smaller and passes into one of the branches of the middle cerebral artery, producing infarction distal to the site of the arterial occlusion. This is characterized by a pattern of neurological deficits consistent with that specific vascular distribution, which may be transient if the embolus fragments and travels into more distal arteries.

## Lacunae

Lacunae, which account for nearly one-fifth of strokes, are the result of occlusion of small penetrating cerebral arteries. These small infarcts may produce no recognizable deficits, or (depending on their location) they may be associated with pure motor or sensory deficits. There is a strong association between lacunae and both atherosclerosis and hypertension, suggesting that lacunar infarction is the result of the effect of arteriosclerosis on small-diameter vessels.

## Intracranial Hemorrhage

Intracranial hemorrhage is the fourth most frequent cause of stroke. The main causes of intracranial hemorrhage are hypertension, rupture of saccular aneurysms or arteriovenous malformations, hemorrhagic disorder, and trauma. Primary (hypertensive) intracranial hemorrhage occurs in deep parenchymal brain areas. The extravasation of blood forms a roughly circular or oval-shaped mass that disrupts and displaces the parenchyma. Adjacent tissue is compressed, and seepage into the ventricular system may occur. Intracranial hemorrhages can range in size from massive bleeds of several centimeters in diameter to petechial hemorrhages of a millimeter or less. They most commonly occur within the putamen and the adjacent internal capsule, thalamus, cerebellum, lobar white matter, and brainstem. Severe headache is a common accompaniment of intracranial hemorrhage and occurs in about 50% of cases. The prognosis is grave, with 70%–75% of patients dying within 1–30 days (Adams and Victor 1985).

## Aneurysms and Arteriovenous Malformations

Ruptured aneurysms and arteriovenous malformations are the most common type of cerebrovascular disease after thrombosis, embolism, lacunae, and intracranial hemorrhage. Aneurysms are usually located at arterial bifurcations and are presumed to result from developmental defects in the formation of the arterial wall; rupture occurs when the intima bulges outward and eventually breaks through the adventitia. Arteriovenous malformations consist of a tangle of dilated vessels that form an abnormal communication between arterial and venous systems. They are developmental abnormalities consisting of persistent embryonic blood vessels. Hemorrhage from aneurysms or arteriovenous malformations may occur within the subarachnoid space or the brain parenchyma.

## Neuropsychiatric Syndromes

### Poststroke Depression

**Frequency.** Depression is one of the most common psychiatric sequelae to occur after a cerebrovascular lesion. Cross-sectional studies have demonstrated that 20%–50% of consecutive samples of stroke patients have depression, regardless of whether these patients are in specialized stroke units, general clinical units, rehabilitation hospitals, or the community (Eastwood et al. 1989; Robinson et al. 1983; Wade et al. 1987). In our studies of patients admitted to the hospital with an acute stroke, 25% met DSM-III (American Psychiatric Association 1980) criteria for major depression, whereas another 20% met criteria for dysthymic (minor) depression (Robinson et al. 1983). This high prevalence of poststroke depression was observed in both short-term and long-term stroke patients (Morris et al. 1990; Robinson et al. 1987) and was also replicated in incidence studies (Kotila et al. 1998). In a rural Chinese community, as many as 62.2% (28 of 45) of stroke survivors met criteria for depression. The mood disorder correlated with loss of daily living activities (Fuh et al. 1997). A recent Finnish study (Pohjasvaara et al. 1998) found major depression in 26% and minor depression in 14% of a consecutive series of 486 patients with ischemic stroke.

**Phenomenology of poststroke depression.** We have identified two types of poststroke depressive disorders: the diagnosis of major depression is based on DSM-IV (American Psychiatric Association 1994) criteria for major depressive episode (excluding the time constraint), and the diagnosis of minor (dysthymic) depression is based on patients meeting DSM-IV criteria for dysthymic disorder (also excluding the time constraint) (Table 27–1). Lipsey et al. (1986) compared the frequency and type of depressive symptoms in a group of 43 patients with major poststroke depression and a group of 43 age-matched patients with “functional” major depression. Both groups showed the same frequency and types of depressive symptoms (Figure 27–1). The only exception was that the major poststroke depression group had a greater frequency of “slowness” than did the other group. This study, however, demonstrated that major poststroke depression is not an atypical form of depression and that these patients present with symptoms identical to elderly patients with major depression. Paradiso et al. (1997) demonstrated that only 2%–3% of stroke patients have depressive symptoms without a depressed mood and suggested that DSM-IV criteria do not overdiagnose major depression

**TABLE 27-1. DSM-IV criteria for major depressive episode and dysthymic disorder****Major depressive episode**

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

**Note:** Do not include symptoms that are clearly due to a general medical condition, or mood-incongruent delusions or hallucinations.

- (1) Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad or empty) or observation made by others (e.g., appears tearful). **Note:** In children and adolescents, can be irritable mood.
  - (2) Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation made by others)
  - (3) Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. **Note:** In children, consider failure to make expected weight gains.
  - (4) Insomnia or hypersomnia nearly every day
  - (5) Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down)
  - (6) Fatigue or loss of energy nearly every day
  - (7) Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick)
  - (8) Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others)
  - (9) Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide
- B. The symptoms do not meet criteria for a mixed episode.
- C. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.
- D. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- E. The symptoms are not better accounted for by bereavement, i.e., after the loss of a loved one, the symptoms persist for longer than 2 months or are characterized by marked functional impairment, morbid

preoccupation with worthlessness, suicidal ideation, psychotic symptoms, or psychomotor retardation.

**Dysthymic disorder**

- A. Depressed mood for most of the day, for more days than not, as indicated either by subjective account or observation by others, for at least 2 years. **Note:** In children and adolescents, mood can be irritable and duration must be at least 1 year.
- B. Presence, while depressed, of two (or more) of the following:
- (1) Poor appetite or overeating
  - (2) Insomnia or hypersomnia
  - (3) Low energy or fatigue
  - (4) Low self-esteem
  - (5) Poor concentration or difficulty making decisions
  - (6) Feelings of hopelessness
- C. During the 2-year period (1 year for children or adolescents) of the disturbance, the person has never been without the symptoms in Criteria A and B for more than 2 months at a time.
- D. No major depressive episode has been present during the first 2 years of the disturbance (1 year for children and adolescents); i.e., the disturbance is not better accounted for by chronic major depressive disorder, or major depressive disorder, in partial remission.
- Note:** There may have been a previous major depressive episode provided there was a full remission (no significant signs or symptoms for 2 months) before development of the dysthymic disorder. In addition, after the initial 2 years (1 year in children or adolescents) of dysthymic disorder, there may be superimposed episodes of major depressive disorder, in which case both diagnoses may be given when the criteria are met for a major depressive episode.
- E. There has never been a manic episode, a mixed episode, or a hypomanic episode, and criteria have never been met for cyclothymic disorder.
- F. The disturbance does not occur exclusively during the course of a chronic psychotic disorder, such as schizophrenia or delusional disorder.
- G. The symptoms are not due to the direct physiological effects of a substance (e.g., a drug of abuse, a medication) or a general medical condition (e.g., hypothyroidism).
- H. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

*Specify if:*

**Early onset:** if onset is before age 21 years

**Late onset:** if onset is age 21 years or older

*Specify (for most recent 2 years of dysthymic disorder):*

**With atypical features**

**FIGURE 27-1.** Symptom clusters from the present state examination in 43 patients with major poststroke depression and 43 patients with functional depression. SD = simple depression; GA = general anxiety; AF = affective flattening; HM = hypomania; OV = overactivity; SL = slowness; ED = special features of depression; AG = agitation; NG = self-neglect; IR = ideas of reference; TE = tension; LE = lack of energy; WO = worrying; IT = irritability; SU = social unease; IC = loss of interest and concentration; OD = other symptoms of depression.

among stroke patients. Several studies have validated the distinction between major and minor poststroke depression and have demonstrated these two types of depression to have different courses of longitudinal evolution (Morris et al. 1990; Robinson et al. 1987), biological markers (Barry and Dinan 1990; Lipsey et al. 1985), effects on cognitive function (Robinson et al. 1986), and correlation with brain lesion location (Robinson et al. 1984; Starkstein et al. 1988b). Kishi et al. (1996) reported that 7% of short-term stroke patients and 11% of long-term (i.e., > 3 months) stroke patients had suicidal ideation. Whereas early suicidal ideation was related to premorbid alcohol abuse, delayed suicidal ideation was related to greater physical impairment and poorer social support during the immediate poststroke period.

**Clinical correlates.** Gender differences in the prevalence of poststroke depression have recently been reported by Paradiso and Robinson (1998). These research-

ers found that the prevalence of major depression in women was double that found in men. Among women, greater severity of depression was associated with prior diagnosis of psychiatric disorder and cognitive impairment, whereas among men depression was significantly associated with greater impairment in daily activities and social functioning.

Poststroke depression has a significant influence on both the recovery in activities of daily living (ADLs) and the intellectual impairment of stroke patients. In a recent study, Ramasubbu et al. (1998) examined the independent association of depression following acute stroke with impairment in ADLs in a cross-sectional epidemiological study. They found that depressed stroke patients had significantly greater impairments in ADLs than nondepressed patients, independent of all other factors that influenced poststroke physical disabilities. Parikh et al. (1990) compared the 2-year recovery from impairments in ADLs between 25 patients with poststroke depression (either major or minor depression) and 38 stroke patients with no mood disorders who were matched for their in-hospital severity of ADL impairments. After controlling for all the variables that have been shown to influence stroke outcome (e.g., short-term treatment on a stroke unit; size, nature and location of brain injury; age; education; and duration of rehabilitation services), patients with in-hospital poststroke depression had significantly poorer recovery than did nondepressed stroke patients even after their depressions had subsided (Figure 27-2).

In another study, we (Robinson et al. 1986) compared patients with major poststroke depression and nondepressed stroke patients for the presence of cognitive impairments. We found that patients with major poststroke depression after left-hemisphere lesions had significantly more cognitive deficits than did nondepressed patients with a similar size and location of brain lesion. These deficits were observed in a wide range of cognitive tasks, including orientation, language, visuoconstructional ability, executive motor functions, and frontal lobe tasks (Figure 27-3) (Bolla-Wilson et al. 1989). In contrast, among patients with right-hemisphere lesions, patients with major depression did not differ from nondepressed patients on any of the measures of cognitive impairment. This finding suggests that left-hemisphere lesions that lead to major depression may produce a different kind of depression than do right-hemisphere lesions. Left-hemisphere lesions can produce a dementia of depression, which does not occur with major depressions following right-hemisphere lesions. It remains to be determined whether these dementias of depression will improve with treatment of depression.

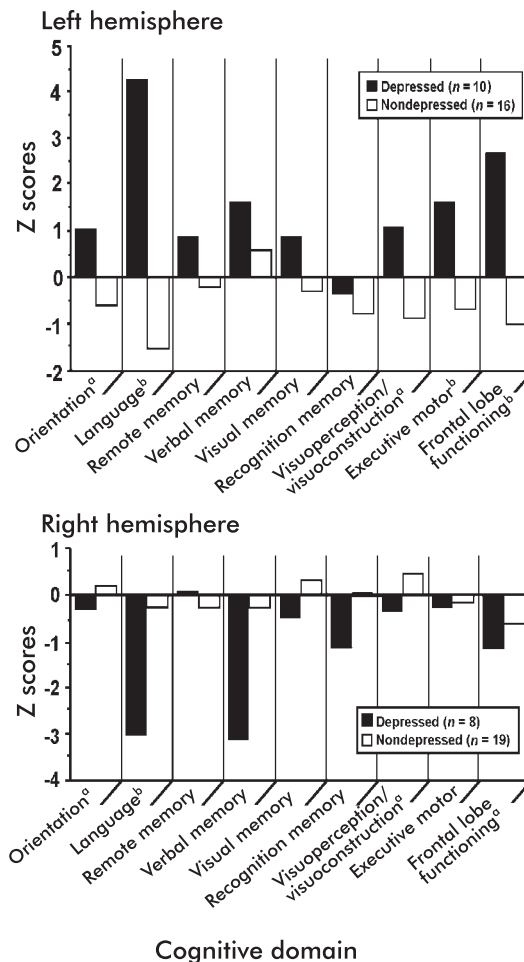

**FIGURE 27-2.** Johns Hopkins Functioning Inventory (JHFI) scores in the hospital and at 2-year follow-up in patients who were depressed or nondepressed. Higher scores on the JHFI indicate greater impairment in activities of daily living. There was a significant group-by-time interaction, with the nondepressed patients having significantly lower (i.e., less impaired) scores than the depressed patients at 2-year follow-up.

showed a significantly higher frequency of lesions in anterior areas of the left hemisphere, namely the left frontal dorsolateral cortex and the head of the caudate nucleus (Robinson et al. 1984; Starkstein et al. 1987). Among patients with right-hemisphere stroke lesions, those with frontal or parietal damage showed the highest frequency of depression (Starkstein et al. 1989). Although some, but not all, of these findings have been replicated by other investigators (Eastwood et al. 1989; House et al. 1991; Morris et al. 1992), a consensus has emerged that there is a significant

correlation between the proximity of the lesion to the frontal pole and the severity of depression.

In 1981, we first reported that in a group of 29 patients with left-hemisphere lesions produced by trauma or stroke there was an inverse correlation between severity of depression and distance of the anterior border of the lesion from the frontal pole ( $r = -.76$ ,  $P < .001$ ) (Figure 27-4) (Robinson and Szetela 1981). Since then, using computed tomographic (CT) imaging, we found the same phenomenon in another group of 10 right-handed patients with single stroke lesions of the anterior left hemisphere ( $r = -.92$ ,  $P < .001$ ) (Robinson et al. 1984). When patients with lesions in the left posterior hemisphere were added ( $n = 18$ ), the correlation decreased ( $r = -.54$ ,  $P < .05$ ) (Table 27-2). This inverse correlation was also found in other groups of patients with purely cortical lesions of the left hemisphere ( $n = 16$ ;  $r = -.52$ ,  $P < .05$ ) (Starkstein et al. 1987), purely left-sided subcortical lesions ( $n = 13$ ) ( $r = -.68$ ,  $P < .01$ ) (Starkstein et al. 1987), and single left-hemisphere lesions in left-handed patients ( $n = 13$ ;  $r = -.78$ ,  $P < .01$ ) (Robinson et al. 1985). This phenomenon has now been replicated by four different groups of investigators using patients from Canada, England, and Australia (Table 27-2).

Some investigators have found a correlation between severity of depression and proximity of the lesion to the frontal pole in combined right- and left-hemisphere lesion groups, whereas others found it only with left-sided lesions

(Table 27-2). Although there is some difference in the strength of this correlation (and therefore the amount of variance in severity of depression explained by lesion location), this phenomenon has emerged as one of the most consistent and robust clinical-pathological correlations ever described in neuropsychiatry. Future experiments aimed at elucidating the mechanism of poststroke depression must provide an explanation for this remarkably consistent phenomenon.

The mechanism by which left anterior lesions produce depression is not known. One possibility is that both the frontal dorsolateral cortex and the dorsal caudate nucleus play an important role in mediating locomotor, intellectual, and instinctive behavior through their connection with the supplementary motor area, temporoparietal association cortex, and limbic system. A lesion of these anterior brain areas may result in low activation of locomotor, sensory, or limbic areas and produce the autonomic and affective symptoms of depression. We (Robinson et al. 1984) have suggested that biogenic amines may also play an important role in poststroke depression. The anatomy of these pathways (i.e., they begin in brainstem nuclei and ascend through subcortical regions, around the corpus callosum to the posterior cortex) may explain the correlations with lesion location, as anterior lesions close to the frontal pole would interrupt more “downstream” pathways than posterior lesions (Robinson et al. 1984).

**FIGURE 27-4.** Relationship between severity of depression as measured by overall depression score and mean distance of the lesion from the frontal pole for patients with lesions that extended into the frontal lobe. The closer the lesion was to the frontal pole, the greater the depression was ( $r = -.76$ ,  $P < .001$ ).

**Treatment.** In a randomized, double-blind, and placebo-controlled study of the efficacy of treatment of poststroke depression, we demonstrated the utility of the tricyclic antidepressant nortriptyline in the treatment of poststroke depression (Lipsey et al. 1984). Patients received 25 mg for 1 week, 50 mg for 2 weeks, 75 mg for 1 week, and 100 mg for 2 weeks. The group receiving the active drug (11 completed the study) showed a significant decrease in depression scores compared with the placebo group (15 completed) (Figure 27-5). Side effects were observed in 6 of 17 patients: 3 developed delirium, 1 had syncope, 1 complained of oversedation, and 1 complained of dizziness.

Andersen et al. (1994a) demonstrated the efficacy of the selective serotonin reuptake inhibitor citalopram in a 6-week double-blind, placebo-controlled trial that included 66 patients with poststroke depression. Significantly greater mood improvement was demonstrated in patients treated with 10 to 40 mg/day of citalopram compared with the placebo group. The only significant side effects of citalopram were nausea and vomiting during the first week of treatment.

One other controlled study demonstrated the useful-

ness of another antidepressant drug (trazodone) for poststroke depression (Reding et al. 1986). Depressed patients taking trazodone were found to have greater improvements in ADL scores than were patients treated with placebo. This trend became statistically significant when

the treatment groups were restricted to patients with abnormal dexamethasone tests. Although antidepressants are effective in the treatment of poststroke depression, the high rate of complications such as delirium dictate that tricyclic drugs should be used cautiously in elderly stroke patients.

### Poststroke Anxiety

Although anxiety is one of the most frequent complaints in the general population, it has rarely been the focus of empirical research among stroke patients.

**Phenomenology and frequency.** In a study on the prevalence of anxiety disorders in stroke patients, we examined 309 patients admitted to the hospital with acute stroke using DSM-III criteria for generalized anxiety disorders (Castillo et al. 1993). We found that 78 patients (26.9%) met criteria for generalized anxiety disorder, whereas the prevalence of anxiety in the chronic stage was 23% (Castillo et al. 1995). In a 3-year longitudinal study, Aström (1996) found a prevalence of anxiety in the acute poststroke period of 28%, and there was no significant decrease through the 3 years of follow-up. However, the presence of the disorder was strongly associated with the presence of depression, as 58 of 78 stroke patients meeting criteria for generalized anxiety disorder in the study by Castillo et al. (1993) were also depressed. Thus, although generalized anxiety disorder is a common finding among stroke patients, it frequently coexists with depression. A recent study by Shimoda and Robinson (1998) demonstrated

a significant interaction of depression and anxiety in stroke. In this study, patients with both anxiety and depression had greater impairment in ADLs at long-term follow-up and worse recovery in social functioning than nondepressed patients.

**Clinical correlates and mechanism.** We examined the clinical and lesion correlates of anxiety and depression in the study of 309 patients with acute stroke (Castillo et al. 1993). The anxious and nonanxious groups were not significantly different in their demographic backgrounds or neurological findings. The nondepressed anxious patients, however, had a significantly higher frequency of alcoholism than did the nonanxious patients (26% generalized anxiety disorder versus 8% nonanxious,  $P < .05$ ). When patients with both generalized anxiety disorder and depression were compared to patients with depression only, patients with anxiety and depression had a significantly higher frequency of cortical lesions (mainly left frontal), whereas the patients with depression only had a significantly higher frequency of subcortical lesions (mainly left basal ganglia) (Starkstein et al. 1990b). Among the anxious patients without depression, 67% had right-hemisphere lesions compared with 43% of the anxious depressed patients ( $P = .04$ ) (Castillo et al. 1993). Finally, among patients with right-hemisphere lesions, the anxious patients had lesions that were significantly more posterior than those of the nonanxious patients ( $P = .038$ ) (Castillo et al. 1993). Aström (1996) found that at the acute

stage after stroke, anxiety plus depression was associated with left-hemisphere lesions, whereas anxiety alone was associated with right-hemisphere lesions.

Although the mechanism of anxiety is still unknown, several studies have reported a significant decrease in cortical metabolic activity with increased anxiety, as well as a lack of correlation between the severity of anxiety and subcortical metabolic rate (Bartlett et al. 1988; Gur et al. 1987). This is in agreement with our finding of significantly more severe anxiety after cortical lesions than after subcortical lesions and suggests a critical role for cortical-subcortical interaction in the modulation of anxious states.

### Poststroke Apathy

Apathy is the absence or lack of feeling, emotion, interest, or concern and has been reported frequently among stroke patients. We examined a consecutive series of 80 patients with single stroke lesions and no significant impairment in comprehension using the Apathy Scale (Figure 27–6). We demonstrated both the validity and reliability of this scale in the assessment of apathy in patients with cerebrovascular lesions (Starkstein et al. 1993a). A score of 14 on this scale separated apathetic from nonapathetic patients with high sensitivity and specificity.

**Prevalence and clinical correlates.** In a study of poststroke apathy (Starkstein et al. 1993a), we found that

14. Would you consider yourself apathetic?	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>	<input type="checkbox"/>

*Note.* For questions 1–8, the scoring system is the following: *not at all* = 3 points; *slightly* = 2 points; *some* = 1 point; *a lot* = 0 points. For questions 9–14, the scoring system is the following: *not at all* = 0 points; *slightly* = 1 point; *some* = 2 points; *a lot* = 3 points.

**FIGURE 27–6.** Apathy scale.

9 of 80 patients (11%) showed apathy as their only psychiatric disorder, whereas another 11% had both apathy and depression. The only demographic correlate of apathy was age, as apathetic patients (with or without depression) were significantly older than were nonapathetic patients. Also, apathetic patients showed significantly more severe deficits in ADLs, and there was a significant interaction between depression and apathy (i.e., Johns Hopkins Functioning Inventory [JHFI] scores were  $4.8 \pm 4.0$  for patients with no disorder,  $6.21 \pm 3.9$  for depressed patients,  $7.6 \pm 5.8$  for apathetic patients, and  $13.7 \pm 5.5$  for depressed and apathetic patients; effect of apathy  $P < .001$ , effect of depression  $P < .002$ , and interaction  $P = .05$ ).

**Clinical-pathological correlates and mechanism of poststroke apathy.** Patients with apathy (without depression) showed a significantly higher frequency of lesions involving the posterior limb of the internal capsule compared with patients with no apathy (Starkstein et al. 1993a). Lesions in the internal globus pallidus and the posterior limb of the internal capsule have been reported to produce important behavioral changes, such as motor neglect, psychic akinesia, and akinetic mutism (Helgason et al. 1988). The ansa lenticularis is one of the main internal pallidal outputs, and it ends in the pedunculopontine nucleus after going through the posterior limb of the internal capsule (Nauta 1989). In rodents, this pathway has a prominent role in goal-oriented behavior (Bechara and van der Kooy 1989), and dysfunction of this system may explain the presence of apathy in stroke patients.

## Poststroke Psychosis

The phenomenon of hallucinations and delusions in stroke patients has been called *agitated delirium*, *acute atypical psychosis*, *peduncular hallucinosis*, *release hallucinations*, or *acute organic psychosis*. We consider *secondary hallucinations* to be sensory perceptions in the absence of appropriate stimuli, with the important qualifications that, first, the patient believes the (nonexistent) sensory perception is real, and, second, this disorder started after a lesion. We use the term *secondary hallucinosis* to refer to a perception without a stimulus, when the patient does not believe the (nonexistent) sensory perception is real and the disorder occurs after a stroke lesion. Finally, we use the term *secondary psychosis* to refer to patients who develop either secondary hallucinations or secondary hallucinosis after stroke lesions. Patients with secondary psychosis, hallucination type, are delusional (i.e., they do not recognize the perception as false), whereas those with secondary psychosis,

hallucinosis type, are usually not delusional unless there is some other independent delusional idea.

**Prevalence and clinical-pathological correlates.** In a study of secondary psychosis after stroke lesions, we (Rabins et al. 1991) found a very low prevalence of this phenomenon among stroke patients (only five in more than 300 consecutive admissions). All five patients had right-hemisphere lesions, primarily involving frontoparietal regions. When compared with five age-matched patients with cerebrovascular lesions in similar locations but no psychosis, patients with secondary psychosis had significantly greater subcortical atrophy, as manifested by significantly larger areas of both the frontal horn of the lateral ventricle and the body of the lateral ventricle (measured on the side contralateral to the brain lesion). Several other investigators have reported a high frequency of seizures among patients with secondary psychosis (e.g., Levine and Finklestein 1982). These seizures usually started after the brain lesion but before the onset of psychosis. We also found seizures in three of our five patients with poststroke psychosis, compared with none of the five poststroke nonpsychotic control subjects.

**Mechanism.** We conclude from these observations that three factors may be important in the mechanism of secondary psychosis, hallucination type: a right-hemisphere lesion involving the temporoparietal cortex, seizures, and subcortical brain atrophy. The mechanism of secondary hallucinosis is even less clear than secondary hallucinations. Although in the literature most patients with secondary hallucinosis had peduncular lesions, patients with lesions in other brain areas, such as the diencephalon, also showed the phenomenon (Cascino and Adams 1986; Geller and Bellur 1987). These lesions have frequently been found to involve primary sensory pathways, mainly visual and auditory. Thus, secondary hallucinosis may be a “release phenomenon” secondary to damage to reticular activating brainstem pathways, and the presence of primary sensory deficits in these patients may be a necessary predisposing factor.

In conclusion, secondary psychosis is a rare finding in stroke patients. We believe that there are at least two types of secondary psychosis. The first is the hallucination type, which is characterized by hallucinations perceived by the patient as real and may result from right temporoparietal lesions in the presence of preexisting subcortical brain atrophy and poststroke seizures. The second is the hallucinosis type, which is characterized by hallucinations perceived by the patient as unreal and may be secondary to lesions in primary sensory or reticular activating pathways.

## Anosognosia

The term *anosognosia* was coined by Babinski (1914) to describe the lack of awareness of hemiplegia, but it was later used to refer to the unawareness of other poststroke deficits, such as cortical blindness, hemianopia, and amnesia (Heilman 1991).

**Prevalence and clinical correlates.** We examined the prevalence of anosognosia in a consecutive series of 80 patients with single acute stroke lesions (Starkstein et al. 1992). We developed an anosognosia questionnaire (Figure 27–7), which we used to determine the existence of anosognosia. To rate the severity of this phenomenon, we also developed the Denial of Illness Scale (Figure 27–8), which allows the classification of patients into those with mild, moderate, or severe anosognosia. Patients with aphasia were included only if they had intact verbal comprehension as measured by their ability to complete Part 1 of the Token Test (De Renzi and Vignolo 1962). The assessment of anosognosia, however, examined only motor, sensory, and visual field disturbances and did not evaluate anosognosia for aphasia.

1. Why are you here?
2. What is the matter with you?
3. Is there anything wrong with your arm or leg?
4. Is there anything wrong with your eyesight?
5. Is your arm or leg weak, paralyzed, or numb?
6. How does your arm or leg feel?

**If denial is elicited ask the following:**

- a. (*pick up the patient's arm*) What is this?
- b. Can you lift it?
- c. Do you have some problem with this?
- d. (*ask the patient to lift both arms*) Can you see that your two arms are not at the same level?
- e. (*ask the patient to identify finger movements in and out of the abnormal visual field*) Can't you see that you have a problem with your eyesight?

**Scoring**

- 0, The disorder is spontaneously reported or mentioned following a general question about the patient's complaints.
- 1, The disorder is reported only after a specific question about the strength of the patient's limb, or visual problems.
- 2, The disorder is acknowledged only after its demonstration through routine techniques of neurological examination.
- 3, The disorder is not acknowledged.

**FIGURE 27–7.** Anosognosia questionnaire.

The first important finding from this study was that about one-third of this consecutive series of patients had anosognosia (19% mild, 11% moderate, and 13% severe) (Starkstein et al. 1992). We also examined potential correlates of anosognosia and found this phenomenon to be significantly associated with the presence of a neglect syndrome (i.e., failure to respond to or orient to stimuli contralateral to the lesion), as well as deficits in recognizing facial emotions and the emotional content of speech (prosody). There also was a significant association between anosognosia and right-hemisphere lesions involving the temporal and parietal lobes, thalamus, and basal ganglia.

Two important negative findings should be noted. First, the frequency of depression was similar among patients with and without anosognosia. Thus the existence of anosognosia does not preclude stroke patients from experiencing or reporting depressive feelings. Second, anosognosic patients did not show more severe sensory deficits than did nonanosognosic patients (i.e., anosognosia is not related to the presence of sensory deficits) (Starkstein et al. 1992).

**Mechanism.** In our study (Starkstein et al. 1992), we found that brain atrophy, probably preexisting the brain lesion, may have been an important predisposing factor for anosognosia, as anosognosic patients had significantly more frontal subcortical and diencephalic atrophy (but not cortical atrophy) than did patients with no anosognosia. Moreover, patients with anosognosia had significantly more deficits in frontal lobe–related cognitive tasks than did patients with no anosognosia but with lesions in similar brain areas.

These findings suggest that lesions in specific cortical and subcortical areas of the right hemisphere, although necessary, may not be sufficient to produce anosognosia; concomitant frontal lobe dysfunction (as expressed by frontal subcortical atrophy and deficits in frontal lobe–related cognitive tasks) may be necessary to produce the syndrome.

Heilman (1991) proposed that anosognosia may result from a dysfunction of a system that monitors the intention to move as well as the actual performance of movements. This mismatch between the intention to move and the (lack of) movement may convey the impression that the movement was actually performed and that the limb is normal. The systems monitoring single sensory and motor modalities may be located in the right parietal lobe, whereas the frontal lobe may constitute a supramodal monitoring structure.

In conclusion, anosognosia is present in one-third of acute stroke patients and is significantly associated with

Items	Scoring		
1. Patient minimizes present symptoms (at interview).	0 (no)	1 (once or twice)	2 (more than twice)
2. Patient alludes to there being nothing really wrong with her or him and that she or he is ready to go home.	0 (no)	1 (once or twice)	2 (more than twice)
3. Patient (past or present) displaces source of symptoms to organs other than brain or complains of symptoms unrelated to the central nervous system.	0 (no)	1 (once or twice)	2 (more than twice)
4. Patient at any time admits to fear of death.	0 (yes)	1 (no)	
5. Patient at any time admits to fear of invalidism.	0 (yes)	1 (no)	
6. Patient verbally denies being in the hospital.	0 (not at all)	1 (sometimes)	2 (every time)
7. Patient displays, at least on the surface, a carefree, cheerful, jovial approach to life.	0 (no)	1 (once or twice)	2 (more than twice)
8. Patient's behavior during interview is characterized by nonchalance, coolness, imperturbability.	0 (no)	1 (once or twice)	2 (more than twice)
9. Patient displaces fear for his or her own illness to family, older patients, weaker patients, and so on.	0 (no)	1 (at least 1 time during the interview)	
10. Patient projects illness or weakness to family, spouse, and so on.	0 (no)	1 (at least 1 time during the interview)	

**FIGURE 27-8.** Denial of Illness Scale.

right-hemisphere lesions in the temporoparietal cortex, basal ganglia, or thalamus. The presence of neglect and frontal lobe dysfunction may constitute important predisposing factors.

### Catastrophic Reaction

*Catastrophic reaction* is a term coined by Goldstein (1939) to describe the “inability of the organism to cope when faced with physical or cognitive deficits.” It is expressed by anxiety, tears, aggressive behavior, swearing, displacement, refusal, renouncement, and, sometimes, compensatory boasting.

**Prevalence and clinical correlates.** The catastrophic reaction has been reported to be a frequent finding among aphasic patients (Gainotti 1972) and has been given the status of a separate neuropsychiatric syndrome. There are no empirical studies regarding the construct validity of the catastrophic reaction, however, and it is possible that the catastrophic reaction may represent a symptom of a major depressive syndrome or anxiety disorder in stroke patients. To empirically examine this issue, we evaluated a consecutive series of 62 patients by using the Catastrophic Reaction Scale (CRS), which we developed to assess the existence and severity of the catastrophic reaction (Figure 27-9). We have demonstrated the CRS to be a reliable instrument in the measurement of catastrophic reaction

symptoms (Starkstein et al. 1993b).

We identified the catastrophic reaction in 12 of 62 consecutive patients (19%) with acute stroke lesions (Starkstein et al. 1993b). Three major findings emerged from this study. First, patients with catastrophic reaction were found to have a significantly higher frequency of familial and personal history of psychiatric disorders (mostly depression) than were patients without the catastrophic reaction. Second, catastrophic reaction was not significantly more frequent among aphasic than with nonaphasic patients, which does not support the suggestion that catastrophic reaction is more frequent among “frustrated” aphasic patients (Gainotti 1972). Third, 9 (75%) of the 12 patients with catastrophic reaction also had major depression, 2 (17%) had minor depression, and only 1 (8%) was not depressed. On the other hand, among patients without catastrophic reaction (i.e., 50 patients), 7 (14%) had major depression, 6 (12%) had minor depression, and 37 (74%) were not depressed. Thus catastrophic reaction was significantly associated with major depression ( $\chi^2 = 20.9$ ,  $df = 2$ ,  $P = .0001$ ). Moreover, patients with a catastrophic reaction had significantly higher scores on the Hamilton Anxiety and Depression Scales compared with patients with no catastrophic reaction.

**Mechanism.** Patients with a catastrophic reaction had a significantly higher frequency of lesions involving the

1. Patient appeared to be anxious (i.e., patient showed an apprehensive attitude or expressed fears).
2. Patient complained of feeling anxious or afraid (i.e., patient referred to feeling tense or having psychological concomitants of anxiety).
3. Patient became tearful (i.e., patient cried at some point during the evaluation).
4. Patient complained of feeling sad or depressed (i.e., patient spontaneously reported sad feelings during the evaluation).
5. Patient behaved in angry manner (i.e., patient shouted, contradicted the examiner, or performed tasks in a careless way).
6. Patient complained of feeling angry (i.e., patient reported being upset with the evaluation and/or the examiner).
7. Patient swore (i.e., patient swore at some point during the evaluation).
8. Patient expressed displaced anger (i.e., patient complained about the hospital, doctors, and fellow patients).
9. Patient refused to do something (i.e., patient stopped doing a task or refused to answer some questions).
10. Patient described a feeling of suddenly becoming depressed or hopeless (i.e., patient reported feeling worthless and sad and had a lack of confidence).
11. Patient boasted about self (i.e., patient reported being able to perform the tasks flawlessly; he or she explained failures as due to lack of concentration and tiredness).

*Note.* Scoring key: 0 = none; 1 = slight (once during the interview); 2 = moderate (several times during the interview); 3 = extreme (most of the interview).

**FIGURE 27-9.** Catastrophic Reaction Scale.

basal ganglia (Starkstein et al. 1993b). When 10 depressed patients with a catastrophic reaction were compared to 10 depressed patients without a catastrophic reaction, the catastrophic reaction group showed significantly more anterior lesions, which were located mostly in subcortical regions (8 of 9 depressed patients with catastrophic reaction had subcortical lesions; 3 of 9 depressed patients without catastrophic reaction had subcortical lesions) ( $\chi^2 = 5.84$ ,  $df = 1$ ,  $P = .01$ ).

We may conclude from the above evidence that the catastrophic reaction is not just a behavioral response of patients confronted with their limitations, as patients with and without a catastrophic reaction showed a similar frequency of aphasia and physical impairments. On the contrary, the catastrophic reaction seems to characterize a specific type of poststroke major depression (i.e., major depressions associated with anterior subcortical lesions). An-

terior brain lesions (both cortical and subcortical) have been consistently associated with poststroke depression. Subcortical damage, however, has usually been hypothesized to underlie the “release” of emotional display by removing inhibitory input to the limbic areas of the cortex (Ross and Stewart 1987).

In conclusion, the catastrophic reaction occurs in about 20% of stroke patients (Starkstein et al. 1993b), mainly among those with a positive familial or personal history of psychiatric disorders. The catastrophic reaction is significantly associated with major depression and may be mediated by a release of emotional display produced by anterior subcortical lesions. Thus the catastrophic reaction may not represent an independent clinical syndrome but may be a behavioral and emotional expression of depressed patients with anterior subcortical damage.

## Emotional Lability

Emotional lability is a common complication of stroke lesions. It is characterized by sudden, easily provoked episodes of crying, which, although occurring frequently, generally occur in appropriate situations and are accompanied by a congruent mood change. Pathological laughing and crying is a more severe form of emotional lability and is characterized by episodes of laughing and/or crying that are not appropriate to the context. They may appear spontaneously or may be elicited by nonemotional events and do not correspond to underlying emotional feelings. Other terms that have been applied to these disorders are *emotional incontinence* and *pseudobulbar affect*.

**Prevalence and clinical correlates.** We examined the clinical correlates and treatment of emotional lability (including pathological laughter and crying) in 28 patients with either acute or chronic stroke (Robinson et al. 1993). We developed a Pathological Laughter and Crying Scale (PLACS) (Appendix 27-1) to assess the existence and severity of emotional lability. We demonstrated in 18 treatment patients and 54 acute stroke patients the reliability and validity of this instrument in the assessment of emotional lability (Robinson et al. 1993). We also found that PLACS scores did not correlate with either Hamilton Depression Scale scores, Mini-Mental State Exam scores, ADL scores, or Social Ties scores, indicating that the PLACS was assessing a factor other than the ones being measured by these instruments.

A double-blind drug trial of nortriptyline was conducted in 31 patients with emotional lability (Robinson et al. 1993). After randomization, patients were given active drug or placebo in a single bedtime dose. Patients were first

given 25 mg of nortriptyline for 1 week, then 50 mg for 2 weeks, 70 mg for 1 week, and 100 mg for the last 2 weeks of the study. One patient dropped out during the study, and two patients withdrew before initiation of the study; there were 28 who completed the 6-week protocol. Patients receiving nortriptyline showed significant improvements in PLACS scores compared with the placebo-treated patients; these differences became statistically significant at weeks 4 and 6 (Figure 27–10). Although a significant improvement in depression scores also was observed, improvements in PLACS scores were significant for both depressed and nondepressed patients with pathological laughing and crying, indicating that treatment response was not related simply to an improvement in depression.

**Mechanism.** Pseudobulbar affect has classically been explained as being secondary to the bilateral interruption of neocortical upper motor neuron innervation of bulbar motor nuclei (Poock 1969). The finding that emotional lability can be successfully treated with tricyclic drugs suggests that biogenic amine systems may also play a role in the pathogenesis of this disorder. Andersen et al. (1994b) reported that stroke patients with relatively large bilateral pontine lesions had more severe pathological crying than did patients with cortical or subcortical hemisphere le-

sions; the researchers speculated that pathological crying may result from partial destruction of the serotonergic raphe nuclei or their ascending projections to the hemispheres.

In conclusion, our study (Robinson et al. 1993) suggests that poststroke depression and emotional lability are independent phenomena, although they may coexist. Moreover, we also found that both depressed and nondepressed patients with emotional lability showed significant improvements in the severity of their emotional lability after treatment with nortriptyline.

## Mania

**Prevalence and clinical correlates.** Mania, or disinhibited behavior, is a relatively rare consequence of acute stroke lesions. Using DSM-III criteria for affective disorder, manic type, we found only three cases of secondary mania among a consecutive series of 309 acute stroke patients in an unpublished study. On the other hand, secondary mania is more frequent among patients with traumatic brain injury. In a study of 66 patients with acute traumatic brain injury (Jorge et al. 1993), we found six cases (9%) of secondary mania. Patients with traumatic brain injury frequently sustain damage to orbitofrontal and basotemporal cortical areas, which may be related to the mechanism of mania. These brain areas are rarely damaged in stroke patients, and this difference in the frequency of frontal and temporal cortical injury between traumatic and ischemic brain injury may explain the different prevalence of mania in these two populations. Cummings and Mendez (1984) found right thalamic stroke lesions in two cases of secondary mania.

In a series of 17 patients with post-brain-injury mania, we (Robinson et al. 1988) reported a high frequency of lesions involving the basal and polar areas of the right temporal lobe and subcortical areas of the right hemisphere, such as the head of the caudate nucleus and right thalamus. Similar lesion location was recently reported in patients with bipolar affective disorder (Berthier et al. 1996). In a study using positron-emission tomography (PET) with [ $^{18}\text{F}$ ]fluorodeoxyglucose, we (Starkstein et al. 1990a) examined metabolic abnormalities in three patients with mania following right basal ganglia strokes. The patients had focal hypometabolic deficits in the right basotemporal cortex. This finding suggested that lesions leading to secondary mania may do so through their distant effects on the right basotemporal cortex. This phenomenon of lesions producing distant effects is a well-recognized consequence of some brain lesions and has been termed *diaschisis*.

**FIGURE 27–10.** Mean Pathological Laughter and Crying Scale (PLACS) scores during 6 weeks of double-blind treatment. The nortriptyline-treated group had significantly lower (more improved) PLACS scores at 4 ( $t = 3.9$ ,  $df = 26$ ,  $P = .0005$ ) and 6 ( $t = 5.1$ ,  $df = 26$ ,  $P = .0001$ ) weeks of treatment compared with the placebo-treated group.

Source. Adapted from Robinson et al. 1993.

Because not every patient with a right orbitofrontal or basotemporal lesion develops a manic syndrome, we have also looked for potential predisposing factors for secondary mania (Robinson et al. 1988; Starkstein et al. 1987). In these studies, we found that patients with secondary mania had a significantly higher frequency of familial history of psychiatric disorders, as well as significantly more subcortical brain atrophy (as determined by increased ventricular-to-brain ratios), than did patients with similar brain lesions but no mania. Interestingly, those patients without a genetic predisposition had significantly more subcortical atrophy than did secondary mania patients with a genetic burden, suggesting that subcortical atrophy and genetic predisposition may be independent risk factors for mania following brain injury.

**Mechanism.** To postulate a mechanism for secondary mania, two clinical-pathological correlations need to be explained. First, most lesions associated with secondary mania involve, directly or indirectly, limbic or limbic-related areas of the brain. Second, virtually all of these lesions are localized to the right hemisphere.

The basotemporal cortex appears to be a crucial area in the production of mania. This paralimbic area receives projections from secondary sensory and multimodal association regions (e.g., the frontal, temporal, and parietal association areas), limbic regions, and paralimbic areas (e.g., the insula and the parahippocampal gyrus) (Moran et al. 1987). The basotemporal cortex is strongly connected to the orbitofrontal cortex through the uncinate fasciculus, and both may exert a tonic inhibitory control over limbic and dorsal cortical regions. Thus, lesions or dysfunction of these areas may result in motor disinhibition (i.e., hyperactivity and pressured speech), intellectual disinhibition (i.e., flight of ideas and grandiose delusions), and instinctive disinhibition (i.e., hyperphagia and hypersexuality).

The second finding, which needs to be incorporated into any explanation of poststroke mania, is that the manias almost always occur following right-hemisphere lesions. In our laboratory studies of the neurochemical and behavioral effects of brain lesions in rats (Robinson 1979), we found that small suction lesions in the right (but not left) frontal cortex of rats produced a significant increase in locomotor activity. Similar abnormal behavior was also found after electrolytic lesions of the right (but not left) nucleus accumbens (which is considered part of the ventral striatum) (Kubos et al. 1987). Moreover, right frontocortical suction lesions also produced a significant increment in dopaminergic turnover in the nucleus accumbens that was not seen with left-hemisphere lesions (Starkstein et al. 1988a). Thus it is possible that, in the presence of pre-

disposing factors such as a genetic burden or subcortical atrophy, significant increments in biogenic amine turnover in the nucleus accumbens produced by specific right-hemisphere lesions may be part of the mechanism that results in a manic syndrome.

In conclusion, secondary mania is a rare complication of stroke lesions. We have identified two risk factors: a genetic burden for psychiatric disorders and increased subcortical atrophy. Most patients with secondary mania have right-hemisphere lesions that involve the orbitofrontal or basotemporal cortex or subcortical structures, such as the thalamus or head of the caudate nucleus. Secondary mania may result from disinhibition of dorsal cortical and limbic areas and/or dysfunction of asymmetric biogenic amine pathways.

## Conclusions

We have discussed several of the emotional and behavioral disorders that occur following cerebrovascular lesions (Table 27–3). Depression occurs in about 40% of stroke patients, with approximately equal distributions of major depression and minor depression. Patients with poststroke depression often have a greater degree of cognitive impairment (i.e., dementia of depression) and significantly less recovery in ADLs than do patients who never develop depression. Poststroke depression is significantly associated with left frontal and left basal ganglia lesions and may be successfully treated with tricyclic antidepressants. Anxiety, which is present in about 27% of stroke patients, is associated with depression in the vast majority of cases. Among the few patients with poststroke anxiety and no depression, there was a high frequency of alcoholism and lesions of the right hemisphere. Apathy is present in about 20% of stroke patients. It is associated with older age, more severe deficits in ADLs, and a significantly higher frequency of lesions involving the posterior limb of the internal capsule.

Hallucinations and hallucinosis are rare complications of stroke lesions. Poststroke hallucinations are associated with right-hemisphere temporoparietal lesions, subcortical brain atrophy, and seizures. Poststroke hallucinosis is associated with damage to reticular activating and primary sensory pathways. Anosognosia is present in about 30% of patients with acute stroke lesions. It is associated with right-hemisphere temporoparietal, basal ganglia, and thalamic lesions; neglect; and subcortical brain atrophy.

Catastrophic reactions occur in about 20% of stroke patients; they are not related to the severity of impairment or the presence of aphasia but may represent a defining symptom for one clinical type of poststroke major depres-

**TABLE 27-3. Poststroke neuropsychiatric syndromes**

Neuropsychiatric syndrome	Prevalence	Neuropathological correlates
<b>Depression</b>		
Major	10.25%	Left frontal cortex and basal ganglia; enlarged ventricles
Minor	10%–40%	Not established
<b>Generalized anxiety</b>		
With depression	20%	Left frontal cortex
Without depression	7%	Right parietal cortex
<b>Apathy</b>		
With depression	11%	Left frontal cortex and basal ganglia
Without depression	11%	Posterior internal capsule
<b>Psychosis</b>	Unknown, rare	Right parietal-temporal-occipital junction
<b>Anosognosia</b>	24%–43%	Right hemisphere and enlarged ventricles; frontal dysfunction
<b>Catastrophic reaction</b>	19%	Anterior cortical lesion
<b>Emotional lability</b>	20%	Bilateral injury
<b>Mania</b>	Unknown, rare	Right hemisphere, or bifrontal, basotemporal, basal ganglia, and thalamus

sion. Catastrophic reactions are associated with anterior subcortical lesions and may result from a “release” of emotional display in depressed patients. Emotional lability is another common complication of stroke lesions that sometimes coexists with depression and may be successfully treated with tricyclic antidepressants. Finally, mania is a rare complication of stroke lesions. It is strongly associated with right-hemisphere damage involving the orbitofrontal cortex, basal temporal cortex, thalamus, or basal ganglia. Risk factors for mania include a family history of psychiatric disorders and subcortical atrophy.

## APPENDIX 27-1. Pathological Laughter and Crying Scale (PLACS)

Ratings are based on clinical assessment. Initial probe questions are given for each item. However, further questions may be used for clarification. Write the number in the spaces provided that most accurately reflects clinical symptoms.

### Part I: Patient Interview

1. Have you recently experienced sudden episodes of laughter?  
 \_\_\_ Rate the frequency of the episodes during the past two weeks.

- 0. Rarely or not at all
- 1. Occasionally
- 2. Quite often
- 3. Frequently

2. Have you recently experienced sudden episodes of crying?  
 \_\_\_ Rate the frequency of the episodes during the past two weeks.

- 0. Rarely or not at all
- 1. Occasionally
- 2. Quite often
- 3. Frequently

*If you have experienced sudden episodes of laughter, please answer the following (questions 3–10), otherwise skip to question 11.*

3. Have these episodes occurred without any cause in your surroundings?  
 \_\_\_ Rate the frequency with which the episodes have occurred without external stimuli in the past 2 weeks.

- 0. Rarely or not at all
- 1. Occasionally
- 2. Quite often
- 3. Frequently

4. Have these episodes lasted for a long period of time?  
 \_\_\_ Rate the average duration of the episodes during the past two weeks.

- 0. Very brief
- 1. Few seconds
- 2. Moderate (less than 30 seconds)
- 3. Prolonged (more than 30 seconds)

5. Have these episodes been uncontrollable by you?  
 \_\_\_ Rate the ability to control the episodes during the past two weeks.

- 0. Rarely or not at all
- 1. Occasionally
- 2. Quite often
- 3. Frequently

6. Have these episodes occurred as a result of feelings of happiness?  
 \_\_\_ Rate the frequency with which the episodes have occurred as a result of happiness in the past two weeks.

- 0. Rarely or not at all
- 1. Occasionally
- 2. Quite often

**APPENDIX 27-1. Pathological Laughter and Crying Scale (PLACS) (continued)**

*If you have experienced sudden episodes of crying, please answer the following (questions 11–18).*

11. Have these episodes occurred without any cause in your surroundings?  
 \_\_\_ Rate the frequency with which the episodes have occurred without an external stimuli in the past two weeks.  
 0. Rarely or not at all  
 1. Occasionally  
 2. Quite often  
 3. Frequently
12. Have these episodes lasted for a long period of time?  
 \_\_\_ Rate the average duration of the episodes during the past two weeks.  
 0. Very brief  
 1. Short (few seconds)  
 2. Moderate (less than 30 seconds)  
 3. Prolonged (more than 30 seconds)
13. Have these episodes been uncontrollable by you?  
 \_\_\_ Rate the ability to control the episodes during the past two weeks.  
 0. Rarely or not at all  
 1. Occasionally  
 2. Quite often  
 3. Frequently
14. Have these episodes occurred as a result of feelings of sadness?  
 \_\_\_ Rate the frequency with which the episodes have occurred as a result of sadness in the past two weeks. The sadness must proceed or accompany the crying and not be a reaction to it.  
 0. Rarely or not at all  
 1. Occasionally  
 2. Quite often  
 3. Frequently
15. Have these episodes occurred in excess of feelings of sadness?  
 \_\_\_ Rate the frequency with which the episodes have been disproportionate to the emotional state in the past two weeks.  
 0. Rarely or not at all  
 1. Occasionally  
 2. Quite often  
 3. Frequently
16. Have these episodes of crying occurred with feelings of happiness?  
 \_\_\_ Rate the frequency of association between the episode and the paradoxical emotion in the past two weeks. The happiness must precede or accompany the crying.  
 0. Rarely or not at all  
 1. Occasionally  
 2. Quite often  
 3. Frequently
17. Have these episodes occurred with any emotions other than sadness or happiness, such as nervousness, anger, fear, etc.?

# Traumatic Brain Injury

Robert B. Fields, Ph.D.

Dawn Cisewski

C. Edward Coffey, M.D.

**M**ore than 2 million people in the United States sustain traumatic brain injuries (TBIs) each year (Kraus et al. 1994). Among individuals under the age of 50, TBI is the leading cause of death and neuropsychiatric dysfunction (Sosin et al. 1989). After young adults and children, older adults compose a third at-risk group for TBI. Although the pathophysiology and neurobehavioral consequences of TBI among young adults are becoming better understood, the corresponding literature on TBI among older adults is relatively sparse. Age is a well-established general risk factor for negative outcome following TBI. However, the specific role that age plays in contributing to outcome is less clear. For example, we do not yet know whether all elderly are at risk for negative outcome following TBI or whether the risk of negative outcome is limited to a subset of vulnerable elderly. Similarly, the specific mechanisms by which aging may make the brain more susceptible to a TBI or through which a TBI may provoke, or exacerbate, a neurodegenerative process in an aging brain are not well understood.

Interest in the topic of TBI in older adults has been increasing for at least three reasons. First, because the population is aging, cases of geriatric TBI now account for a greater percentage of all patients with TBI treated in emergency rooms and on trauma services, making findings such as the age-related increase in mortality rates and lengths of hospital stay following geriatric TBI more relevant to clinicians, hospital administrators, and insurance companies. Second, the increased referral of patients for neuropsychiatric and neuropsychological evaluation following geriatric TBI has increased the need for practical guidelines for the differentiation of the syndrome of geriatric TBI from other conditions, such as dementia. A third reason for increased interest in geriatric TBI is the growing body of literature on the apparent epidemiological and pathogenetic association between TBI in adulthood and risk for Alzheimer's disease (AD) in later life (see Chapter 24 in this volume).

This chapter begins with an overview of the general literature on TBI. In subsequent sections, we review the unique characteristics of geriatric TBI, the neuro-

behavioral consequences of TBI and geriatric TBI, and the diagnosis and treatment of geriatric TBI. Finally, we also include a review of the proposed relationship between TBI and AD within the context of current conceptualizations about the pathogenesis of AD.

## Overview of Traumatic Brain Injury

### Terminology

**Definition of traumatic brain injury.** Universal agreement on the definition of a TBI has been difficult to establish, in part because of differences of opinion about where to place the theoretical threshold between non-injury and mild TBI. For example, some definitions of TBI require loss of consciousness, whereas others take into account the finding that loss of consciousness is not necessary for subsequent brain dysfunction to occur. Most definitions of TBI require that the known or suspected injury to the brain was sufficiently severe to cause at least one of the following: 1) alterations in consciousness, 2) posttraumatic amnesia, or 3) physical, radiological, or objective evidence of injury-related abnormalities.

### Utility of the term “traumatic brain injury.”

The use of terms such as *traumatic brain injury*, *head injury*, or *brain injury* can be both informative and problematic. The utility of these terms stems from the implied causal connection between an acquired lesion and abnormal behavior. For patients who have sustained a TBI, there is an assumption that subsequent alterations in thinking, mood, and behavior are the results of the specific neurological damage associated with the traumatic event. The well-known case of Phineas Gage in the 1860s is an example of a TBI (i.e., penetration by a railroad spike through the left frontal lobe) that produced specific and dramatic changes in personality and comportment (Harlow 1868).

However, the use of these terms can also be misleading. In younger adults, for example, the term brain injury typically connotes a traumatic injury, whereas in older adults, the term brain injury is often used to describe a variety of etiologies (e.g., stroke, aneurysm, and tumor), as well as traumatic injury. The terms also imply a misleading homogeneity of patients across studies. Just as strokes of different types, sizes, and locations can produce a wide range of neurological and neurobehavioral dysfunctions, so too can traumatic brain injuries of different types and severities cause different symptoms. Comparing studies of outcome following “TBI,” therefore, will likely produce different conclusions if this anatomic heterogeneity is not

taken into account. A third problem with these terms is the risk of assuming a direct correspondence between the brain injury and subsequent behavior and of minimizing other factors that have been shown to contribute to outcome. These factors include, but are not limited to, premorbid personality, previous brain injury or dysfunction, substance abuse, vocational history, social support network, involvement in treatment, involvement in litigation, and the experience of being in a traumatic event (Parker 1990; Richardson 1990; Wood 1990).

**Types of traumatic brain injury.** TBIs are categorized as *open* or *closed*, depending on whether or not the skull has been penetrated (and the brain exposed). The manner in which an injury is sustained has important implications for the neuroanatomical, neurochemical, metabolic, and neurobehavioral disruption that follows. Dysfunction following open head injuries such as a gunshot wound is dependent on factors such as the path of the bullet, tissue disruption by associated force waves, the spread of bone chips, and the development of cerebral edema (Bigler 1991; Kirkpatrick and DiMaio 1978). In contrast, the dysfunction that follows a closed head injury may be the result of *focal* damage caused by impact at the site of the injury (e.g., from a fall or an assault) or *diffuse* damage caused by rapid acceleration/deceleration or twisting movements of the brain within the cranial vault (e.g., from a high-speed motor vehicle collision). *Primary* brain injuries are those that occur at the moment the TBI takes place (e.g., cerebral contusion from impact). *Secondary* brain injuries are those that develop following the initial trauma (e.g., edema, increased intracranial pressure, delayed hemorrhage).

**Severity of traumatic brain injury.** TBIs are typically characterized as being either mild, moderate, or severe, based on criteria such as degree of initial neurological dysfunction, duration of unconsciousness, and duration of memory loss for events following the injury (i.e., posttraumatic amnesia [PTA]). TBIs are considered to be mild when there is no, or brief, loss of consciousness and less than 60 minutes of PTA. In contrast, TBIs are considered severe when unconsciousness lasts hours to days and PTA lasts more than 24 hours. While specific estimates vary, the majority (i.e., 70%–90%) of TBIs are classified as mild (Lezak 1995). Because severity of injury is a good predictor of outcome, the use of additional categories of severity has been suggested (e.g., very mild, no loss of consciousness, less than 5 minutes of PTA; very severe, 1–4 weeks of unconsciousness or PTA; extremely severe, more than 4 weeks of unconsciousness or PTA) (Bigler 1990b).

Several objective measures of severity of TBI have

been developed. Of these instruments, the Glasgow Coma Scale (GCS) (Teasdale and Jennett 1974) remains the “gold standard” because of its quick and convenient numerical quantification of level of consciousness and its widespread use in trauma data banks (Diringer and Edwards 1997; Juarez and Lyons 1995; Menegazzi et al. 1993). The GCS is a 15-point global index of consciousness that assesses functioning in three domains (eye opening, verbal response, and motor response) (Teasdale and Jennett 1974) (Table 28–1). GCS scores are generally interpreted as follows: 13–15, mild; 9–12, moderate; and 3–8, severe. Although the GCS has been found to have high interrater reliability and to be a reasonable predictor of poor outcome in TBI (i.e., death or vegetative state), it appears to have limited predictive power in terms of functional and cognitive outcome (Diringer and Edwards 1997; Zafonte et al. 1996) and is also limited when used with selected populations (e.g., children, patients with chronic disabilities, elderly patients with hearing loss, and patients whose injuries affect the eyes and mouth) (Menegazzi et al. 1993; Sorenson and Kraus 1991). These limitations are becoming more pronounced as prehospital treatment (i.e., pharmacological paralysis, sedation, and intubation) increases (Marion and Carlier 1994), thereby limiting the ability to obtain accurate GCS scores for many individuals (Marion and Carlier 1994; Prasad 1996).

As a result of these limitations, several other scales of

injury severity have been developed. Examples include 1) the Abbreviated Injury Scale (AIS) (American Association for Automotive Medicine 1985), which incorporates the Injury Severity Scale (ISS) (Baker et al. 1976) and which was designed to rate overall injury by measuring the cumulative damage across six body regions, including the head; 2) the revised APACHE (Acute Physiology, Age, and Chronic Health Evaluation, II and III) (Knaus et al. 1985; Wagner et al. 1989) system, which also measures more physiological variables than the GCS, including underlying diseases and comorbidity; and 3) the Reaction Level Scale (RLS85) (Starmark et al. 1988), which allows the assessment of TBIs among individuals who are intubated or have severe preorbital swelling. Although these measures overcome some of the problems with the GCS, many of them have significant limitations (e.g., limited information on reliability and validity, increased time and difficulty of administration). Thus, the GCS remains the most widely used tool to measure severity of TBI.

## Pathophysiology of Traumatic Brain Injury

Excellent reviews of the biomechanics and pathophysiology of TBI can be found elsewhere (e.g., Alexander 1995; Bigler 1991; Gennarelli 1993; Gualtieri 1995; McIntosh et al. 1996; Parker 1990; Richardson 1990). The following is a brief overview of the pathophysiology of primary and secondary brain injuries.

**Primary brain injury.** Among patients who experience closed TBIs, primary brain injuries usually occur as a result of impact/contact forces or inertial/acceleration motions (Katz 1992; McIntosh et al. 1996). Impact/contact injuries can cause local skull distortion as well as stress waves through the brain from the point of impact. The consequences of contact injuries include distorted or fractured skulls (with or without extradural hematomas) and contusions or lacerations of the brain. Contrecoup injuries are also common, although the term contrecoup may be somewhat misleading because the location of these injuries may not be exactly opposite the point of initial impact (McIntosh et al. 1996; Richardson 1990).

Many TBIs also involve linear or rotational movements of the brain within the skull. The accelerating and decelerating or twisting movements of the brain produce lacerations or contusions when the moving brain comes into contact with the more stationary bony protuberances of the base of the skull. Within the cranial vault, the orbital, frontal, and temporal areas are most vulnerable to this type of injury (Adams et al. 1977; Bigler 1990a, 1991; Gennarelli

1993; McIntosh et al. 1996; Ommaya et al. 1971; Richardson 1990). An important by-product of these movements is diffuse axonal injury (Adams 1988; Adams et al. 1982; Alexander 1995; Gualtieri 1995; McIntosh et al. 1996). Straining, shearing, and rupture of axonal fibers are common following TBI of all severities and are generally associated with more significant neuropsychiatric disorders (Alexander 1995; Bigler 1990a; Jennett and Teasdale 1981; McIntosh et al. 1996; Parker 1990; Richardson 1990). In severe cases, dramatic rotation of the brain around the brainstem may lead to coma (Parker 1990).

**Secondary brain injury.** Some damage to brain structure and function may be initiated at the time of the TBI but may not be clinically present for minutes, hours, or even days following the injury. Examples of secondary brain injuries include: hematoma, edema, ischemia, increased intracranial pressure, infection, ventricular enlargement, seizures, and alterations in neurochemical functioning (Bachman 1992; Katz 1992; McIntosh et al. 1996; Parker 1990; Richardson 1990).

Intracranial hematomas and cerebral edema are considered to be two of the most frequent types of acute secondary brain injury (Richardson 1990). In his review of this literature, Richardson (1990) reported that intracranial hemorrhage occurs in approximately 50% of patients with severe injuries and often is responsible for the development of delayed coma or other types of neurological deterioration. The presence of a skull fracture dramatically increases the risk of intracranial hematomas (Jennett and Teasdale 1981). Diffuse brain swelling develops in approximately 10% of patients who have sustained severe brain injuries (Adams et al. 1989; Richardson 1990). Brain edema may lead to herniation, occlusion of intracranial vessels with secondary strokes (e.g., subfacial herniation may occlude the anterior cerebral artery, and transtentorial herniation may occlude the posterior cerebral artery), or to strain effects on axonal fibers (Bigler 1990a; Cummings and Benson 1992). The occurrence of subdural hematomas secondary to the tearing of veins is particularly problematic in elderly patients in whom brain atrophy increases the distance from the brain surface to the venous sinuses, thus increasing the vulnerability of bridging veins to rupture with even minor trauma (Bachman 1992; Cummings and Benson 1992; Levy et al. 1993; McIntosh et al. 1996).

Regarding other secondary brain injuries that may complicate the postinjury course, ventricular enlargement is common following moderate-to-severe TBI (Levin et al. 1981) and has been associated with greater neuropsychological impairment (Cullum and Bigler 1986) and worse prognosis (Gudeman et al. 1981; Kishore et al.

1978). Changes in ventricular size may not be fully apparent (via computed tomography [CT] scan analysis) until 1–3 months after the injury (Cope et al. 1988; Gudeman et al. 1981).

Posttraumatic epilepsy is another delayed consequence of brain injury that can affect eventual outcome. Approximately 5% of patients develop seizures within the first week after a TBI (Bachman 1992; Teasdale 1995). Risk factors for early posttraumatic epilepsy include prolonged posttraumatic amnesia, depressed skull fracture, intracranial hematoma, and a history of childhood seizures (Bachman 1992; Hendrick and Harris 1968; Jennett and Teasdale 1981). Late seizures (i.e., beyond the first week) have also been reported in approximately 5% of patients following TBI but may not develop until more than a year after the injury. Risk factors for late epilepsy include severity of injury, early epilepsy, and depressed skull fracture (Annegers et al. 1980b; Bachman 1992; Jennett and Teasdale 1981). Mathematical models exist to predict the likelihood of seizures for individual patients (Feeney and Walker 1990). Among patients who have already had one late seizure, 75% continue to have seizures (Bachman 1992). The use of prophylactic anticonvulsant medication following brain injury reduces the risk of early seizures, but not late seizures (Malec and Basford 1996; Schierhout and Roberts 1998; Temkin et al. 1990). Because anticonvulsants often produce sedation, their use among elderly patients may be problematic (e.g., increased risk of subsequent head injuries as a result of falls) (see Chapter 34 in this volume).

In addition to the structural damage caused by primary and secondary brain injuries, changes in brain neurochemistry also occur following a TBI (Bohnen and Jolles 1992; Gennarelli 1993; Gualtieri 1995; McIntosh et al. 1996). These changes appear to be related to the nature and extent of the structural damage and can be seen as “neuroprotective” or “autodestructive” (McIntosh et al. 1996). For example, it has been suggested that because of their location, size, and widespread projections from the lower brainstem to subcortical and cortical areas, the monoaminergic pathways are particularly vulnerable for disruption as a result of diffuse axonal injury (Gualtieri 1995). Alterations in acetylcholine, norepinephrine, and dopamine have been reported following experimentally induced TBI in animals (McIntosh et al. 1996). Such changes have been postulated to be linked to the changes in intracranial pressure and blood pressure that sometimes follow TBI. Similarly, postinjury changes in arousal, attention, and information processing have been attributed to disruption of dopaminergic and noradrenergic pathways, whereas postinjury changes in mood, appetite, sleep, sexual

function, motor activity, anxiety, and aggression have been associated with disruption of serotonergic neurons (Gualtieri 1995) (see Chapter 2 in this volume).

Changes in neurochemistry can result from primary or secondary brain injuries. For example, the immediate disruption of neural pathways and vasculature following diffuse brain injuries may cause a defect in the axonal membrane that results in changes in intracellular ions (particularly calcium). The sudden loading of calcium ultimately leads to a depolarization of axons that then disrupts neural transmission. Secondary brain injuries such as ischemia can also lead to disruptions in cerebral metabolism, which can, in turn, lead to the release of excitatory amino acids (EAAs) such as glutamate and aspartate. EAAs have been called “excitotoxic” because of their destructive effect on cells *in vitro*. EAAs can excessively stimulate neurons, leading to cellular exhaustion or the formation of free radicals that are toxic to cells. Choi (1987) has postulated that two sequential mechanisms mediate cell death resulting from excitotoxin exposure: 1) acute neuronal swelling resulting from an influx of chloride and sodium and 2) delayed damage resulting from an influx of calcium. Other neurochemical changes that have been reported following TBI include the release of: 1) oxygen free radicals, which can cause peroxidative damage to membrane phospholipids, and 2) neurotrophic substances (e.g., nerve growth factor), which may play a role in reducing damage and promoting recovery from brain injury (McIntosh et al. 1996). The possibility that increased deposition of  $\beta$ -amyloid protein ( $\beta$ AP) following brain injury may increase the risk of AD is reviewed below.

## Outcome Following Traumatic Brain Injury

For patients who experience TBIs, and their families, the most pressing injury-related concerns pertain to survival, rate of recovery, and quality of life following the injury.

**Measurement strategies.** Assessment of global progress through the initial stages of recovery can be accomplished with several instruments. The most frequently used outcome measure is the Glasgow Outcome Scale (GOS) (Clifton et al. 1993; Jennett and Bond 1975). The GOS uses a 5-point scale to classify outcome: 1) good recovery, 2) moderate disability, 3) severe disability, 4) persistent vegetative state, and 5) death (Clifton et al. 1993; Hofer 1993; Zafonte et al. 1996). Although widely used, the GOS has several significant limitations. These include 1) lack of sensitivity to change during recovery because the categories of outcome are too broad (Clifton et al. 1993),

2) reduced sensitivity to the multidimensional nature of patients’ deficits with an overemphasis on physical disability and an underemphasis on cognitive and neurobehavioral problems (Anderson et al. 1993), and 3) few or no guidelines regarding the incorporation of problems such as epilepsy, preexisting personality disorders, chronic illness, and preexisting substance abuse, which are common among patients with TBIs.

Other outcome measures exist, some of which address the limitations of the GOS. These measures include 1) the Rancho Los Amigos Levels of Cognitive Function Scale, which uses an 8-level categorical scoring system to evaluate level of awareness, interaction with the environment, cognition, and behavior; 2) the Disability Rating Scale (DRS), which measures arousal, awareness, cognitive ability for self-care, physical dependence, and psychosocial abilities; and 3) the Functional Independence Measure (FIM), which assesses the amount of assistance an individual needs in performing daily activities.

In addition to the aforementioned instruments, global indices have also been used in assessing outcome. These include survival rates, length of hospital stay, discharge destination, and ability to return to preinjury activities. Although these indices can provide important information about functional status, the determination of more subtle or specific neurobehavioral deficits requires comprehensive neuropsychiatric assessment and neuropsychological testing.

**General predictors of outcome.** Severity of the injury is the best general predictor of outcome following TBI. Regarding outcome in the first few weeks following the injury, patients whose injuries are more severe are at greater risk for death, longer hospital stays, and placement in supervised care settings following hospitalization (Combes et al. 1996; Cowen et al. 1995; Jennett and Teasdale 1981; Katz 1992; Marshall et al. 1983; Richardson 1990; Russell and Smith 1961). For example, in one sample of adults (ages 25–54 [ $N = 1,487$ ]) hospitalized for TBI (Fields 1991), the rate of in-hospital mortality following a severe injury was 23 times greater than the mortality rate following a mild injury. Similarly, in this sample, length of hospital stay was 3.8 times longer and likelihood of transfer to a rehabilitation or skilled nursing facility (rather than home) was 9.6 times greater following severe TBI than following mild TBI.

Other specific variables that have been associated with poor initial outcome include 1) alterations in pupillary response, systolic blood pressure, and intracranial pressure; 2) duration of posttraumatic amnesia; and 3) presence of CT scan abnormalities such as skull fractures and hema-

tomas. For example, Cowen et al. (1995) found an inverse relationship between CT abnormalities and good prognosis. Specifically, 81% of patients in their study who had normal CT scans, but only 45% of patients with one CT scan abnormality, were classified as having a good recovery. Furthermore, among patients with a skull fracture, 67% were classified as having a poor outcome.

Severity of injury is also the most important predictor of longer-term outcome. Severe injuries are associated with greater generalized impairment than are mild injuries (Cifu et al. 1997; Ip et al. 1995; Masson et al. 1996; Mazaux et al. 1997). Vollmer et al. (1991) found the following outcome statistics (based on GOS) for a sample of adults (ages 26–55 [ $N = 279$ ]) 6 months after a severe brain injury: good recovery, 22%; moderate-to-severe disability, 35%; and vegetative survival or death, 43%. Other studies have also documented that more severe TBIs are associated with greater difficulty in areas such as ability to return to work, drive, initiate participation in social and recreational activities, use public transportation, and perform administrative tasks such as banking, writing letters, and making a weekly schedule (Mazaux et al. 1997; Ponsford et al. 1995; Tennant et al. 1995).

## Summary

Much has been learned during the past few decades about the pathophysiology of, and outcome following, TBI. Rather than considering TBI a unitary phenomenon, it is probably more appropriate, and more useful, to conceptualize TBI as an ongoing process during which numerous events take place, many of which have implications for subsequent neurobehavioral functioning. In addition to considering noninjury factors, an understanding of postinjury outcome can be enhanced greatly by knowledge of factors such as mechanism of primary injury, types of secondary injuries, and disruption of neurochemical functioning. Much of our current understanding about the pathophysiology of TBI comes from animal models of TBI and from studies of adults who did not survive their TBI. Although severity of injury is clearly the most important factor in predicting outcome following TBI, it appears that age also plays an important, but less well-understood, role in mediating the consequences of TBI.

## ■ Unique Characteristics of Geriatric Traumatic Brain Injury

The available literature suggests that there are age-related differences in both occurrence and outcome of TBI.

## Occurrence

**Epidemiology.** Several factors make it difficult to determine the exact prevalence of TBI and geriatric TBI. These factors include variability in diagnostic criteria used in different countries and different hospitals, double counting of patients transferred between acute hospitals, variation in hospital documentation policies, and the estimate that 20%–40% of individuals who sustain mild TBIs do not seek medical treatment (Bohnen and Jolles 1992; Gualtieri 1995; Jennett 1996).

Despite these limitations, most epidemiological studies have estimated the incidence of TBI as approximating 200–300 cases per 100,000 individuals (Bigler 1990b; Bohnen and Jolles 1992; Gualtieri 1995; Jennett 1996; Kraus et al. 1984; Naugle 1990; Sorenson and Kraus 1991). These injuries do not, however, occur randomly, with the risk for TBI being clearly age-related. TBIs are most common among young adult males (ages 16–25), for whom the incidence is approximately 400 per 100,000. Typically, these injuries occur in motor vehicle accidents where alcohol is often involved (Bigler 1990b; Goldstein and Levin 1990; Goldstein et al. 1994; Jennett 1996; Naugle 1990). Children, between the ages of 1 and 5, are a second risk group, with the incidence rate approximating 150 per 100,000 individuals (Goldstein and Levin 1990; Rosenthal et al. 1990). The elderly population comprises a third at-risk group. As can be seen in Figure 28–1, following a period of relative low risk in middle adulthood, the risk for TBI steadily increases after age 65, to a rate of 200 per 100,000 (Goldstein and Levin 1990; Goldstein et al. 1994; Roy et al. 1986). In addition, the large gender difference in incidence rates that exists in young adults is not present in elderly adults. Whereas young adult men are approximately three times more likely than young adult women to sustain a TBI, in the elderly population, men and women are at equal risk (Jennett 1996; Kraus and Nourjah 1989; Naugle 1990).

**Mechanism of injury.** Differences also exist across age groups in how injuries are sustained. Among the general population, motor vehicle collisions are the leading cause of TBI, and falls are the second leading cause. Among the elderly, this order is reversed (Jennett 1996; Levy et al. 1993; Parker 1990; Rakier et al. 1995; Sorenson and Kraus 1991). Although geographic differences exist for other types of injuries (e.g., more assaults with firearms in larger cities), a consistent finding across studies is that with advancing age there is an increased risk of TBI as a result of falls and pedestrian accidents and a corresponding decreased risk of TBI as a result of motor vehicle collisions (Figure 28–2).

**FIGURE 28-1.** Incidence rates of traumatic brain injury by age and sex.

**FIGURE 28-2.** Causes of traumatic brain injury by age.  
 $P < .0001$   
 Source. Reprinted from Fields RB: “The Effects of Head Injuries on Older Adults” (abstract). *Clinical Neuropsychologist* 5:252, 1991.

**Prior traumatic brain injury.** Among young adults, previous TBI is a known risk factor for future head injury (Annegers et al. 1980a; Edna 1987; Naugle 1990; Sims 1985). Documentation of prior TBIs is somewhat difficult because it is typically based on self-report, memory, and

subjective interpretation. With these limitations in mind, preliminary data collected in one large trauma database (M. Lovell and S. Smith, personal communication, September 1994) suggest that the frequency of patients hospitalized following a TBI reporting a previous TBI is higher among younger adults than older adults. Specifically, in this sample, prior TBI was reported by 32% of a young to middle-aged sample (ages 20–50,  $n = 535$ ), but only 20% of an older adult sample (ages 60–90,  $n = 97$ ).

**Role of alcohol.** Alcohol is another factor that is significantly related to etiology and outcome following TBI in young adults (Desai et al. 1983; Edna 1987; Frankowski 1986; Parkinson et al. 1985; Ruff et al. 1990). It is also another factor that has not been adequately addressed in the literature on geriatric TBI and one for which our data suggest that the assumptions based on young adults may not apply to older adults. As expected, among a sample of more than 3,500 patients hospitalized following a TBI at Allegheny General Hospital in Pittsburgh, the frequency of young adults with blood alcohol levels at or above the legal definition of intoxication when brought to the emergency room was relatively high (e.g., ages 15–24, 44%; ages 35–54, 39%). Alcohol was associated with the TBI much less often among the older sample (e.g., ages 65–95, with legally intoxicated blood alcohol levels, 11%).

Another unique characteristic of the geriatric population is the age difference in the circumstances in which alcohol is involved in the TBI. In our database, legally intoxicated blood alcohol levels were found among young and middle-aged adults whose TBIs occurred in motor vehicle accidents (39%) at approximately the same rate as among those whose TBI occurred because of a fall (35%). In contrast, in the older adult group, among whom alcohol use was less prevalent overall, a legally intoxicated blood alcohol level was significantly more likely when the injury occurred during a fall (17.3%) than when the injury occurred during a motor vehicle accident (6.1%). These data suggest that drinking and driving is less of a problem for the elderly than for younger adults and that our understanding of outcome following TBIs that occur as the result of a fall in the elderly must take into account the role of alcohol.

**Outcome**

Older adults are usually thought to have less favorable outcomes than younger adults following TBI. In 1932, for example, Russell (Russell and Smith 1961) reported an increase in mortality associated with TBI beginning in the fifth decade of life. In their influential work, Jennett and Teasdale (1981) described a “continuous” and essentially

linear relationship between age and negative outcome across the life span. Other studies have also documented increased mortality rates, increased length of hospital stay, increased likelihood of nursing home placement, increased long-term disability, and other signs of poor prognosis among older adults following brain injury (Annegers et al. 1980a; Carlsson et al. 1968; Cartlidge and Shaw 1981; Cifu et al. 1996; Edna 1983; Fife et al. 1986; Jennett and Teasdale 1981; Kilaru et al. 1996; Kotwica and Jakubowski 1992; Levy et al. 1993; Luerssen et al. 1988; Marshall et al. 1991; Pentland et al. 1986; Ross et al. 1992). In addition, the literature on general trauma in humans (Dries and Gamelli 1992) and the limited experimental literature on brain injury in animals (Hamm et al. 1991) also suggest that advanced age is a risk factor for adverse outcome.

Although the weight of evidence is impressive, studies comparing the effects of TBI on older versus younger adult humans have been problematic for a number of reasons. First is the influence of preexisting conditions on subsequent outcome. Preexisting neurological impairment may affect the cause of injury (e.g., a patient with dementia who falls), initial presentation (e.g., inaccurate history or delay in seeking treatment), postinjury course (e.g., exaggeration of preinjury neuropsychological deficits), and diagnosis (e.g., attribution of dementia-related cognitive impairment to the brain injury). Whether a TBI is the cause or the result of brain dysfunction is more likely to be a question among older adults in whom, for example, degenerative brain changes or medication sensitivity is more common than in younger adults. In a study of brain injury among the “old old” (ages 80–96), for example, a factor that contributed to the injury (e.g., previous stroke, postural dizziness, and medication) could be identified for 75% of the patients whose injury was the result of a fall (Amacher and Bybee 1987). Assessing outcome in this sample, therefore, might underestimate the potential recovery of “normal” elderly individuals who fall for other reasons.

A second problem has been controlling for severity of brain injury, as well as for total body injuries, when comparing samples of different age groups. If older adults have more severe injuries (as Sorenson and Kraus [1991] contend), increased negative outcome among the elderly may be simply a reflection of severity of injury rather than of age. A third problem is that even when severity of injury is controlled, comparisons of different age groups generally do not control for differences in the type of injury sustained. Finally, the definition of “old” varies considerably from study to study. Many reports of change in outcome with “age” involve a comparison between young adults (usually ages 20–40) and middle-aged adults (ages 40–65), with very little representation of geriatric patients includ-

ing the “old old.” With these cautions in mind, the following is a review of specific outcome measures.

**Postinjury neurological sequelae.** Advanced age is a risk factor for subdural hematomas, intracranial hemorrhages, and posttraumatic infections following TBI (Amacher and Bybee 1987; Dries and Gamelli 1992; Fogel and Duffy 1994; Miller and Pentland 1989). Postinjury bleeds are more common and more problematic in the elderly for a number of reasons. First, the incidence of nontraumatic intracerebral hemorrhage in the general population increases exponentially with age, making the elderly an at-risk population in general (Broderick et al. 1993). Second, as noted above, older adults are also at greater risk for subdural hematomas because age-related brain atrophy increases the distance from the brain surface to the venous sinuses (Cummings and Benson 1992). Third, because falls are the most common cause of geriatric TBI and because subdural hematomas are common consequences of falls, the elderly are particularly vulnerable for subdural bleeds. Finally, these types of injuries may develop in a delayed fashion over time and may go unrecognized in the presence of other injuries (Fogel and Duffy 1994). For example, in one study of older patients admitted to a hospital because of a fractured bone, 10% were found to have a subdural hematoma as well (Oster 1977).

The age-related increased risk of posttraumatic intracranial hematomas is particularly problematic after injuries that are classified as being in the mild-to-moderate range of severity. For example, in their comparison of older (i.e., > 65 years,  $n = 449$ ) and younger (i.e., < 65 years,  $n = 1,571$ ) patients following TBI of all severities, Pentland et al. (1986) reported a threefold increase in intracranial hematomas among the older sample. However, there was no age difference in the patients whose injuries were severe, among whom intracranial bleeds were common at all ages. In contrast, following TBIs of mild-to-moderate severity, the frequency of intracranial hematoma was six times greater in the older group. In our study (Fields and Ackerman 1991) of patients who sustained a mild TBI as the result of a fall or a motor vehicle accident, the incidence of intracranial bleeds was related to age and type of injury. Specifically, intracranial bleeds were significantly more common in the elderly sample in general but were also more common among those whose injury was sustained in a fall than among those whose injury occurred during a motor vehicle accident.

For other neurological sequelae, there are no age differences or the effects of age are not well known. Despite the logical prediction that an older skull might be more vulnerable to fracture than a younger skull during a TBI, no

consistent evidence indicates that this is the case. For example, in one large study of patients with TBI of all severities (Pentland et al. 1986), no age differences were found in the frequency of skull fracture; in another study of patients with severe TBIs (Vollmer et al. 1991), only a slight increase in frequency of fracture with age was found. In our study of the effects of mild TBI across the life span, the developing skulls of children were found to be more vulnerable to fracture than the aging skulls of the adult and elderly samples, and no significant increase in the frequency of skull fracture was found with advancing age (Fields 1997).

Older adults do not appear to be at increased risk of developing brain swelling or a posttraumatic seizure disorder following a TBI (Richardson 1990). Similar to the data on skull fractures, posttraumatic seizures are in fact more common following TBI in children than TBI in adults (Dalmady-Israel and Zasler 1993; Fields 1997) (Table 28–2). Although it has been postulated that axonal shearing and damage from the release of excitotoxic neurotransmitters are greater among the elderly (Hamm et al. 1991, 1992), this prediction has not yet been definitively proven.

**Indices of general outcome.** Following TBIs that are classified as severe, death, permanent disability, and inability to return to work are more common at all ages. However, age appears to play an independent and significant role in increasing the risk of negative outcome. In the most comprehensive study of age differences in outcome following severe TBI to date, Vollmer et al. (1991) found dramatic age-related differences in outcome at 6 months. The mortality rate at 6 months was 28% for the 26- to 35-year-old group and 80% for the over 55-year-old

group. In addition, 28% of the younger group were rated as having made a good recovery (based on the GOS) after 6 months, whereas among the older group, 0% had made a good recovery. One of the advantages of this study was that the role of age in influencing outcome was assessed by systematically ruling out the effect of other variables. The authors concluded that the variable of age clearly made an independent contribution to outcome in their sample. Other studies have also documented the independent contributions of age to slower recovery and more negative eventual outcome (as measured by GOS) following TBI, particularly following moderate-to-severe injuries (e.g., Cifu et al. 1996; Katz et al. 1990; Kilaru et al. 1996; Pentland et al. 1986; Ross et al. 1992; Ruff et al. 1990).

**Mortality.** With regard to the specific question of survival rate following TBI, in keeping with the Vollmer et al. (1991) study, a fairly robust finding in the literature is that older adults are at greater risk for death following head injury than are young adults or children (e.g., Amacher and Bybee 1987; Annegers et al. 1980a; Edna 1983; Fields 1991; Fife et al. 1986; Kilaru et al. 1996; Pentland et al. 1986; Rakier et al. 1995; Ross et al. 1992). However, as noted above, most studies of this outcome measure did not control for factors such as severity of brain injury or severity of other nonbrain injuries. In our attempts to do so (Table 28–3), an age by severity of injury interaction was found. As can be seen in Figure 28–3, when all patients were included regardless of severity of injury, mortality rate was relatively stable through middle adulthood, but it increased significantly beginning at age 55 and continued to increase with advancing age. In follow-up analyses (Table 28–3), among patients whose injuries were severe, mor-

**TABLE 28–2. Based on age and type of injury, differences in neurological sequelae following mild traumatic brain injury**

Age group	Type of injury	n	Percentage of patients with		
			Skull fracture	Intracranial bleed	Seizures
0–10	Fall	63	29	6	6
	MVA	42	12	9	0
15–24	Fall	82	15	18	5
	MVA	795	10	4	1
35–54	Fall	169	17	19	5
	MVA	545	11	2	2
65–95	Fall	248	16	40	1
	MVA	229	13	15	0

*Note.* MVA = motor vehicle accident.

tality was greater for patients at all ages but again was highest among the oldest group.

Among patients whose TBIs were considered to be mild, but whose total injuries were not accounted for in the analysis, the mortality rate among the oldest group was approximately 8 times greater than the middle-aged group and 24 times greater than the young adult group. However, when severity of head injury (e.g., mild, GCS = 13–15) and severity of total body injury (e.g., mild, ISS < 10) were controlled, mortality was extremely low for all age groups (Table 28–3). These data suggest that although age increases the risk for in-hospital mortality following a TBI at any level of severity, other factors (e.g., severity of other injuries) play a role in the apparent age difference in outcome.

#### Length of hospital stay and discharge destination.

Several outcome studies have documented that, following TBIs of similar severity, older adults stay in hospital longer and are more likely to be discharged to a nursing home and less likely to be discharged to their home (e.g., Edna 1987; Fields 1991; Fife et al. 1986; Katz et al. 1990; Roy et al. 1986). Given changes in reimbursement for health-care services, these age-related differences have enormous practical and economic significance. Although length of hospital stay increases with age, this increase appears to be a reflection of the interaction between length of stay and discharge destination. In our sample, the mean length of stay for patients discharged to home or to a nursing home did not differ significantly by age (Fields 1991). That is, patients of any age who are discharged to nursing homes had stayed in hospital much longer than patients who return home. Because more older adults are discharged to nursing homes and fewer older adults are discharged home, the overall increase in hospital length of

stay for the elderly actually reflects that a larger percentage of elderly are discharged to nursing homes, rather than the implied impression that it takes all older adults longer to recover from their injuries.

**Return to preinjury functioning.** Finally, the literature on young and middle-aged adults suggests that advanced age is a relevant factor in the prediction of return to previous level of functioning. One frequently used index of outcome among young adults is return to school or work. Although this indicator is not meaningful for many older adults (who are retired), and despite the fact that the majority of the studies in this area do not include patients above age 65, it is worth noting that conclusions about the effect of age are, nevertheless, often made. For example, in three studies (Ip et al. 1995; Ponsford et al. 1995; Ruff et al. 1993), age was found to be a small but significant predictor of eventual outcome following severe TBI (among young and middle-aged adults). In the few studies that have assessed this variable among older adults (Alberico et al. 1987; Davis and Acton 1988; Pentland et al. 1986), advanced age has also been found to predict increased difficulty with activities of daily living, increased general disability, and decreased likelihood of returning to work (among those who were working prior to their injury).

#### Summary

There are several unique characteristics of geriatric TBI. First, TBI occurs more frequently among older adults than among middle-aged adults. Second, in contrast to TBI among young adults, no gender difference exists in the occurrence of TBI among older adults. Third, with advancing age there is an increase in the likelihood that TBIs

**FIGURE 28-3.** Age differences in mortality rate following traumatic brain injury—all levels of severity.  $\chi^2 = 87.8$ ;  $P < 10^{-8}$ .

occur as the result of a fall or pedestrian accident and a decrease in the likelihood that the TBI occurred as the result of a motor vehicle collision. Fourth, a history of TBI is more common in younger adults than it is in older adults who are treated for TBIs. Fifth, alcohol is involved less often in the TBI among older adults, but when it is a factor, the TBI is more likely to be caused by a fall than by a motor vehicle collision. Finally, as a group, older adults are at greater risk for negative outcome (e.g., mortality, disability) following TBI than are younger adults. Elderly are at risk for some (e.g., subdural bleeds), but not all (e.g., skull fractures), postinjury sequelae. Furthermore, not all elderly are at greater risk for negative outcome, and some preliminary evidence suggests that factors such as preexisting impairment and the severity of other injuries contribute to the findings of worse outcome with advancing age.

## ■ Neuropsychiatric Consequences of Traumatic Brain Injury

As with other consequences of TBI, severity of injury is the best predictor of the type and severity of neuropsychiatric problems. Sufficient differences exist between groups of patients with mild TBIs and patients with severe TBIs to consider them separately.

### Mild Traumatic Brain Injury

**Cognitive and postconcussive symptoms.** Following mild TBI, patients frequently display time-limited neuropsychological impairment and report a constellation of symptoms known as the *postconcussive syndrome*

(PCS). Neuropsychological deficits are typically seen in the areas of attention/concentration, speed and efficiency of information processing, and short-term memory (Alexander 1995; Barth et al. 1983; Bigler 1990a; Bohnen and Jolles 1992; Fann et al. 1995; Gentilini et al. 1989; Gronwall 1989; Gualtieri 1995; Klonoff and Lamb 1998; Kutner and Barth 1998; Masson et al. 1996; Mazaux et al. 1997; Ruff et al. 1989b). In addition to problems with cognitive processing (e.g., concentration), the PCS includes physical symptoms (e.g., headache, dizziness, blurred vision, tinnitus, fatigue, and increased sensitivity to light and noise) and mood/behavioral symptoms (e.g., anxiety, depression, and irritability) (Alexander 1995; Barth et al. 1983; Bigler 1990a; Binder 1986; Bohnen and Jolles 1992; Gronwall 1991; Gualtieri 1995; Masson et al. 1996; Mazaux et al. 1997). Symptoms of posttraumatic stress disorder (e.g., intrusive recollections, nightmares, avoidance, increased startle response) are also common following mild TBI because the traumatic event is more likely to be remembered than following severe TBI.

The majority of patients who sustain a mild TBI experience a relatively complete recovery of neuropsychiatric symptoms within 1–3 months of their injury. However, a minority of patients report that these symptoms persist for months, or in some cases years, after the injury (Alexander 1995; Bigler 1990a; Gronwall 1991; Gualtieri 1995; Kutner and Barth 1998; Masson et al. 1996; Mazaux et al. 1997; Raskin et al. 1998). For example, in studies by Masson et al. (1996) and Mazaux et al. (1997), a subgroup of patients reported ongoing problems in areas such as headache, dizziness, mood, memory, energy, sleep, and initiative/motivation 5 years following a mild TBI.

The etiology of persistent neuropsychiatric deficits remains controversial. The role that psychological factors including “secondary gain” play in mediating response to a traumatic event has not been clearly defined. In addition, factors such as premorbid psychiatric problems, previous head injury, chronic pain, little education, and litigation have been correlated with persistent neurobehavioral complaints (Dikmen et al. 1989). Some studies, for example, have found that patients involved in litigation following a mild TBI performed more poorly on neuropsychological tests than did patients with documented severe TBI (Youngjohn et al. 1995). However, other studies suggest that, for at least some patients, the persistence of neuropsychiatric symptoms may be caused by unknown or undetected neurological damage. For example, in one study of patients evaluated 6 months following a TBI, Bohnen et al. (1992) found that those who reported postconcussive symptoms also performed less well on tests of divided and selective attention than did patients without post-

concussive symptoms or healthy control subjects. Prigatano (1992) has suggested that symptoms that remain relatively stable over time, such as emotional lability, irritability, and restlessness, may be primary effects resulting from neurological damage, whereas symptoms that worsen over time, such as fatigue, sensitivity to distress, and apathy, may be secondary effects resulting from having to cope with the neurological deficits. Although the development of postconcussive symptoms occurs independent of litigation status (Merskey and Woodforde 1972; Steadman and Graham 1970), several factors including pending litigation, preinjury personality, length of posttraumatic amnesia, alcohol use, fault for injury, and social network all must be evaluated when assessing the relationship between a TBI and late postconcussive symptomatology (Alexander 1992; Rutherford 1989).

**Depression.** Reports of depressive symptomatology are common following mild TBI, with studies identifying approximately 22%–36% of individuals with mild TBI meeting criteria for a major depressive episode (Busch and Alpern 1998). Although it can be difficult to distinguish between depression and PCS, such a distinction is important for accurate and effective treatment. Complicating the issue is that many individuals who report depressive symptoms have significant premorbid conditions (e.g., psychiatric/psychological histories, substance abuse, neurological disorders) that can contribute to depressive symptomatology following a TBI. In addition, the psychological reaction to the consequences of the accident (e.g., death of friends/family) and to the subsequent cognitive and physical deficits may influence the development or exacerbation of depressive symptomatology.

When trying to isolate the cause of depression following mild TBI, several conflicting findings have emerged. Pharmacological studies indicate little or no improvement with antidepressants for depression in persons with mild TBI cases (Busch and Alpern 1998). Other studies examining relationships between lesion location and depression following mild TBIs have found significant associations (Busch and Alpern 1998). For example, Federoff et al. (1992) found a significant association between a major depressive episode and left dorsolateral frontal, left basal ganglia, and, to a lesser extent, right parieto-occipital lesions. Although this study did not exclusively use mild TBI cases, 35% of the group with depression were identified as having a mild TBI. In another study by Gasparri et al. (1978), a significant difference was found between left and right hemisphere damage and depressive symptomatology in mild TBI cases. Using the Minnesota Multiphasic Personality Inventory (Hathaway and McKinley 1970), their

results indicated that left hemispheric damage produced significantly higher scores on the depression scale.

Neuroimaging studies also support the relationship between neurological impairment following mild TBI and depression. In several studies, abnormal CT scans and magnetic resonance imaging (MRI) results indicate a possible relationship between depression and lesions in the frontal, temporal, or frontotemporal areas (Jenkins et al. 1986; Levin et al. 1987a; Sekino et al. 1981). Thus, there appears to be increasing evidence suggesting an interactional relationship between the location of brain injury following a mild TBI and the development of depressive symptomatology. However, further research in this area is needed to help differentiate secondary psychological reactions from primary neurological factors.

## Severe Traumatic Brain Injury

**Cognitive deficits.** Following severe TBI, patients often display significant deficits in the areas of attention/concentration, speed of information processing, memory, and executive functioning (Cullum et al. 1990; Levin et al. 1982; Mazaux et al. 1997; Olver et al. 1996; Ponsford et al. 1995; Tennant et al. 1995). Specifically, impairments have been reported on measures of divided attention; the ability to tune out distractions; speed of processing, learning, and retaining new information; initiation; planning; organization; and awareness/insight. As a result, even without deficits in basic language, perceptual, or motor capacities, patients who have had severe TBIs often have difficulty following conversations, sustaining attention, sustaining efficiency at work, learning without repeated exposure, initiating activity, making plans, correcting errors, shifting cognitive sets, and having insight into their changes in behavior.

In contrast to the majority of patients with mild TBI, neuropsychological dysfunction following severe TBI is more significant and more long lasting (Parker 1990). Persistent deficits in intellectual functioning have been found in most patients following severe TBI (Levin et al. 1979) although the pattern of impairment is not always uniform. For example, Levin et al. (1990) found that although basic language and visuospatial skills had returned to normal 1 year after a severe TBI, young adult patients continued to demonstrate memory impairment and slowed information processing. Other studies documented deficits 5–7 years postinjury. For example, Tennant et al. (1995) found that 56% of their sample were continuing to report memory problems 7 years after a severe TBI. Similarly, Mazaux et al. (1997) found that mental fatigability, memory difficulties,

lack of initiative and motivation, conceptual disorganization, difficulties in mental flexibility, and poor planning were common complaints 5 years following severe TBI.

**Mood.** With regard to affective symptoms following severe TBI, consistent findings are lacking in the literature. This inconsistency is probably the result of the considerable variability in methodologies used to assess severity of injury, time since injury, definition of mood symptoms, and approach to assessment. For example, studies of depressive symptoms following severe brain injury have found prevalence rates varying from 10% to 70% (Silver et al. 1991, 1992). Depressive symptoms are apparently not related to factors such as length of unconsciousness, length of posttraumatic amnesia, or presence of skull fracture (Silver et al. 1992) but may be related to neuropsychological status (Bornstein et al. 1989) and, as described above, lesion location (Federoff et al. 1992).

Other causes of mood or behavioral change following TBI include grief or other adjustment-related mood disturbances and neuropsychiatric syndromes such as apathy, amotivation, slowed cognitive processing, and affective lability (Mazaux et al. 1997; Ponsford et al. 1995; Prigatano 1992; Raskin 1998; Silver et al. 1991; Tennant et al. 1995). In addition, whether depressive symptoms predated or caused the head injury (e.g., suicidal car crash) must be taken into account when assessing the role of brain injury in “causing” depression (Silver et al. 1991).

The use of comprehensive assessment procedures and an agreed-on classification system to diagnose mood disturbance (and other neuropsychiatric disorders) following TBI has been rare. Even when structured interviews and specific diagnostic criteria are used, reported prevalence rates vary and depend, in part, on the point at which patients are assessed. For example, in a sample of patients who were assessed during the first year after a TBI (Jorge et al. 1993b), the frequency of major depression diagnosed according to DSM-III (American Psychiatric Association 1980) was 42%, whereas the frequency of major depression among a sample assessed 2–8 years after their injury was 77% (Varney et al. 1987). In both studies, a substantial portion of these patients reported that their depressive symptoms developed at least 3–6 months after the injury (39% in the Jorge et al. [1993b] study and 46% in the Varney et al. [1987] study).

One series of studies took an important step toward clarifying the causes and course of depressive symptoms following TBI (Federoff et al. 1992; Jorge et al. 1993a, 1993b). The presence of neuropsychiatric disturbance was assessed among 66 young adults on an inpatient trauma service with a structured psychiatric interview (i.e., modi-

fied Present State Examination [Wing et al. 1974]) and scales of depression, cognitive capacity, activities of daily living, and social functioning. Patients were initially evaluated during the acute postinjury period and then reassessed 3, 6, and 12 months later. During the 1-year follow-up period, 42.4% of the patients met DSM-III criteria for major depression (25.7% during the acute period and 16.7% during one of the follow-up examinations). Patients with the “acute-” and the “delayed-”onset depression had a higher frequency of previous psychiatric problems and impaired social functioning than did the patients without depression, but these groups also differed on a number of other dimensions. Lesions in the left frontal region (particularly left dorsolateral frontal or left basal ganglia) were associated with major depression among only the patients with the acute-onset depression. In contrast, patients with delayed-onset depression had significantly poorer social functioning, but less severe depression and less impairment in activities of daily living, than did the group with acute-onset depression. In addition, no specific relationship between location of brain lesion and the occurrence of delayed-onset depression has been found (Fann et al. 1995). Based on these findings, Jorge et al. (1993b) suggested that acute-onset depression may be more related to biological changes in an injured brain, whereas delayed-onset depression may be more psychologically based.

**Behavior and personality.** Long-term alterations in behavior and personality are also common following severe TBI. For example, Jennett and Teasdale (1981) found personality changes in approximately two-thirds of patients who sustained severe brain injuries. Changes that are commonly associated with TBI include impulsivity, irritability, diminished drive, altered frustration tolerance, agitation, aggression, and impaired social judgment (Bigler 1991; Jennett and Teasdale 1981; Mazaux et al. 1997; Olver et al. 1996; Ponsford et al. 1995; Prigatano 1992; Silver et al. 1987; Tennant et al. 1995).

Prigatano (1986) described three types of personality and behavioral disturbances that occur following severe TBI: organic disturbances, emotional reactions to injury or attempts to cope with injury, and preinjury personality characteristics that influence the expression of neurological damage. “Organic” personality changes, such as reduced tolerance for stimulation, mental fatigue, irritability, and difficulty with impulse control, are presumed to be linked to the site of the injury. For example, specific lesions in the orbitofrontal area have been linked to a behavioral dyscontrol syndrome that includes disinhibition, impulsivity, emotional lability, hyperactivity, and diminished awareness or concern for the implications of one’s

behavior (Cummings 1985; Gualtieri 1991; Mattson and Levin 1990) (see Chapter 32 in this volume). Generalized frontal lobe lesions have also been associated with perseveration, apathy, indifference, amotivation, abulia, loss of empathy, poor social judgment, and a loss of the capacity for accurate self-monitoring (Lewis et al. 1992). Temporal lobe injuries have been associated with irritability and aggression. Frontotemporal lesions have been associated with mood lability, inappropriate laughing and crying, and hypersexuality or hyposexuality. Temporoparietal injuries have been associated with suspiciousness, paranoia, and a tendency to misinterpret the intentions of others (Gualtieri 1991).

## Summary

While significant gaps in our knowledge remain, the neuropsychiatric sequelae of TBI are becoming better understood. Following mild TBI, time-limited deficits in areas of higher level cognitive processing such as complex attention and working memory are common, as are mild symptoms of mood and behavioral disturbance. For the majority of patients, symptom resolution occurs within 3 months of the injury. For a minority of patients, symptoms of cognitive and behavioral disturbance persist. The persistence of symptoms in these patients appears to be related to multiple factors, ranging from “secondary gain” in some to documented brain dysfunction in others. Among patients whose TBIs are severe, more long-standing changes in cognitive processing and behavior are likely. Although more research is needed, preliminary evidence suggests that some types of mood and behavioral disturbances do correlate with TBI lesion location.

## ■ Neuropsychiatric Consequences of Geriatric Traumatic Brain Injury

### Animal Studies

Most of the experimental literature has focused on the neuropathological changes that are associated with TBIs and the course of these injuries over time. Experimentally induced TBIs via methods such as fluid percussion, weight drop, rigid indentation, and angular acceleration have been helpful in elucidating the type and extent of injuries that occur following TBIs at different levels of severity (McIntosh et al. 1996; Povlishock and Coburn 1989). Studies have demonstrated that the greater plasticity of an immature central nervous system enhances the ability of very young animals to recover from experimental brain in-

juries (Finger 1978). To date, however, the effect of advanced age on head injury in animals has received only limited attention (Hamm et al. 1992).

In one study, Hamm et al. (1991) reported that the mortality rate for older rats (20 months) was approximately three times greater than that for younger rats (3 months) following experimentally produced (fluid percussion) “mild” brain injury. Following a more severe fluid percussion brain injury (i.e., “moderate injury”) mortality was five times greater among the older rats. Using a similar model, Hamm et al. (1992) also found age-related motoric and cognitive deficits following a lower level (i.e., “mild”) fluid percussion brain injury. In this study, weight was used as an index of general health, balance beam performance as an index of motor skill, and the Morris Water Maze Task as an index of cognitive capacity. Older rats (20 months) had no general health changes following the injury but did demonstrate significant motoric and cognitive deficits. In contrast, the younger rats (3 months) did not display any postinjury motor deficits and had less severe cognitive deficits than did the older rats. Other investigators have demonstrated slower and more deficient neuronotopic response following experimentally induced TBI in older rats relative to that in younger rats (Needles et al. 1985; Whittemore et al. 1985). Finally, as reviewed in the last section of this chapter, specific genetic factors also appear to mediate neuronal repair and neurobehavioral recovery following TBI in animals (Chen et al. 1997).

### Human Studies

Although limited, the available data on the neuropsychiatric consequences of geriatric TBI have begun to shed light on some of the central questions that must be addressed to define the syndrome of geriatric TBI. These questions include 1) Can the effects of geriatric TBI be differentiated from the effects of normal aging? 2) Do the neuropsychological effects of TBI differ with age? 3) Can the syndrome of geriatric TBI be differentiated from the syndrome of dementia on the basis of neuropsychological test performance? and 4) Do the neuropsychiatric and psychosocial consequences of TBI differ with age?

**Can geriatric traumatic brain injury be differentiated from normal aging?** Indirect support for the hypothesis that the neuropsychological effects of TBI in the elderly can be differentiated from the effects of normal aging comes from the extensive literature on the effects of TBI among young adults (e.g., Levin et al. 1982, 1990) as well as one study (Mazzucchi et al. 1992) that found a high rate of generalized cognitive impairment

(e.g., approximately 50%) among a sample of older adults (e.g., 50–75 years of age) who had recently sustained a TBI.

Two studies have directly tested and supported this hypothesis. In the first, Goldstein et al. (1994) compared the performance of older (50 years and older) patients who had sustained a TBI of mild ( $n = 6$ ) or moderate severity ( $n = 16$ ) with the performance of an older adult control group ( $n = 16$ ) on selected measures in four cognitive domains: attention (e.g., reciting alphabet, reciting serial 3s, reciting months forward and backward), language (e.g., visual naming, controlled oral word associating), memory (e.g., California Verbal Learning Test [CVLT] [Delis et al. 1986], Continuous Visual Recognition Test [Hannay and Levin 1998]), and executive functioning (Wechsler Adult Intelligence Scale—Revised [WAIS-R] [Wechsler 1981], similarities, modified card sorting). Nineteen of the 22 patients with geriatric TBI were tested within 3 months of their injury. Consistent with the literature on TBI among young adults, significant between-group differences were found in three of the four domains (language, memory, and executive functioning). The authors concluded that their “findings indicate that mild to moderate closed head injury in older adults produces cognitive deficits involving the same neurobehavioral areas affected in young survivors” (Goldstein et al. 1994, p. 964).

In a second study (Goldstein et al. 1996), the performance of 15 geriatric patients with TBI was compared with the performance of 15 normal elderly control subjects (and 15 patients with AD; see below) on measures of memory (dementia version of the CVLT) and language processing (naming and verbal fluency). Consistent with the findings of their previous study (Goldstein et al. 1994), the geriatric TBI group in this study performed significantly worse than the elderly control group on measures of memory and language.

An important methodological issue was raised by a third recent study in this area. Aharon-Peretz et al. (1997) also found that older patients (i.e., 60 years or older) with TBI performed more poorly on neuropsychological tests than did psychiatrically normal elderly control subjects. However, in this study, the patients with TBI did not perform more poorly than orthopedic patients, suggesting that the postinjury deficits in both patient groups may have been partly the result of preexisting cognitive impairments, which may have contributed to the etiology of the injuries.

**Do the neuropsychological effects of traumatic brain injury differ with age?** To provide conclusive support for the contention that TBI produces similar deficits among young and older survivors, a

large-scale study of young and older adult patients with TBI is needed that takes into account factors such as premorbid level of functioning, role of substance abuse, history of prior head injury, type of injury, severity of injury, type and severity of other nonbrain injuries, and availability of rehabilitation and psychosocial support resources. No such study exists. The assumption that older age is associated with greater impairment comes from studies such as the one by Raskin et al. (1998) in which it was reported that older adults performed more poorly than younger adults following TBI on a memory test. However, in this study, the mean age of the sample was 38.1, “old” was defined as over 40, and raw scores were used rather than age-corrected scores.

In an attempt to address one aspect of this question, Fields (1994) compared the neuropsychological test performance of young ( $n = 472$ ) and older ( $n = 96$ ) adults who 1) sustained a mild TBI (GCS = 13–15) and 2) recovered sufficiently within the first week following their injury to complete a neuropsychological evaluation. A limitation of this study was that it did not address the issue of whether more elderly than young adults were too impaired to be tested (i.e., had more severe initial outcome). However, this design did ensure the comparability of the two groups by requiring that all patients met the same inclusion criteria.

As can be seen in Table 28–4, while the raw scores of the older adults were significantly worse on seven of the eight measures chosen, when the effects of age were controlled by converting raw scores to age-based percentile scores, the groups differed on only one of the eight measures (Digit Span Backward) (Table 28–4). These preliminary data support the conclusion of Goldstein et al. (1994) and suggest that the *acute* neuropsychological effects of mild TBI among patients whose initial recovery is relatively uncomplicated are not significantly different with age. However, whether there are age differences in the *long-term* neuropsychological effects of TBI or the course of neuropsychological recovery over time is not yet known.

**Can geriatric traumatic brain injury be differentiated from dementia?** The ability to differentiate the syndrome of geriatric TBI from dementia is important for clinical, as well as legal, reasons. Two studies have provided preliminary guidelines in this area. Goldstein et al. (1996) compared the performance of 15 geriatric patients following mild-to-moderate TBI (GCS = 9–15) with the performance of 15 patients with probable AD (all of whom were considered to be in the early stages of the disease) and 15 elderly control subjects. Geriatric patients with TBI were tested approximately 6 weeks postinjury.

**TABLE 28-4. Comparison of neuropsychological test performance of geriatric patients ( $n = 96$ ) versus that of young adult patients ( $n = 472$ ) following mild traumatic brain injury**

Test	Results	
	Raw score	Percentile score
Digit span forward	NS	NS
Digit span backward	$P < .01$	$P < .05$
Trails A	$P < .001$	NS
Trails B	$P < .001$	NS
Wechsler Memory Scale-Revised		
Logical Memory-I	$P < .05$	NS
Logical Memory-II	$P < .01$	NS
Visual Reproduction-I	$P < .001$	NS
Visual Reproduction-II	$P < .001$	NS

Note. NS = not significant.

The test battery chosen for this study specifically included two areas that are impaired in early AD, that is, memory (via the dementia version of the CVLT) and language processing (via tests of object naming and verbal fluency). Not surprisingly, the elderly control subjects performed better on the language and memory tasks than did both of the patient groups. Of relevance to the current discussion, compared to the patients with TBI, the patients with AD 1) displayed poorer recall on the dementia version of the CVLT, and 2) did not show the normal facilitation of verbal fluency when asked to generate words in specific semantic categories

**TABLE 28-5. Comparison of neuropsychological test performance of geriatric patients with traumatic brain injury ( $n = 33$ ) versus patients with mild dementia ( $n = 35$ )**

Test	Geriatric patients with TBI	Patients with dementia	$P$ value
Digit span forward	7.8	6.9	
Digit span backward	5.0	4.5	
Trails A	69.1	97.6	
Trails B	193.8	266.4	$P < .01$

(fruits/vegetables), as opposed to the generation of word lists in more specific phonemic categories (words beginning with specific letters).

In a second study, Young et al. (1995) compared the test performance of 33 geriatric patients who had sustained a recent TBI (in the previous week) with 35 elderly patients who met criteria for mild dementia on measures of attention (Digit Span [Wechsler 1987], Trails A [Army Individual Test Battery 1944]), memory (Hopkins Verbal Learning Test [HVL] [Brandt 1991]), and executive functioning (Trails B [Army Individual Test Battery 1944]). In keeping with the finding of Goldstein et al. (1996), Young et al. (1995) (Table 28-5) found that although the geriatric group with TBI performed better overall than did the group with AD, the only significant between-group differences were on measures of memory (HVL, learning and delayed recall) and executive functioning (Trails B), with worse performance in the group with AD.

#### Does neuropsychiatric functioning differ with age following traumatic brain injury?

Among young adults, neuropsychiatric complaints are frequent in the month following a TBI and can include physical changes (e.g., headache, dizziness, sensitivity to light and noise), cognitive difficulties (e.g., concentration, memory), and alterations in mood (e.g., depression, post-traumatic anxiety) and behavior (e.g., impulsivity, irritability) (Binder 1986; Bohnen and Jolles 1992; Bohnen et al. 1992). For most patients, these symptoms resolve in 3-6 months. Among the elderly, preliminary evidence suggests that neurobehavioral recovery may be different and slightly more complicated.

Levin (1995) reported on a preliminary study using the Neurobehavioral Rating Scale to assess the functioning of elderly patients with TBI or AD and elderly control subjects. One month following their injury, patients with TBI

reported difficulties in the areas of cognition, metacognition, and language. When a subsample of this group was reassessed 6 months following their injury, no significant change in overall symptomatology was reported.

Similar results were found in another study of the natural history of post-TBI complaints in which the self-reports of older patients (ages 50–95,  $n = 49$ ) were compared with the self-reports of younger patients (ages 18–45,  $n = 139$ ) acutely and 4 months following their injury (Fields et al. 1993). For this study, a 29-item questionnaire (Post-Traumatic Neurobehavioral Screening Inventory [PTNSI]) (Fields and Coffey 1994), which assesses symptoms commonly reported following TBI, was used (C. A. Taylor et al. 1993). The two age groups were comparable in terms of severity of head injury and severity of other non-brain injuries. One month following the injury, neurobehavioral complaints were common among both younger and older patients, and the overall symptom profiles were quite similar, although symptoms of posttraumatic stress disorder were more common among the younger group and fatigue was reported more often in the older group. At the 4-month follow-up, however, age-related differences began to emerge (Table 28–6). The older patients endorsed fatigue, difficulty processing information, dysphoric mood, dizziness, and sensitivity to noise significantly more than did the younger patients. In addition, there was an age by time interaction found on three of the six subscales of the test (cognitive, behavior, posttraumatic stress) such that the older patients reported similar, or greater, distress in these areas at 4 months than they had 3 months earlier, whereas the younger patients reported improvement in all of these areas across the same time period. Thus, although preliminary, these findings suggest that the course of neurobehavioral recovery following TBI in elderly patients may be different, and somewhat worse, than that in younger patients.

## Summary

To summarize, although limited, the available data on neuropsychiatric outcome suggest that TBI in the elderly produces neuropsychological effects that are qualitatively similar to the effects of TBI in young adults and that are distinguishable from the effects of normal aging and dementia. One important implication of these data is that if elderly are evaluated with age-appropriate tests and norms, a significant percentage (perhaps a majority) perform in a manner that is not significantly worse than that of younger adults, suggesting that not all elderly are at greater risk for negative outcome. With regard to the differentiation of geriatric TBI from dementia, the available data suggest that learning, delayed recall, semantic processing, and executive functioning are cognitive domains that may differentiate these two syndromes. With regard to neuropsychiatric outcome, in addition to the general finding that older adults are less likely to return to their preinjury level of functioning, there is now preliminary evidence that the course of recovery for older patients following a TBI may be different, and somewhat worse, than the course for younger patients.

## ■ Diagnosis and Management of Neuropsychiatric Sequelae

The neuropsychiatric assessment and treatment of patients who sustain TBIs will be more straightforward once diagnosis becomes more accurate, double-blind medication trials for specific syndromes have been completed, and the role of factors, such as age, in mediating response to treatment is understood. Until then, the literature suggests a number of potential principles that may provide guides for developing assessment and treatment strategies.

**TABLE 28–6.** Age differences in symptom report at 1 and 4 months following traumatic brain injury using the Posttraumatic Neurobehavioral Screening Inventory

Percentage of sample endorsing symptom	Age 18–45	Age 50–95	<i>P</i>
<b>1 month</b>	( $n = 139$ )	( $n = 49$ )	
Fatigue	48.6	66.0	$P < .05$
<b>4 months</b>	( $n = 54$ )	( $n = 25$ )	
Fatigue	30.9	72.0	$P < .001$
Difficulty processing information	12.0	44.0	$P < .005$
Dysphoric mood	20.1	45.8	$P < .05$
Dizziness	5.4	24.0	$P < .05$
Sensitivity to noise	5.4	20.0	$P < .05$

## Diagnosis

The general assessment of symptoms following TBI can be a difficult process, given the ambiguity present in the symptom presentation, as well as the conflicting reports of the accident. As Parker and Rosenblum (1996) discuss, relevant information is often incomplete or inaccurate following traumatic injuries. This incomplete or incorrect information may be the result of a variety of factors. Many individuals with TBI may have presenting symptomatology (e.g., memory loss) that prevents them from accurately reporting the traumatic incident and resulting effects. In addition, the treatments that are used to prevent secondary problems (e.g., paralyzing drugs, intubation, pain management) may also hinder the information-gathering process. Lastly, patients may experience embarrassment or anxiety about re-experiencing the traumatic event, which may result in a reluctance to accurately report the incident and subsequent symptoms (Parker and Rosenblum 1996). As a result, many individuals with TBIs may not be adequately assessed, and thus not properly treated.

The diagnosis of a specific psychiatric disturbance in patients following TBI is often problematic as well (Coffey 1987; Ross and Rush 1981). For example, valid and reliable historical information may be difficult to obtain in patients with language deficits (e.g., aphasia) or neglect syndromes (e.g., unawareness or denial or illness). In addition, brain disorders may distort the signs and symptoms of psychiatric disturbances (e.g., complaints of hopelessness and helplessness secondary to depression may appear unconvincing in a patient with aprosody). Behavioral disturbances that result from TBI may be misdiagnosed as a psychiatric disorder, or, conversely, the behavioral disturbances that often accompany psychiatric illness may be mistakenly attributed to a brain disorder (e.g., psychomotor retardation of depression attributed to posttraumatic parkinsonism). These difficulties in recognizing psychiatric illness in patients with TBI impede efforts to determine the neuroanatomical correlates of behavior and may lead to inappropriate diagnosis and treatment.

**Diagnostic process and tools.** Accurate diagnosis requires an understanding of the neuropsychiatric sequelae and the course of recovery of traumatic injuries of different types, locations, and severities. In addition, because there are multiple possible causes of neuropsychiatric symptoms, the evaluation of the patient with a TBI should include a review of prior head trauma, developmental and academic history, occupational history, and social history as well as a comprehensive psychiatric, medical, and

substance abuse assessment. Because discrepancies between the reports of patients and families are common following TBI (Oddy et al. 1985), the importance of collateral history from relatives and hospital records is also critical.

With these general guidelines in mind, the assessment of specific disorders may require flexible strategies. Regarding the assessment of depression, for example, Ross and Rush (1981) suggest that, in addition to obtaining history from the patient and a reliable informant, clinical cues such as a complicated recovery from the brain injury, multiple “vegetative signs” of depression, atypical emotional outbursts, aprosody, and an abrupt deterioration in the patient’s neurological status can be used to make a diagnosis. Among elderly patients, additional factors that must be considered include the presence of systemic medical conditions, preexisting neurodegenerative disorders, and possible developmental changes in the phenomenology of depressive symptoms related to aging (Caine et al. 1993).

Comprehensive assessment is further complicated by the lack of assessment tools and an inadequate classification system. Although current psychiatric diagnostic systems provide a useful starting point for studying patients with TBIs, it is possible that neuropsychiatric symptomatology following such injuries may be better classified by other approaches. For example, the “bottom up” approach of the Schedules for Clinical Assessment in Neuropsychiatry (SCAN) (World Health Organization 1992) is promising in that it assesses the presence and severity of a comprehensive list of symptoms rather than (or in addition to) the traditional method of establishing a specific diagnosis. This approach allows for the generation of clusters of symptoms that may have clinical significance but that do not meet diagnostic criteria.

A related issue pertains to the limits of the current diagnostic classification system for patients with neuropsychiatric disorders. Following TBIs, patients may have an identifiable pattern of symptoms but may not meet criteria for a DSM-IV disorder (American Psychiatric Association 1994). Furthermore, even when diagnostic criteria are met, it may be difficult to determine whether the brain disease is causal of the neuropsychiatric symptoms. Such etiological judgments may at times be unreliable and invalid, and it has been suggested that Axis I diagnoses such as major depression be kept purely phenomenological, with relevant causal or contributory organic factors identified on Axis III (Fogel 1991).

**Imaging.** An improved diagnostic classification system for patients with TBIs will ultimately depend on the sensitivity of neuropsychiatric and neuropsychological assessment instruments and the correlation between these

measures and indices of brain structure and function. Brain imaging is critical for the assessment of most patients who sustain a TBI, particularly for those with severe injuries (GCS 3–8). Although controversy remains about performing CT scans after mild and moderate TBIs, evidence suggests that approximately one-fifth of patients with mild TBIs have abnormal CT scans (Wald 1995). Therefore, routinely performing this procedure on individuals diagnosed with TBIs is still advisable. CT scanning is widely used and the modality of choice for its ability to detect intracranial hematomas, delineate bony structures of the craniofacial skeleton, and identify skull fractures in the acute (1–3 days) posttrauma period (Chakares and Bryan 1986; Pieper et al. 1996; Wald 1995; Yoshino and Seeger 1989).

Brain MRI is more sensitive than CT for assessing parenchymal damage, including the diffuse axonal “shear” lesions, and providing information about subcortical structures and the brainstem (Alavi 1989; Levin et al. 1985, 1987; Wald 1995). MRI also provides a better view of brain tissue adjacent to the skull (e.g., inferior frontal regions and temporal lobes) because, unlike CT, MRI is not subject to beam-hardening artifact. However, because MRI does not image bone, it is not helpful in assessing possible fractures, nor can MRI be used in patients attached to metal respirators or in those who have metal fragments (e.g., bullets or shrapnel) in their heads (Levin et al. 1992; Pieper et al. 1996; Wald 1995). In addition, the use of MRI may be impractical in the initial assessment because it tends to be time-consuming and often unavailable for immediate use (Pieper et al. 1996). However, increased sensitivity of MRI to the presence of brain lesions is particularly apparent among patients with mild-to-moderate TBIs (Levin et al. 1992), and follow-up MRI studies have been shown to be more predictive of eventual outcome (Wilson et al. 1988). Structural brain imaging studies of elderly patients must be interpreted within the context of changes that occur with normal aging (see Chapter 9 in this volume).

Functional brain imaging studies (e.g., regional cerebral blood flow [rCBF], single photon emission computerized tomography [SPECT], positron-emission tomography [PET], and functional MRI) have not yet found a role in the routine assessment of patients with TBI. Cerebral blood flow and metabolism are reduced acutely after brain injury, and the degree of metabolic suppression may be related to the severity of injury (Fieschi et al. 1974; Obrist et al. 1979). Metabolic imaging techniques appear to be more sensitive than either CT or MRI in detecting areas of brain abnormalities after TBI (Alavi 1989; Alavi et al. 1986; Langfitt et al. 1986; Ruff et al. 1989a), and such abnormalities correlate more closely with neuropsychological per-

formance postinjury than do the structural changes seen on CT or MRI (Ruff et al. 1989a). The clinical use of these metabolic imaging techniques and their particular characteristics in elderly patients must await further research (see Chapters 10 and 11 in this volume).

## Management

**Early considerations.** Based on age-related differences in the occurrence, pathophysiology, and sequelae of TBI in elderly individuals, Fogel and Duffy (1994) recommended guidelines for the acute and subacute assessment and treatment of older adults. In the acute postinjury phase, these recommendations include increased vigilance regarding possible early or delayed vascular complications (e.g., subdural hematoma and intracranial hemorrhage); identification and management of neuropsychiatric comorbidities (e.g., preexisting cognitive impairment, depression, and alcoholism); and ongoing monitoring of neuropsychiatric status if other medical problems predominate (e.g., serial assessment of mental status or functional capacity during treatment for orthopedic injuries). In the postacute phase, neuropsychiatric input is recommended for determining capacity to benefit from formal rehabilitation (e.g., based on degree of cognitive impairment, as well as physical deficits); assessing and managing functional deficits (e.g., capacity to take medication, live independently, or drive); and treating the behavioral and psychosocial consequences of the TBI (Fogel and Duffy 1994).

**Acute pharmacological treatment of brain injury.** The diverse nature of TBIs and the need for acute management of multiple problems have made it difficult to conduct double-blind studies of potentially beneficial pharmacological strategies for TBI. In the absence of clinically proven algorithms of care, a number of studies have offered suggestions for treatment, as well as avenues for further research. These treatment strategies include the use of antioxidants or free-radical scavengers, as well as gangliosides and cyclooxygenase inhibitors, to prevent secondary brain damage (Faden 1996; Wald 1995). Gangliosides have been used with some success in patients with acute strokes, subarachnoid hemorrhages, and spinal cord injuries (Wald 1995).

The use of nimodipine, a calcium channel antagonist, is also being investigated in the treatment of TBI. It has been hypothesized that calcium channel blockers may moderate the influx of calcium that occurs following traumatic injuries, thereby reducing secondary excitotoxic damage. Although initial studies using nimodipine were

favorable, subsequent studies demonstrated no significant differences when compared with an untreated control group (Wald 1995). The efficacy of other potential strategies (e.g., narcotics, barbiturates, corticosteroids, and *N*-methyl D-aspartate [NMDA] receptor antagonists) has yet to be established in humans.

Finally, as discussed above, approximately 5% of patients with TBI develop posttraumatic seizures. As a result, the use of anticonvulsants as a prophylactic measure has been examined. Although some research suggests that the use of prophylactic anticonvulsants reduces the occurrence of seizures during the first week following head injury, there is no demonstrated effect on reducing seizures after the initial week (Malec and Basford 1996; Schierhout and Roberts 1998; Temkin et al. 1990; Wald 1995).

**Pharmacological treatment of neuropsychiatric disorders.** With regard to the neuropsychiatric sequelae of TBI, a number of studies offer suggestions for treatment, as well as avenues for further research. Reviews of the literature (Dubovsky 1992; Silver et al. 1992) (Chapter 34 in this volume) make several general points regarding the pharmacological treatment of younger and older adults with neuropsychiatric symptoms. First, until therapeutic interventions are able to limit the initial brain damage from the traumatic injury, a primary role for medication remains the control of certain target symptoms such as depression, anergia, mania, mood lability, agitation, anxiety, psychosis, and aggression (Silver et al. 1992). Control of such symptoms will have the additional beneficial effect of increasing the patient's capacity to participate in other ongoing therapies, including psychotherapy and cognitive rehabilitation (Silver et al. 1992) (also see Chapters 36 and 39 in this volume).

Second, patients who have experienced TBIs and patients who are elderly may be more sensitive to the effects of many psychotropic medications including heterocyclic antidepressants, monoamine oxidase inhibitors, lithium, antianxiety agents, and neuroleptics (Dubovsky 1992; Silver et al. 1992). As a result, starting with lower doses, titrating medications in smaller increments, and ultimately using lower maintenance doses have been recommended (Dubovsky 1992; Silver et al. 1992). Sedative and anticholinergic side effects are of particular concern (Dubovsky 1992; Silver et al. 1992). Other side effects include the risk of lowering seizure threshold among patients with TBI (Silver et al. 1992) and the risk of cardiovascular changes among elderly patients (Dubovsky 1992). To date, the extent to which the interaction between a TBI and an older brain alters sensitivity to medication is not known.

One example of the process of balancing efficacy with

the possible complications associated with pharmacotherapy after brain injury concerns the treatment of depressive and anergic-abulic states. As noted above, one important limiting factor in this type of treatment is the risk of lowering seizure threshold in patients who are already at greater risk for seizures because of their brain injury (Silver et al. 1991, 1992). Tricyclic antidepressants, for example, have been reported to increase the likelihood of seizures after severe brain injuries (Wroblewski et al. 1990), whereas methylphenidate apparently does not (Wroblewski et al. 1992). Therefore, methylphenidate may be a consideration in retarded depressive and apathetic states following brain injury.

Rummans et al. (1999) reviewed the world's literature for controlled blinded treatment trials in neuropsychiatry and identified one study of TBI that met their criteria. In that study, Wroblewski et al. (1996) randomly selected 10 patients with major depression, diagnosed according to DSM-III-R, and recent TBI for a 3-month trial of desipramine (105–300 mg/day) ( $n = 4$ ) or placebo ( $n = 6$ ). Response was defined by a 50% reduction in number of DSM-III-R depression symptoms. All four patients on placebo were blindly crossed over to desipramine after 1 month because of nonresponse. Three of the six patients on desipramine and three of the four patients on placebo crossed over to desipramine responded to the active drug. Two patients receiving desipramine dropped out as a result of adverse effects.

Uncontrolled studies have reported variable findings. Modest improvement in depressive symptoms has been reported among patients with TBI following trials of carbamazepine (Varney et al. 1987) and fluoxetine (Cassidy 1989). In contrast, Dinan and Mobayed (1992) reported improvement in depressive symptoms in only 4 of 13 patients with mild TBI who met DSM-III criteria for depression and who were treated with amitriptyline, compared with 11 of the 13 patients with DSM-III major depression without TBI. Similarly, Saran (1985) found no significant improvement in mood in a sample of 10 patients with mild brain injury who were treated with phenelzine or amitriptyline.

Variability in responsiveness to treatment for depression across studies may be a result of several factors including differences in degree of structural brain changes (Coffey et al. 1989) and differences in diagnostic criteria (Silver et al. 1991). It is also possible that different subtypes of depression exist among this population. For example, Silver et al. (1991) hypothesized that depressive symptoms related to stroke-like focal disruption of neurotransmitter receptors may be more responsive to selective serotonin reuptake inhibitors than those symptoms that may be

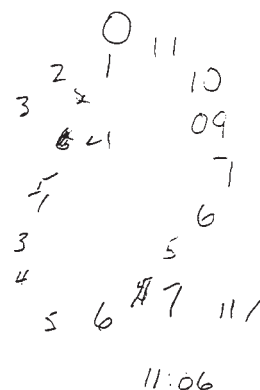

caused by the release of neurotoxins during more diffuse and severe injuries. Similarly, as discussed above, Jorge et al. (1993b) proposed subtypes of depression based, in part, on the point at which symptoms develop (e.g., early-onset depression was associated with lesion location; delayed-onset depression, with social factors). Until issues relating to diagnostic subtypes have been resolved and effective treatment strategies have been established, the focus of pharmacotherapy for posttraumatic neuropsychiatric disorders among elderly patients will remain the application of conventional treatment strategies for symptom management.

With regard to the cognitive sequelae of TBI, a recent case study (Taverni et al. 1998) of two patients (ages 21 and 46) suggested that donepezil (an acetylcholine-esterase inhibitor approved for use with patients with AD) may be helpful in reducing memory dysfunction following TBI. Figure 28–4 includes three clock drawings from a 79-year-old patient (with a doctoral-level education) who was started on donepezil and placed in a personal care facility after his fourth known TBI in 3 years. In this patient, who also had a history of lacunar infarctions, the addition of donepezil to his previous medication regimen (which included methylphenidate [Ritalin]) resulted in a generalized improvement in the areas of orientation, attention, short-term memory, and visuospatial capacities.

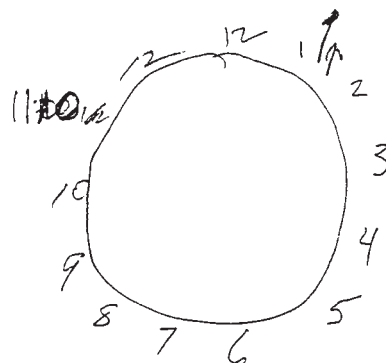

**Psychotherapeutic strategies.** For most of this century, a brain injury was considered to be an exclusionary criterion for psychotherapy. However, a number of authors have now argued convincingly for the role of psychotherapy following TBI (Burke 1995; Cicerone 1991; Cicerone et al. 1996; Lewis 1991; Lewis et al. 1992; Prigatano 1991a; Prigatano and Klonoff 1990). As with pharmacological strategies, this literature has focused on younger patients and lacks well-controlled studies.

In a review of the literature, Starratt and Fields (1991) suggested that two major themes are consistently emphasized by those conducting psychotherapy with patients with brain injury: 1) maintenance of self-identity and self-esteem in the face of loss and 2) the management of anxiety and affect. Attempts to adjust to the emotional dysregulation and to the cognitive, physical, vocational, and interpersonal losses that often accompany TBI are complicated by factors such as embarrassment, guilt, and premorbid attitudes and beliefs about persons with disabilities. The process of therapy, therefore, includes efforts to help patients understand their changed experience of the world, to facilitate the process of mourning over personal and other losses, and to promote adaptation to different types of existence (Lewis et al. 1992).

March 1998

May 1998

July 1998

**FIGURE 28–4.** Serial clock drawings from a 79-year-old patient with four known traumatic brain injuries before (3/98) and after (5/98 and 7/98) starting donepezil and moving to a personal care facility.

Although psychotherapeutic strategies for patients with brain injury range from psychoanalytical to social learning and behavioral, a common denominator has been the need to depart from traditional approaches (Forrest 1992). The importance of this point cannot be overstated, as the demands and process of traditional psychotherapy can make some patients more distressed. Prigatano et al. (1988), for example, warned of increased paranoia among delusional patients with brain injury in “insight-oriented” groups and of behavior modification programs that may be

perceived by patients as overly intrusive or controlling.

Based on the degree to which patients with brain injury are able to tolerate individual therapy sessions, the length, frequency, and location of these sessions may need to be modified. Barth and Boll (1981) suggested a number of such modifications. First, the behavior of patients with brain injury should not necessarily be equated with that of other therapy patients. For example, failure to keep an appointment may reflect a cognitive deficit rather than “avoidance.”

Second, the type(s) of therapy will differ based on the nature and the severity of the injury. Some patients with significant cognitive and memory deficits may have limited awareness of their deficits (Prigatano 1991b) and may become increasingly distressed when confronted with their impairments (e.g., patients with frontal lobe lesions who demonstrate “catastrophic” reactions during challenging neuropsychological testing). Others may be able to identify their deficits but may not have the executive functioning capacities necessary to deal with them in an insight-oriented manner, and, as a result, they may become overwhelmed by this approach. Psychoeducational approaches are often helpful in providing the context for promoting postinjury adjustment, but all approaches should be tailored to the needs and resources of the individual patient. Insight-oriented, interpersonal, supportive, and cognitive approaches may be useful with patients whose relatively mild injuries have resulted in narcissistic injuries, survival guilt, and adjustment disorders. In contrast, behavioral approaches may be more applicable for patients with significant cognitive impairment who display more severe behavioral disruption.

Third, the timing of the intervention is important. Early in the postinjury period, patients may deny or may be unaware of the existence of neuropsychiatric problems and may resist treatment. Fourth, the pace of therapy may need to be slower with more frequent sessions. Finally, the goals for therapy may be different for patients with brain injury. Rather than seeking a complete resolution of conflicts, more appropriate goals may include increasing tolerance for frustration, improving acceptance of deficits, and establishing contingency plans for daily stressors (Starratt and Fields 1991).

Psychotherapy with older adults who have sustained TBIs is similar to psychotherapy with older adults who have experienced other types of physical or cognitive losses (see Chapter 36 in this volume). Like patients with TBIs, some patients who have had strokes or signs of early dementia are distressed by their losses, whereas others have limited awareness of these changes in functioning. Dealing with issues such as loss, mortality, financial concerns, envi-

ronment change, and unresolved personal and family matters is common among older adults in distress. Among those patients who are less distressed, the focus of intervention is typically on the caregiver who may experience both the burden of caregiving and the loss of emotional support from the injured patient. A number of “barriers” exist that limit the use of mental health services by elderly individuals (Gatz et al. 1985). These barriers include those related to the patients themselves (e.g., lack of psychological sophistication and importance of self-reliance), their therapists (e.g., ageist stereotypes, countertransference issues, and economic considerations), and their environments (e.g., travel and accessibility of location).

### **Rehabilitation and family considerations.**

Because of the difficulties inherent in researching the effectiveness of rehabilitation on TBI populations, much controversy and skepticism exist in regard to the benefits of such programs. A number of these criticisms pertain to the lack of a physiological focus, the ambiguity of defining “success,” and the difficulty in monitoring the quality of the programs (Cope 1995). However, evidence of the beneficial effects of rehabilitation is increasing (see Chapter 39 in this volume). For example, studies have demonstrated that early (less than 7 days postinjury) rehabilitation in the acute setting resulted in shorter hospital stays and better functional outcomes. Other studies have demonstrated the effectiveness of outpatient and vocational rehabilitation in increasing employment and productivity, while decreasing emotional distress and the need for supervision (Cope 1995; Eames et al. 1995; Malec and Basford 1996).

With regard to elderly patients with TBI, even less is known about the effect of rehabilitation. Although the conventional wisdom is that the elderly will not benefit as much from traditional rehabilitation methods, little research has been conducted in this area. As Malec and Basford (1996) point out, although many studies report a negative association between age and the outcome of rehabilitation, a majority of these studies do not include elderly patients. Therefore, questions still exist as to the benefits of incorporating such treatment into their medical care.

The treatment of patients with TBIs must also take into account the resources of the patient’s social support network. Involvement with the family may need to include psychoeducational approaches, stress management, and episodic or prolonged grief therapy. Such involvement also needs to take into account the specific neurobehavioral deficits of the patient. For example, patients whose frontotemporal injuries affect their capacity to tolerate frustration, learn new information, and deal with ambiguity may do better if families provide them with highly struc-

tured, predictable, and low-stress environments. In contrast, patients with frontal or right-hemisphere lesions who are anergic and may not perceive, or who misperceive, subtle nuances of verbal and nonverbal communication may do better when family members exaggerate facial expressions and voice quality to increase the likelihood that they are understood accurately. Among elderly patients, intervention strategies such as these become problematic when social support systems are limited in size or capacity (e.g., spouse with dementia).

## Summary

The diagnosis and management of the neurobehavioral consequences of TBI is still a relatively new endeavor. In the absence of clear diagnostic criteria and proven treatment algorithms, clinicians will benefit from an approach that is more comprehensive, open, and flexible and less reductionistic. For some patients, like Phineas Gage, changes in behavior can be explained by a specific acquired lesion. For most patients (like the patient who drew the clocks in Figure 28–4), however, diagnosis, and certainly treatment, is more complicated and needs to take into account multiple factors.

## ■ Traumatic Brain Injury and Alzheimer's Disease

### Findings From Dementia Pugilistica

A potential link between TBI and AD is a logical hypothesis, given the relatively high prevalence of dementia among former boxers who experienced repeated head injuries earlier in life (Corsellis et al. 1973; Roberts 1969; Roberts et al. 1990). Dementia pugilistica (DP), or “punch-drunk” syndrome, can develop late in a boxer's career or several years after retirement. Typically, DP includes parkinsonian-like symptoms such as dysarthria, tremor, ataxia, and bradykinesia as well as general cognitive deterioration and personality change (Roberts 1969). Neuroanatomically, abnormalities of the septum pellucidum, cerebellar scarring, and degeneration of the substantia nigra have been reported (Corsellis et al. 1973). Histopathologically, DP was initially described as including neurofibrillary tangles in the absence of senile neuritic plaques (Corsellis et al. 1973). However, studies (Roberts et al. 1990) have documented that patients with DP have  $\beta$ -amyloid deposits (i.e., plaques) that are comparable to those seen in AD, suggesting that AD and DP may result from similar pathogenetic processes (Allsop et al. 1990; Roberts et al. 1990).

## Epidemiological Studies

The question of whether a single significant head injury in adulthood increases the risk of developing dementia in later life has been posed for some time (e.g., Corsellis and Brierly 1959) but has received increased attention over the past two decades, with somewhat conflicting results. In the majority of studies comparing patients with AD with matched elderly control subjects, TBI was found to be significantly more common in the histories of the patients (Graves et al. 1990; Henderson et al. 1992; Heyman et al. 1984; Mayeux et al. 1993a; Mortimer et al. 1985; O'Meara et al. 1997; Rasmusson et al. 1995; Salib and Hillier 1997; Schofield et al. 1997). Despite methodological differences between studies in areas such as how the TBI or “head injury” was defined, the odds ratio (OR), or estimate of relative risk for AD in patients with a history of TBI, was fairly comparable in several studies (e.g., Graves et al. 1990, OR = 3.5; Mayeux et al. 1993a, OR = 3.7; Mortimer et al. 1985, OR = 4.4). Not surprisingly, other studies have reported greater variability in risk for AD (e.g., Van Duijn et al. 1992, OR = 1.6; Rasmusson et al. 1995, OR = 13.75), and a minority of studies did not find a significant association between a history of TBI and AD (Broe et al. 1990; Chandra et al. 1987; Williams et al. 1991). In their meta-analysis of the literature in this area, Mortimer et al. (1991) pooled data from several studies and concluded that a history of TBI with loss of consciousness was significantly more common in patients with AD than it was in control subjects and that it appeared to be more of a risk factor for men than for women and for sporadic cases of AD than for familial cases. More recent studies have supported the conclusions that the association between TBI and AD is stronger 1) in men (O'Meara et al. 1997; Salib and Hillier 1997), 2) when the length of consciousness is longer (Mayeux et al. 1993a; Schofield et al. 1997), 3) when the patient is older (Mayeux et al. 1993a), and 4) when the injury occurred within 5 years of the onset of symptoms of AD (Mayeux et al. 1993a).

The sporadic versus familial genetic question remains an unresolved one. In one study, Rasmusson et al. (1995) found that although a history of TBI was reported in 29% of their cases with AD and in only 3% of their control subjects, the OR was higher for the sporadic cases of AD (25.4) than it was for the familial cases (8.25). Similarly, O'Meara et al. (1997) found an association between TBI and AD among the men in their sample, but no increased risk for AD among their patients who had a specific genotype that increases risk for AD (i.e., apolipoprotein e-4; see below). Dramatically different conclusions were reached by Mayeux et al. (1995) and Tang et al. (1996), who found that

a history of TBI was associated with increased risk for AD only in the presence of the specific apolipoprotein E e-4 genotype. Increased risk for AD was not associated with a history of TBI in these studies but was increased 10-fold when there was a history of TBI and at least one e-4 allele. Mayeux et al. (1995) concluded that “the biological effects of head injury may increase the risk of AD, but only through a synergistic relationship with apolipoprotein E-4” (p. 555).

### **Role of $\beta$ -Amyloid Deposition in Alzheimer’s Disease and Traumatic Brain Injury**

Deposition of  $\beta$ -amyloid is one of the central pathological events in the neuronal degeneration that occurs in AD (Hardy 1994; Hardy and Allsop 1991) (see Chapter 24 in this volume).  $\beta$ AP deposits are found at the core of the senile plaques that are common in AD and selected other neurodegenerative disorders, and abnormalities in the processing and deposition of  $\beta$ -amyloid have been linked to increased risk for AD (Hardy 1994).  $\beta$ AP is part of a large transmembrane  $\beta$ -amyloid precursor protein ( $\beta$ APP) that is encoded by a gene on chromosome 21 (Kang et al. 1987).  $\beta$ -Amyloid originates in the metabolism of  $\beta$ APP, and soluble  $\beta$ AP accumulates in the brains of patients with AD until it polymerizes into amyloid fibers (Tabaton 1994). Deposition of  $\beta$ AP as the result of this “amyloid cascade” (Hardy and Higgins 1992; Selkoe 1993) produces neuronal degeneration.

The high prevalence of AD and diffuse deposition of  $\beta$ AP in the brains of patients with Down’s syndrome (trisomy 21) (Giaccone et al. 1989) and in patients with mutations of the  $\beta$ APP gene on chromosome 21 (Murrell et al. 1991) provide strong evidence of the critical role that  $\beta$ APP plays in the development of early-onset AD (Hardy 1994). These findings also provide a genetic model of how the apparently lifelong overexpression and metabolism of the  $\beta$ APP may cause AD.

An environmental model of how this process occurs has been proposed based on the findings from patients with DP and young adults who die following severe TBIs. As noted above, the findings of  $\beta$ -amyloid deposits in patients with DP (Roberts et al. 1990) suggest a causative role of repeated brain injuries in producing a dementia that resembles AD neuropathologically. Furthermore, in a study of patients of various ages who died following a severe head injury,  $\beta$ -amyloid deposits were found in 30% of the patients and  $\beta$ APP immunoreactivity was increased in all of the patients examined (Roberts et al. 1991, 1994). Although more common in older adults,  $\beta$ AP deposition in

this study was found in young adults and children as young as 10 years of age. Of relevance to the elderly was the finding that, in addition to increased likelihood of  $\beta$ AP deposition with advancing age, there was an increased likelihood of  $\beta$ AP deposition following an injury sustained in a fall than in any other type of injury.

These findings extended the conclusions based on the patients with DP and suggested that even one significant brain injury can have a significant effect on the process of amyloid deposition and that this process occurs rapidly following brain injury. Although the mechanism by which this process occurs is not yet clear, Roberts et al. (1994) hypothesized that increased expression of  $\beta$ APP may be part of an acute phase response to neuronal injury in the human brain designed to stabilize damaged synaptic membranes, promote synaptic plasticity, and facilitate repair and regeneration. They suggest further that induction of  $\beta$ APP in the brain may be a normal, and possibly protective, response to neuronal injury, which, in susceptible individuals, might initiate a disease process.

### **Role of Apolipoprotein E-4 Allele in Dementia Pugilistica, Alzheimer’s Disease, Traumatic Brain Injury, and Cholinergic Function**

Another apparently critical component in understanding both amyloid deposition specifically and neuronal repair in general is the now well-documented finding that risk for AD has been linked to a specific allele for apolipoprotein E (ApoE) on chromosome 19 (Saunders et al. 1993; Strittmatter et al. 1993) (see Chapter 24 in this volume). ApoE was previously identified as having a role in cholesterol metabolism and, as a result, related to risk for coronary artery disease and stroke (Mahley 1988). Of relevance to AD, ApoE also has been found to bind with high affinity to  $\beta$ -amyloid in the cerebrospinal fluid and to be present in the senile plaques and tangles that are the hallmark of AD (Saunders et al. 1993). One hypothesis is that ApoE contributes to the risk of AD by mediating amyloid deposition (Rebeck et al. 1993; Schmechel et al. 1993) via genetic variability of the ApoE allele, which has three common variants: e-2, e-3, and e-4. The e-3 allele is most common and accounts for approximately 78% of the ApoE alleles in American and European whites (vs. 15% for the e-4 allele and 7% for the e-2 allele) (Utermann et al. 1980). It now appears that the presence of the e-4 allele increases the risk for AD (Brousseau et al. 1994; Corder et al. 1993; Mayeux et al. 1993b; Myers et al. 1996; Poirier et al. 1993; Saunders et al. 1993; Strittmatter et al. 1993), whereas the presence of the e-2 allele may be protective against AD (Corder et al. 1993;

Myers et al. 1996; Talbot 1994). In one study (Mayeux et al. 1993b), for example, the OR for AD for older adults who were homozygous for the e-4 allele (i.e., two e-4 alleles) was 17.9 and the OR for those who were heterozygous (i.e., one e-4 allele and one other allele) was 4.2 compared with that in older adults with other ApoE alleles.

The role that ApoE plays following nervous system injury is not well understood. Following peripheral nervous system injury, it has been reported that ApoE levels increase 250-fold (Boyles et al. 1990), possibly to increase cholesterol acquisition by the regenerating nerve (Rubinsztein 1995). A similar process has been postulated for central nervous system injury (Mahley 1988) and has received significant support from the animal literature. An animal model of ApoE deficiency was developed via ApoE-targeted genetic disruption and recombination of embryonic stem cells (Thomas and Capecchi 1987). Initial studies of ApoE-deficient mice revealed specific impairments in behavioral (e.g., working memory) and neurochemical (e.g., reduced cortical and hippocampal choline acetyltransferase activity) functioning. Recently, the role of ApoE mediation in neuronal repair following experimentally induced TBI (i.e., via weight drop) was investigated (Chen et al. 1997). In this study, ApoE-deficient and control mice were compared on measures of susceptibility to injury, rate and extent of recovery from injury, degree of cognitive and neurological dysfunction, and histopathological changes in the hippocampus. Overall, the results suggested a clear role for ApoE in mediating neuronal repair and behavioral recovery following TBI. Specifically, although the initial effects of the TBI were equivalent among the two groups, the ApoE-deficient mice displayed: 1) greater cognitive and motor impairment, 2) markedly impaired learning, and 3) greater neuronal death of CA3 hippocampal cells relative to the control mice. The authors concluded that the increased vulnerability for negative consequences following TBI among ApoE-deficient mice appeared to be the result of defects in ApoE-dependent neuronal repair mechanisms.

In humans, a role for ApoE in neuronal repair and remodeling after neuronal injury has been suggested, wherein the apolipoprotein E e-3 genotype is more effective in promoting neuronal repair than is the e-4 genotype (Weisgraber and Mahley 1996). This hypothesis has received support from two recent studies. Jordan et al. (1997) reported an association between ApoE genotype and degree of chronic neurological deficits in boxers. Specifically, while "low-exposure" boxers had less severe neurological deficits regardless of ApoE status, the severity of neurological deficits among "high-exposure" boxers was significantly worse among those with the ApoE e-4 allele. Simi-

larly, Teasdale et al. (1997) found that negative outcome (e.g., death, vegetative state, or severe disability) 6 months following TBI was significantly worse among patients with an ApoE e-4 allele (57%) than among patients without an ApoE e-4 allele (27%). A limitation of this study was that 64% of the ApoE e-4 sample had moderate-to-severe injuries (GCS = 3–12), whereas only 34% of the non-ApoE e-4 sample had moderate-to-severe injuries. The authors pointed out, however, that the association between ApoE status and outcome remained significant even when adjustments were made to control for age, GCS, and CT findings.

## Summary

Recent studies have suggested a link between TBI in adulthood and the development of AD in later life. Although more prospective longitudinal studies of this proposed association are needed, the available data are intriguing and provide a conceptual model for considering TBI as one piece of the pathogenetic puzzle of AD. In this model, a TBI at any age (but apparently more so in older men with less capacity for neuronal repair) can set into motion a response that may be protective at the time of the injury but that, for some patients, may lay the foundation for the beginning of AD. More research is needed to determine whether this occurs in a manner in which the TBI per se is an environmental risk factor for AD and therefore is more common in sporadic cases (as suggested by Rasmusson et al. 1995); interacts synergistically with a genetic predisposition (e.g., ApoE e-4), and therefore is more common in genetically vulnerable individuals (as suggested by Mayeux et al. 1993 and Tang et al. 1996), or occurs via some other mechanism. The results of such studies may tell us a great deal about the pathophysiology of both TBI and AD.

## Final Summary

Epidemiological studies consistently document that geriatric TBI in the elderly is a relatively common phenomenon with several unique features. Compared to TBI among young adults, the occurrence of geriatric TBI is associated with differences in gender distribution, mechanism of injury, history of TBI, role of alcohol, and severity of injuries. Although older adults are, as a group, more likely to experience negative outcome, not all elderly are at greater risk for negative outcome. Determining the role that age plays in mediating outcome requires an awareness of factors such as preexisting impairment, type of injury, and the severity of other (i.e., nonbrain) injuries.

The neuropsychiatric assessment and treatment of geriatric TBI in the elderly is in its infancy. There is preliminary evidence that the syndrome of geriatric TBI can be distinguished from normal aging and from dementia based on neuropsychological test performance and that neuropsychiatric recovery following TBI may take longer among older adults. The limited data on the neuropsychological effects of TBI in the elderly suggest that these effects are similar to the effects on younger adults following TBI; however, studies on the long-term neuropsychological effects of TBI among older adults do not exist. With regard to neuropsychiatric treatment, until better diagnostic criteria and treatment algorithms are established, clinicians may benefit from following principles such as 1) monitoring for specific age-related problems (e.g., subdural bleeds), 2) monitoring for increased sensitivity to medication side effects, 3) looking for possible altered responsiveness to treatment, 4) reducing seizure threshold, and 5) considering nontraditional pharmacological and psychotherapeutic strategies.

Finally, the proposed link between TBI and AD may lead to a better understanding of the pathogenesis of both TBI and AD. The hypothesis that TBI increases the risk for AD via early deposition of the  $\beta$ AP among individuals with deficient neuronal repair mechanisms is becoming more credible; however, additional work is needed to determine if this or some other hypothesis will provide the most convincing explanation of the available data.

# Epilepsy

Mario F. Mendez, M.D., Ph.D.

Epilepsy is associated with a variety of behavioral conditions that may be especially severe in elderly patients (Table 29–1). Seizure disorders can have psychosocial consequences, neuropsychological effects, seizure-related behavioral manifestations, and medication-induced behavioral changes. Moreover, throughout much of recorded history, patients with epilepsy have been considered to be prone to psychopathology during their seizure-free periods (Kraepelin 1923). In modern times, the belief in a universal epileptic predisposition to psychopathology has declined in favor of a specific predisposition of patients with temporal lobe epilepsy (TLE) to psychosis, depression, and other psychopathology (Gibbs et al. 1948). Although not systematically studied in the elderly population, this psychopathology can persist in later years. In this chapter, I explore the behavioral aspects of epilepsy that might affect elderly patients and conclude with a discussion of management issues.

## ■ Demography and Definitions

Seizures result from abnormal neuronal discharges in the brain. They are sudden, involuntary behavioral events caused by excessive or hypersynchronous electrical dis-

charges, often from hyperexcitable neurons. Seizures can be primary, secondary to a brain lesion, or symptomatic from acute, situational conditions such as sleep deprivation or drug withdrawal. The term *epilepsy* refers specifically to recurrent unprovoked seizures and includes primary and secondary epileptic seizures, but excludes symptomatic ones. The International Classification of Epileptic Seizures (Commission on Classification and Terminology of the International League Against Epilepsy 1981) further divides epileptic seizures into generalized (characterized by an initial widespread bihemispheric involvement) and partial (characterized by an initial focal onset in part of one hemisphere) (Table 29–2).

Epilepsy is a common neurological disorder. It affects up to 2 million people in the United States, has prevalence rates of 5–8 per 1,000, and has an overall annual incidence of about 30–50/100,000 person-years (Annegers 1997). The incidence of new-onset epilepsy is highest in the first year, drops to a minimum in individuals in their 30s through 50s, and increases again in those over age 60 to an annual incidence of 77–92/100,000 (Annegers 1997; Hauser 1992). Although two-thirds of epilepsy in young adults is idiopathic, more than half of elderly patients with epilepsy have a known cause (Hauser 1992). In those over age 65, about one-third have a cerebrovascular etiology for their seizures, approximately 10%–15% have brain tu-

**TABLE 29-1. Behavioral disorders in epilepsy****Psychosocial**

- Low self-esteem, dependency, helplessness
- Fear of loss of control
- Stigmatization

- Associated marital, job, transportation, and related problems

**Neuropsychological**

- From seizures
- From underlying lesions/disease
- From antiepileptic drugs (AEDs)

**Ictally related**

- Prodromal symptoms: dysphoria, apprehension, etc.
- Ictal automatisms and psychic symptoms
- Nonconvulsive status: simple partial seizures, complex partial seizures, absence, and periodic lateralizing epileptiform discharges
- Postictal confusion and other postictal behaviors
- Ictal/postictal intermixed behaviors: twilight states, etc.
- Psychotic episodes related to the ictus

**Interictal**

- Chronic schizophrenic psychosis
- Depression
- Suicide
- “Heightened significance” and other personality changes
- Miscellaneous: hyposexuality, aggression, dissociative states, etc.

mors, and up to 23% have infections, trauma, or other secondary lesions (Luhdorf et al. 1986; Sanders and Murray 1991). Furthermore, in a study of elderly people with unexplained seizures, small vascular changes occurred more commonly in those with epilepsy than in nonepileptic control subjects (Shorvon et al. 1984).

## ■ Clinical Aspects of Epilepsy

In adults, the three most common types of seizures are 1) generalized tonic-clonic seizures (GTCSs), with convulsions (also known as *grand mal seizures*); 2) complex partial seizures (CPSs), with an alteration of consciousness; and 3) simple partial seizures (SPSs), with isolated motor, somatosensory, autonomic, or psychic symptoms (Table 29-2). SPSs that evolve to CPSs are considered *auras*, and CPSs that evolve to GTCSs are *secondarily generalized*. Al-

**TABLE 29-2. The International Classification of Epileptic Seizures**

- I. Partial (focal, local) seizures
  - A. Simple partial seizures (SPSs)
    - Motor, somatosensory, autonomic, or psychic symptoms
  - B. Complex partial seizures (CPSs)
    1. Begin with symptoms of simple partial seizure but progress to impairment of consciousness
    2. Begin with impairment of consciousness
  - C. Partial seizures with secondary generalization
    1. Begin with simple partial seizure
    2. Begin with complex partial seizure (including those with symptoms of simple partial seizures at onset)
- II. Generalized seizures (convulsive or nonconvulsive)
  - A. Absence (typical and atypical)
  - B. Myoclonus
  - C. Clonic
  - D. Tonic
  - E. Tonic-clonic (GTCSs)
  - F. Atonic/akinetic
- III. Unclassified

*Source.* Adapted from Commission on Classification and Terminology of the International League Against Epilepsy 1981.

though about one-third of all patients with epilepsy have CPSs, about one-half of elderly patients with epilepsy have CPSs, reflecting the increased specific focal causes of their epilepsy (Hauser 1992). On electroencephalography (EEG), these seizure disorders may have interictal spikes and other markers of abnormal electrical activity, most commonly emanating from a temporal lobe. In addition, variants of childhood absence (*petit mal*) seizures, which result in brief lapses of consciousness, occur occasionally in elderly patients.

The evaluation of new-onset seizures in the elderly includes the identification of cerebrovascular, neoplastic, and other acquired neuropathology; the exclusion of acute, symptomatic seizures; and the characterization of any epileptiform discharges. These patients need neuroimaging of the brain, preferably magnetic resonance imaging with its superior resolution for most parenchymal lesions. Routine X-ray and laboratory studies help exclude the presence of symptomatic seizures. In addition, a lumbar puncture is indicated in the presence of a persistent alteration of consciousness, especially if accompanied by fever and meningeal signs. EEGs are more likely to define the type of epileptiform changes if the patient attains

drowsiness or sleep during the tracing. However, computerized EEG techniques, which may help in mapping a structural lesion, are not very useful for evaluating these discharges.

Epileptic seizures must be differentiated from syncope and from nonepileptic seizures. Patients with brief lapses of consciousness but without typical ictal features or postictal confusion usually have syncope from a cardiovascular, toxic-metabolic, or cerebrovascular cause; however, these lapses could be atypical seizures, particularly if they are of frontal lobe origin. Some elderly patients may have syncope-like ictal events such as brief periods of amnesia or falling episodes (Godfrey 1989). Nonepileptic seizures, or pseudoseizures, are the most frequent conversion reaction among patients with seizures. Patients with nonepileptic seizures are most commonly young women with psychological stressors and poor coping skills, but nonepileptic seizures may occur in elderly patients. Nonepileptic seizures are characterized by a sudden collapse or by motor activity that does not fit a typical CPS or GTCS, ictal durations of two or more minutes, occurrence in the presence of a witness, possible induction with injections or suggestion, poor responsiveness to antiepileptic drugs (AEDs), and lack of a seizure-induced rise in serum prolactin levels (Kuyk et al. 1997; Lesser 1996).

The neuropsychiatric aspects of epilepsy include four categories: psychosocial, neuropsychological, ictally related behavioral alterations, and interictal psychopathology (Table 29–1). Psychosocial aspects are those directly the result of the stress of having a seizure disorder, and neuropsychological aspects refer to persistent disturbances in cognitive abilities. Temporary behavior changes also occur either before, during, or after a seizure as a direct result of ictal or seizure discharges. A final group of behaviors manifest as sustained psychopathology during the interictal or seizure-free period. Although these categories overlap and some behaviors are eventually reclassified as underlying mechanisms are identified, these categories are useful for discussing the neuropsychiatric aspects of epilepsy (D. B. Smith et al. 1991).

## ■ Psychosocial Impact of Seizures

The presence of a seizure disorder in later life has important psychosocial implications (Table 29–1). Epilepsy is associated with low self-esteem, a sense of decreased control and self-efficacy, and the perception of being stigmatized (Collings 1994; Tedman et al. 1995). Patients with epilepsy are subject to low self-esteem particularly arising from the greater dependency that the disorder engenders.

Self-esteem problems can be greater in elderly individuals, who already may be heavily reliant on family and others. The possibility of having a seizure at any time results in feelings of loss of control (Hermann and Wyler 1989). Elderly subjects tend to be cautious and conservative, and the potential for public loss of control can be particularly distressing. In addition to an overall increased sense of vulnerability is a very real fear of falling and sustaining incapacitating hip fractures or other trauma. There also is continued stigmatization from the disorder, and people often misunderstand and fear those with epilepsy. This can lead to housing problems; some nursing homes do not accept elderly patients with seizures.

The independence of elderly patients may already be impaired or tenuous, and epilepsy further narrows their ability to function independently (Luhdorf et al. 1986). Seizures may critically compromise the function of the elderly individuals who are still able to keep a job, provide their own transportation, maintain their economic status, and perform other independent activities. Although seizures by themselves rarely result in institutionalization, in an already impaired elder, seizures may be the final condition that terminates independent living. In addition, given the higher frequency of secondary epilepsy in the elderly, older patients are often already disabled from underlying neurological disorders such as stroke or dementia.

## ■ Neuropsychological Impact of Seizures

Neuropsychological functions are vulnerable to the effects of seizures. Prolonged seizures can result in metabolic and direct electrical injury to the brain. By age 70, significant loss of neuronal tissue has occurred, as well as a decline in cognitive efficiency, particularly on time-dependent tasks and in memory retrieval (Botwinick 1981). With this decreased neuronal reserve, elderly patients have a greater neuropsychological decline from neuronal damage as a result of ongoing seizure activity than do younger patients. For this reason alone, seizure duration and rate of recurrence of seizures are important clinical variables in the elderly.

In older patients with secondary epilepsy, seizures are often associated with disorders that impair cognition. Seizures can temporarily exacerbate stroke- or tumor-related deficits such as aphasias (Godfrey 1989). Furthermore, seizures occur in dementing disorders including Alzheimer's disease, vascular dementia, frontotemporal dementia, and other neurodegenerative disorders (McAreavey et al.

1992). Alzheimer's disease, the most prevalent dementia, may have seizures (usually GTCSs) in 10%–20% of patients, particularly late in the course (Mendez et al. 1994; Romanelli et al. 1990).

Although most seizures can be controlled with AEDs, these medications have potential neuropsychological side effects. Elderly patients have a slowed elimination of these drugs, require lower doses, are often on multiple interacting medications, and are, therefore, more likely to experience AED toxicity (Leppik 1992). With the already significant susceptibility to confusional states of the aged brain, the addition of AEDs greatly adds to the possibility of drug-induced delirium. Even at therapeutic levels, some drugs can cause specific problems. For example, barbiturates may need discontinuation because of drug-induced depression, suicidal ideation, sedation, psychomotor slowing, and paradoxical hyperactivity. The added susceptibility for AED-induced toxicity in elderly patients indicates the need for closer monitoring, especially of AED serum levels such as free phenytoin or carbamazepine epoxide levels, renal and liver function test values, and AED-induced hyponatremia.

## ■ Ictally Related Behavioral Alterations

Ictally related behavioral alterations occur immediately before, during, and soon after seizures (Table 29–1). First, a prodrome of dysphoria, insomnia, anxiety, or buildup of tension may precede seizures or be relieved by them. Second, ictal discharges can produce both reactive automatisms involving semipurposeful activity and psychic manifestations producing affective, cognitive, language, memory, and perceptual changes. Examples of automatisms include ictal laughter from left-hemisphere discharges and ictal crying from right-hemisphere discharges (Dark et al. 1996). Examples of psychic manifestations include affective changes such as ictal fear and depression and cognitive changes such as derealization and depersonalization. Even a recurrent, uninvited thought can be a seizure manifestation (Mendez et al. 1996a). Moreover, prolonged alterations of responsiveness may result from non-convulsive status epilepticus or from recurrent electrical discharges with EEG complexes known as *periodic lateralizing epileptiform discharges* (PLEDs) (Engel et al. 1978). Third, the postictal period includes a confusional state lasting minutes to hours or, occasionally, days. The postictal period can be particularly prolonged in elderly patients, who may take longer to recover from the disruption of seizures (Godfrey 1989). Although semidirected ictally related aggression is extremely rare, nondirected de-

structive behavior frequently occurs during the postictal confusional state as a response to attempts at restraint (Treiman 1991). Finally, occasional protracted periods with intermixed ictal and postictal changes can produce twilight states; compulsive wandering, or poriomania; an agitated state; and depressive delirium (Betts 1981).

One final class of ictally related behavioral manifestations is comprised of brief psychotic episodes, which usually follow a flurry of seizures, but may occasionally alternate with seizures (Devinsky et al. 1995; Kanemoto et al. 1996; Sachdev 1998). These episodes involve days to weeks of agitated, hallucinatory, paranoid, and impulsive behaviors often with sudden mood swings and suicide attempts. Most patients develop their psychotic episodes 12–48 hours after a flurry of seizures and may occasionally continue to display psychotic symptoms for an extended period of time. Another group develops psychotic episodes after seizures are controlled, and this “alternating psychosis” promptly resolves once the seizures recur (Pakalnis et al. 1987). *Forced (or paradoxical) normalization* refers to this subgroup with an antagonism between psychotic episodes and the seizures or EEG discharges (Landolt 1958).

## ■ Interictal Psychopathology

Patients with epilepsy are susceptible to psychopathology during the seizure-free periods (Table 29–1). These behavioral disorders usually occur in patients with longstanding, incompletely controlled seizures, and, although not specifically studied in the elderly, these disorders can occur in older patients. Community epidemiological studies have shown a high prevalence of interictal psychiatric problems among patients with epilepsy (Gudmundsson 1966; Pond and Bidwell 1959/1960). The percentage of patients with epilepsy in psychiatric hospitals has ranged from 5% to 10%, significantly higher than the prevalence of epilepsy in the general population (Betts 1981; Mendez et al. 1986). Of patients attending epilepsy clinics, about 30% have had a prior psychiatric hospitalization (Stevens 1975), and about 18% were on at least one psychotropic drug (Wilensky et al. 1981). Studies report more psychopathology among patients with epilepsy than among control subjects with other neurological disorders (Mendez et al. 1993a, 1993d). Moreover, patients with epilepsy with CPSs of temporolimbic origin, particularly in the presence of psychic auras, may have a greater predisposition to psychopathology than other patients with epilepsy (Mendez et al. 1996b). In summary, although most patients with epilepsy do not have psychiatric disease, about one-quarter of patients with epilepsy, particularly those with long-

standing CPSs and auras, have interictal psychosis, depression, suicidality, hyposexuality, and other psychopathology.

## Interictal Psychosis

The best-known psychiatric disorder in epilepsy is the chronic “schizophreniform” psychosis (Sachdev 1998; Trimble 1991). The influential study by Slater and Beard (1963) reported 69 patients with both epilepsy and an interictal schizophrenic disorder and concluded that these two disorders occurred together more frequently than expected by chance. Although some investigators have interpreted this association as reflecting selective sampling (Stevens 1991), most subsequent studies indicate that 7%–12% of patients with epilepsy develop a psychotic disorder, usually a chronic, interictal schizophrenic illness (Trimble 1991). For example, in a controlled investigation of 1,611 outpatients with epilepsy, interictal schizophrenic disorders were 9–10 times more common among patients with epilepsy than among control subjects with other neurological disorders (Mendez et al. 1993d). Moreover, on the Minnesota Multiphasic Personality Inventory (MMPI), patients with epilepsy had more elevated schizophrenia and paranoia scale scores than did patients with other neurological disabilities (Dikmen et al. 1983).

The schizophrenic disorder may be especially associated with CPSs. One study found psychosis in 12% of 1,675 patients with CPSs of TLE origin, especially those with left-sided foci, compared with less than 1% of 6,671 patients with generalized epilepsy (Gibbs 1951), and a psychotic illness occurred in 9 (10%) of 87 children with TLE epilepsy followed for up to 30 years (Lindsay et al. 1979). In conclusion, patients with epilepsy have a severalfold greater risk for a chronic schizophrenic illness than does the general population, and the risk is particularly high for patients with CPSs, regardless of age.

Unlike ictally related psychotic episodes, the chronic interictal schizophrenic disorder has no direct relationship to individual seizures (Mendez et al. 1993d; Trimble 1991). Although the exact relationship of seizure activity and schizophrenia is debated (Sachdev 1998), these patients often have an 11- to 15-year history of poorly controlled seizures (Slater and Beard 1963). Furthermore, the schizophrenic symptoms commonly increase with increased CPS activity or with AED withdrawal (Mendez et al. 1993d) (Figure 29-1). Although removal of the seizure focus does not prevent the development of psychosis (Manchanda et al. 1996), left temporal mediobasal lesions are particularly associated with this psychotic disorder (Sherwin et al. 1982).

**FIGURE 29-1.** Correspondence of psychotic symptoms to seizure frequency. *Increased psychotic symptoms:* Total schizophrenic epilepsy group ( $n = 149$ ): increased seizures in 42 and decreased seizures in 2 ( $\chi^2 = 40.56$ ,  $df = 1$ ,  $P < .001$ ). Matched schizophrenic epilepsy group ( $n = 62$ ): increased seizures in 24 and decreased seizures in 1 ( $\chi^2 = 24.25$ ,  $df = 1$ ,  $P < .001$ ). *Decreased psychotic symptoms:* Total group: increased seizures in 9 and decreased seizures in 0 ( $\chi^2 = 7.33$ ,  $df = 1$ ,  $P < .007$ ). Matched group: increased seizures in 8 and decreased seizures in 0 ( $\chi^2 = 6.55$ ,  $df = 1$ ,  $P < .011$ ).

*Source.* Reprinted with permission from Mendez MF, Grau R, Doss RC, et al.: “Schizophrenia in Epilepsy: Seizure and Psychosis Variables.” *Neurology* 43:1073–1077, 1993d.

The schizophrenic disorder resembles an episodic schizoaffective psychosis with prominent paranoia, positive symptoms, relatively preserved affect, and normal premorbid personality (Perez and Trimble 1980; Slater and Beard 1963; Trimble 1991). Compared with idiopathic schizophrenia, there may be more hallucinations and religiosity and less social withdrawal, systematized delusions, schneiderian first-rank symptoms, and family history of schizophrenia. However, these features are not clearly atypical or unique, and most schizophrenic syndromes in epilepsy can correspond to typical schizophrenic disorder categories (Mendez et al. 1993d).

## Depression

Less well-known than the interictal psychosis is the problem of depression in epilepsy. Depression is undoubtedly a frequent neuropsychiatric disturbance in older patients with seizures. Depression occurs in up to 75% of patients in mixed epilepsy groups (Standage and Fenton 1975), and

there are elevations in depressive traits in patients with epilepsy compared with those in control subjects (Robertson 1991). Depression is also the main reason for the psychiatric hospitalization of patients with epilepsy (Betts 1981; Mendez et al. 1986). Furthermore, most investigations report a twofold greater frequency of interictal depression among patients with seizures than among comparably disabled individuals (Kogeorgos et al. 1982; Mendez et al. 1986; Rodin and Schmaltz 1984; Standage and Fenton 1975). Depression is particularly prevalent among those with CPSs and ranges from 19% to 65% among patients with CPSs (Currie et al. 1971; Dongier 1959/1960; Roy 1979; Victoroff et al. 1994).

Patients with depression with epilepsy most commonly have a chronic interictal depression or dysthymia that is distinct from ictal depression (Devinsky and Bear 1991; Robertson et al. 1994). This interictal depression frequently has endogenous features, paranoia, and other symptoms suggesting a continuum with schizoaffective disorder (Mendez et al. 1986). According to most investigators, seizures relieve depression in patients with epilepsy (similar to the effects of electroconvulsive therapy [ECT]), whereas better seizure control or decreased secondarily generalized seizures make it worse (Mendez et al. 1993a; Robertson 1991). A few investigators have also reported depression with increased seizure activity or no relationship (Dodrill and Batzel 1986; Roy 1979). Depression is specifically associated with CPSs from left-sided temporal foci, suggesting neurobiologically based organic mood disorder rather than a nonspecific psychosocial reaction to a chronic disability (Altshuler et al. 1990; Mendez et al. 1986; Perini and Mendius 1984; Victoroff et al. 1994). Conversely, most studies have not confirmed the proposed association of right-hemisphere foci with the much rarer cases of mania found in epilepsy (Flor-Henry 1969).

## Suicide

Elderly individuals with epilepsy are at greater risk for suicide than those without epilepsy. Among all patients with epilepsy, the estimated risk of death by suicide is 3%–22% or 4–5 times higher than that for the general population (Mathews and Barabas 1981). Among those with CPSs of TLE origin, the risk of suicide is as much as 25 times greater (Barraclough 1981). Furthermore, as many as one-third of all patients with epilepsy have attempted suicide at some point in time. A comparison of suicide attempts among patients with epilepsy and comparably impaired control subjects without epilepsy revealed suicide attempts in 30% of the subjects with epilepsy compared with only 7% of the control subjects (Mendez et al. 1986),

and this increased risk of suicide continued even long after temporal lobectomy and successful control of seizures (Jensen 1975).

Patients with epilepsy are likely to attempt suicide not only from psychosocial stress, but also because of the increased interictal psychopathology such as depression, psychosis, and borderline personality characteristics (Mendez et al. 1989). They are most likely to complete suicide when they have psychosis with paranoid hallucinations, agitated compunction to kill themselves, and occasional ictal command hallucinations to commit suicide (Mendez and Doss 1992). Ictal depression also has resulted in successful suicide attempts (Mendez and Doss 1992).

## Personality Characteristics

Patients with epilepsy have a high prevalence of personality disorders (Mendez et al. 1993c; Perini et al. 1996; Swanson et al. 1995). Patients with epilepsy with personality disorders show dependent and avoidant personality traits. Those with epilepsy are stigmatized, feared, and subject to difficulties in obtaining a job, driving an automobile, and maintaining a marriage. These psychosocial difficulties along with underlying neurobiological factors may predispose patients with epilepsy to personality disorders.

Although no specific epileptic personality exists, a group of traits termed the Gastaut-Geschwind syndrome occur in a subset of patients with CPSs. Because most studies with the MMPI proved insensitive to the personality traits attributed to epilepsy, the Bear-Fedio Inventory was developed to assess these traits (Bear and Fedio 1977). Bear and Fedio found that patients with CPSs of TLE origin had a personality characterized by a sense of “heightened significance” indicated by sobriety and humorlessness, tenaciousness or “viscosity” in interpersonal encounters, a deepened affect, a pronounced sense of personal destiny, and an intense interest in religious, moral, and philosophical issues. Such patients are circumstantial, give overly detailed background information, and write copiously about their thoughts and feelings (Rao et al. 1992). In addition, patients with left-sided temporal foci tended to maximize their problems, whereas those with right-sided foci minimized them (Bear and Fedio 1977). Conclusive proof that patients with CPSs are prone to the Gastaut-Geschwind syndrome has remained illusive. Other applications of the Bear-Fedio Inventory found the same “personality” characteristics in patients without epilepsy who had psychiatric disorders or comparable physical disabilities (Rodin and Schmaltz 1984). Some patients with CPSs of TLE origin are explosive and dyscontrolled with emotional lability and poor impulse control (Blumer 1991).

## Hyposexuality and Other Behavioral Disorders

Surveys suggest that incompletely treated patients with epilepsy experience hyposexuality (Toone 1987), a problem that can still affect elderly patients. Both men and women experience disturbances of sexual arousal and a lowered sexual drive (Morrell and Guldner 1996; Murialdo et al. 1995). Patients with epilepsy appear to lack libido and may experience impotence or frigidity. This hyposexuality improves after seizures are controlled (Toone 1987). Other patients with epilepsy experience physiological signs of decreased sexual arousal and possible subclinical hypogonadotropic hypogonadism (Murialdo et al. 1995).

The association of epilepsy with other conditions is less certain. Most directed aggression in epilepsy correlates less with seizures than with psychosis, “episodic dyscontrol” (intermittent explosive disorder with ictal-like features), subnormal intelligence, lower socioeconomic status, prior head injuries, and possible orbital frontal damage (Herzberg and Fenwick 1988; Mendez et al. 1993b). Case reports describe dissociative states in epilepsy (i.e., multiple personality disorder, possession and fugue states, and psychogenic amnesia) (Ahern et al. 1993); however, the relationship with epilepsy is not clear.

## Etiology and Pathology

Although the mechanisms of psychopathology are not established, current theories of the psychopathology of epilepsy emphasize a physiological disturbance in the temporal limbic system rather than psychodynamic processes. As previously described, psychosis, depression, personality disorders, and hyposexuality are two to three times more common in patients with CPSs (most of whom have a temporal lobe focus) compared with patients with GTCSs. The most common pathological findings in patients with epilepsy are mediobasal temporal lobe lesions involving limbic structures. Stimulation and ablation studies in animals and humans link these temporal limbic structures to emotional behavior. Psychotic-like behavior in animal subjects has followed repeated application of epileptic agents to *kindle* limbic structures (Adamec 1990; P. F. Smith and Darlington 1996), patients with schizophrenia have had limbic discharges on depth electrode monitoring (Heath 1982), and disinhibition of the mesolimbic dopamine system has resulted from kindling in the limbic system (Stevens and Livermore 1978).

Several specific mechanisms are potentially responsible for psychiatric disturbances in epilepsy (Table 29–3). First, the underlying brain lesions could be the source of

both seizures and behavioral changes. Psychosis may be more common with left temporal lobe pathology such as hamartomas or gangliogliomas (Taylor 1972), and depression is associated with strokes and other hypoactive lesions in the left hemisphere (Robinson and Szetela 1981). Second, ictal discharges could kindle behavioral changes by facilitating limbic-sensory associations and other neuronal connections. The schizophrenic psychosis is associated with increased frequencies of CPSs, and personality disorders may occur in those with auras (Mendez et al. 1993c). Third, decreased function, such as the focal interictal hypometabolism observed on positron-emission tomography (PET) (Bromfield et al. 1992), may lead to interictal behavioral changes. Depression often follows seizure control sufficient to inhibit secondary generalization to GTCSs (i.e., the surrounding hypometabolism may result in depression by preventing the spread of temporal limbic epileptic foci). Fourth, seizures may result in neuroendocrine or neurotransmitter changes including increased dopaminergic or inhibitory transmitters, decreased prolactin, increased testosterone, and increased endogenous opioids. These changes probably explain, at least in part, the hyposexuality found in some patients with

**TABLE 29–3. Proposed relationships of psychiatric disturbances to epilepsy**

Common neuropathology, genetics, or developmental disturbance
Ictal or subictal discharges potentiating abnormal behavior
Kindling or facilitation of a distributed neuronal matrix
Changes in spike frequency or inhibitory-excitatory balance
Altered receptor sensitivity (e.g., dopamine receptors)
Secondary epileptogenesis
Absence of function at the seizure focus
Inhibition and hypometabolism surrounding the focus
Release or abnormal activity of remaining neurons
Dysfunction or downregulation of associated areas
Neurochemical alterations
Dopamine and other neurotransmitters
Endorphins
Gonadotrophins and other neuroendocrinological changes
Psychodynamic influences
Dependence, learned helplessness, low self-esteem
Disruption of reality testing
Weakening of defense mechanisms
Organic and psychodynamic factors potentiating each other
Sleep disturbance
Drug-induced neurophysiological changes

epilepsy. Finally, physiological factors may be potentiated by psychodynamic factors. For example, a proposed role for auras in personality disorders or psychosis may relate to their impact on reality testing (Mendez et al. 1993c).

## Treatment

Most epileptic seizures respond to AEDs. Phenytoin, carbamazepine, and valproate are primary drugs for partial seizures and GTCSs, the main seizures of adulthood (Table 29–4). Side effects and elimination half-lives are important considerations in choosing among AEDs. Monitoring of blood levels helps avoid dose-dependent side effects, but clinical monitoring of patients for idiosyncratic side effects is also necessary. The more sedating AEDs are considered secondary drugs in the management of seizures.

Another important property of AEDs is the time it takes for their serum concentrations to be reduced by half. For example, one may choose to use phenytoin over carbamazepine because it has a consistently longer half-life and can be potentially given once per day. The use of multiple AEDs affects efficacy, side effects, and half-lives; therefore, it is preferable to treat seizures with one AED rather than with several. For those patients who do not respond to

the primary AEDs, several newer drugs (e.g., gabapentin, lamotrigine, tiagabine, topiramate, vigabatrin) are available. Ultimately, when drug therapy fails to control seizures, patients may be considered for epilepsy surgery.

In the treatment of patients with epilepsy who are psychiatrically disturbed, a first consideration is the use of psychoactive AEDs (Pollack and Scott 1997) (Table 29–5). These medications may relieve some behavioral symptoms either through direct psychotropic properties or through their effects on seizure control (Post et al. 1985). The psychotropic properties of AEDs are particularly important in the management of depression (Robertson and Trimble 1985). If possible, discontinue phenobarbital and other barbiturates, which may promote depression in elderly patients, and use carbamazepine, valproate, or lamotrigine, which stabilize mood and provide prophylaxis against recurrent depressive episodes. Carbamazepine, valproate, gabapentin, and lamotrigine have significant antimanic properties, probably through mood stabilization effects. Carbamazepine, valproate, and gabapentin may also ameliorate some dyscontrolled, aggressive behavior in patients with brain injury. Clonazepam (Klonopin), in addition to its anxiolytic properties, can serve as a supplement to other antimanic therapies. Gabapentin also decreases anxiety and improves general well-being in some

**TABLE 29–4. Antiepileptic drugs (AEDs)**

AEDs (trade name)	Indications	Half-life (hours)	Therapeutic level (mg/L)	Usual adult dose (mg/day)	Dosing regimens
<b>Primary drugs</b>					
Phenytoin (Dilantin)	CPS, SPS, GTCS	10–34	10–20	300–500	bid–qd
Carbamazepine (Tegretol, Epitol)	CPS, SPS, GTCS	11–32	4–12	600–1200	tid
Valproic acid (Depakene), divalproex sodium (Depakote)	CPS, SPS, GTCS absence, atonic myoclonic	5–20	40–50	1000–3000	tid–qid bid (Depakote only)
Ethosuximide (Zarontin)	Absence	30–60	40–100	1000–2000	tid–qid
<b>Secondary drugs</b>					
Gabapentin (Neurontin)	CPS, SPS, 2 GTCS	4–7	2–20	900–3600	tid
Lamotrigine (Lamictal)	CPS, SPS, 2 GTCS	15–24	2–20	75–600	bid
Topiramate (Topamax)	CPS, SPS, 2 GTCS	12–30	NE	200–400	bid
Tiagabine <sup>a</sup> (Gabitril)	CPS, SPS, 2 GTCS	6–8	NE	32–56	bid
Vigabatrin <sup>a</sup> (Sabril)	CPS, SPS, 2 GTCS	4–8	NE	1000–6000	bid–qd
Phenobarbital (various)	CPS, SPS, GTCS	46–140	15–40	90–120	bid–qd
Primidone (Mysoline)	CPS, SPS, GTCS	5–18	5–12	750–1000	tid–qid
Clonazepam (Klonopin)	Absence, atonic, myoclonic	20–40	.005–.07	2–6	tid–qid

Note. NE = not established.

<sup>a</sup>Pending approval.

**TABLE 29–5. Psychiatric effects of antiepileptic drugs (AEDs)**

Anticonvulsant	Psychiatric effects
Carbamazepine	Mood stabilizer, antimanic, mild antidepressant
Phenytoin	May cause depression
Valproic acid	Antimanic, possibly a mild antidepressant
Gabapentin	Mood stabilizer; treatment for bipolar, panic, and general anxiety disorders
Lamotrigine	Mood stabilizer, treatment for bipolar disorder and depression, may cause psychosis
Topiramate	May cause depression and psychosis
Tiagabine	May cause depression and psychosis
Vigabatrin	May cause depression and psychosis
Phenobarbital/primidone	May cause depression, hyperactivity, conduct disorder, and additional deficits
Ethosuximide	May cause psychosis
Clonazepam	May cause hyperactivity and additional deficits

patients with epilepsy. Both carbamazepine and ethosuximide may have value for borderline personality disorder.

Encephalopathic changes occur at toxic levels of all anticonvulsant drugs. Even at therapeutic levels, barbiturates may need discontinuation because of drug-induced depression, suicidal ideation, sedation, psychomotor slowing, and paradoxical hyperactivity in the very young and the very old. Gabapentin may induce aggressive behavior or hypomania, and vigabatrin may precipitate depression and psychosis. In addition, clinicians need to be aware of the potential emergence of psychopathology on withdrawal of anticonvulsant medications (Ketter et al. 1994). Anxiety and depression are the most common emergent symptoms, but psychosis and other behaviors may also occur.

Another therapeutic consideration is the seizure threshold-lowering effect of psychotropic medications (Itil and Soldatos 1980; Luchins et al. 1984; Oliver et al. 1982) (Table 29–6). This is usually not a problem, but can occasionally reach clinical significance. Psychotropic drugs are most convulsive when introduced rapidly or given in high doses. Clozapine and bupropion, particularly in combination, may be especially convulsant. When initiating psychotropic therapy, it is best to start low and go slow while monitoring anticonvulsant levels and EEGs. For example, clozapine has induced seizures in 1%–4.4% of patients when the dose was rapidly increased.

A potential exists for interaction of anticonvulsant and psychotropic medications. Attention to drug interactions is particularly important in elderly patients, who are often on multiple medications. In addition to increasing the metabolism of other AEDs, the addition of an AED most commonly increases the metabolism of psychotropic drugs with a consequent decrease in their therapeutic effective-

ness (Linnoila et al. 1980). The exception is the addition of valproic acid, which can increase psychotropic levels, rarely to a toxic range. Withdrawal of AEDs can precipitate rebound elevations in psychotropic levels. Alternatively, the initiation of a psychotropic can result in competitive inhibition of anticonvulsant metabolism with elevations of AED levels to toxicity (Vincent 1980).

Other therapeutic considerations that can affect the neuropsychiatric aspects of epilepsy include epilepsy surgery, ECT, and allowing patients to experience occasional partial or generalized seizures. Although epilepsy surgeries such as temporal lobectomy or corpus callosotomy are rarely performed in elderly patients, the removal of a secondary epileptogenic lesion such as a tumor may ameliorate seizures and associated behavioral disturbances (Krahn et al. 1996). Unfortunately, some patients with epilepsy continue to develop psychosis, personality changes, and suicidal behavior even long after primary epilepsy surgery (Falconer 1973; Jensen 1975; Koch-Weser et al. 1988). In addition to the occasional behavior alleviated by strict seizure control, allowing seizures under carefully controlled conditions, much like ECT, can relieve interictal depression, some cases of ictally related psychotic episodes, episodic dyscontrol, and, less frequently, other behaviors.

## Summary

The neuropsychiatric aspects of epilepsy include a broad range of behavioral changes that can occur in elderly patients. The incidence of seizure disorders in those over age 65 is higher than at any time since infancy; consequently, understanding the particular psychosocial impact of seizures on older people is beneficial. In later life, neuro-

**TABLE 29–6. Seizure threshold effect of psychotropic medications**

Potential	Antipsychotic	Antidepressant	Other psychotropic
<b>Proconvulsant</b>			
High	Clozapine Chlorpromazine	Bupropion Imipramine Maprotiline Amitriptyline Amoxapine Nortriptyline	
Moderate	Most piperazines Thiothixene	Protriptyline Clomipramine	Lithium

<b>Anticonvulsant</b>			
Low	Methylphenidate Dextroamphetamine	Monoamine oxidase inhibitors	Oral benzodiazepine
High		Barbiturates	

psychological effects from seizures, from the causative brain lesions, and from anticonvulsant medications increase. There can be an increased severity of ictally related behavioral disturbances such as prolonged periods of postictal confusion. Moreover, patients with epilepsy have an increased frequency of interictal psychiatric disturbances, such as depression, psychosis, suicide, personality disorders, hyposexuality, and others. Management of these behavioral disorders requires attention to the behavioral effects of anticonvulsant medications, the convulsant effects of psychotropic medications, and the interactions between them.

# Neoplastic, Demyelinating, Infectious, and Inflammatory Brain Disorders

Douglas W. Scharre, M.D.

Acquired diseases of the brain are common in the elderly population. Neuropsychiatric disorders are frequent complications of these conditions and may be the sole manifestations of the brain dysfunction. In this chapter, I discuss the neuropsychiatric manifestations of the major neoplastic, demyelinating, infectious, and inflammatory disorders of the brain.

## ■ Neoplastic Disorders

### Demography

Primary and metastatic neoplasms of the central nervous system (CNS) are common in the geriatric population. The overall incidence of CNS tumors is 15/100,000 per year, and the age-specific incidence peaks between 60 and

80 years. Eighty-five percent of all primary CNS neoplasms occur intracranially; the rest are intraspinal. In clinical series, 45% of intracranial tumors are gliomas, 15% are meningiomas, 7% are pituitary adenomas, and 6% are metastatic (Tyler and Byrne 1992). However, many tumors go unrecognized during life, and in autopsy series meningiomas account for up to 40% and metastatic tumors for up to 18% of all intracranial neoplasms (Kurtzke and Kurland 1983). The most common cancers to metastasize to the brain are lung, breast, kidney, colon, testis, melanoma, and lymphoma (Alvord and Shaw 1991).

### Physiology

There are multiple ways for CNS neoplasms to alter brain function. Direct invasion and compression will produce focal neurological deficits such as aphasia, hemiparesis,

amnesia, or visual field deficits. Vasogenic brain edema is produced in many neoplasms secondary to capillary leakage across a defective blood-brain barrier (Adams et al. 1997). This edema in conjunction with the mass effect of the tumor often leads to increased intracranial pressure. The typical signs and symptoms of increased intracranial pressure are headache, nausea, vomiting, papilledema, sixth cranial nerve palsy, and mental status changes. Neuropsychiatric evaluation often shows diminished arousal, impaired attention, impaired cognition, irritability, emotional lability, and psychomotor retardation. Eventually, with continued increased intracranial pressure, bradycardia, hypertension, and herniation syndromes develop.

Tumors located near the ventricular system often cause obstructive hydrocephalus. Headache, cognitive decline, incontinence, and gait disturbances are frequent sequela. Tumors may also cause vascular obstruction, particularly of the venous system, resulting in ischemic infarctions, hemorrhages, and increased intracranial pressure. Thirty percent of all brain tumors will produce focal or generalized seizures.

## Pathology

Intracranial neoplasms consist of rapidly growing tumor cells, tumor-related blood vessels, and necrotic tissue. Astrocytomas are classified as low grade, intermediate grade, or high grade (glioblastoma multiforme) according to the degree of nuclear atypism, mitosis, endothelial proliferation, and necrosis exhibited. Elderly individuals tend to have higher-grade astrocytomas. Oligodendrogliomas frequently contain calcifications and may bleed. Meningiomas are derived from cells of the arachnoid, pia mater, and dura mater and do not invade the brain parenchyma. Pituitary adenomas arise from one of several cell types in the anterior lobe of the pituitary. Most of the adenomas in the geriatric age range are nonfunctional chromophobe types (Alvord and Shaw 1991).

## Laboratory Evaluations

Lumbar puncture is generally avoided because of the risk of precipitating a herniation syndrome when there is a mass lesion in the brain. When cerebrospinal fluid (CSF) is collected, it typically reveals a mild pleocytosis, elevated protein, and normal glucose (Cummings and Benson 1992). CSF cytology is helpful in cases of meningeal carcinomatosis.

Electroencephalography (EEG) in patients with brain tumors is usually abnormal, revealing either focal or generalized slowing, sharp waves and spikes, or frank epilepti-

form activity. Angiography demonstrates the amount of tumor vascularity, which, in gliomas, is often correlated to tumor growth rate. Angiography of meningiomas often shows a meningeal blood supply and a distinct vascular blush (Tyler and Byrne 1992).

Magnetic resonance imaging (MRI) and computed tomography (CT) reveal evidence of mass processes, edema, midline shifts, hydrocephalus, and hemorrhage. Contrast enhancement greatly improves tumor detection. MRI is more sensitive than is CT in the detection of small tumors, but CT can demonstrate calcifications and bony erosions better. Unfortunately, neither CT nor MRI can accurately define intraparenchymal tumor boundaries. For most intracranial tumors, MRI shows increased signal on T2-weighted and gadolinium-enhanced T1-weighted images. Meningiomas exhibit an extra-axial location, dural base, and marked enhancement with contrast agents. MRIs of a glioblastoma multiforme and a meningioma are shown in Figures 30–1 and 30–2, respectively. Cerebral metastases often appear as multiple ring-enhancing nodular masses (Tyler and Byrne 1992).

Magnetic resonance angiography (MRA), single photon emission computed tomography (SPECT), and positron-emission tomography (PET) can now provide infor-

**FIGURE 30–1.** Gadolinium-enhanced, T1-weighted magnetic resonance image (MRI) of a 56-year-old man with a left parieto-occipital glioblastoma multiforme. The MRI reveals a ring-enhancing mass with a necrotic center.

**FIGURE 30-2.** T1-weighted magnetic resonance image (MRI) of a 56-year-old woman with a left-sided posterior falx meningioma. A large, dural-based, extra-axial mass homogeneously enhances with gadolinium.

mation on tumor blood flow, grade, recurrence, and response to treatment (Tyler and Byrne 1992).

### Treatment and Prognosis

The location and type of CNS neoplasms determines the approach to treatment. Surgical removal, debulking, chemotherapy, or radiation therapy are often used in some combination. Chemotherapy agents depend on the breakdown of the blood-brain barrier at the tumor site for selective drug delivery. The complications of radiation therapy include hypothalamic-pituitary dysfunction with resultant hypothyroidism, hypogonadism, or panhypopituitarism (Constine et al. 1993). Radiation-induced and chemotherapy-related leukoencephalopathy is discussed in the demyelinating disorders section below.

Corticosteroids are useful in reducing cerebral edema secondary to CNS neoplasms and thereby also aid in reduction of any associated increased intracranial pressure. Anticonvulsants are given to prevent seizures. Treatment of neuropsychiatric symptoms should avoid aggravating cognitive deficits. Psychosis is treated with very low dose haloperidol (0.5–1 mg/day) or with an atypical antipsychotic agent and increased slowly until an adequate re-

sponse is achieved. Depression is treated with antidepressants, usually a selective serotonin reuptake inhibitor. Mania is treated with divalproex sodium, carbamazepine, or a benzodiazepine; lithium is usually avoided because of its potential for exacerbating seizures (T. R. P. Price et al. 1992). Apathy and psychomotor retardation may be helped with methylphenidate or pemoline.

Astrocytomas and oligodendrogliomas are treated with surgery, radiation therapy, and chemotherapy, depending on their degree of malignancy. Meningiomas can be completely removed surgically in approximately 90% of cases but have a high rate of recurrence. Pituitary microadenomas are removed through a transphenoidal approach or treated with chemotherapy. Macroadenomas with extensive extraglandular extension often require craniotomies for removal, and postsurgical hormonal replacement is often required. Thirty percent of metastases are solitary and are candidates for surgical removal (Alvord and Shaw 1991). The 5-year survival rate for meningiomas is 60%, for gliomas 20%, and the median survival for glioblastoma multiforme is about 1 year (Kurtzke and Kurland 1983).

### Neuropsychiatric Manifestations of Neoplastic Disorders

**Frontal lobe tumors.** Frontal lobe tumors produce mental status and personality changes in 90% of cases and frank dementia in 70% of cases, but few focal neurological findings (Cummings and Benson 1992). Apathy, disinhibition, or impulsivity are the hallmarks of frontal involvement. Euphoria or depression, irritability, lack of concern, poor judgment, disorientation, and poor attention are additional frequent early findings. Patients with right frontal tumors may display more euphoria, whereas those with left frontal tumors may display more depression and abulia (Belyi 1987). Psychosis with paranoia, delusions, and hallucinations can also be observed. The dementia is characterized by impaired word list generation and aphasia with dominant hemisphere tumors, decreased design fluency with nondominant hemisphere tumors, constructional deficits, motor programming deficits, perseveration, forgetfulness, poor abstraction, and psychomotor retardation. Large subfrontal meningiomas, gliomas spreading to both frontal lobes, and metastatic tumors frequently result in severe dementia. Fifty percent of patients with frontal lobe tumors develop seizures, usually focal motor (jacksonian) type, and a few develop hydrocephalus as a result of obstruction of the interventricular foramen. Tumors located in the posterofrontal region pro-

duce hemiparesis, olfactory groove meningiomas produce anosmia, sphenoid ridge meningiomas produce unilateral exophthalmos and cranial nerve palsies, prefrontal tumors often produce a grasp reflex, and involvement of the frontal eye fields produces a conjugate deviation of the eyes to the side of the tumor.

**Temporal lobe tumors.** Temporal lobe tumors may cause personality changes, irritability, euphoria, depression, anxiousness, psychosis, hallucinations (auditory, formed visual, and simple olfactory or gustatory), or cognitive impairment early in their course. Dominant hemisphere tumors can produce aphasia and verbal memory deficits (amnesia), whereas nondominant hemisphere tumors produce nonverbal memory deficits. Hydrocephalus may result from obstruction of the third ventricle or compression of the midbrain with obstruction of the cerebral aqueduct. Partial complex seizures are frequent and manifest with staring, blinking, complex motor activity, déjà vu phenomena, visual distortions, hallucinations, and other psychomotor disturbances (see Chapter 29 in this volume).

**Parietal lobe tumors.** Tumors that are located in the anterior parietal area may produce somatosensory disturbances including deficits in two-point discrimination; identification of finger writing (agraphesthesia); identification of objects by their shape, size, texture, or weight (astereognosis); simultaneous identification of bilateral stimulation (inattention); and localization of tactile stimuli (atopognosis). Parietal lobe tumors may cause a contralateral lower-quadrant field cut resulting from disruption of the superior optic radiations. Difficulties in drawing, apraxia, and focal sensory seizures may also occur with parietal lobe lesions.

Tumors involving the right parietal lobe are most likely to cause a neglect syndrome of the contralateral body and extrapersonal space (inattention). In the full-blown condition, patients will not see, dress, shave, or groom the neglected side of the body and do not respond to stimuli in the neglected hemispace. They may deny a contralateral hemiparesis (anosognosia). Left parietal lobe tumors in the angular gyrus region cause Gerstmann syndrome, including difficulties with writing (dysgraphia), finger identification, calculations (acalculia), and the ability to distinguish right from left. Often, aphasia and constructional disturbances are also present.

**Occipital lobe tumors.** Occipital lobe tumors commonly produce contralateral homonymous visual field deficits, simple visual seizures with generalization, and visual hallucinations consisting of unformed images such as

flashes, streaks, or simple geometric patterns. Bilateral medial occipitotemporal tumors may cause a disturbance in visual recognition of objects (visual agnosia), identification of familiar faces (prosopagnosia), or recognition of familiar environments (environmental agnosia). Occasionally right-sided lesions alone may produce some of these syndromes.

**Deep midline tumors.** Deep midline tumors often lead to bihemispheric dysfunction as a result of invasion or brain compression by surrounding edema. Tumors within or near the third ventricle can obstruct the interventricular foramen or the cerebral aqueduct and cause hydrocephalus. Tumors within the ventricle can cause intermittent obstruction resulting in severe headaches and vomiting that are position dependent.

Pituitary and hypothalamic area tumors often cause bitemporal hemianopsia, optic atrophy, endocrine disturbances, diabetes insipidus, somnolence, personality changes, and cognitive decline. Excessive somnolence, rage attacks, and hyperphagia are occasionally seen with direct hypothalamic involvement.

Thalamic tumors produce memory loss, confusional states, emotional lability, hemiparesis, and hemihypesthesia with hemianesthesia. Basal ganglia tumors result in impaired attention, memory loss, personality changes, depression, and movement disorders including chorea, dystonia, or rigidity.

Pineal tumors compress the superior colliculus, producing aqueduct occlusion, hydrocephalus, and Parinaud's syndrome with paralysis of upward gaze and ptosis. Brainstem tumors produce cranial nerve deficits, long tract signs, cerebellar symptoms, and hydrocephalus. Personality changes, lethargy, disorientation, memory impairment, and mutism may also occur (Cummings and Benson 1992).

**Posterior fossa tumors.** Tumors in the posterior fossa can obstruct the fourth ventricle or the outflow into the basal cisterns, resulting in hydrocephalus. Prominent signs and symptoms include headache, vomiting, mental status changes, cranial nerve palsies, nystagmus, ataxia, dysmetria, hypotonia, and intention tremor.

## Paraneoplastic Syndromes

The remote effects of carcinoma on the nervous system are poorly understood. The symptoms usually develop rapidly over a few weeks; they may occur before the discovery of the neoplasm. The production of onconeural autoantibodies directed against antigens shared by both the cancer and the nervous system is the most likely pathogenesis of these syndromes (Posner 1997). There are several syn-

dromes affecting the brain that have been described.

Subacute cerebellar degeneration syndrome features ataxia, dysarthria, nystagmus, and diplopia as a result of antibodies against Purkinje cell cytoplasm (anti-Yo or anti-Tr) or neuronal nuclei (anti-Hu, also known as anti-neuronal nuclear antibody [ANNA-1]) of Purkinje cells. Opsoclonus paraneoplastic syndrome is characterized by uncontrolled eye movements as a result of antibodies against neuronal nuclei (Anti-Ri, also known as anti-neuronal nuclear antibody [ANNA-2]) probably directed to brainstem regions. Retinal degeneration paraneoplastic syndrome typically produces scotomas, blindness, and visual hallucinations as a result of anti-Recoverin antibodies of retina photoreceptors (Posner 1997).

Limbic encephalopathy, of all the paraneoplastic syndromes, is the one most associated with neuropsychiatric symptoms. Limbic encephalopathy has been seen most commonly with small-cell lung carcinoma and Hodgkin's disease. Other associations include carcinoma of the breast, uterus, ovary, prostate, and kidney; multiple myeloma; lymphosarcoma; reticulum cell sarcoma; neuroblastoma; and acute leukemia. The age at onset is typically 50–80 years, and men are more commonly affected. The condition may last several years. The syndrome is characterized by an amnesic memory disturbance, cognitive decline, depression, anxiety, personality changes, paranoia, hallucinations, and diminished alertness. Often a severe sensory neuropathy is present. Occasionally complex partial seizures, cerebellar deficits, brainstem signs, myelopathy, and autonomic failure are observed (Dalmau et al. 1992).

Neuronal loss and perivascular inflammatory infiltrates, particularly in the medial temporal areas, are found at autopsy (Newman et al. 1990). Sometimes the cerebellum, brainstem, spinal cord, dorsal root ganglia, and autonomic ganglia are involved. Neuroimaging is typically unrevealing. Rarely, MRI demonstrates increased signal on T2-weighted images in the frontal and temporal lobes (Kodama et al. 1991). CSF examination usually shows mild transient lymphocytic pleocytosis and persistent elevated protein, increased immunoglobulin G (IgG), and oligoclonal banding. Anti-Hu antibodies are seen in many cases and found in the nuclei of neurons (Dalmau et al. 1992). A new antibody to a subset of glial cells (anti-CV2) has been discovered in some patients with paraneoplastic encephalomyelitis (Honnorat et al. 1996). Treatments are being tested, but most have not shown great effect on the neurological symptoms. On the other hand, small-cell lung cancers with the Hu antigens appear more susceptible to therapy than those without (Posner 1997).

## ■ Demyelinating Disorders

Although demyelinating conditions are more common in young individuals, many examples of these disorders appear with late survival or presentation in the elderly population. A comprehensive list of common and rare white matter disorders is presented in Table 30–1. Primary demyelination involves the loss of the myelin sheath, leaving the axon intact but denuded. Dysmyelinating conditions reflect impairment in the formation or development of the myelin sheath. These two types of myelin disease give similar clinical and neuropsychiatric features.

### Multiple Sclerosis

Multiple sclerosis (MS) is the most common demyelinating disorder of the CNS. Typically it presents in young adults, but 0.6% of the patients do not have their first symptom until age 60 or later (Hooze and Redekop 1992). The prevalence at age 70 is about 50/100,000 (Kurtzke and Kurland 1983). MS is rare in the tropics; its frequency increases in more northern latitudes. Women are affected more often than men by a 2 to 1 ratio.

**Clinical features.** The clinical course of MS has three forms: relapsing-remitting, acute progressive, and chronic progressive. Relapsing-remitting type is characterized by symptoms that may evolve over a few days and then partially or totally resolve over weeks. Rarely the course is an acute, rapidly progressive one over a few weeks or months to death. The most common pattern, particularly in those with onset over age 40, is a chronic, slowly progressive course.

Brainstem and spinal cord regions are frequently affected and may cause internuclear ophthalmoplegia, diplopia, trigeminal neuralgia, vertigo, myelopathy, acute transverse myelitis, bladder dysfunction, urinary frequency and urgency, urinary incontinence, constipation, autonomic dysfunction, sensory disturbances, paresthesias, loss of vibratory and position sense, gait imbalance, and pain syndromes, particularly of the back and lower extremities. Brain demyelination often results in optic neuritis, spastic weakness, gait imbalance, appendicular and truncal ataxia, intention tremor, dysmetria, sensory dysfunction, paroxysmal disorders, and neuropsychiatric syndromes. Treatment with steroids and other medications can complicate and contribute to the cognitive and psychiatric disturbances. Most patients with the onset of symptoms after age 50 or 60 have a slowly progressive myelopathy with spastic paraparesis, gait imbalance, and bladder impairment (Hooze and Redekop 1992; Noseworthy et al. 1983).

**TABLE 30-1. Causes of demyelinating disorders in elderly patients**

Lyme disease
<b>Neoplastic</b>
Lymphoma of the central nervous system
Paraneoplastic syndromes

**Neuropsychiatric aspects.** Neuropsychiatric symptoms may be the presenting complaint and, like other MS symptoms, may exacerbate and remit or may be continuously present after onset. Treatment with steroids or other medications can contribute to these symptoms. Table 30-2 lists the principal neuropsychiatric manifestations of MS and their approximate frequencies.

Fatigue—a sense of tiredness or lack of energy that is greater than expected for the effort required for a task or the degree of disability evidenced by the patient (The Canadian MS Research Group 1987)—occurs in approximately 75% of patients with MS, often preventing normal activities (Murray 1985). It must be differentiated from symptoms of depression, weakness, lack of rest, or excessive exercise. Fatigue in patients with MS is exacerbated by heat and improves with cooler temperatures (Krupp et al. 1988).

Approximately 75% of men and 50% of women with MS report sexual dysfunction (Stenager et al. 1992). In men, two-thirds have erectile dysfunction, and one-third report decreased libido. In women, painful genital dysesthesias, inability to achieve orgasm, and decreased libido are common. Nearly 90% of the men have neurogenic causes for their erectile dysfunction (Kirkeby et al. 1988). Hypersexuality is uncommon, but has been reported in 4% of patients with MS (Mahler 1992).

Sleep disturbances are seen in a quarter of patients with MS (Clark et al. 1992). Most have problems with sleep initiation or maintenance and do not awaken feeling rested. The sleep disturbance may be associated with depression, fatigue, spasticity, bladder difficulties, or periodic leg movements.

It is important to distinguish between how the patient subjectively feels (mood) and the outward expression of his emotion (affect). Approximately 11% of patients with MS have difficulties regulating their emotional expression, resulting in rapid mood swings or inappropriate emotional responses (Minden and Schiffer 1990). Many patients have depressed moods in spite of a euphoric affect.

**TABLE 30-2. Frequency of neuropsychiatric manifestations in multiple sclerosis**

Neuropsychiatric manifestation	Frequency
Fatigue	75%
Sexual dysfunction	50% (women) 75% (men)
Hypersexuality	4%
Sleep disturbance	25%
Emotional lability	11%
Depression	50%
Euphoria	25%
Mania	13%
Personality changes	40%
Psychosis	1%–3%
Cognitive dysfunction	30%–50%

Compared with patients with other chronic neurological diseases, patients with MS have significantly more depression. Approximately half of all patients with MS experience at least one episode of major depression during their illness. No association has been found between their depression and a family history of depression, duration of illness, age, gender, or socioeconomic status (Minden et al. 1987). Depression is associated with recent exacerbations of MS symptoms requiring steroid therapy, but not with severity of disability or cognitive impairment in most studies (Good et al. 1992; Schiffer and Caine 1991).

Euphoria—a cheerful affect inappropriate to the situation—occurs in about 25% of patients with MS (Rabins 1990). It is not associated with steroid use and does not have other features of hypomania. In fact, many patients with euphoria have a depressed mood. Euphoria appears to be produced by bilateral subfrontal demyelination (Minden and Schiffer 1990), and patients with euphoria have more neurological and cognitive deficits than those without euphoria (Rabins 1990).

Mania occurs in up to 13% of patients with MS (Joffe et al. 1987), and patients with MS have twice the risk of developing bipolar disorder as the general population. Human leukocyte antigen (HLA) analysis and family history studies suggest a genetic predisposition for bipolar disorder in patients with MS who manifest manic behavior (Schiffer et al. 1988).

Apathy, lack of concern over their disabilities, lack of initiation, impaired insight, irritability, and poor judgment are personality changes observed in as many as 40% of patients with MS (Mahler 1992) and may be related to frontal lobe dysfunctioning (Mendez 1995).

Psychosis in MS—including auditory or visual hallucinations, delusions, or paranoia—is seen in approximately 1%–3% of patients, and it occurs at a later age than in idiopathic schizophrenia (Feinstein et al. 1992; Ron and Logsdail 1989). Psychosis can occur without steroid use and without a family history of schizophrenia. Psychosis in MS is associated with increased temporal and temporoparietal lobe abnormalities on MRI (Feinstein et al. 1992; Honer et al. 1987; Ron and Logsdail 1989).

Cognitive dysfunction occurs in 40%–65% of patients with MS (Fennell and Smith 1990; Rao 1996), with most investigators emphasizing memory impairment. Approximately 20%–30% of patients with MS meet criteria for a dementia syndrome with deficits primarily involving poor retrieval memory, slowed information processing, visuospatial abnormalities, and frontal-executive dysfunctioning: a pattern suggestive of a subcortical dementia syndrome (Huber et al. 1987; Rao 1986). Corpus callosal atrophy on MRI and increased plaque volume correlate with

the severity of cognitive impairment (Huber et al. 1992b; Swirsky-Sacchetti et al. 1992). The cognitive changes do not correlate with duration of disease or depression, but may be more severe in the chronic progressive type of MS typical of that in elderly patients (Minden et al. 1990; Rao et al. 1991). The cognitive changes weakly correlate with physical disability in some studies (Rao et al. 1991), but not in others (Maurelli et al. 1992).

Both verbal and nonverbal memory are impaired, with spatial memory being more severely affected in most studies (Beatty et al. 1988; Grafman et al. 1990). The memory deficit is a retrieval abnormality and not a true amnesia (Rao 1986). Remote memory is usually spared (Rao et al. 1991). Verbal IQ is generally better preserved than is performance IQ (Rao 1986). However, word list generation, also called *verbal fluency* (the number of words beginning with a certain letter produced in 1 minute or the number of animals named per minute), is often decreased (Beatty et al. 1988; Rao et al. 1991). Rarely, aphasic syndromes have been described (Achiron et al. 1992). Executive functions including planning, abstraction, concept formation, set shifting, sustained attention, and organization skills are affected in MS (Fennell and Smith 1990) and suggest frontal lobe dysfunction (Mendozzi et al. 1993). Frontal white matter lesions on MRI correlate with these disturbances (Comi et al. 1995; Huber et al. 1992a). Signs of corpus callosal disconnection have been identified with dichotic listening tasks (Rubens et al. 1985), with tachistoscopic object-naming tasks (Rao et al. 1989), and from the clinical examination demonstrating left-hand apraxia, agraphia, and astereognosis (Schnider et al. 1993). Corpus callosal atrophy on MRI has been demonstrated in these patients.

**Pathophysiology and diagnosis.** MS is believed to be caused by an immune-mediated response triggered by exposure to an unknown environmental agent in the genetically predisposed individual. This response results in multifocal discrete inflammatory demyelinated areas scattered throughout the white matter, including the arcuate U-fiber regions. MRI shows these plaques in the white matter as areas of high signal on T2-weighted images (Figure 30–3), and gadolinium contrast can distinguish active from inactive plaques (Bastianello et al. 1990). Diagnosis is aided by finding increased immunoglobulin production and oligoclonal bands in the CSF (Table 30–3) and prolonged latencies on evoked potential testing (Poser et al. 1983).

**Treatment.** Oral prednisone, intravenous methylprednisolone, and intramuscular adrenocorticotrophic hormone (ACTH) appear to speed the recovery of an acute

**FIGURE 30-3.** Magnetic resonance image (MRI) of a 65-year-old woman with chronic progressive multiple sclerosis. MRI shows multiple areas of increased signal on the proton-density-weighted image in the right and left centrum semiovale regions.

exacerbation. Immunosuppressive drugs such as azathioprine, cyclophosphamide, and cyclosporin might have the potential to slow down the progression of MS, but their use is limited by potentially serious side effects. Intravenous immune globulin has also been recently tried (Achiron et al. 1996).

New therapies for relapsing-remitting MS, including interferon beta-1b given subcutaneously on alternate days (IFNB Multiple Sclerosis Study Group 1993; IFNB Multiple Sclerosis Study Group and University of British Columbia MS/MRI Analysis Group 1995; Lublin et al. 1996; Paty et al. 1993), interferon beta-1a given intramuscularly once weekly (Jacobs et al. 1996), and glatiramer acetate given subcutaneously daily (K. P. Johnson et al. 1995, 1998), are aimed at modifying the immune processes thought to be responsible for the pathogenesis of MS. These agents have had some effect on reducing the frequency and severity of relapses in patients with relapsing-remitting MS, reducing the progression of disability, and diminishing the number and size of MRI lesions. Combination therapies with corticosteroids, interferon beta, and glatiramer are being tried, but no formal results are available. Interferon beta products can produce antibodies

that may be associated with loss of efficacy under some circumstances in some patients, but this has not been consistent. Those with high titers may be more likely to become treatment nonresponders. Glatiramer, so far, has not been noted to produce antibodies associated with loss of efficacy.

Unfortunately, many of the immunotherapies can produce neuropsychiatric and other adverse effects. If used longer term, adrenocorticosteroids may cause serious infections, electrolyte disturbances, peptic ulcers, osteoporosis, myopathy, cataracts, and Cushing's habitus. Behavior disturbances include nervousness, insomnia, depression, mania, and psychosis. Immunosuppressive agents may also cause serious infections, increase risk of neoplasia, and cause multiple organ toxicities. The most common side effects of the immune modifying agents (interferon betas and glatiramer) are the injection site reactions. Postinjection flushing, palpitations, throat constriction, urticaria, and dyspnea can also occur. Dizziness, hypertonia, and tremor are seen with glatiramer, and seizures have been reported with the interferons. Neuropsychiatric side effects include fatigue, anxiety, depression, psychotic depression, and suicidality. Depression is a common reason for discontinuation of the interferon betas and glatiramer (Copaxone prescribing insert; Neilley et al. 1996). Although only 1% of patients spontaneously report depression after taking interferon beta-1b, as many as 40% in one study were actually experiencing new or increased symptoms of depression within 6 months of initiating therapy (Mohr et al. 1997). Treatment of the depression significantly reduced discontinuation of the interferon beta-1b (Mohr et al. 1997).

Management of specific symptoms may contribute to improved patient functioning. Spasticity is treated with a combination of physical therapy, tizanidine (Nance et al. 1997), baclofen, benzodiazepines, botulinum toxin, or dantrolene. Paroxysmal disorders respond to anti-convulsants. Bladder disorders and urinary tract infections are reduced by anticholinergics, self-catheterization, and prophylactic antibiotics.

Treatments for the neuropsychiatric manifestations are also available. Cognitive impairment may be helped with cholinesterase inhibitors (Leo and Rao 1988) or the use of memory aids, lists, routinization of daily activities, and other cognitive retraining strategies (LaRocca 1990). Pathological laughing or crying can be treated with low-dose amitriptyline (Schiffer et al. 1985) or fluoxetine (Seliger et al. 1992). Depression is treated with selective serotonin reuptake inhibitors with low side effects and very high response rates (Scott et al. 1996). Bipolar disorder is treated with lithium (Schiffer 1990) or sodium valproate. Anticholinergic agents may impair cognition but aid blad-

**TABLE 30-3. Cerebrospinal fluid profiles of various conditions**

Infection	White cells	Protein (mg/dL)	Glucose (mg/dL)	Miscellaneous
Multiple sclerosis	0–20 lymphocytosis	Normal, 100	Normal	Oligoclonal bands, IgG increase
Acute disseminated encephalomyelitis	10–4000 PMN, lymphocytes	Normal, 344	Normal	Increased pressure, occasional oligoclonal bands
Creutzfeldt-Jakob disease	0–15 lymphocytosis	Normal, 50–120	Normal	Occasional IgG increase, 14–3–3 brain protein
Herpes simplex encephalitis	50–1000 lymphocytosis	50–400	Normal	Culture, serology
Aseptic meningoencephalitis	5–1000 lymphocytosis	45–80	20–40, normal	Culture
HIV-1 dementia complex	0–8 lymphocytosis	< 80	Occasional decrease	IgG increase, culture
PML	0–8 lymphocytosis	< 80	Normal	PCR for JC virus DNA
Acute bacterial meningitis	100–60,000 PMN	100–1000	5–40	Culture, antigen detection
Brain abscess	0–500 PMN, lymphocytes	40–100	Occasional decrease	
Fungal meningitis	5–800 lymphocytosis	45–500	10–40, normal	Culture, cryptococcal antigen
Neurosyphilis	5–1000 lymphocytosis	50–100	< 40, normal	VDRL test, IgG increase
Neuroborreliosis (Lyme disease)	0–150 lymphocytosis	40–100	Normal	IgG increase, serology
Isolated angiitis of the CNS	0–800 lymphocytosis	40–600	Occasional decrease	Occasional IgG increase
Lymphomatoid granulomatosis	0–225 atypical lymphocytes	40–780	Normal	Occasional oligoclonal bands
Behçet's syndrome	0–500 lymphocytosis	Normal to 160	Normal	Occasional IgG increase, blood-brain barrier breakdown
SLE	0–50 lymphocytosis	Normal to 100	Normal	Oligoclonal bands, IgG increase, antineuronal antibodies, blood-brain barrier breakdown
Sjögren's syndrome	Mild lymphocytosis	Normal to 100	Normal	Oligoclonal bands, IgG increase

*Note.* CNS = central nervous system; IgG = immunoglobulin G; HIV-1 = human immunodeficiency virus type 1; PCR = polymerase chain reaction; PML = progressive multifocal leukoencephalopathy; PMN = polymorphonuclear cells; SLE = systemic lupus erythematosus; VDRL = Venereal Disease Research Laboratory.

der symptoms; the choice of treatment in any individual will depend on the relative anticholinergic effect desired. Fatigue may be ameliorated by amantadine (The Canadian MS Research Group 1987; Murray 1985) or pemoline (Weinshenker et al. 1992) or with steroids if associated with an acute exacerbation. Pharmacotherapy reassessment is essential to eliminate agents no longer needed. Support groups and psychotherapy are useful for information exchange, social interaction, stress reduction, and emotional support (Minden and Moes 1990).

### Acute Disseminated Encephalomyelitis

Acute necrotizing hemorrhagic, postinfectious, and postvaccinal encephalomyelitis are forms of acute disseminated encephalomyelitis, an immune-mediated condition resulting in CNS demyelination. It can occur at any age. It is typically, but not exclusively, a monophasic illness presenting with fever, headache, and altered consciousness and typically preceded days or weeks earlier by either viral illness or vaccination (Geerts et al. 1991). The hemor-

rhagic form is usually, but not always, rapidly fatal (Huang et al. 1988). If the individual survives the acute condition, gradual recovery over days to weeks ensues. Hemiparesis, sensory deficits, seizures, dysarthria, or dysphasia may be present initially (Geerts et al. 1991). The neuropsychiatric residua vary depending on the degree of injury and extent of recovery. A subcortical dementia syndrome similar to that seen in multiple sclerosis is typical. Inflammation, demyelination, and variable hemorrhage occurs in the white matter. Neuroimaging studies show multifocal abnormalities and large lesions that often involve the cortex with very little periventricular or callosal involvement (Kesseling et al. 1990). CSF cultures are negative (Table 30–3). A brain biopsy may be required to rule out infection or tumor. Treatment is supportive and may require reduction of increased intracranial pressure. Surgical decompression has been recommended for the hemorrhagic form (Huang et al. 1988). Immunosuppression has been used with some success (Seales and Greer 1991).

### **Binswanger's Disease**

Binswanger's disease, also called *subcortical arteriosclerotic encephalopathy*, is a vascular dementia resulting from hypoxic ischemia involving the small penetrating vessels supplying the deep white matter of the cerebral hemispheres. It occurs in elderly individuals, most with a history of chronic hypertension. A gradually progressive course of dementia with frontal features and personality change is typical. Neuropsychiatric findings include memory deficits, executive impairment, decreased attention, poor judgment, lack of spontaneity, reduced drive, apathy, perseveration, pseudobulbar palsy, emotional incontinence, and at times euphoria, elation, and aggressiveness (Babikian and Ropper 1987; McPherson and Cummings 1996). Weakness, ataxia, rigidity, small-stepped gait, frequent falls, frontal release signs, dysarthria, and urinary incontinence are typical neurological abnormalities. White matter demyelination is seen pathologically, and MRI reveals hyperintensities on T2-weighted images in the periventricular and deep white matter regions. Binswanger's disease and lacunar state commonly co-occur.

### **Marchiafava-Bignami Disease**

Marchiafava-Bignami disease is characterized by demyelination of the corpus callosum and adjacent white matter. It is rare and occurs mostly in middle to late adult life in men who are chronically alcoholic. Many individuals exhibit a chronic dementia syndrome that progresses over months to years. Remissions are possible. Severe cases

present in stupor or coma, and the patient dies rapidly.

The neuropsychiatric features vary widely from case to case. The CNS manifestations include dementia, aphasia, slow information processing, frontal release signs, dysarthria, incontinence, hemiparesis, seizures, apraxic gait, and signs of corpus callosum interhemispheric disconnection such as left-sided limb apraxia, left-hand anomia, and agraphia (Lechevalier et al. 1977; Victor 1993). Personality changes, apathy, violence, and sexual deviations have also been reported.

Demyelination of the corpus callosum with relative sparing of the splenium and absence of inflammatory changes is the characteristic pathology. Less often, the anterior or posterior commissures, centrum semiovale, superior cerebellar peduncles, or the white matter of the pons are involved. MRI scans show demyelination essentially limited to the callosum (Chang et al. 1992). Alcoholic abstinence and proper nutrition is recommended.

### **Subacute Combined Degeneration**

Subacute combined degeneration is caused by vitamin B<sub>12</sub> (or rarely folate) deficiency, which produces demyelination in the spinal cord and brain. This condition can occur at any age and may be secondary to pernicious anemia, malabsorption syndromes, acquired immunodeficiency, stomach or small bowel resections, stomach acid-reducing agents, or rarely from a dietary B<sub>12</sub> deficiency (Swain 1995). Clinical features of subacute combined degeneration are variable from case to case, but may include peripheral neuropathy, myelopathy, gait disturbance, incontinence, visual impairment, megaloblastic anemia, dementia, and neuropsychiatric syndromes.

Confusion, memory impairment, slow reaction time, and perseveration are common cognitive findings (Cummings and Benson 1992). The dementia may occasionally precede other systemic manifestations of the vitamin deficiency (Karnaze and Carmel 1990). Neuropsychiatric manifestations include apathy, depression, personality changes, agitation, aggression, paranoia, delusions, and hallucinations (Clementz and Schade 1990; Lindenbaum et al. 1988). Numbness, tingling, lower-extremity weakness, and gait disturbance may progress to flaccid paralysis and incontinence.

The dorsal and lateral columns of the spinal cord and the white matter in the brain show areas of spongiform degenerative demyelination. EEG reveals generalized slowing in those with dementia. A low serum B<sub>12</sub> level is usually diagnostic. Serum methylmalonic acid and homocysteine are good confirmatory tests, and malabsorption is demonstrated by performing a Schilling test. Administration of

vitamin B<sub>12</sub> may reverse or stop the progression of the neurological symptoms and dementia.

### Postanoxic/Posthypoxic States

Elderly individuals are particularly prone to anoxia/hypoxia from cardiopulmonary failure or sleep apnea. Chronic hypoxia results in a slowly progressive dementia syndrome, whereas acute anoxia can lead to profound neuronal injury and death. Rarely, patients may develop extensive white matter demyelination a few weeks after apparent recovery from an acute anoxic insult. The delayed symptoms include slowed responses, somnolence, irritability, depression, inattentiveness, disorientation, forgetfulness, pseudobulbar palsy, mutism, incontinence, gait disturbances, and spasticity (Plum et al. 1962). Death often occurs, but moderate recovery has been observed. Postanoxic demyelination is seen diffusely over both cerebral hemispheres on MRI.

### Radiation and Chemotherapy-Related Leukoencephalopathy

Neoplastic conditions are very common in the geriatric population, and both radiation therapy and chemotherapy are often used either alone or in combination to treat the tumors. These therapies can be used either to reduce the tumor burden or as a prophylactic to reduce the likelihood of potential brain or spinal cord metastases. However, both may also lead to delayed demyelination of the CNS occurring from 3 months to 5 years after the treatment. The neurological complications of cranial irradiation include memory loss, cognitive decline, abulia, gait disturbance, ataxia, pyramidal tract signs, and tremors. Patients may become severely disabled with dementia and paresis (B. E. Johnson et al. 1985).

Chemotherapeutic agents cause a delayed demyelination thought to be secondary to oligodendrocyte neurotoxicity. The neurological findings are similar to the delayed effects of radiation treatment. Methotrexate is the most notable example of such an agent, especially when given intrathecally (Ojeda 1982). Cyclosporine (de Groen et al. 1987), cytosine arabinoside (Lee et al. 1986), and 5-fluorouracil combined with levamisole (C. C. Hook et al. 1992) have all been reported to cause demyelination. The combination of radiation therapy and chemotherapy, particularly when using methotrexate, cisplatin, lomustine, or amphotericin B, appears to enhance the neurotoxicity (So et al. 1987; Walker and Rosenblum 1992).

Demyelination with necrosis is the pathological finding seen with the delayed effects of radiation on the CNS.

Demyelination with or without necrosis has also been reported with the use of chemotherapeutic agents (C. C. Hook et al. 1992; Ojeda 1982). Diffuse symmetric white matter low attenuation, cerebral atrophy, ventricular dilation, and occasionally mass effect are seen with CT scanning of the head (So et al. 1987). MRI reveals increased signal on the T2-weighted images in the periventricular white matter in a diffuse, symmetric, and confluent pattern. Scattered focal lesions that enhance with gadolinium are also common (C. C. Hook et al. 1992; So et al. 1987).

### Metachromatic Leukodystrophy

Metachromatic leukodystrophy (MLD) is a dysmyelinating disorder with infantile, juvenile, and adult forms. The adult form may present from ages 16 to 40 and will usually last from 5 to 20 years, but occasionally as long as 40 years. The enzyme deficient in this autosomal recessive inheritable disorder is arylsulfatase A. Personality changes and cognitive decline mark the insidious onset of the adult form (Baumann et al. 1991). Disinhibition, poor judgment, dishevelment, inappropriate affect, emotional lability, looseness of associations, diminished attention span, memory deficits, abstraction and calculation difficulties, spatial disorientation, and constructional problems are seen (Merriam et al. 1990). This progresses to psychosis (present in more than 50% of cases), occasionally mania, and dementia (Hyde et al. 1992). Spasticity, ataxia, and seizures are often present. Resting and postural tremors and choreoathetosis have occasionally been described (Merriam et al. 1990). Peripheral neuropathy, in the adult form, may not be clinically evident though present electrophysiologically. Sulfatide deposits are present around both central and peripheral nerves and in viscera. Demyelination sparing the arcuate fibers (U-fibers) is present in the cerebral hemispheres and evident on neuroimaging. Motor and sensory nerve conduction velocities are mildly slowed, and increased CSF protein is occasionally found. Diagnosis is made by measuring the enzyme deficiency in leukocytes or measuring the amount of sulfatide in urine (Baumann et al. 1991). Genetic counseling is indicated.

### Adrenoleukodystrophy

Adrenoleukodystrophy (ALD) is an X-linked dysmyelinating disorder featuring a deficiency of a peroxisomal enzyme that results in the excessive storage of very long chain fatty acids (VLCFAs) (Naidu and Moser 1990). There are neonatal, juvenile, adolescent, and adult cerebral forms as well as an X-linked adrenomyeloneuropathy (AMN) form. The adult cerebral form, representing ap-

proximately 3% of all cases, may present from ages 18 to 57 (Weller et al. 1992). The AMN form, found in 21% of all cases, typically has its onset between ages 20 and 35 and rarely occurs in later adult life. Approximately 10%–15% of the women who are ALD carriers develop neurological deficits resembling AMN with onset between age 15 and 76 (Naidu and Moser 1990).

The initial finding in the adult cerebral form of ALD is usually dementia. Other neurological findings include upper motor neuron signs, paresis, ataxia, gait apraxia, dysarthria, homonymous hemianopsia, impaired visual acuity leading to cortical blindness, ocular movement disorders, and hearing loss. Seizures are a late finding. Psychiatric features are seen in nearly 40% of patients, often occur early in the course, and include hypomania, emotional lability, depression, hyperactivity, physical and sexual aggression, and psychosis (Kitchin et al. 1987). Adrenal insufficiency and a bronze discoloration of the skin typically become evident after the neurological symptoms begin. The AMN form begins with a progressive spastic paraparesis and a mild peripheral neuropathy, with 20% of patients eventually developing dementia. Emotional lability and depression have also been observed (Naidu and Moser 1990). In ALD, there is demyelination of cerebral white matter sparing the arcuate fibers. Increased signal on T2-weighted images is present in the periventricular white matter on MRI scanning, typically starting occipitally and progressing anteriorly. CSF protein is increased. Diagnosis is made by assaying VLCFAs in plasma or skin fibroblasts. A low cortisol level or a reduced adrenal response to stimulation indicates adrenal insufficiency. Treatment includes a low-VLCFA diet with erucic and oleic acid; adrenal steroids are used for the adrenal dysfunction.

### Cerebrotendinous Xanthomatosis

Cerebrotendinous xanthomatosis is an autosomal recessive disorder resulting in impaired hepatic synthesis of bile salts, leading to markedly increased levels of cholestanol. Age at onset ranges from infancy to the seventh decade. Clinical features include cataracts, tuberous and tendon xanthomas, dementia, ataxia, pyramidal tract signs, spasticity, dysarthria, seizures, depression, and a demyelinating neuropathy. Early atherosclerosis with coronary artery disease is also common. The tendon xanthomas often begin between ages 20 and 40. Cognitive decline can appear in childhood or be delayed well past middle age. Spasticity and ataxia progress, and, in the terminal stage, incontinence and pseudobulbar palsy are present. Pathology shows extensor tendon xanthomas and brain deposi-

tion of high-density lipoprotein. CSF examination demonstrates a mildly elevated protein. CT and MRI scanning reveal atrophy, focal tuberous xanthomas, and demyelination in the cerebellum and cerebrum (Hokezu et al. 1992). Diagnosis is confirmed by finding elevated levels of cholestanol in plasma or bile. Early treatment with chenodeoxycholic acid to reduce the formation of cholestanol may reverse and prevent the clinical findings (Bjorkhem and Skrede 1990).

## ■ Infectious Disorders

Infectious conditions producing neuropsychiatric signs and symptoms are common at all ages. In the elderly population, diagnosis is more difficult because certain systemic signs such as fever may not be present, whereas other non-specific symptoms such as confusion, headache, malaise, generalized weakness, and diminished appetite may be more prominent. Progression to an acute confusional state or delirium with hallucinations, delusions, paranoia, impaired attention, disorientation, cognitive deficits, sleep disturbance, and tremors may occur rapidly. Consideration of infectious etiologies at an early stage enables prompt diagnosis and treatment. Neuroimaging with MRI or CT followed by lumbar puncture and, potentially, brain biopsy are often necessary to determine the specific pathogen. Common CNS infections of the geriatric age group are listed in Table 30–4.

### Prion Infections

*Prions* are proteinaceous infectious particles consisting of protein without nucleic acid. They can cause transmissible diseases, can be inherited on chromosome 20 in 10%–15% of cases, or may occur sporadically (DeArmond and Prusiner 1995; Prusiner 1995). The normal prion protein is hypothesized to be converted posttranslationally from an  $\alpha$ -helix to an abnormal  $\beta$ -sheet conformation that is insoluble to detergents, tends to aggregate, and can induce normal prion proteins to change their conformation to the abnormal form, causing accumulation of prions to sufficient levels to cause a progressive neurodegenerative disease state (Prusiner and Hsiao 1994).

**Creutzfeldt-Jakob disease.** Creutzfeldt-Jakob disease (CJD) has a worldwide incidence of approximately 1 per 1 million. Approximately 90% of CJD cases arise sporadically without evidence of any infectious source, 5%–15% are familial, with an autosomal dominant inheritance, and rare iatrogenically transmitted cases have oc-

curred in humans from corneal transplants, depth electrodes, neurosurgical instrumentation, a cadaveric dura mater graft, and human growth hormone that was extracted from human cadaveric pituitaries (Rappaport 1987; Wasielewski et al. 1997).

The usual age at onset is between 50 and 70, with a range from 20 to 79 (Cummings and Benson 1992). The clinical course is typically very rapid: death usually comes within several months to 1 year. Occasionally, individuals have survived for several years. The familial forms have an earlier age at onset and a longer duration of illness (Brown et al. 1992).

Initially, the patient has complaints of generalized fatigue, anxiety, sleep disturbance, appetite change, depression, impaired concentration, and forgetfulness. After a few weeks, a progressive dementia ensues with aphasia, am-

nesia, apraxia, and agnosia. Myoclonus, chorea, tremor, ataxia, cerebellar signs, pyramidal signs, spasticity, rigidity, and seizures typically occur after the dementia has started. Hallucinations and delusions are also seen. Mutism, incontinence, decerebrate rigidity, and akinesia occur in the final phases (Brown et al. 1986; Cummings and Benson 1992).

Pathology shows a spongiform state in the cortical and subcortical gray matter with loss of neurons and gliosis (Masters et al. 1981). The spongiform changes reflect the occurrence of intracellular vacuoles. Occasionally, white matter gliosis and demyelination are also seen. Some patients with CJD have amyloid plaques in the cerebellum and cerebrum similar to those found in kuru. MRI results may be normal or reveal mild atrophy and areas of increased signal on T2-weighted images (Milton et al. 1991). PET and SPECT show multiple diffuse areas of hypometabolism/hypoperfusion in both cortical and subcortical regions (Goldman et al. 1993; Watanabe et al. 1996) (Figure 30-4). CSF showing a positive immunoassay for the 14-3-3 brain protein is strongly supportive of CJD (Hsich et al. 1996) (Table 30-3). The EEG shows background slowing and a characteristic periodic polyspike discharge (Chiofalo et al. 1980); this EEG pattern may be absent in the familial forms of CJD (Brown et al. 1992). Diagnosis can be made by the clinical features, EEG, and CSF and is confirmed by brain biopsy if the features are atypical. Treatment is not available except for supportive care.

**Other prion diseases.** Gerstmann-Straüssler-Scheinker (GSS) syndrome is a rare autosomal dominant disorder with onset between ages 40 and 60. Seven known point mutations in the prion protein gene can result in the GSS syndrome (Prusiner 1996), which is characterized by a mild dementia with pyramidal, extrapyramidal, and cerebellar signs (Farlow et al. 1989). Ataxia is the usual presenting manifestation followed by dementia. Gaze palsies, deafness, and blindness may occur.

Fatal familial insomnia (FFI), sometimes referred to as familial thalamic dementia, is caused by a point mutation on the prion protein gene at codon 178 combined with a polymorphism at codon 129 (Medori et al. 1992; Petersen et al. 1992). FFI does not appear to be transmissible and has a course and presentation similar to CJD with the addition of progressive insomnia and dysautonomia. Onset is usually at about age 50 with a 12- to 13-month course to death. Patients often develop dysarthria, ataxia, myoclonus, pyramidal tract signs, insomnia, and autonomic disturbances including hyperhidrosis, hyperthermia, tachycardia, and hypertension. Although the neuropathology in FFI of neuronal loss and gliosis seems mostly restricted to the anterior and dorsal medial thalamic nuclei, these nuclei

have tremendous connections with specific frontal lobe regions, and neuropsychological evaluation of these patients reveals significant executive dysfunctioning with difficulties with working memory, attention, sequencing, and planning abilities (Gallassi et al. 1992). Confusion, disorientation, and hallucinations can also be seen.

Kuru and new variant CJD are transmissible prion diseases affecting humans. Kuru is seen in certain New Guinea tribes who practice ritualistic cannibalism. New variant CJD appears to be a novel epidemic caused by the spread of bovine spongiform encephalopathy (BSE), a prion disease affecting cattle, to humans who consume BSE-contaminated cattle-derived products (Epstein and Brown 1997; Schonberger 1998).

### Viral Infections

Viral infections can be classified as either acute, with a rapid onset of symptoms, or slow, with a chronic course over months to years (Table 30-4). The clinical features of the

infection relate to the selective vulnerability of certain cell types to the particular virus (R. T. Johnson 1982).

**Herpes simplex encephalitis.** Herpes simplex encephalitis, an acute infection, is a common cause of encephalitis in elderly patients and is often treatable, but mortality is high. Incidence is about 1/400,000 per year, with half of all cases occurring in those over age 50 (Whitley 1991).

Initial clinical features include headache, fever, stiff neck, and photophobia. These symptoms progress over a few days to produce lethargy, mental status changes, memory impairment, aphasia, focal neurological deficits, seizures, and eventually coma (Whitley 1991). Recovery may be complete or partial. Frontal and temporal lobe involvement are common (Kapur et al. 1994). Frontal lobe injury often results in grasp reflexes, frontal release signs, motor impersistence, disinhibition, impulsivity, psychomotor hyperactivity, hyperoral behavior, apathy, echolalia, mutism, anomia, inattention, and utilization behaviors (Brazzelli et

**FIGURE 30-4.** Positron-emission tomography (PET) image of a 63-year-old man with autopsy-proven Creutzfeldt-Jakob disease. *Panel A:* PET shows multifocal areas of cortical hypometabolism involving the right parieto-occipital region and the bilateral frontal areas (*arrows*). *Panel B:* A slightly caudal PET slice revealing the relative hypometabolism seen in the right basal ganglia region (*arrow*).

al. 1994). Temporal lobe damage often causes amnesia, hallucinations, and, if bilateral, the Klüver-Bucy syndrome, which is characterized by hyperoral behavior, dietary changes, hypersexuality, placidity, visual agnosia, and hypermetamorphosis (excessive tactile exploration of the environment). Aphasia or dementia syndrome may be permanent (Cummings and Benson 1992).

Hemorrhagic necrosis and petechial hemorrhages are seen in the brain at autopsy. The medial temporal, insular, cingulate, and orbitotemporal regions are the areas most commonly involved (Okazaki 1983). Periodic lateralizing epileptiform discharges (PLEDs) are the usual focal EEG abnormality, seen in 80% of patients (Bale 1991). MRI often shows focal areas of increased T2 signal in the temporal/insular or frontal regions (Schroth et al. 1987). An imaging study is often necessary before the lumbar puncture to rule out a mass lesion. The lumbar puncture usually suggests a viral infection, and application of polymerase chain reaction (PCR) can confirm a specific diagnosis of herpes simplex virus infection in the brain (Whitley and Lakeman 1995) (Table 30–3). Brain biopsy is diagnostic, but is not always accurate, and it has an acute morbidity of at least 3% (Whitley 1991). Therapy with acyclovir (30 mg/kg body weight per day in three divided doses for 10 days) is started empirically and immediately because the toxic effects are minimal and mortality is reduced from 70% to 19% (Whitley 1991).

**Other meningoencephalitides.** The arboviruses are frequent causes of meningoencephalitis in the elderly population (Ho and Hirsch 1985). All are mosquito borne, and all have seasonal and geographic preferences. St. Louis encephalitis is the most common type in the United States. In a study of eastern equine encephalitis, 40% of all cases occurred in patients over age 50 (Przelomski et al. 1988). Western equine encephalitis is common particularly in young children and the elderly. Rubella, mumps, measles, Coxsackieviruses, polio, and adenoviruses typically occur in younger age groups (Bale 1991).

The acute prodromes of viral meningoencephalitides are all similar to that described for herpes simplex encephalitis above. The specific neurological deficits depend on the extent and distribution of the infection. Lethargy, mental status changes, focal neurological deficits, seizures, and coma may occur. The syndrome of inappropriate antidiuretic hormone (SIADH) secretion is common with St. Louis encephalitis (Ho and Hirsch 1985). Permanent postencephalitic intellectual deficits have been observed with several arbovirus infections including western equine, eastern equine, Japanese, and St. Louis encephalitis (Cummings and Benson 1992).

**Human immunodeficiency virus type 1.** Human immunodeficiency virus type 1 (HIV-1) is a retrovirus that preferentially infects helper T cells (Pantaleo et al. 1993). As the number of helper T cells declines, acquired immunodeficiency syndrome (AIDS) occurs, making the individual susceptible to numerous opportunistic infections (Centers for Disease Control 1992). The virus is constantly mutating, and certain virus types are able to enter the CNS easily and early in the course of the infection, making neurological symptoms common. High-risk groups include homosexual men, intravenous drug users, users of crack cocaine, individuals who receive contaminated blood products, heterosexual partners of HIV-1-infected individuals, and children of HIV-1-infected mothers (Rosenblum et al. 1988). Although this disease is most prevalent among men between ages 25 and 44, undoubtedly an increasing number of cases will be identified in the geriatric population.

It is estimated that 30 million people worldwide are infected with HIV-1 (Kahn and Walker 1998). Nearly everyone infected is expected to eventually develop AIDS. In 1996, more than 235,000 cases of AIDS in the United States alone were recorded (Centers for Disease Control 1997). The median period of time between the initial infection and the development of AIDS is 10 years. Elderly individuals, however, have a more rapid course.

Only 40%–90% of new HIV-1 infections are associated with symptomatic illness (Kahn and Walker 1998). The most common signs and symptoms of HIV-1 infection include fever, lethargy, rash, headache, lymphadenopathy, pharyngitis, myalgias, arthralgias, diarrhea, vomiting, and night sweats (Kahn and Walker 1998). Neurological and neuropsychiatric symptoms occur early, and opportunistic infections account for many additional clinical syndromes (Table 30–5).

Diagnosis of HIV-1 infection itself is made by detecting serum antibodies to HIV-1 proteins using HIV-1 enzyme-linked immunosorbent assay (ELISA) testing (Kahn and Walker 1998). At the time of seroconversion, some individuals develop a primary HIV-1 meningitis consisting of fever, headache, meningismus, and CSF pleocytosis (Cooper et al. 1985). Individuals may then become asymptomatic and have either mild (Bornstein et al. 1992) or no (McArthur et al. 1989) abnormalities on neuropsychological testing. However, once systemic findings appear (lymphadenopathy syndrome or AIDS-related complex [ARC]), 50% of these individuals have neurological signs or symptoms, and 50% have abnormalities on neuropsychological testing (Janssen et al. 1988). Mental and motoric slowness (Kiebertz and Schiffer 1989), referred to as the *HIV-1 associated minor cognitive/motor disorder*, is the most

**TABLE 30–5. Neurological disorders in human immunodeficiency virus–type 1 (HIV-1) infection****Primary HIV-1 infection**

- Aseptic meningitis
- HIV-1–associated minor cognitive/motor disorder
- HIV-1–associated dementia complex
- HIV-1–associated myelopathy
- HIV-1–associated acute inflammatory demyelinating polyradiculoneuropathy (HIV-1–associated Guillain-Barré syndrome)
- Chronic inflammatory demyelinating polyneuropathy
- HIV-1–associated predominantly sensory polyneuropathy
- Mononeuritis multiplex
- HIV-1–associated myopathy
- Vasculitis (stroke)

**Opportunistic infections**

## Viral

- Cytomegalovirus (meningoencephalitis, retinitis, myelitis)
- Papovavirus (progressive multifocal leukoencephalopathy)
- Herpes simplex virus (myelitis, encephalitis)
- Varicella zoster virus (myelitis, encephalitis)

## Nonviral

- Toxoplasma gondii* (meningoencephalitis)
- Mycobacteria (meningitis)
- Cryptococcus neoformans* (meningitis, brain abscess)
- Aspergillus fumigatus* (meningitis, brain abscess)
- Histoplasma capsulatum* (meningitis, brain abscess)
- Candida albicans* (meningitis, brain abscess)
- Coccidioides immitis* (meningitis, brain abscess)
- Nocardia asteroides* (brain abscess)
- Mucormycosis (brain abscess)
- Listeria monocytogenes* (meningitis)
- Escherichia coli* (meningitis)
- Syphilis (meningovascular)
- Amebic infections (brain abscess)

**Opportunistic neoplasms**

- Primary central nervous system lymphoma
- Metastatic systemic lymphoma
- Metastatic Kaposi's sarcoma

**Other conditions**

- Stroke (endocarditis, tumor hemorrhage)
- Drug intoxication or withdrawal

common abnormality (American Academy of Neurology AIDS Task Force 1991). Impaired memory, poor reasoning skills, and slow information processing speed are common (Rao 1996). By the time AIDS has been diagnosed, neurological complications are seen in 60% of individuals, and at autopsy neurological damage is found in 70%–90% (Kiebertz and Schiffer 1989).

HIV-1–associated dementia (subacute encephalopathy, HIV encephalopathy, or AIDS dementia complex) is the initial manifestation of AIDS in 7% of all patients with AIDS, but in those over age 74 it is the initial manifestation in 19% (Janssen et al. 1992). It affects 15%–20% of all patients with AIDS (Power and Johnson 1995). It is characterized by progression over weeks to months of a subcortical dementia syndrome with mental slowness, impaired concentration, forgetfulness, cognitive abnormalities, apathy, social withdrawal, slowed motor skills, ataxia, and weakness, potentially resulting in severe global cognitive dysfunction, paraplegia, mutism, and incontinence (American Academy of Neurology AIDS Task Force 1991; R. W. Price et al. 1988). Agitation, delusions, and hallucinations occur in a few patients (Cummings and Benson 1992). Neuropsychological testing reveals deficits particularly in nonverbal tasks and frontal lobe tasks including Trails B and verbal fluency (Hestad et al. 1993; Power and Johnson 1995). CT and MRI scans show generalized cerebral atrophy and periventricular white matter abnormalities (Ekholm and Simon 1988; Navia et al. 1986b). EEG results are either normal or show moderate diffuse slowing (Koppel et al. 1985). CSF is abnormal but nonspecific (Marshall et al. 1988; Navia et al. 1986b) (Table 30–3). The pathology of the HIV-1–associated dementia consists of reactive gliosis and microglial nodules, especially in the subcortical white and gray matter (Masliah et al. 1992; Navia et al. 1986a). Since the advent of zidovudine and other antiviral agents, HIV-1–associated dementia occurs less frequently and its progression is slowed (Atkinson and Grant 1994; Bartlett and Moore 1998; Schmitt et al. 1988).

Using combinations of newer antiviral agents, treatment of the neurological complications of AIDS has dramatically improved (Henry 1995). Currently the most effective treatments involve three of four drugs: two nucleoside analogues that inhibit reverse transcriptase and one or two protease inhibitors that prevents cleavage of HIV proteins (Bartlett and Moore 1998). Neuropsychiatric side effects of these treatments include fatigue, malaise, myopathy, and confusion with zidovudine; dose-related, occasionally painful, peripheral neuropathy with stavudine, didanosine, and zalcitabine; and paresthesias with ritonavir (The Medical Letter 1997).

Opportunistic infections and neoplasms involving the CNS are listed in Table 30–5 (Bale 1991; Kiebertz and Schiffer 1989; Levy and Bredesen 1988). Progressive multifocal leukoencephalopathy (PML) and cryptococcal meningitis are discussed below. CMV encephalitis in its severe forms causes diffuse, bilateral cerebral dysfunction with impaired alertness. Neuroimaging can occasionally

show subependymal enhancement (Price 1996). Cerebral toxoplasmosis and primary CNS lymphoma can be diagnosed by clinical presentation, neuroimaging, and a treatment trial or occasionally a brain biopsy (Bale 1991). Cerebral toxoplasmosis evolves in only a few days, with focal neurological findings and enhancing lesions with mass effect and edema on MRI (Figure 30–5). Primary CNS lymphoma also causes focal neurological deficits but progresses more slowly, and MRI lesions are more diffuse in the deep white matter. Treatment with zidovudine and other antiviral agents lowers the frequency and mortality of opportunistic infections (Bartlett and Moore 1998; Schmitt et al. 1988). Specific treatments are also available for many of the opportunistic infections and neoplasms (Bale 1991).

Intracerebral hemorrhages, embolic infarctions from nonbacterial thrombotic endocarditis, strokes resulting from vasculitis, and medication effects also contribute to the neurological deficits seen with HIV-1 infection (Engstrom et al. 1989; Ochitill and Dilley 1988) (Table 30–5).

**FIGURE 30–5.** Gadolinium-enhanced T1-weighted magnetic resonance image (MRI) of an individual with acquired immunodeficiency syndrome (AIDS) and a cerebral abscess resulting from toxoplasmosis. MRI reveals a mass lesion in the left medial frontal region with surrounding edema.

**Progressive multifocal leukoencephalopathy.** PML caused by the papovavirus, JC virus, typically occurs in patients with deficits in cell-mediated immunity, particularly in association with AIDS or lymphoproliferative diseases or in those receiving immunosuppressive therapy (Holman et al. 1991). Onset is usually between ages 30 and 70, but can range from ages 6 to 84 (Stoner et al. 1988). The disease typically progresses over several weeks or months to death in less than 1 year (Bale 1991).

The neurological manifestations are multifocal. Impaired concentration, visuospatial deficits, memory impairment, speech disturbance, aphasia, calculation deficits, cognitive decline, hemianopsia, slowing of motor speed, paresis, sensory deficits, incoordination, and ataxia are common (Berger et al. 1987; Cummings and Benson 1992). Depression and agitation have been reported (Stagno et al. 1990). Fever or other systemic signs are not present.

Pathologically, multifocal demyelination is found in the subcortical white matter, particularly in the frontal and parieto-occipital regions (Whiteman et al. 1993). In these subcortical regions, axons are spared, but the oligodendrocytes and myelin are destroyed. Circling the demyelination foci, enlarged oligodendrocytes with intranuclear inclusions consisting of papovavirus are present (R. T. Johnson 1982). MRI shows areas of demyelination without mass effect or contrast enhancement (Berger et al. 1987; Brink and Miller 1996), and PET studies show diminished metabolism in the same areas (Kiyosawa et al. 1988). CSF may confirm PML by detection of the CSF JC virus DNA (Brink and Miller 1996) (Table 30–3). Diagnosis is also made by brain biopsy, and treatment is supportive (Greenlee 1998).

## Bacterial Infections

**Acute bacterial meningitis.** The incidence of bacterial meningitis is 5/100,000 per year. Mortality can be as high as 35% in those over age 65 (Behrman et al. 1989). Common organisms causing acute bacterial meningitis in the elderly population are *Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae* type B, and other Gram-negative bacilli (Ashwal 1995; Behrman et al. 1989; Durand et al. 1993; Stacy and Roeltgen 1991). Predisposing conditions such as diabetes, cancer, recent craniotomy, sinus surgery, skull fractures, or immunosuppressive therapy are present in about 35% of cases, and concurrent infections occur in approximately 40% of cases (Behrman et al. 1989).

Initial symptoms of a bacterial meningitis include

fever, headache, stiff neck, photophobia, nausea, and vomiting. Agitation, lethargy, and often, especially in the elderly, acute confusional states follow. Mental status changes are more common than are meningismus or headache (Behrman et al. 1989). Focal neurological deficits including hemiparesis, visual field defects, aphasia, cranial nerve palsies, and seizures are usually the results of cerebrovascular complications or acute obstructive hydrocephalus (Durand et al. 1993). Long-term sequela include dementia, aphasia, hydrocephalus, seizures, and persistent focal neurological deficits. Personality changes are common.

Purulent meningitis and brain edema are seen at autopsy. CT or MRI may show evidence of hydrocephalus, edema, or infarct. CSF is diagnostic, revealing increased intracranial pressure, polymorphonuclear pleocytosis, elevated protein, hypoglycorrhachia, positive cultures, and bacterial antigen detection (Ashwal 1995) (Table 30–3). Antibiotics are required for treatment. Adjunctive steroid use is now being considered more frequently for bacterial meningitis at any age (Ashwal 1995). Vaccination for some of the more common pathogens (*Streptococcus pneumoniae*) protects against disease and is cost-effective in the elderly (Monto and Terpenning 1996).

**Brain abscess and epidural abscess.** Abscesses consist of collections of purulent material that may be present in brain parenchyma, subdural space, or epidural space. The incidence of brain abscess is 4/1 million per year. Fifteen percent of all brain abscesses and 25% of all spinal epidural abscesses occur in patients over age 60. Typical organisms for brain abscesses include aerobic and anaerobic *Streptococcus*, *Bacteroides*, *Fusobacterium*, and *Clostridium* species. In immunocompromised individuals, various fungal species, cysticercosis, and toxoplasmosis are prevalent (Wispelwey and Scheld 1992). *Staphylococcus aureus*, anaerobic bacteria, and Gram-negative organism infections are frequent causes of brain abscesses after extension of a frontal sinusitis or middle ear infection (Luby 1992).

Headache, fever, mental status changes, and focal neurological signs are common initial symptoms (Wispelwey and Scheld 1992). Seizures and increased intracranial pressure may occur. Long-term sequela include late seizures and persistent focal neurological deficits. Enhanced MRI is very helpful in diagnosing brain abscesses (Sze and Zimmerman 1988), and EEG usually shows focal delta activity. Lumbar puncture may precipitate a herniation syndrome and is contraindicated in brain abscesses (Table 30–3). Treatments for brain abscesses include broad coverage antibiotics and occasionally surgical drainage (Wispelwey and Scheld 1992).

## Fungal Infections

Half of all chronic fungal meningitis infections occur in individuals with depressed immune systems or chronic debilitation (Cummings and Benson 1992), making these infections frequent among the geriatric population. Cryptococcal meningitis is the most common of these infections (Jones and Nathwani 1995). Other causative organisms include *Coccidioides*, *Histoplasma*, *Candida*, *Blastomyces*, and *Aspergillus*.

Fungal infections begin insidiously and progress slowly over weeks to months. Headache, fever, and stiff neck are common, but may not always be present. Mental status changes occur more frequently and include lethargy, apathy, disorientation, poor concentration, memory deficits, and aphasia. Focal neurological deficits, cranial nerve dysfunction, gait imbalance, dementia, or hydrocephalus may also occur (Cummings and Benson 1992). CSF examination reveals lymphocytic pleocytosis, increased protein, and hypoglycorrhachia. Cryptococcal antigen in the CSF is specific for cryptococcal meningitis (Fishman 1992) (Table 30–3). Cultures or titers are necessary for diagnosis of other infections. Fluconazole and other new azole antifungal agents are safe and effective as first-line therapies without the severe toxicity seen with amphotericin B (Slavoski and Tunkel 1995).

## Spirochete Infections

**Syphilis.** Syphilis, caused by the spirochete *Treponema pallidum*, is spread by sexual contact, and CNS invasion occurs in many patients, although most are asymptomatic (Scheck and Hook 1994). Syphilis recently is increasing in frequency, especially in patients with HIV-1 (Hook 1989). The annual incidence of syphilis of all types was 20/100,000 in the United States in 1990 (Hook and Marra 1992); for neurosyphilis it is estimated to be 2/100,000 (Simon 1985). Primary syphilis presents as a chancre that heals in several weeks and is followed by a diffuse skin rash indicative of the bacteremia of secondary syphilis. Meningeal neurosyphilis may be seen at this early stage. Tertiary syphilis occurs 2–50 years after the primary infection and occurs in various forms, including cardiovascular (aortitis), meningovascular, parietic, and tabetic. Because of the long incubation times, neurosyphilis frequently begins between ages 30 and 60 (Cummings and Benson 1992).

General paresis results from syphilitic invasion into the brain parenchyma. Before penicillin treatment, general paresis accounted for up to 20% of all admissions to mental hospitals (Hook and Marra 1992), but now it is extremely uncommon. The frontal lobes are classically involved in

general paresis. Clinical features, many of which suggest frontal region impairment, include inattention, memory and cognitive deficits, dementia, tremulous speech, anomia, impaired judgment, irritability, pseudobulbar palsy, paralysis, tremor, ataxia, incontinence, optic atrophy, and Argyll Robertson pupils. Mania is seen in 20%–40% of patients, depression in 6%, and peculiar deportment, grandiose delusions, paranoia, and hallucinations in 3%–6% (Cummings and Benson 1992).

The pathology of syphilis is varied and includes meningitis, stroke, vasculitis, inflammatory infiltrates, neuronal loss, gliosis, and rarely gumma formation. MRI shows bilateral frontal and/or temporal lobe atrophy and subcortical abnormalities (Zifko et al. 1996). Screening for neurosyphilis should be done with the fluorescent treponemal antibody absorption (FTA-ABS) test because other screening tests may be nonreactive in tertiary syphilis (Simon 1985). False positives can occur with systemic lupus erythematosus and some infectious conditions (Hook and Marra 1992). If the FTA-ABS is positive, a lumbar puncture is indicated. CSF in neurosyphilis shows lymphocytic pleocytosis, elevated protein, positive Venereal Disease Research Laboratory (VDRL) test, occasional hypoglycorrhachia, and increased IgG (Table 30–3). Penicillin is the treatment of choice for all forms of syphilis, with the intravenous route and longer duration of treatments required for patients with neurosyphilis and syphilis associated with HIV-1 (Hook and Marra 1992). Desensitization is recommended for those with penicillin allergies (Centers for Disease Control 1989).

**Lyme disease.** Lyme disease is caused by the tick-borne spirochete *Borrelia burgdorferi*. Age at onset ranges from 7 to 86 (Halperin et al. 1991). After the tick bite, an acute localized erythema chronicum migrans (ECM) rash and a viral-like syndrome occur. Dissemination occurs within a few weeks to months, with symptoms including a multifocal ECM rash, acute arthritis, cardiac conduction block, myocarditis, myositis, hepatitis, or meningoradiculoneuritis. Some individuals develop a chronic course leading to chronic arthritis, radiculoneuritis, encephalomyelitis, or encephalopathy.

Early neurological manifestations occur in 10% of patients and can include bilateral seventh nerve palsies, oculomotor disturbances, other cranial neuropathies, radiculopathies, mononeuritis multiplex, myopathy, and an acute lymphocytic meningitis with headache, photophobia, and meningismus (Finkel and Halperin 1992). Chronic neurological features typically include memory loss, anomia, cognitive deficits, and mild dementia. Deficits in executive function, attention, organization, initia-

tion, abstract concept formation, and verbal fluency are also typical and suggest frontal lobe dysfunction (Fallon and Niels 1994; Waniek et al. 1995). Behavioral disturbances include depression, emotional lability, sleep disturbances, anorexia nervosa, fatigue, irritability, psychosis with paranoia and hallucinations, and violent outbursts (Fallon and Niels 1994). Rarely, patients develop focal CNS deficits including paresis, ataxia, seizures, or a severe dementia with CSF evidence of an encephalitis (Halperin et al. 1991).

Neuropathological findings include peripheral neuritis, vasculitis, focal demyelination, and, in the late stages, neuronal loss, gliosis, and signs of brain parenchyma infection. MRI may reveal multifocal regions of increased signal in the white matter consistent with demyelination (Halperin et al. 1991). Diagnosis is made with a positive serology in the setting of appropriate clinical findings. Demonstration of intrathecal antibody production and CSF PCR for the spirochete may help with diagnosis (Pachner 1995) (Table 30–3). Intravenous antibiotics can prevent or halt the neurological complications and may lead to significant improvement.

## ■ Inflammatory Disorders

The inflammatory disorders include the vasculitides, the collagen vascular diseases, and certain other conditions. Most of these diseases can present at any age, but some are particularly prevalent in elderly individuals. Causes of inflammatory disorders involving the CNS in the geriatric age group are listed in Table 30–6. Some of these conditions have already been addressed.

### Vasculitides

**Giant cell (temporal) arteritis.** Giant cell (temporal) arteritis is a systemic vasculitis seen predominantly in the geriatric population. Nearly all patients are over age 50, and women are affected twice as often as are men. The incidence is as high as 7/100,000 per year (Boesen and Sorensen 1987), and it rises dramatically with increasing age to over 25/100,000 per year over age 80. Systemic symptoms are rarely absent and include fever, weight loss, anorexia, and malaise. The classic features of polymyalgia rheumatica syndrome, including pain and stiffness in the muscles of the neck, shoulders, and pelvis, are seen in 50% of those with giant cell arteritis. Headache, jaw claudication, scalp tenderness, and tenderness and nodularity of the superior temporal artery are common (Berlit

**TABLE 30–6. Causes of inflammatory disorders involving the central nervous system in elderly patients****Vasculitides**

 Scleroderma  
 Rheumatoid arthritis  
 Sjögren's syndrome  
 Dermatomyositis  
 Cogan's syndrome  
 Mixed connective tissue disease

**Other**

Vogt-Koyanagi-Harada syndrome  
 Paraneoplastic disorders

1992; Chmielewski et al. 1992). The headache is characterized by a stabbing or throbbing pain, which is centered over the temple and radiates over the scalp and face. Scalp necrosis, muscular wasting, and angina occur infrequently.

Except for visual disturbance, CNS involvement is infrequent. Blurred vision, amaurosis fugax, and diplopia are reported, with blindness occurring, usually without warning, in 8%–23% of cases (Caselli and Hunder 1993). Multiple infarcts, more common in the posterior circulation territories, have been reported, but dementia syndromes unexplained by strokes are also seen (Caselli 1990). Less frequently, facial neuralgia, vertigo, and neuropathy occur (Nadeau and Watson 1990). Depression is the most common psychiatric manifestation.

Pathology shows a patchy giant cell arteritis frequently involving the branches of the external carotid, ophthalmic, and vertebral arteries. The large- and medium-sized arteries throughout the body are also involved, but are rarely symptomatic. Involvement of the intracranial arteries is uncommon. Multinucleated giant cells with destruction of the internal elastic lamina are seen. Anemia is common, and an elevated Westergren sedimentation rate (more than 50 mm/hour and often more than 100 mm/hour) is almost

always found. A superior temporal artery biopsy is positive in approximately 70% of cases and should be done in all suspected cases (Nadeau and Watson 1990). Negative biopsies should not dissuade treatment in those with the typical clinical features. Prednisone, typically in doses of 40–60 mg/day, is an effective treatment and should be initiated without waiting for biopsy confirmation (Berlit 1992).

**Polyarteritis nodosa.** Polyarteritis nodosa (PAN) characterizes a group of acute systemic necrotizing vasculitides, which includes Churg-Strauss angiitis. Immune complex deposition in PAN causes a relapsing and remitting vasculitis, which eventually leads to infarction or hemorrhage in multiple organs. The incidence of polyarteritis nodosa is approximately 0.2/100,000 per year, with males affected twice as often as females. Age at onset ranges from 6 to 80, with a mean of about 45. Common systemic findings include fever, weight loss, headache, anorexia, asthma, dyspnea, proteinuria, hypertension, arthralgias, skin rash, congestive heart failure, and gastrointestinal pain.

Neurological manifestations occur in up to 80% of cases, mostly resulting from peripheral nervous system involvement, giving rise to mononeuritis multiplex, polyneuropathy, cranial neuropathy, or myopathy. CNS involvement is seen in approximately 40% of cases and typically occurs later in the course with dementia, encephalopathy, psychosis, seizures, or strokes (Moore and Calabrese 1994). Specific neuropsychiatric symptoms occur in approximately 20% of cases and include disorientation, attentional deficits, memory impairment, cognitive deterioration, visual hallucinations, mania, paranoia, and hypoarousal progressing to coma. Hemiparesis, homonymous hemianopia, and ataxia occur secondary to the strokes.

Pathology shows a necrotizing vasculitis of the small and medium muscular arteries. Elevated sedimentation rate, anemia, leukocytosis, and thrombocytosis are common. Angiography reveals aneurysms and arteriopathy. MRI and CT may reveal evidence of infarction. CSF shows increased pressure, elevated protein, lymphocytic pleocytosis, and occasionally subarachnoid bleeding. Diagnosis is made clinically and confirmed by tissue biopsy (muscle, skin, sural nerve, or kidney) and angiography. Corticosteroids and immunosuppressive agents are the treatments of choice and often lead to remissions or recovery (Nadeau and Watson 1990).

**Isolated angiitis of the central nervous system.** Isolated angiitis of the CNS, also known as *granulomatous angiitis*, is a rare vasculitis of unknown etiol-

ogy and is confined to the CNS. It occurs at any age, with age at onset ranging from 3 to 96. Lymphoma, sarcoidosis, and herpes zoster conditions are occasionally associated with this vasculitis. Fever and weight loss are noted in 25% of cases. Usually, an initial subacute presentation with severe headache and encephalopathy is followed gradually by focal deficits, including strokes, and progressing to a vascular dementia syndrome affecting medium and small vessels (Vollmer et al. 1993).

Other common manifestations include seizures, aphasia, hemiparesis, supranuclear cranial nerve palsies, cerebellar signs, and myelopathy. Increased intracranial pressure may occur, leading to papilledema and potentially coma and brainstem herniation. Behavioral changes and psychosis are commonly seen.

A segmental vasculitis with fibrinoid necrosis and giant cells is found in the medium and small arteries, capillaries, and veins of the CNS. The sedimentation rate is increased in 60% of the patients but only to a mean of about 35 mm/hour. CT or MRI may be normal or reveal focal, occasionally enhancing, lesions, hemorrhage, or edema, which are found most commonly in the temporal and frontal cortical regions (Vollmer et al. 1993). Angiography may show vasculopathy, but usually does not. CSF findings are nonspecific (Table 30–3). Diagnosis is made clinically and confirmed by brain biopsy. Treatment with prednisone and cyclophosphamide is often ineffective, and there is an 87% mortality rate, with deaths occurring a mean of 6 months after onset of symptoms (Younger et al. 1988).

**Wegener's granulomatosis.** Wegener's granulomatosis is a granulomatosis systemic necrotizing vasculitis that always affects the respiratory tract and often the kidneys. Typical systemic clinical manifestations include fever, weight loss, sinusitis, otitis media, saddle-nose deformity, cough, hemoptysis, pleuritis, glomerulonephritis, visual symptoms, ulcerative or papular skin lesions, arthralgias, myalgias, and pericarditis (Duna et al. 1995).

Neurological involvement consists mostly of cranial and peripheral neuropathies, including mononeuritis multiplex. The brain can be affected by infarction, hemorrhage, diffuse periventricular white matter lesions, meningeal inflammation, or granulomatous mass lesions causing seizures, focal deficits, and encephalopathy (Duna et al. 1995). Contiguous extension of granulomatous inflammation from the paranasal sinuses to the brain and often the frontal lobes is typical (Geiger et al. 1992).

Vasculitis, necrosis, and granulomas are seen pathologically on biopsy. Diagnosis is made by cytoplasmic antineutrophil cytoplasmic antibodies (c-ANCA) with a sensitivity and specificity of about 90% (Duna et al. 1995).

Angiography is not helpful, neuroimaging is useful but nonspecific, and CSF can rule out infection. Corticosteroids and cytotoxic agents are needed for successful treatment.

**Lymphomatoid granulomatosis.** Lymphomatoid granulomatosis, a rare condition typically affecting the lungs, skin, and nervous system, is characterized by a perivascular mature T-cell lymphocytic infiltrate suggestive of a lymphomatous condition. In 60% of cases, a malignant lymphoma develops (Bushunow et al. 1996). Common manifestations include fever, weight loss, cough, chest pain, skin ulcers and papules, and peripheral neuropathies.

CNS dysfunction occurs in 20%–40% of cases and includes a broad spectrum of deficits such as monocular blindness, internuclear ophthalmoplegia, dysphagia, dysarthria, spasticity, paraparesis, hemiparesis, ataxia, aphasia, encephalopathy, and dementia. Behavioral symptoms reported include personality change, irritability, disinhibition, impulsivity, distractibility, and mood disturbance (Bushunow et al. 1996; Kleinschmidt-DeMasters et al. 1992).

CSF shows pleocytosis with atypical cells (Bushunow et al. 1996) (Table 30–3). Angiography can show a vasculitic pattern, and neuroimaging can show mass lesions, enhancement, or white matter changes. Treatment with prednisone and cyclophosphamide is usually necessary to maintain prolonged remissions. Adjunctive radiotherapy or chemotherapy can also be effective.

**Behçet's syndrome.** Behçet's syndrome is an inflammatory disorder of uncertain etiology characterized by recurrent oral and genital ulcers, uveitis, thrombophlebitis, and arthritis (Moore and Calabrese 1994). Fever and gastrointestinal complaints are also common. Prevalence is uncertain, with reports ranging from 4 to 100 per 100,000. Cases have been reported from ages 6 to 72.

Up to 40% of cases have neurological symptoms. A relapsing focal meningoencephalitis affecting the brainstem, with headache, cranial neuropathies, dysarthria, long tract signs, and bulbar and pseudobulbar palsies, is the most common neurological manifestation. A dementia syndrome with memory deficits, aphasia, and cognitive impairment can occur. Seizures, increased intracranial pressure, and peripheral neuropathy have also been reported (Serdaroglu et al. 1989). Personality changes, disinhibition, emotional disturbances, apathy, and akinetic mutism are frequently described behaviors (Yamamori et al. 1994).

A chronic small vessel vasculitis is seen pathologically, often involving the brainstem, spinal cord, globus pallidus,

hypothalamus, cerebral white matter, retina, and skin (Totsuka et al. 1985; Yamamori et al. 1994). Meningeal inflammation is also common. MRI sometimes reveals venous thrombosis and frequently shows deep subcortical and brainstem abnormalities (Al Kawi et al. 1991). Angiography is usually normal, and CSF examination shows a nonspecific lymphocytic pleocytosis with elevated protein (McLean et al. 1995) (Table 30–3). Diagnosis is based on clinical features. Treatment for CNS disease includes high-dose steroids and immunosuppressive agents.

## Collagen Vascular Diseases

**Systemic lupus erythematosus.** Systemic lupus erythematosus (SLE) is a multisystem immunological disorder of uncertain etiology. The incidence of SLE is about 5/100,000 per year, and the prevalence is about 45/100,000 (Nadeau and Watson 1990). Women are much more often affected. Although SLE is a disease primarily of young to middle-aged adults, it can occur in the very old. Systemic manifestations may include fever, anorexia, rash, lymphadenopathy, arthralgias, pericarditis, valvular disease, pleuritis, Raynaud's phenomenon, alopecia, renal insufficiency, nephrotic syndrome, and hypertension (Nadeau and Watson 1990).

SLE has the highest incidence of neuropsychiatric and focal CNS manifestations of any of the collagen vascular disorders. CNS dysfunction may occur from primary involvement of the brain or secondarily from complications of the disease including infection, embolism from endocarditis, steroid treatment toxicity, and severe hypertension.

Neuropsychiatric manifestations are seen in 40%–75% of cases and often occur early in the disease course. More than 60% of cases develop memory and cognitive deficits (Carbotte et al. 1986), whereas 35%–60% have symptoms of impaired attention, an acute confusional state or delirium, psychosis with hallucinations and delusions, depression, hypomania, mania, phobias, or anxiety (West 1994). Neuropsychological testing shows deficits in information processing, cognitive flexibility, working memory, attention, and verbal fluency (Denburg et al. 1993). Focal CNS involvement, including seizures, strokes, supranuclear cranial nerve deficits, chorea, ataxia, parkinsonism, transverse myelitis, and focal paresis, is present in 10%–35% of cases (West 1994).

Occasionally associated with SLE is the antiphospholipid antibody syndrome consisting of the presence of antiphospholipid antibodies (particularly lupus anticoagulant and anticardiolipin antibodies), venous or arterial

thrombotic strokes or ischemia, recurrent abortions, and thrombocytopenia (Brey et al. 1993; Lockshin 1992; Rosove and Brewer 1992). Myelopathy, deep vein thrombosis, Guillain-Barré syndrome, migraine, chorea, and seizures have also been associated with this syndrome (Levine and Welch 1987). Antiphospholipid antibodies are present in up to 50% of patients with SLE.

The main pathological feature of SLE is a small vessel vasculopathy with fibrinoid degeneration and endothelial proliferation of the small vessels, resulting in microinfarcts and microhemorrhages. Less commonly, a true vasculitis is seen. Angiography usually is unable to identify the microangiopathy of SLE. MRI is useful in localizing strokes, but is often normal even in those with neuropsychiatric symptoms and CNS involvement (neuropsychiatric lupus) (West et al. 1995). Nearly all individuals with neuropsychiatric lupus have abnormal CSF findings, including IgG index, oligoclonal bands, and/or CSF antineuronal antibodies, which may improve with response to therapy (West et al. 1995) (Table 30–3). An autoimmune process with these antineuronal antibodies may be an important cause of neuropsychiatric lupus and CNS involvement. Serum antiribosomal P protein antibodies are often seen in patients with neuropsychiatric lupus with psychosis and depression (Teh and Isenberg 1994). Diagnosis of SLE is based on clinical features, a positive antinuclear antibody test, and other specific antibody tests (Tan et al. 1982). Treatments include nonsteroidal anti-inflammatory agents, steroids, and immunosuppressive agents. Oral anticoagulants are advisable to prevent the recurrent thrombotic events seen with antiphospholipid antibodies (Khamashta et al. 1995). Neuroleptics are used for psychosis; anticonvulsants, for seizures.

**Sjögren's syndrome.** Sjögren's syndrome, seen mostly in women, is a systemic autoimmune disorder characterized by symptoms of dry eyes and dry mouth and may involve the lung, liver, kidney, heart, blood vessels, skin, muscles, joints, peripheral nerves, spinal cord, and brain. CNS manifestations, reported in up to 25% in some centers (Alexander 1993) and rarely observed in others (Moutsopoulos et al. 1993), include migraine, focal neurological deficits, intracerebral hemorrhage, subarachnoid hemorrhage, seizures, myelitis, aseptic meningitis, dementia, and psychiatric symptoms (Alexander 1993). The dementia syndrome has subcortical features, and the psychiatric symptoms include mood disturbances, depression, and obsessive-compulsive traits (Alexander 1993; Moutsopoulos et al. 1993).

Lymphocytic infiltration of the exocrine glands causes dry eyes and dry mouth. In the CNS, Sjögren's causes a

vasculopathy of the small vessels, and so angiography shows a vasculitis in only 20% of cases (Alexander 1993). Laboratory evaluations are frequently positive for antinuclear antibodies and occasionally for anti-SS-A (Ro) (seen with more serious CNS disease) and anti-SS-B (La) antibodies. CSF often is abnormal but nonspecific (Table 30–3). Biopsy of a minor salivary gland is diagnostic. MRI shows subcortical and periventricular white matter lesions in 80%. SPECT, however, can show cortical hypoperfusion in patients with neuropsychiatric dysfunction without cortical MRI lesions (Alexander 1993). Corticosteroids and rarely other immunosuppressive agents are used for treatment.

## Summary

Most acquired brain disorders occur in the geriatric population. Some conditions have their onset in late life, whereas other conditions have chronic courses and persist into advanced age. Diagnosis and treatment of these disorders in the elderly patient is influenced by the frequent co-occurrence of other chronic medical conditions, multiple medication regimens, and the normal physiological changes that accompany aging.

Neoplastic disorders involving the CNS occur frequently in elderly individuals, and they present as primary tumors, metastatic tumors, or paraneoplastic syndromes. MS often begins in early adulthood, but many patients survive well past 70. Neuropsychiatric features of MS include depression, psychosis, and mania. Toxic and metabolic causes of demyelination may begin in elderly patients. Both common and rare infectious disorders affecting the CNS have characteristic presentations in the elderly population, and most are treatable. Giant cell arteritis occurs almost exclusively in patients over age 50. Finally, SLE is a common disorder with frequent late survival and significant CNS manifestations.

# Medical Therapies

Karen Blank, M.D.

James D. Duffy, M.D., Ch.B.

Physicians caring for older patients aim to follow the Hippocratic promise to “First do no harm.” However, although medications are vital for the treatment of disease, the balance between benefits and risks of their use in elderly patients becomes precarious. In particular, the adverse behavioral effects of prescription medications can be devastating. Unfortunately, when physicians fail to recognize the drug-related etiology of these behavioral changes and prescribe psychotropic medications, they precipitate a pattern of escalating use of medications, increased side effects, and drug interactions.

Although the elderly (defined as those over age 65) represent 12% of the population in the United States, they are the largest group of users of pharmaceuticals, accounting for 34% of all pharmaceutical expenditures, almost three times that of the general population (Mueller et al. 1997). Multiple medication use is prevalent in elderly patients because they often have multiple chronic illnesses. Thirty-six percent of the elderly have three or more chronic conditions and account for 57% of drug expenditures for this group (Mueller et al. 1997). Among community-dwelling elderly, 83% consume at least one medica-

tion (Ostrom et al. 1985), with the average being 3.1 prescription drugs (Ouslander 1981; Rogowski et al. 1997). Medication usage rises drastically each time an elderly patient is hospitalized, with the typical elderly patient receiving 8–15 medications (Piraino 1995). Multiple medication use increases both the risk of adverse drug events and non-compliance (Graves et al. 1997). The elderly are two to three times more likely to experience adverse reactions compared with younger patients (Vestal and Cusack 1990). Rates of adverse drug reactions vary widely and have risen in recent surveys—perhaps as a reflection of adverse drug reaction monitoring mandated by the Joint Commission of the Accreditation of Healthcare Organizations. Hospitalizations attributable to adverse drug reactions have been estimated to account for 1.7%–16.8% of medical hospitalizations and 0.6%–7.5% of psychiatric admissions (Popli et al. 1997; Salzman 1995).

When considering drug use in the elderly population, it is important to remember that elderly patients frequently self-medicate with nonprescription drugs, buying 40% of all over-the-counter (OTC) drugs (Mueller et al. 1997; Piraino 1995). These drugs include nonsteroidal anti-inflammatory drugs (NSAIDs), antihistamines, analgesics,

H<sub>2</sub> blockers, and psychostimulants including caffeine or phenylpropanolamine. In addition, only sometimes with their physicians' recommendation, older patients consume alternative medications including melatonin, ginseng, Chinese herbal preparations, and vitamins in excess of recommended daily allowances. Many OTC and alternative agents have significant behavioral side effects, can cause drug interactions, or contain contaminants known to cause neuropsychiatric syndromes. A complete OTC and alternative therapies usage history must be obtained to anticipate and diagnose neurobehavioral changes (see discussion below) (Ernst 1998).

Although some drug reactions are idiosyncratic and unexpected, most can be appreciated as resulting from high-risk prescribing. A Canadian study (Tamblyn et al. 1994) found that 52.6% of the elderly patients in their sample received "high risk" prescriptions. McLeod and colleagues (1997) outline inappropriate or risk-laden practices as the prescription of medications that 1) are contraindicated for elderly people because of unacceptable risk/benefit ratios, 2) can cause drug-drug interactions, or 3) can cause drug-illness interactions. (Significant drug-drug interactions are shown in Appendix 31-1.) Considerable overlap exists between the drugs most frequently used by elderly patients and those known to cause neurobehavioral side effects. The most prevalent conditions among the elderly in the 1987 National Medical Expenditure Survey (Mueller et al. 1997) were arthritis and hypertension. Among elderly diabetics, 34% of drug expenditures were for cardiovascular and renal drugs, 21% for hormonal drugs, and 12% for pain relievers (Mueller et al. 1997). The Boston Collaborative Drug Surveillance Program (1971), which examined 90,000 drug exposures occurring during 10,600 hospital admissions, found the following drugs to be most frequently associated with behavioral side effects: prednisone, isoniazid, methyl dopa, insulin, diazepam, furosemide, phenobarbital, chlorthalidone, and aminophylline. Hanlon and colleagues (1997) found that among ambulatory patients taking five scheduled medications per day, 35% had an adverse drug reaction over a 1-year period—many requiring emergency room and in-hospital care. Twenty-nine percent of these were central nervous system (CNS) reactions, with cardiovascular medications (33.3%) and CNS medications (17.8%) the most common offending agents. Table 31-1 lists some patient risk factors for interactions.

In this chapter, we review the pharmacodynamic and pharmacokinetic alterations in normal aging, their interactions with pathological processes, and the implications of polypharmacy. We also review the neuropsychiatric effects of prescribed and OTC medications in elderly patients and

summarize how these medical therapeutic agents can interfere with a wide range of neurobehavioral functions including cognition, mood, arousal, sleep, ambulation, and sexual function.

## ■ Special Considerations in Geriatric Medical Therapy

Elderly patients are particularly susceptible to the neuropsychiatric complications of medical therapies because of age-related changes in CNS vulnerability, as well as changes in the body's ability to absorb, distribute, metabolize, and excrete drugs. Aging also increases the likelihood of multiple intercurrent illnesses and consequent drug interactions. In addition, aging may be associated with changes in drug-taking behaviors. The failure to recognize drug misuse and abuse in the elderly population can contribute to the development of neuropsychiatric complications of medical therapy. Rational medical treatment depends on an understanding of the interrelationships between these factors. Catterson et al. (1997) suggest conceptualizing these interactions as the "magnitude of effect" (the clinical response, both desired and untoward). Magnitude of effect is the product of the pharmacodynamics (the

action of the drug at the targets), the pharmacokinetics (the manner in which the drug is handled by the body and distributed to its target sites), and the biological variance (the individual biology of the patient and nature of the disease process). The following provides a brief review of some of the pertinent factors involved in the expected and undesired magnitude of effect of drug therapies in aging patients.

### Pharmacodynamic Alterations in Normal Aging and in Common Diseases

The normal aging process is associated with predictable physiological alterations that influence the elderly person's response to medications. Although substantial interindividual and intraindividual variability in the extent and type of changes is associated with the aging process, certain characteristic neurochemical and neurophysiological changes have been well documented.

Age-related alterations in the major neurotransmitter systems contribute to the increased pharmacodynamic sensitivity of the elderly. Although some of the data remain contradictory, these predictable age-related changes include alterations in neuronal cell numbers and neurotransmitter production and breakdown, selective changes in the number of presynaptic and postsynaptic receptors with age, and alterations in the receptor binding site–second messenger system (Sunderland 1992). Functionally, these changes result in both reduced transmission of neuronal messages in the aging brain and reduced ability for the receptor to upregulate or downregulate in response to drugs. These CNS changes are believed to be responsible for many of the neuropsychiatric syndromes that occur in old age (Sunderland 1992) as well as the more prevalent toxic neuropsychiatric reactions secondary to medical treatments. The age-related pharmacodynamic changes in the major neurotransmitters are reviewed below and are summarized in Table 31–2 (Catterson et al. 1997).

**Cholinergic system.** Normal aging involves loss and shrinking of the cholinergic neurons in the basal forebrain (Mesulam et al. 1987) with resulting decreases of cholinergic innervation throughout the brain and reduced amount of the acetylcholine-synthesizing enzyme choline acetyltransferase (CAT) (Catterson et al. 1997). The cholinergic cell loss and decreases in CAT activity are thought to be responsible for some of the memory decline in normal aging. Because acetylcholine plays a vital role in memory storage and retrieval, drugs with anticholinergic properties cause further disruption of acetylcholine transmission, resulting in mild to severe cognitive impairment.

Dementia of the Alzheimer type is characterized by a dramatic degradation of cholinergic systems, with pronounced cholinergic cell loss and decreased CAT activity in the cerebral cortex, pyramidal cells of the hippocampus, and nucleus basalis of Meynert (Catterson et al. 1997; Sunderland 1992). Anticholinergic drugs commonly have a deleterious effect on the already compromised memory of these patients, frequently causing delirium with relatively low doses. In addition to changes in the cholinergic system, persons with dementia of the Alzheimer type exhibit alterations in adrenergic and serotonergic systems. The impact of these changes on drug response remains to be determined.

Patients with Parkinson's disease also demonstrate an increased sensitivity to anticholinergic agents. One study found the development of an acute confusional state in 93% of patients with Parkinson's disease who were taking anticholinergic medications (De Smet et al. 1982).

**Dopaminergic system.** In normal aging, reduced dopamine synthesis and transmission can result from declines in the activity of the enzymes tyrosine hydroxylase and dopa decarboxylase (Jeste and Wyatt 1987; Sunderland 1992). In addition, the number of dopamine neurons in the nigrostriatal tract decreases with age. The most frequent manifestation of this reduction in dopamine activity is the occurrence of movement and gait disorders and in the older patient's (often exquisite) sensitivity to neuro-

leptic-induced extrapyramidal symptoms. Significant changes also develop in the ratio of the subtypes of dopamine receptors with a progressive loss of D<sub>2</sub> receptors (Catterson et al. 1997; Sunderland 1992). These receptor changes may help explain the increased incidence of drug-induced extrapyramidal syndromes (Catterson et al. 1997) and the susceptibility of older persons to chronic effects of dopamine blockers and resultant high rates of tardive dyskinesia (Sunderland 1992). In this regard, it is important to appreciate the dopamine blocking action of nonpsychotropic medications such as metoclopramide, which frequently produce extrapyramidal side effects in elderly patients.

The profound dopamine depletion (and subsequent neuroleptic supersensitivity) associated with Parkinson's disease often poses a therapeutic dilemma because these patients frequently develop delusional disorders and/or hallucinations as a consequence of dopamine agonist treatment (Cummings 1991). The selective dopamine subtype 4 (D<sub>4</sub>), receptor blocking agents clozapine and olanzapine provide viable therapeutic options in such situations (Rabey et al. 1995; Rosenthal et al. 1992; Wolters et al. 1996; Young et al. 1997). Patients with Alzheimer's disease also experience reduction in dopaminergic function, which accounts for their increased susceptibility to the extrapyramidal effects of neuroleptics prescribed for control of their agitated behavior (Cross et al. 1984).

**Serotonin system.** Research has yielded contradictory results regarding age-related alterations in 5-hydroxytryptamine (5-HT, serotonin) CNS characteristics. However, most evidence indicates decreased function and sensitivity of the 5-HT<sub>1</sub> and frontal cortex 5-HT<sub>2</sub> receptors with aging (Sunderland 1992). A decrease in both serotonin production (Shih and Young 1978) and serotonin receptor number and sensitivity (Lawlor et al. 1989) has been linked to the alterations in appetite and sleep seen in elderly patients and may explain their apparently reduced response to serotonergic drugs (Sunderland 1992).

**Adrenergic system.** Studies of the noradrenergic system reveal, as yet unexplained, age-related reductions in responses mediated by  $\beta$ -adrenergic and  $\alpha_2$ -adrenergic receptors. Drugs such as propranolol ( $\beta$ -adrenergic blocker) and clonidine ( $\alpha_2$ -adrenergic agonist) may be therefore less effective in older patients (Catterson et al. 1997).

**Gabaminergic system.** Within the CNS,  $\gamma$ -aminobutyric acid (GABA) functions as an inhibitory neurotransmitter and therefore plays a major role in modulating neuronal transmission. Reduced GABA neurotrans-

mission is thought to be important in Huntington's disease, Parkinson's disease, and some forms of epilepsy, but the changes with normal aging are less understood (Sunderland 1992). Research suggests a role for the benzodiazepine-GABA receptor complex in the etiology of anxiety. Increased density and sensitivity of the benzodiazepine binding sites with age may explain the heightened sensitivity of the aging CNS to benzodiazepine sedating effects and to their deleterious effects on psychomotor performance (Catterson et al. 1997; Sunderland 1992).

**Additional physiological changes of pharmacodynamic significance.** In addition to alterations in the specific neurotransmitters described above, other age-related physiological changes can have significant implications for drug effects. These changes render the older person more susceptible to the adverse side effects of many medications and involve neurodegenerative changes in the autonomic nervous system that predispose to orthostatic hypotension and thermal dysregulation (Brocklehurst 1974; Caird et al. 1987; Nemeroff 1989).

Although these age-related physiological and pathological changes make the elderly more sensitive to the CNS effects of medical therapies, older patients may actually be less sensitive to the peripheral effects of some drugs (e.g., the chronotropic effects of isoproterenol,  $\beta$ -adrenergic blockage by propranolol, PR prolongation by verapamil and diltiazem, and the hypoglycemic effect of tolbutamide [Vestal and Cusack 1990]). The clinician must carefully balance these altered central and peripheral pharmacodynamics when prescribing for elderly patients.

## Pharmacokinetics

Aging causes several changes that alter drug pharmacokinetics, the manner in which the drug is handled by the body and distributed to its target sites of action. The expected processes of normal aging, as well as an increased incidence of comorbid disease states, result in physiological and environmental changes that alter the absorption, distribution and transport, metabolism, and excretion of drugs.

**Absorption.** In theory, age-related changes of the gastrointestinal track would be expected to result in impairments of absorption of orally ingested drugs. These changes include reductions in stomach acid and mesenteric blood flow, decreases in the number of absorptive cells, decrease in the size of the absorbing surface, and impaired transport across the intestinal epithelial membrane. However, there appears to be little clinical impact of these

changes in healthy older persons (Abernethy 1992; Greenblatt 1993). Thus, in normal aging, the rate of absorption (generally described as the time required for the drug to reach maximum plasma concentration [ $T_{max}$ ]) is not significantly altered for most medications. Exception to this, however, are the absorption characteristics of levodopa and clorazepate. The increased gastric pH can contribute to decreased steady-state concentrations of clorazepate, and decreased dopa decarboxylase activity in the gastric mucosa can cause a threefold increase in the bioavailability of levodopa in elderly patients (Wood and Castleden 1991). When certain pathological processes and medications are present, however, the age-related changes become significant. Antacids can cause considerable decrements in the absorption of medications, and drugs and anticholinergics can impair intestinal motility and impair absorption. When these interactions lead to treatment failure, drug dosage escalation and toxicity can result.

**Distribution.** The physicochemical properties of a drug substantially influence how it is distributed. Lipophilicity greatly influences how rapidly a given drug will reach targets in the brain and how extensively it will distribute through the body (Greenblatt 1993). Increases in the volume of distribution of lipophilic drugs result in part from the general increase in total body fat (with decreased lean muscle mass) with aging. At age 25, the total body fat of the average 70-kg person is approximately 20%. By age 70, it is 30% or even higher in sedentary persons (Piraino 1995). Conversely, total body water content declines with age, from 60% to 54% in men and from 52% to 46% in women. The decline in body water tends to be exacerbated by a diminished sense of thirst and reduced fluid intake (Piraino 1995). As a result, hydrophilic medications, such as digoxin and lithium, will have smaller volumes of distribution and higher serum levels.

The most important clinical implication of these age-related changes stems from the relationship of volume of distribution ( $V_d$ ) to clearance. Lipid-soluble drugs with high volumes of distribution accumulate more extensively in the elderly, and the time required for elimination of the drug is prolonged, often substantially. Another clinical effect of this change in  $V_d$  is that a single dose of medication may have diminished effect because of lowered presence in the plasma as a result of dilution into peripheral tissues. In chronic drug therapy, this effect is of little clinical importance (Abernethy 1992).

Another drug characteristic that strongly affects its volume of distribution is the extent to which it binds to plasma proteins. Albumin, the most important binding protein, typically decreases with age, particularly in the

face of poor nutrition or renal failure. Even small reductions in albumin significantly increase the free fraction of drugs that normally would be extensively protein bound (Piraino 1995). The result will be higher concentrations of free, unbound drug to diffuse to CNS receptors. Elderly patients receiving several highly protein-bound medications will have increased drug-free fractions resulting from competition for limited binding sites. Changes in albumin and  $\alpha_1$  acid glycoprotein with aging will, in addition, make the interpretation of total plasma drug concentration assays more complicated (Greenblatt 1993).

**Metabolism and excretion.** After absorption, the first-pass extraction by the liver (or presystemic extraction) often substantially reduces the amount of drug that reaches the systemic circulation. Aging results in decreased liver size, decreased blood flow, generally decreased activity of the hepatic microsomal enzymes, at least those involved in phase I metabolism (Catterson et al. 1997), and increased prevalence of slow acetylator status. For drugs typically highly metabolized by first-pass effects, less drug is removed from the splanchnic circulation, resulting in increased bioavailability in the systemic circulation. Low flow conditions and congestive heart failure can further diminish this first-pass effect.

Once a drug reaches the systemic circulation in an elderly patient, it tends to be cleared more slowly than that in a younger patient. Phase I enzymatic reactions (oxidation, reduction, and hydrolysis of drugs) are affected by aging far more than are the conjugation of drugs and metabolites (phase II enzymatic reactions). Drugs requiring oxidation for biotransformation will have a greatly prolonged half-life in elderly patients (Erwin 1993). Because the elimination half-life is dependent on clearance and volume of distribution, those drugs with an increased volume of distribution and a decreased hepatic clearance (e.g., diazepam) will have a significantly prolonged half-life in elderly patients. Because lorazepam and oxazepam are metabolized by phase II reactions, they are the most appropriate benzodiazepines for older patients.

Important drug interactions occur through induction or inhibition of hepatic enzymes. Advances have been made in understanding the family of hepatic microsomal drug-metabolizing enzymes known as cytochromes. Two cytochrome P450 systems, the P450 IID6 and P450 IIIA4, appear to be responsible for the biotransformation of more than 90% of the drugs used in clinical practice that undergo hepatic metabolism. These systems have come under particular scrutiny since the introduction of the selective serotonin reuptake inhibitor (SSRI) medications and the observation that coadministration of fluoxetine with a con-

siderable number of other medications caused significant elevations of the plasma levels and the effects of the latter drugs (Anastasio et al. 1997; Greenblatt 1993) (Table 31–3).

Regarding excretion, although there is significant individual variation in renal function in elderly individuals, renal functioning begins a linear decline at age 40, and, by age 60, the decline becomes exponential (Catterson et al. 1997). Renal blood flow and glomerular filtration decrease as a function of age. On average, in those over age 65, renal clearance is reduced approximately 35% compared with that of the young. The function of the aging kidney is further diminished by congestive heart failure, diabetes, hypertension, and the concomitant use of sodium-depleting diuretics, nonsteroidal antiinflammatory medications and  $\beta$ -blockers. Thus, plasma clearance of water-soluble drugs and metabolites is often substantially compromised in elderly patients.

### Compliance Concerns

In general, little evidence suggests that older patients, as a group, are less compliant than other patients. However, because the risks of noncompliance are more serious, greater emphasis on strict compliance is required to properly treat

these patients (Lamy et al. 1992). Also, the causes of noncompliance may be different from those in younger age groups. Reasons for noncompliance in the elderly include 1) greater medication use and multiple simultaneous medication use; 2) unintentional noncompliance because of forgetting or not understanding the dosage schedule or reasons for medication; 3) intentional noncompliance because of cost or side effects; and 4) higher rates of adverse drug reactions (Salzman 1995).

The likelihood of noncompliance rises with the number of prescribed drugs and the disability of the patient (Ostrom et al. 1985). Noncompliance has been found to increase dramatically among the elderly when four or more medications are prescribed and/or when dosing more than twice a day is required (Salzman 1995). Bergman and Wilholm (1981) showed that in patients over age 65 the rate of noncompliance doubles when more than three drugs are prescribed (32% versus 69%). Cost appears to account for noncompliance in 10% of elderly patients, with higher noncompliance rates occurring when monthly medication costs exceed \$90 (Salzman 1995). Patients with cognitive impairment require extra monitoring (Kennedy 1992). Those elderly patients who use several physicians and who may provide inconsistent medication histories (Jackson et al. 1989) are at risk for increased adverse events.

**TABLE 31–3. Examples of drugs<sup>a</sup> that might interact with an antidepressant**

CYP 1A2	CYP 2C19	2C9	CYP 2D6 <sup>b</sup>	CYP 3A3/4
Acetaminophen	Barbiturates	Diclofenac	Chlorpheniramine	Benzodiazepines, alprazolam, clonazepam, diazepam, triazolam
Clozapine	Citalopram	Ibuprofen	Codeine	Cisapride
Haloperidol	Diazepam	Naproxen	Desipramine, secondary TCAs	Corticosteroids
Phenacetin	Mephenytoin	Omeprazole	Dextromethorphan	Cyclosporine
Phenothiazines	Moclobemide	Phenytoin	Flecainide/encainide	Dapsone
R-Warfarin (minor)	Propranolol	Piroxicam	Haloperidol	Estrogens
Tacrine	Tertiary TCAs	S-Warfarin	Hydrocodone	Ketoconazole, itraconazole
Tertiary TCAs		Tolbutamide	Phenothiazines	Lovastatin
Theophylline			Propranolol, timolol, metoprolol	Macrolide antibiotics
Thiothixene			Reduced haloperidol	Nonsedating antihistamines <sup>c</sup>
			Risperidone	Paclitaxel
			Quinidine	Quinidine
				Tamoxifen
				Zolpidem

Note. CYP = cytochrome P450; TCA = tricyclic antidepressant.

<sup>a</sup>Drug can be substrate and/or inhibitor of a given enzyme system.

<sup>b</sup>Inhibitor at 2D6, not a substrate.

<sup>c</sup>Terfenadine and astemizole contraindicated with CYP3A inhibitors; loratadine not contraindicated.

A benefit that may result from technological advances in health care delivery may be that physicians will have ready access to computerized databases and pharmacy records and with them be better able to orchestrate the patient's care.

## Underrecognition of Drug Abuse and Misuse

Substance misuse and abuse in elderly patients can lead to a variety of neuropsychiatric complications of medical therapy (Gambert 1992; Lawson 1989). Alcohol, prescription sedatives and analgesics, OTC medications, and caffeine are the most frequent substances of abuse. Significant symptomatology can result from both their use and also from abrupt withdrawal (Graves et al. 1997). One study found that the presence of benzodiazepines in the admission urine of cognitively intact elderly patients accounted for 29% of the cases of delirium that occurred in hospital (Foy et al. 1995). Many patients will conceal their OTC drug use or may not consider them as drugs. Only one-sixth of patients will inform their physicians of their OTC use, and those with cognitive impairment are particularly vulnerable to OTC misuse (Atkinson et al. 1992).

The anticholinergic effects of diphenhydramine and other antihistamines found in most OTC sleep and cold remedies can cause significant cognitive effects, delirium, and psychosis in elderly patients, even in therapeutic doses. There is also an age-associated increased sensitivity to caffeine and other stimulants such as phenylpropanolamine, ephedrine, and pseudoephedrine found in OTC allergy and cold preparations. Elderly patients can also be at increased risk from the neuropsychiatric effects of NSAIDs in OTC preparations. These effects include aseptic meningitis, psychosis, and cognitive dysfunction (Hoppmann et al. 1991). (The neuropsychiatric aspects of drug abuse and misuse in the elderly population are discussed further in Chapter 16 in this volume.)

## ■ Drug-Induced Neuropsychiatric Syndromes

Appendix 31–2 summarizes the drugs associated with specific neuropsychiatric syndromes in elderly patients. These are further discussed below.

### Delirium and Cognitive Impairment

Delirium occurs at rates ranging from 14% to 56% of elderly hospitalized patients, with associated hospital mortality rates of 10%–65%. Delirium results in longer, cost-

lier hospitalizations and increased rates of nursing home placements (Inouye 1994). Drugs, particularly anticholinergic agents, represent the most common cause of confusional states across all age groups (Hodkinson 1973). (Delirium is discussed further in Chapter 19, and dementia, in Chapter 24 in this volume.) Identified factors predisposing to the development of delirium are 1) age greater than 60 years (Lipowski 1984; Liston 1982) and 2) brain dysfunction (Erkinjuntti et al. 1986; Lipowski 1990). Other independent risk factors for its development include severe illness or sudden change in neurological, cardiac, pulmonary, or metabolic state; dehydration; malnutrition; infection; withdrawal from sedative-hypnotics or alcohol; and vision impairment. Independent precipitating factors appear to be the use of physical restraints, use of bladder catheter, and the rapid addition of three or more medications in a short time period (Inouye and Charpentier 1996; Rummans et al. 1995).

Many of the same drugs that produce delirium can also cause chronic cognitive impairment in elderly patients. Katzman et al. (1988) reviewed nine published series and found drug-induced states to be the most common of the reversible causes of dementia, and Larson et al. (1987) implicated drugs as either a primary or contributing cause in 35 of their 300 patients evaluated for dementia. The sedative-hypnotic agents, especially long-acting benzodiazepines, were the drugs most commonly associated with cognitive impairment. Appendix 31–2 indicates the various medical therapies reported to be associated with the development of delirium and dementia. The most important agents causing cognitive impairment are discussed below.

**Anticholinergic agents.** A postulated mechanism of drug-induced delirium is the accumulation of anticholinergic effects (Tune et al. 1992). Narcotic analgesics, antiparkinsonian drugs, neuroleptics, tricyclic antidepressants, antispasmodics, and OTC cold and sleep preparations containing antihistamines all have significant anticholinergic effects. Anticholinergic agents are particularly likely to induce delirium and are postulated to induce an imbalance in the cholinergic and adrenergic pathways of the reticular activating system and thalamocortical projections, thereby disrupting the attentional matrix (Itil and Fink 1966).

As discussed above, the elderly brain is likely to be more sensitive to the anticholinergic effects of drugs, particularly if there is associated neurodegenerative disease. Indeed, the neurologically compromised elderly patient may develop delirium even after receiving 1% scopolamine eye drops or transdermal patches (Danielson et al. 1981; MacEwan et al. 1985). The extent of this hazard faced by el-

derly patients is highlighted by the finding that 60% of nursing home residents and 23% of elderly community dwellers are receiving at least one anticholinergic drug at any one time (Blazer et al. 1983). Of the 25 most commonly prescribed medications in elderly patients, 14 were found to have detectable anticholinergic effects (Tune et al. 1992). P. S. Miller et al. (1988) evaluated the effects of low-dose scopolamine (0.005 mg/kg body weight) versus placebo in presurgical elderly patients and found the degree of impairment on the Saskatoon Delirium Symptom Checklist and performance on the Rey Auditory-Verbal Learning test (Lezak 1983) to relate to both serum and cerebrospinal fluid anticholinergic levels. It is important to recognize that elderly patients may experience the central muscarinic toxicity that produces a confusional state or a dementia-like syndrome without necessarily manifesting the characteristic autonomic (nicotinic) changes of urinary retention, tachycardia, piloerection, or pupillary dilation (Crawshaw and Mullen 1984).

Although the mechanisms by which corticosteroids alter cognition and cause delirium are not clearly understood, these agents are known to have high anticholinergic potency. Corticosteroid-induced neuropsychiatric side effects occur in 5% of patients. The larger the corticosteroid dose or the more rapidly changes in dose are made, the higher the prevalence of delirium and other neuropsychiatric complications. Other mechanisms by which corticosteroids are postulated to exert neurobehavioral effect are through altered serotonergic, somatostatin, and GABA agonist activity. Changes in hippocampal activity have also been implicated (Vincent 1995). Factors that predispose to corticosteroid-induced delirium include advanced age, intercurrent illness, and female gender (Stoudemire et al. 1996).

The cognitive impairment and delirium that occur with tricyclic antidepressants are primarily a result of their anticholinergic effect. Although tricyclics continue to be used for depression and pain management, their use for depression has been diminished by the SSRIs and novel antidepressants. Most of the SSRIs, norepinephrine reuptake inhibitors, and reversible inhibitors of monoamine oxidase are essentially devoid of anticholinergic activity and have either no memory effect or may improve cognition (Oxman 1996). The minimal anticholinergic effects of these agents are likely to present a significant clinical advantage over the tricyclic agents. However, their use is still associated with delirium in isolated case reports (Bonne et al. 1995) through drug interactions (Rothschild 1995), development of hyperserotonergic states (Amir et al. 1997) (see serotonergic syndrome below), development of the syndrome of inappropriate antidiuretic hormone (SIADH)

with resultant hyponatremia, and possibly through withdrawal (although the latter is reported only in case reports) (Kasantikul 1995).

Recent reports of delirium with, and after, clozapine therapy hypothesized mechanisms mediated through the cholinergic system with withdrawal delirium caused by a central cholinergic rebound (Pitner et al. 1995; Stanilla et al. 1997; Wilkins-Ho and Hollander 1997).

**Cardiovascular medications.** Several antihypertensives have been reported to produce delirium.  $\beta$ -blockers in particular have been implicated in producing not only delirium (Kuhr 1979), but also hallucinosis, sleep disruption, and chronic fatigue (McGahan et al. 1984). The topical  $\beta$ -blocker timolol, used to treat glaucoma, can also produce delirium (Shore et al. 1987). Other antihypertensives implicated in the production of delirium include calcium channel blockers, clonidine, and methyl dopa (Adler 1981; Hoffman and Ladogana 1981; Jacobsen et al. 1987). Methyl dopa, propranolol, hydrochlorothiazide, and reserpine can also produce significant global cognitive impairment in the elderly (Larson et al. 1987).

Delirium can occur with therapeutic blood levels (Eisendrath and Sweeney 1987) of digoxin and herald the onset of potentially fatal cardiac arrhythmias (Sagel and Matisson 1975). In addition to alterations in attention, digoxin can produce hallucinosis, sleep disruption, dysphoria, and irritability (Eisendrath and Sweeney 1987). Siberian ginseng has been reported to lead to increased digoxin levels (Ernst 1998). The muscarinic-blocking properties of the antiarrhythmics quinidine and disopyramide can also result in cognitive impairment in elderly patients.

**Nonsteroidal anti-inflammatory drugs and other analgesic medications.** Any of the NSAIDs can produce delirium and cognitive impairment in elderly patients (Allison and Shantz 1987; J. S. Goodwin and Regan 1982; Thornton 1980). NSAIDs are widely prescribed (in 1991 more than 70 million prescriptions were filled), and four NSAIDs, ibuprofen, ketoprofen, naproxen, and aspirin are available without prescription. The adverse effects of indomethacin are best recognized, but systematic information about the newer NSAIDs has been sparse. There are many case reports implicating most of the NSAIDs in causing delirium, mania, paranoid psychosis, and other depressive disorders with suicidal ideation (Browning 1996). Another case report describes a tacrine ibuprofen combination as causing delirium (Hooten and Pearson 1996). As interest grows in using

NSAIDs for delaying onset and progression of Alzheimer's disease, delirium may become a treatment-limiting side effect. Elderly individuals are particularly susceptible to acute or chronic salicylate toxicity that can occur at "therapeutic levels" and frequently presents with delirium (Cupit 1982). Although the opiate analgesics are less likely to produce delirium, the anticholinergic effects of normeperidine (a metabolite of meperidine) can result in a syndrome characterized by agitation, hallucinosis, and confusion (Eisendrath et al. 1987), and meperidine, in combination with MAO inhibitors, can cause a fatal serotonin syndrome.

#### Histamine subtype 2 receptor antagonists.

The histamine subtype 2 (H<sub>2</sub>) receptor blockers cimetidine, ranitidine, and famotidine are available over the counter and generally have been considered to have a benign side-effect profile. Adverse CNS reactions including malaise, dizziness, somnolence, and headaches occur in less than 3% of adult patients. However, serious neuropsychiatric complications including mental confusion, agitation, depression, and hallucinations have been reported, predominantly in geriatric patients with impaired renal or hepatic function (Picotte-Prillmayer et al. 1995), causing delirium in as many as 17% of these patients (Schentag et al. 1979). Whereas cimetidine has traditionally been implicated in most cases of CNS side effects, no clear evidence supports a higher incidence of adverse reactions with cimetidine compared with the other H<sub>2</sub> blocking agents. A recent study (Kim et al. 1996) showed no significant difference between cimetidine and ranitidine in the occurrence of postoperative delirium. The observation that physostigmine can reverse cimetidine-induced delirium (Jenike and Levy 1983) suggests that there may be indirect cholinergic involvement.

**Antiparkinsonian medications.** Patients with Parkinson's disease receiving levodopa are at risk for developing delirium. Patients of advanced age with Parkinson's disease, those with dementia, and those with significant cortical atrophy appear to be at most risk for developing not only delirium, but other behavioral side effects such as hallucinosis and psychosis (Celesia and Barr 1970; Fennelly 1987; Young et al. 1997). Not surprisingly, the anticholinergics often prescribed to treat the tremor of Parkinson's disease also frequently produce confusion and cognitive impairment. The dopamine agonists bromocriptine and amantadine have also been reported to produce delirium in as many as 20% of patients (Cummings 1991; Lieberman et al. 1979; Postma and Vantilburg 1975).

**Anesthesia.** Postoperative delirium and less severe cognitive impairments are not uncommon in elderly patients. Several possible etiologies should be considered including anticholinergic preoperative preparations, hypoxia, metabolic disturbances, infection, fat embolism, hemodynamic disturbances, meperidine intoxication, pulmonary embolism, and sedative-hypnotic withdrawal (Irvin 1995; Lipowski 1990; Tzabar et al. 1996).

**Serotonergic drugs.** The serotonin syndrome is a potentially fatal complication of serotonergic drug therapy and is characterized by the triad of altered mental status, autonomic dysfunction, and neuromuscular abnormalities (Martin 1996). Clinical manifestations include agitation, delirium, mutism, ataxia, mydriasis, diaphoresis, hyperthermia, shivering, fluctuating blood pressure, tremor and myoclonus, cardiovascular collapse, coma, seizures, and death. The serotonin syndrome is sometimes mistaken for the neuroleptic malignant syndrome but, in all but the most severe cases, lacks the serious muscle breakdown of the latter (Gelenberg 1995; Martin 1996; Stahl 1997; Sternbach 1991). The syndrome occurs because of toxic amounts of serotonin, rarely caused by a single serotonergic medication (Kolecki 1997), but more often by drug combinations of serotonergic acting medications or when MAO inhibitors are combined with an SSRI or with meperidine. Clinical features of serotonin syndromes are shown in Table 31-4.

**Other drugs causing delirium and cognitive impairment.** Low doses of benzodiazepines, relating to the plasma concentration, can also cause significant cog-

**TABLE 31-4. Most common clinical features of the serotonin syndrome in 38 patients in 12 reports**

Clinical Feature	N	%
Mental status changes		
Confusion	16	42
Hypomania	8	21
Restlessness	17	45
Myoclonus	13	34
Hyperreflexia	11	29
Diaphoresis	10	26
Shivering	10	26

nitive impairment in elderly patients (Pomara et al. 1984). The ability of benzodiazepines to impair the acquisition of new information (anterograde amnesia) and impair attention has been clearly documented. Deleterious effects on vigilance and encoding have been observed (Coenen and van Luijtelaaar 1997). Several studies have confirmed improved memory, cognitive functioning, energy, and sense of well-being in elderly nursing home residents after discontinuation of benzodiazepines (Griffiths and Weerts 1997). The long-acting benzodiazepines are worrisome because of their increased accumulation and the persistence of side effects. But the ultra-short acting benzodiazepines used as hypnotics have also been shown to have substantial cognitive impact including anterograde amnesia and delirium in susceptible individuals (Patterson 1987; Reynolds et al. 1985). After news that triazolam causes amnesic episodes was disseminated through the popular press, its sales dropped dramatically. Recently, Lobo and Greene (1997) have concluded from their literature review that the new and popular hypnotic zolpidem is strikingly similar to triazolam. Although not a benzodiazepine, zolpidem binds with the GABA receptor (although selective for subtype 1) and shares triazolam's pharmacokinetic properties. Zolpidem has been found to cause confusion, visual hallucinations, and amnesic periods occurring during the night and sometimes persisting into the next day.

The Veterans Affairs cooperative study of the cognitive effects of anticonvulsants in 622 patients with epilepsy reported that patients on phenobarbital, primidone, and phenytoin exhibit significant cognitive impairment compared with matched control subjects receiving carbamazepine (Smith et al. 1987). Carbamazepine and sodium valproate have shown less tendency to induce cognitive impairment in most studies, although the latter has been implicated as causing a dementia-like syndrome associated with reversible cerebral atrophy (McLachlan 1987). In a study of 36 patients with epilepsy who were on long-term valproate therapy, 32 were found to have reversible parkinsonism with cognitive impairment that had developed insidiously (Armon et al. 1996). Willmore (1995) cautions that elderly patients with declining intellectual function, motor impairments, or altered sensory function may be especially susceptible to dose-related CNS side effects of antiepileptic drugs and delineates the special cautions of polypharmacy and drug interactions in the elderly.

Other drugs reported to cause cognitive impairment include lithium, various antibiotics, radio-contrast agents, interferon, heavy metals, organic solvents, cyclosporine, various antineoplastic agents, phenylpropanolamine, and caffeine. (For an excellent review, see Morrison and Katz 1989.)

## Anxiety

Anxiety can be caused by a variety of pharmacological agents (Appendix 31–2). There is an increased sensitivity to stimulants with aging, and the elderly may be particularly susceptible to caffeinism—even without a history of excessive intake (Williams and Caranasos 1992). Caffeine may also be taken unknowingly in various OTC cold and allergy preparations. Sympathomimetic amines, which may be present in such OTC preparations, are common causes of secondary anxiety in elderly patients (Lader 1982). Elderly individuals, particularly those with cognitive impairment, are susceptible to paradoxical excitement manifested by anxiety and agitation as a result of alcohol, benzodiazepines, barbiturates, and other sedative-hypnotics. Short-acting benzodiazepines can cause rebound anxiety, precipitating escalating use of the drug. Erratic use of sedative-hypnotics can cause withdrawal insomnia and daytime anxiety. Tricyclic antidepressants, bupropion, and fluoxetine have all been reported to produce restlessness, anxiety, and insomnia (Williams and Caranasos 1992).

The withdrawal effects of narcotics, alcohol, benzodiazepines, and other sedative-hypnotics are also frequent causes of anxiety. Other drugs implicated as causing anxiety include corticosteroids, theophylline, thyroxine, anti-parkinsonian drugs (particularly levodopa and bromocriptine), various cardiac drugs (disopyramide and nifedipine), cycloserine, anticonvulsants, antihistamines, anticholinergics, and various respiratory drugs. Ten percent to 15% of patients treated with dopaminergic agents will develop anxiety symptoms (Cummings 1991).

## Depression, Mania, and Psychosis

Drugs implicated in causing affective and psychotic disorders are listed in Appendix 31–2. In this section, we discuss the most important of these as they pertain to elderly patients.

**Cardiac medications.** Cardiac glycosides, antiarrhythmics, and antihypertensives have all been associated with the development of psychotic and affective symptoms. The long-known catecholamine-depleting effects of reserpine account for the frequent association of depression with the use of this antihypertensive (F. K. Goodwin and Bunney 1971).  $\alpha$ -Methyldopa has also long been associated with depressive symptoms, acting primarily via its metabolite  $\alpha$ -methylnorepinephrine, a potent  $\alpha_2$ -adrenergic agonist. In their extensive review of the literature, Paykel et al. (1982) also found an incidence of depression of 1.5% for clonidine, another  $\alpha_2$ -adrenergic agonist; 1.1% for the  $\beta$ -adreno-receptor blocker propranolol; and 1.9% for guanethidine.

The association between  $\beta$ -blockers and the development of a major depressive disorder is inconclusive (Patten et al. 1997), but propranolol has been reported to cause other neuropsychiatric side effects including visual hallucinations and psychosis (Fleminger 1978; Fraser and Carr 1976). Fleminger (1978) found that 17.5% of 115 patients had visual hallucinations and/or illusions with propranolol. Although the incidence of depression with propranolol is probably much less than originally thought, atenolol, being less lipophilic than propranolol and thus crossing the blood-brain barrier less easily, is probably the preferable  $\beta$ -blocker to use in those susceptible to the development of depression.

Digitalis has a very narrow therapeutic index, and toxic levels can produce delirium, aphasia, and hallucinations (Levenson 1979). Depression can occur as a side effect at therapeutic levels, particularly in elderly patients (Pascualy and Veith 1989). The psychiatric side effects of digoxin are associated with elevated serum levels, and the susceptibility of elderly patients is probably related to decreased clearance of the drug. Patten et al. (1996) found an association of the use of angiotensin-converting enzyme (ACE) inhibitors and the presence of depression, particularly in women and subjects over age 65. Although case reports have suggested an association of calcium channel blockers with depression, this association was not observed in two more systematic studies (Patten et al. 1995, 1996).

The antiarrhythmics quinidine, procainamide, and disopyramide have all been associated with the development of hallucinations and psychosis. This may relate to their anticholinergic effects, although their psychiatric side effects are frequently associated with polypharmacy (K. A. Wood et al. 1988).

**Corticosteroids.** The Boston Collaborative Drug Surveillance Program study (1971) found prednisone to be the most frequent drug-related cause of moderate or severe psychiatric side effects, occurring in 2.6% of patients. Lewis and Smith (1983), in an extensive review of the literature, reported a 5% incidence of serious psychiatric symptoms in patients receiving corticosteroids, with higher rates in oncology patients (Vincent 1995). This association was found to be dose-related, with doses of prednisone greater than 80 mg causing psychiatric disturbances at a rate of 18.4%. In patients who develop psychosis, 77% are receiving more than the dose equivalent of 40 mg daily (Vincent 1995). Most patients develop neuropsychiatric complications early in their course of treatment, 43% during the first week and 93% during the first 6 weeks. In a review of cases of steroid-induced psychiatric disorders, depression was seen in 40% of patients, 28% experienced hypomania (with 8% having a combination of depression

and mania), 14% were acutely psychotic, and 10% were delirious. Suicidal ideation has been reported in 17%–33% of patients with steroid psychosis, and the suicide rate in these cases is approximately 2%. Minor psychiatric syndromes occur commonly and include anxiety, irritability, and panic reactions. Most cases of steroid-induced psychiatric disorders last 2–6 weeks (Vincent 1995). Female sex, systemic lupus erythematosus, and high doses of prednisone are risk factors. Decreasing the steroid dose (slowly to avoid precipitating a steroid withdrawal syndrome) and administering neuroleptics, benzodiazepines, valproate, or electroconvulsive therapy are generally effective treatments. Lithium has been found to be effective prophylaxis for those patients known to be at risk (Vincent 1995). Tricyclic antidepressants do not appear to be as effective and, in fact, can exacerbate steroid-induced mania.

**Nonsteroidal anti-inflammatory drugs.** Hoppmann et al. (1991) reviewed the neuropsychiatric reports of side effects of NSAIDs. Elderly patients have been suspected as being particularly susceptible, especially with NSAIDs that are mostly protein bound, although one review found no data to support age alone as being an independent risk factor, but rather comorbidities and co-medications confer the heightened risk (Solomon and Gurwitz 1997). Psychosis has been reported as a side effect of both indomethacin and sulindac, agents that are structurally related. The mechanism of inducing psychosis could relate to the indolic moiety of indomethacin, similar to serotonin. Ibuprofen, naproxen, salicylates, and other NSAIDs have also been associated with depression and cognitive impairment, particularly in elderly patients. Browning's report (1996) of four patients who developed severe exacerbations of underlying psychiatric disorders emphasizes the need for caution when NSAIDs are used in patients with psychiatric histories.

**Antiparkinsonian drugs.** In a review of antiparkinsonian drug treatment, Young and colleagues (1997) found that the most prominent neuropsychiatric adverse effects were psychosis and delirium. Cummings (1991) reviewed the neuropsychiatric complications of the treatment of Parkinson's disease. He found that 30% of patients treated with dopaminergic agents develop visual hallucinations; 10% have delusional syndromes; 10%, euphoria; 1%, mania; and 10%–15%, anxiety symptoms. Elderly patients and patients with dementia appear more susceptible to these complications. Younger patients can be more susceptible to depression and insomnia (Wagner et al. 1996). Clozapine and olanzapine can be effective in treating psychotic symptoms if they do not resolve with dosage

reduction (Friedman and Lannon 1989; Rabey et al. 1995; Rosenthal et al. 1992; Wolters et al. 1996). However, patients with Parkinson's disease are exquisitely sensitive to the anticholinergic side effects of clozapine and can become encephalopathic at even small doses (i.e., >25 mg daily) (Duffy and Kant 1996). Anticholinergics used in Parkinson's disease are more frequently associated with delirium, but can also present with delusions and/or hallucinations.

**H<sub>2</sub> blockers.** The H<sub>2</sub> blockers cimetidine and ranitidine have been reported to cause depression, mania, and psychosis (Billings and Stein 1986; Billings et al. 1981; Hubain et al. 1982; Russell and Lopez 1980). Both have also been found to induce neurobehavioral symptoms when discontinued. In this situation, the symptoms have been found to be associated with a drop in prolactin levels and ameliorated by treatment with domperidone, an agent that causes hyperprolactinemia (Rampello et al. 1997). Cimetidine has traditionally been viewed as more neuroactive, but a recent study by Kim et al. (1996) found postoperative patients on cimetidine or ranitidine to be equally likely to experience decrements in their Mini-Mental State Exam scores (Folstein et al. 1975). As the role of histamine as a central neurotransmitter is still unclear, the mechanism of action of these neurobehavioral effects is not certain. Jenike and Levy (1983) reported that physostigmine can reverse cimetidine-induced delirium, suggesting that there may be indirect cholinergic involvement. Cimetidine interacts significantly with a number of other medications (Appendix 31-1), and care must be taken in patients taking numerous drugs. Because cimetidine and ranitidine are both excreted primarily by the kidney, the clinician should be particularly cautious in prescribing H<sub>2</sub> blockers in elderly patients with diminished renal function.

**Psychotropics.** Reports of benzodiazepine-induced depression and psychosis are difficult to evaluate because the patients often had preexisting psychiatric illness and/or concomitant therapies. In a retrospective review, Greenblatt et al. (1976) reported that 3% of more than 2,000 patients on flurazepam manifested depression, although almost half of these were on other drug therapy as well. (The extremely long half-life of flurazepam makes it unsuitable for use in the elderly.) Confusion, hallucinations, and seizures also occur with benzodiazepine withdrawal. Also, a number of cases of mania with antidepressant therapy and withdrawal, as well as with stimulants and sympathomimetics, have been reported (Sultzer and Cummings 1989). (The neuropsychiatric aspects of psychotropic medication are discussed further in Chapter 34 in this volume.)

## Gait and Mobility Disorders and Falls

Disorders of gait, particularly those that result in a fall, represent a significant source of hazard and subsequent disability in elderly people. As many as 15% of people over age 65 have a gait disorder (Newman et al. 1960); the incidence rises to 25% after age 79 (Lundgren-Lindquist et al. 1983). The annual incidence of falls in the elderly is approximately 220 per 1000, resulting in approximately 7 million falls annually (Monane and Avorn 1996). The magnitude of the problem is highlighted by the finding that, in people over age 75 in the community, more than one-third of them fall each year (Tinetti 1977), and as many as 10% of these falls result in serious (sometimes fatal) injury (Smallegan 1983). The psychological and physical repercussions of these falls frequently necessitate placement in a nursing home (Kellogg International 1987). The problem in nursing homes reaches catastrophic proportions where the annual incidence of falls is 1,600 per 1,000 residents (Sudarsky 1990). Medications are important contributors to these statistics and profoundly influence the ability of elderly patients to ambulate safely and efficiently.

Normal changes in ambulation associated with aging include 1) shorter, broader strides; 2) decreased speed; 3) diminished pelvic rotation; and 4) a decreased capacity for adjusting posture in response to environmental demands (MacDonald and MacDonald 1977). In addition to these expected changes, the elderly person can also develop gait abnormalities as a consequence of some other identifiable pathology such as musculoskeletal changes, Parkinson's disease, myelopathies (e.g., cervical spondylosis), cerebellar degeneration, normal pressure hydrocephalus, and subcortical atherosclerotic disease (Sudarsky 1990). Medications can aggravate these pathological processes or can produce gait abnormalities independently.

A large-scale study of "frequent fallers" in St. Louis found the following drugs to be associated with falls: diazepam, laxatives (may have reflected the more frail and inactive contingent), diuretics, and diltiazem (Cumming et al. 1991). Other medications that have been conclusively demonstrated to increase the risk of falling include psychotropic medications, especially long-acting benzodiazepines (Monane et al. 1996), barbiturates, tricyclic antidepressants, neuroleptics (particularly phenothiazines), antihypertensives, including diuretics and calcium channel blockers (J. B. Schwartz 1996), digitalis (Koski et al. 1996), levodopa, and NSAIDs (Davie et al. 1981; MacDonald 1983; MacDonald and MacDonald 1977; Prudnam and Evans 1981; Ray et al. 1989). The risk of falls in an elderly person rises proportionally to the number of medications he or she is taking. Particularly hazardous are combina-

tions of medications that have additive side effects (e.g., antihypertensives in combination with sedative-hypnotics) (MacDonald 1983).

The age-related changes in CNS vulnerability in elderly patients discussed above may predispose them to drug-induced movement disorders. (The problems of hyperkinetic movement disorders and tardive dyskinesia are discussed further in Chapter 25 in this volume.) Neuroleptics are the most common cause of drug-induced movement disorders, but dopamine agonists also frequently produce dyskinesias, and a variety of other medical therapies have been associated with movement abnormalities (Table 31–5). Elderly patients are at an increased risk particularly for drug-induced parkinsonism from antiemetic and antipsychotic medications, related, perhaps, to the diminished number of nigral dopaminergic neurons associated with aging (Friedman 1992). This can be a significant cause of immobility, gait disturbance, falls, and mortality in elderly patients (Wilson and MacLennen 1989). Parkinsonism has also been reported with chronic valproate treatment (Armon et al. 1996) and has infrequently been reported with the SSRIs (Leo et al. 1995). (For excellent reviews, see Lang and Weiner 1992 and L. G. Miller and Jankovic 1992.)

### Sleep Disorders Produced by Medical Therapies

The predictable alterations in sleep architecture associated with aging are reviewed in Chapter 17 in this volume. The incidence of insomnia increases as a function of age and

physical status (Gillin and Byerly 1990). Many elderly persons complain of poor sleep and/or unacceptable daytime drowsiness and frequently seek treatment—either from their physician or via OTC medications. In the context of neurodegenerative disorders, sleep problems frequently exhaust relatives and precipitate the family's decision to seek institutionalization of a loved one (Berry and Webb 1985). Medications can play a significant role in producing sleep disturbances in the elderly. In addition, the particular vulnerabilities of the aging brain demand the judicious selection of appropriate treatment strategies for sleep disorders. A failure to do so may result in escalating sleep and behavioral problems.

The use of benzodiazepines, which are frequently prescribed for elderly patients, presents particular hazards (Closser 1991). The elderly are more sensitive to benzodiazepines secondary to their altered pharmacokinetics and enhanced postsynaptic receptor sensitivity (Swift 1986). Benzodiazepines are frequently administered to elderly patients who complain of insomnia. The extent of benzodiazepine use is highlighted by studies that reported that half of all elderly medical admissions were receiving benzodiazepines (Foy et al. 1986), and among institutionalized elderly, more than 90% were prescribed sedative-hypnotic drugs (Reynolds et al. 1985).

Ironically, although benzodiazepines are usually initially prescribed to treat insomnia, they are a frequent cause of deteriorating sleep quality (Schneider-Heimert 1988). Sustained use results in diminished slow-wave and rapid-eye-movement (REM) sleep, with no alteration in total sleep time (Schneider-Heimert 1988). The problem

**TABLE 31–5. Drug-induced movement disorders**

Movement disorders	Drugs
Accentuated physiological tremor	Epinephrine, isoproterenol, caffeine, theophylline, lithium, tricyclic antidepressants, thyroid hormone, hypoglycemic agents, sodium valproate, nicotinic acid, cyclosporine
Cerebellar ataxia and tremor	Phenytoin, barbiturate, lithium, 5-fluorouracil, cimetidine-triazolam interaction
Chorea-dyskinesia	Neuroleptics, levodopa, bromocriptine, phenytoin, ethosuximide, carbamazepine, oral contraceptives, chloroquine, antidepressants, metoclopramide, lithium, antidepressants, benzodiazepines, antihistamines, calcium channel blockers, cocaine, methylodopa, cimetidine
Dystonia	Neuroleptics, levodopa, bromocriptine, lithium, metoclopramide, carbamazepine, cimetidine, chlorzoxazone, calcium channel blockers
Myoclonus and tics	Neuroleptics, amphetamines, methylphenidate, fenfluramine, levodopa, bromocriptine, antidepressants, pemoline, cocaine
Parkinsonism	Neuroleptics, reserpine, tetrabenazine, methylodopa, $\alpha$ -methyltyrosine, lithium, diazoxide, physostigmine, metoclopramide, trazodone, meperidine, etretinate, cimetidine, cinnarizine, flunarizine
Akathisia	Neuroleptics, reserpine, tetrabenazine, metoclopramide, antidepressants, calcium channel blockers, buspirone, methysergide, cimetidine

may be further compounded when the elderly person develops rebound insomnia after missing even a single dose of a short-acting preparation, often resulting in escalating hypnotic use (Gillin et al. 1989). Patients receiving ultra-short-acting benzodiazepines such as triazolam can experience this rebound phenomenon within a few hours of their last dose and can require more than one dose per evening to maintain sleep and avoid becoming agitated or confused. In addition, the ultra-short-acting benzodiazepines have been reported to produce in susceptible individuals myriad behavioral changes, including anterograde amnesia, delirium, anxiety, and dysphoria (Patterson 1987; Reynolds et al. 1985). The deleterious effects of triazolam and zolpidem have been shown to occur during the night and sometimes persist into the next day (Lobo et al. 1997).

The long half-life benzodiazepines (e.g., flurazepam) should be avoided in elderly patients because these drugs are likely to produce prolonged daytime drowsiness, cognitive disturbances, and potentially hazardous ataxia (Carskadon et al. 1982). Sleep apnea increases with age and may be significantly aggravated by the use of sedative-hypnotics, thereby creating a potentially serious risk (Ancoli-Israel et al. 1985; Reynolds et al. 1985). Overall, the use of benzodiazepines for insomnia in elderly patients remains controversial. Their administration should probably be limited to the brief use of the intermediate benzodiazepines in stressful situations.

Several cardiovascular drugs have been reported to exert a powerful influence on sleep architecture.  $\beta$ -blockers (particularly lipophilic agents such as propranolol, metoprolol, and pindolol) and reserpine have been associated with nightmares, hallucinations, fatigue, and diminished sleep quality (Henningsen and Mattiason 1979). Clonidine causes REM suppression with decreased time in deep sleep and more awakenings (i.e., decreased quality of sleep) (Spiegel and Devos 1980). Several antiarrhythmics including amiodarone, lorcaïnide, and quinidine have been reported to produce insomnia (Greene et al. 1983; Guillemenault and Silvestri 1982; Karacan et al. 1976).

Methylxanthines, found in theophylline, theobromine, and caffeine, are common causes of insomnia. Caffeine, available in beverages such as tea or coffee and frequently found in OTC preparations, produces difficulty initiating sleep and delays the onset of REM sleep to the latter part of the night (Karacan et al. 1976). Psychostimulants such as methylphenidate that are sometimes used to treat depression in the elderly produce a significant reduction in slow-wave and REM sleep (Kay et al. 1976).

Corticosteroids also cause sleep disturbances, with insomnia commonly reported. Nightmares, excessively mor-

bid or vivid dreams, and even psychosis can also occur (Force et al. 1997; Vincent 1995). Melatonin, popularly used for sleeplessness and aging and sold over the counter in the United States (though not in Europe), has been reported to cause nightmares, fatigue, hypotension, and sleep disorders with highly irregular sleep-wake cycles (Middleton et al. 1996). There is particular concern when melatonin is taken on an inappropriate time schedule, at high doses, or over long periods (Guardiola-Lemaitre 1997).

Finally, nonspecific causes of diminished sleep quality should be considered. These include prolonged confinement to bed, physical discomfort caused by medical illness (e.g., arthritis, Parkinson's disease, and orthopnea), and the alteration in sleep cycle characteristic of confusional states.

## Sexual Disorders

Sexuality in older people is a subject of considerable misunderstanding. Older people do experience some age-associated alterations in sexual function, but these do not preclude an active and satisfying sex life. Sexual activity continues well into later life. A national survey reported that more than half of married persons between ages 66 and 70 report having sex at least four times per month. More than one-quarter of married people over age 76 report an active sex life, with an average frequency of sex of more than twice per month (Marsiglio and Donnelly 1991). It is important to note that, unless physical disability intervenes, the sexual behavior of older people tends to remain consistent over time (George and Weiler 1981). These statistics highlight the importance of obtaining a sexual history in all older patients. Any change from their premorbid baseline may herald recent physical or psychosocial stressors.

Although growing older does not mandate an abandonment of sexuality, predictable age-related physiological changes do affect the elderly person's sexual functioning (Grenshaw 1985). The older male is likely to experience some decrease in libido and a slowing of sexual arousal that may delay ejaculation. The postmenopausal woman is likely to experience a number of physiological changes that may reduce the pleasure of sexual intercourse. These changes include decreased vaginal lubrication, atrophic changes in the mucosal lining of the vaginal wall, and decreased turgidity of the vaginal outlet. In addition, physical disability is likely to exert a powerful negative influence on the older person's sexual activity (Marsiglio and Donnelly 1991). As a consequence, elderly people are likely to be more vulnerable to the drug-induced disorders in sexual

functioning outlined in Table 31–6.

The SSRIs are well known to induce sexual dysfunction. Data are not yet available from studies of this complication specifically in the elderly population, but extrapolation from data on younger patients gives reason for concern. In a prospective Spanish study of outpatients

(Montejo-Gonzalez et al. 1997) with a mean age of 39.6, researchers found SSRI-induced sexual dysfunction in a majority (58%) of the patients, with a significant increase in the incidence when physicians asked the patients direct questions about decreased libido, delayed orgasm or anorgasmia, delayed ejaculation, inability to ejaculate, and

**TABLE 31–6. Effects of commonly prescribed drugs on sexual function**

Drugs	Libido	Effects on sexual function, arousal, or erection	Orgasm or ejaculation
<b>Psychotropic agents</b>			
Amphetamines and cocaine	Enhanced with low doses; decreased with high doses	Decreased with chronic use	Increased with low doses; diminished with high doses
Monoamine oxidase–inhibiting antidepressants	–	–	Impaired
Tricyclic antidepressants	May be impaired	May be impaired	May be impaired; may cause spontaneous seminal emission
Bupropion	Increased	–	–
Trazodone	Increased	May cause priapism	–
Fluoxetine	Increased	–	–
Lithium carbonate	Impaired	Impaired	–
Neuroleptic agents	May be decreased	Impaired (rare priapism)	Retrograde ejaculation rarely
Sedative-hypnotics	Reduced	Reduced	–
Benzodiazepines	–	Impaired with chronic usage	–
Buspirone	Increased	–	–
Narcotics	Impaired in high doses	Impaired in high doses	Impaired in high doses
<b>Antihypertensive agents</b>			
Reserpine, 97-methyldopa	Decreased	Decreased (common)	May be impaired
Diuretics	–	May be impaired	–
Clonidine	–	–	May block emission in males
Propranolol	May be decreased	May be decreased	–
<b>Anticholinergic agents</b>			
–	–	May be impaired	–
<b>Sympathomimetics</b>			
Phendimetrazine	Increased	–	–
Fenfluramine	Increased	–	–
<b>Hormonal agents</b>			
Androgens	Increased	Increased (men)	Increased (men)
Estrogens	Decreased (men) Variable (women)	May cause impotence in men	Delayed
Thyroxine	Increased	–	–
Adrenal steroids	Decreased in high doses	–	–
<b>Miscellaneous</b>			
Levodopa	May be increased	–	–
Cholestyramine	Increased	–	–
Disulfiram	–	Occasional impotence	Delayed

impotence versus when sexual dysfunction was spontaneously reported (14%). This finding is of special note for geriatric care because older patients are less frequently asked about their sexual functioning and are less likely to volunteer the information. Sexual dysfunction was found to correlate with dose and have a higher incidence in men. Retrospective chart studies show lower incidence (16.3%), but still involving significant numbers of patients treated with SSRIs (Keller Ashton et al. 1997).

A recent study revealed that, although erectile dysfunction is a frequent disorder in hyperlipidemia, hypolipidemic drugs additionally increase the incidence of impotence (Bruckert et al. 1996). Other medications reported to induce a variety of sexual dysfunctions include apomorphine, carbamazepine, metoclopramide, chlorthalidone, hydrochlorothiazide, and other antidepressants. A more complete listing is outlined in Table 31-6.

### **Disturbances in Taste and Smell**

The loss or distortion of sense of smell or taste significantly compromises a person's nutritional status and enjoyment of his or her environment. Drug-induced disturbances are common and include anosmia and ageusia (absence of smell and taste, respectively), dysosmia (distortion and misinterpretation of smells), parageusia (misinterpretation of tastes as foul), parosmia (perception of an odorant that is not present), and dysgeusia (the distortion or misinterpretation of a taste while eating). The medical disorders associated with impairments of olfaction and the sense of taste are lengthy. (The reader is referred to the excellent review by Ackerman and Kasbekar 1997.) Symptoms require a careful differential diagnosis. Anosmia occurs in 90% of patients with Alzheimer's disease and Huntington's chorea and 70% of those with idiopathic Parkinson's disease (Ackerman and Kasbekar 1997). For such patients, and other frail elderly, further interference with their sense of smell or taste may cause them to avoid eating. Drugs associated with anosmia are levodopa, alpha interferon, chemotherapeutic agents, nifedipine, and diltiazem. Distortions in taste (dysgeusia) or loss of the sense of taste (ageusia) have been reported to occur with the ACE inhibitors (oral and topical), nifedipine, and medications with sulfhydryl groups (propylthiouracil, penicillamine, and captopril). Captopril is considered to be the agent most commonly associated with dysgeusia. The ACE inhibitors are reported to cause dysgeusia in 8.4% of patients. Dysgeusia has, in rare instances, been reported to become persistent and permanent (Ackerman and Kasbekar 1997). Xerostomia, or dry mouth, a common side effect of anticholinergics, commonly interferes with taste, dentition, and oral intake.

### **Herbal Remedies**

Recent years have witnessed an explosive rise in the popularity of alternative therapies—most particularly herbal and so-called natural remedies. The market for botanical therapies continues to grow rapidly and has become a multibillion dollar industry. Unfortunately, despite the enormity of this burgeoning financial trade in herbs, their clinical efficacy and safety remain unproved and untested. Adding to this confusion, most clinicians fail to question their patients about alternative therapy use, and most patients remain embarrassed to broach the subject with their physician. As evidenced in a recent survey of 400 users of herbal remedies who reported an 8% incidence of adverse effects, although the incidence of adverse effects from herbal remedies is probably comparatively low, they do occur (Abbot et al. 1996).

Adverse effects from herbs may result as a consequence of 1) allergic reactions, 2) toxic effects, 3) drug interactions, 4) mutagenic effects, and 5) the toxicity associated with contaminants (Ernst 1998). Drug interactions are particularly important in the context of elderly patients who are already consuming many prescription medications. Recognized drug interactions include coagulation abnormalities in patients using warfarin concurrently with Chinese herbal teas (Tam et al. 1995). The Ayurvedic remedy shankhapushpi has been reported to lower phenytoin levels, thereby placing the patient at increased risk for seizures. Undoubtedly, many other drug interactions will be recognized as the popularity of herbal remedies increases. Currently recognized direct toxic effects of herbal remedies are outlined in Table 31-7.

Poor quality control over the preparation of herbal remedies results in unacceptable contamination of these products. Identified contaminants in Ayurvedic preparations have included lead, mercury, arsenic, aluminium, tin, aspirin, and acetaminophen (Bayly et al. 1995). Heavy metal and prescription medication contamination of Chinese herbal remedies has also been frequently reported. Kelp, a popular and presumably benign remedy, may contain toxic levels of arsenic that may produce clinical toxicity (Gertner et al. 1995).

### **Summary**

Medical therapies not uncommonly cause neuropsychiatric morbidity in elderly patients. These complications can become serious enough to warrant hospitalization, with 8% or more of geriatric admissions attributable to adverse drug reactions. The increased susceptibility of the elderly

**TABLE 31-7. Adverse effects with likely cause-effect relationship**

Name of plant/constituent	Adverse effect	Reason for assuming causality
Aconite	Palpitations, arrhythmias, nausea, abdominal pain	Adverse effect reported frequently
Aristolochic acid	Nephrotoxic	Adverse effect reported often
Ayurvedic remedies	Heavy metal poisoning	Heavy metals used in processing and found in preparations
Broom	Oxytocic properties	Documented adverse effect of sparteine (a constituent of broom)
Chaparral	Liver damage	Case reports
Chinese herbal mixtures	Heavy metal poisoning	Case reports; heavy metals found in preparations
Comfrey	Liver damage	Case reports
Flavonoids	Hemolytic anemia, renal damage	Case reports
Germander	Liver damage	Case reports
Guar gum	Gastrointestinal obstruction	Case reports
Licorice root	Hypokalemia, hypertension, arrhythmias, edema	Case reports
Pennyroyal	Liver damage	Case reports
Pyrrrolizine	Liver damage	Case reports

to the CNS side effects of medical therapies should always be considered when neurobehavioral changes occur in older medical patients. Medical therapies may cause depression, mania, psychosis, sexual disorders, delirium, dementia, anxiety, sleep disturbances, movement disorders, falls, and changes in olfaction and the sense of taste. To minimize the risk of these adverse effects, one must consider the following factors in prescribing medications to elderly patients:

1. Understand alterations in pharmacokinetics and neurochemistry associated with aging.
2. Identify the presence of any neurodegenerative process and understand the possible ramifications of these diseases for drug effects and sensitivity.
3. Identify social and physical determinants that make medication compliance problematic (e.g., living alone, financial constraints, vision and hearing loss).
4. Always consider the possible involvement of OTC medications and herbal therapies or misuse of prescription medication.
5. Obtain a baseline mental status examination. If patients are treated with high-risk medications or combinations, follow the mental status carefully.
6. Always consider drug toxicity when the patient exhibits an alteration in attention or cognition or any behavioral change.
7. Be aware of inappropriate medication practices for the treatment of elderly patients.
8. Have a table of drug-drug interactions readily available for use when polypharmacy is required.

**APPENDIX 31-1. Significant potential drug-drug interactions in psychogeriatrics**

<b>Drugs</b>	<b>Interacting drugs</b>	<b>Consequences</b>
Salicylates	$\beta$ -Adrenergic blockers	Decreased antihypertensive action
	Hypoglycemics (chlorpropamide)	Large acetylsalicylic acid doses may cause hypoglycemia
	Lithium	Possible lithium toxicity
	Valproate	Possible valproate toxicity
Nonsteroidal anti-inflammatory drugs	$\beta$ -Blockers	Decreased antihypertensive action
	Captopril	Indomethacin-decreased antihypertensive action
	Furosemide	Decreased diuretic action and antihypertensive effect
	Haloperidol	Possible severe sedation with indomethacin
	Potassium	Indomethacin-induced hyperkalemia
	Thiazide diuretics	Hyponatremia
Antidepressants, tricyclic	Clonidine	Decreased antihypertensive effect
	Disulfiram	Organic mental disorder
	Guanethidine	Decreased antihypertensive
	Hypoglycemics (chlorpropamide)	Doxepin-induced hypoglycemia
	Nitroglycerin (sublingual; tolazamide)	Nortriptyline-induced hypoglycemia
	Trimethoprim-sulfamethoxazole	Nitroglycerine may not dissolve; loss of antidepressant effect
Antidepressants, nontricyclic	Tricyclic antidepressants	Fluoxetine, fluvoxamine, and other stressors may inhibit metabolism of some tricyclic antidepressants
	Digoxin	Trazodone may increase risk of digoxin toxicity
	Phenothiazines	Trazodone combined may produce severe hypotension
	Triazolam, alprazolam, haloperidol	Nefazodone may inhibit metabolism of triazolam, benzodiazepines and haloperidol
Carbamazepine	Anticoagulants	Prothrombin time decreased
	Cimetidine	Carbamazepine levels increased
	Desipramine	Carbamazepine and desipramine levels increased
	Diltiazem	Neurotoxicity
	Metoclopramide	Neurotoxicity
	Theophylline	Theophylline concentration decreased
	Thiazide diuretics	Hyponatremia
	Verapamil	Carbamazepine levels increased
$\beta$ -Adrenergic blockers	Alcohol	May block signs of delirium tremens
	Cimetidine	Decreased $\beta$ -adrenergic blocker metabolism
	Clonidine	Paradoxical hypertension
	Diltiazem	Heart failure
	Haloperidol	Profound hypotension
	Sulfonylureas	Prolonged hypoglycemia with hypoglycemic overdose
	Insulin	Prolonged hypoglycemia with hypoglycemic overdose
	Maprotiline	Decreased maprotiline metabolism
	Methyldopa	Hypertensive reaction
	Nifedipine	Heart failure
	Chlorpromazine	Levels increased of both medications
	Thioridazine	Thioridazine levels increased

# Neurobehavioral Syndromes

Mark D'Esposito, M.D.

A wide variety of neurobehavioral syndromes can arise from focal or diffuse damage to the cerebral cortex. The mental status examination, as reviewed in Chapter 6 in this volume, is an examination of the cerebral cortex and subcortical structures with cognitive functions. It is helpful heuristically to organize disorders of cognition in a fashion similar to how the mental status examination is organized, that is, by the principal cognitive domains—attention, language, memory, visuospatial perception, and executive function. One goal of this chapter is to review clinicoanatomical relationships by describing the neuroanatomical correlates of each of the cognitive domains. Knowledge of these syndromes and their anatomical basis will allow the clinician to accurately characterize the cognitive impairments found in age-related disorders, leading to more accurate diagnosis. For example, although Alzheimer's disease and Pick's disease are both dementia syndromes, they differ dramatically in their clinical presentation. Alzheimer's disease, which predominantly affects temporoparietal cortex, presents as a disorder of memory, language, and visuospatial skills, whereas Pick's disease, which affects

frontotemporal cortex, presents as a disorder of executive function and behavior.

## Disorders of Attention

Attention is not a unitary concept, but rather it likely is comprised of many related processes. For example, normal attention requires 1) awareness of stimuli presented in one's environment, 2) the ability to voluntarily focus one's attention on a specific stimulus, 3) the ability to resist other stimuli by suppressing an involuntary shift of attention, 4) the ability to shift attention quickly and smoothly and the ability to decide which of many competing stimuli should be the focus of one's attention, and 5) the ability to redirect that focus by voluntary control (Geschwind 1982). It is not currently possible to attribute each of these processes to specific regions of the brain. Attention can be impaired after focal or diffuse insults to the brain. If focal, damage will be within a network of brain regions that includes the ascending pathways of the mesencephalic reticular activating system or thalamocortical projections

to association areas within parietal and prefrontal cortex (Mesulam 1985). If diffuse, the spectrum of etiologies causing impaired attention is broad, such as ingestion of prescription or nonprescription drugs, metabolic derangements, or infections (Lipowski 1990).

### Acute Confusional State

Acute confusional state, also referred to as delirium, is defined as a disorder of attention. This syndrome is described in detail in Chapter 19 in this volume. In brief, the onset of this syndrome is sudden, and the level to which a patient can maintain attention often fluctuates, either from minute to minute or hour to hour. The patient may concurrently have altered alertness, but attentional difficulties can be present in the setting of completely intact alertness. Because attention is critical for all other types of information processing, patients will often exhibit deficits in other cognitive domains such as memory, perception, and executive function, even though there is not focal damage to the anatomical structures that support these abilities.

As mentioned, acute confusional states typically arise from diffuse damage to the brain. Rarely, focal damage will cause acute confusion. A middle cerebral artery causing right parietal lobe damage (Mesulam et al. 1976) or unilateral posterior cerebral artery strokes involving the parahippocampal-fusiform-lingual gyri (Medina et al. 1974) can present as confusion. On the surface, patients with Wernicke's aphasia secondary to a middle cerebral artery stroke will appear confused, although the deficit is of language and not attention. These patients will not be making any sense when they speak and will not understand what other people are saying to them. Attributing the deficit to a confusional disorder is a common misinterpretation of the patient's clinical problem, especially among family members or friends who are the first to encounter the patient at the time of the stroke.

### Syndrome of Neglect

The most important function subserved by the right hemisphere is the ability of individuals to direct their attention into their environment. It is postulated that the right hemisphere can direct attention into both the left and right half of space, whereas the left hemisphere mostly directs attention into the right half of space (Mesulam 1985). Thus, damage to the right hemisphere will cause a deficit directing attention into the left visual space. This deficit is known as neglect and is defined as the inability to respond to or acknowledge stimuli present in the left hemispace (Heilman and Valenstein 1991). Although neglect can also occur after

left hemisphere lesions, it is much more common and more severe after right hemisphere damage. Neglect is one of several impairments that are more commonly found after damage to the right hemisphere (Table 32–1).

Studies of patients with right hemisphere damage have demonstrated that there are at least three forms of neglect: attentional, representational, and intentional (Heilman and Valenstein 1991). Evidence indicates that four major cerebral regions (Figure 32–1) provide an integrated network for directing attention within extrapersonal space and inner representations (Mesulam 1981). *Attentional* neglect is the failure to attend to stimuli in the left hemispace. This type of neglect is easily demonstrated on the clinical examination. The patient seems to ignore people on their left side or will not eat items on the left side of their plate. On formal mental status testing, the patient will show marked rightward deviation when attempting to bisect a line in half. Another easy test for neglect is to place a number of lines on a blank page and ask the patient to cross off all of the lines. The patient will cross off lines on only the right side of the page and fail to acknowledge that there are lines on the left side of the page. A writing sample, line cancellation test, and clock drawing from a patient with neglect are provided in Figure 32–2.

It is vital that the clinician be able to recognize the difference between left visual neglect and left visual hemianopia, that is, the inability to see in the left visual field. The latter is a result of damage to the visual system, usually at the level of the optic radiations in the temporal and parietal lobes or primary visual cortex in the occipital lobes. When the line bisection or line cancellation test is given to patients with neglect or a visual field deficit, performance may be identical. One way to distinguish between these two possibilities is to move the piece of paper with target stimuli into the right visual field of the patient. The patient with the left visual field deficit should now be able to see the targets and bisect or cross them off correctly.

**TABLE 32–1. Clinical characteristics of the right hemisphere syndrome**

#### Cognitive impairment

- Neglect
- Visuospatial impairment
- Aprosody
- Motor impersistence

#### Behavioral impairment

- Denial of illness (anosognosia)
- Variety of behavioral deficits including agitation and delusions

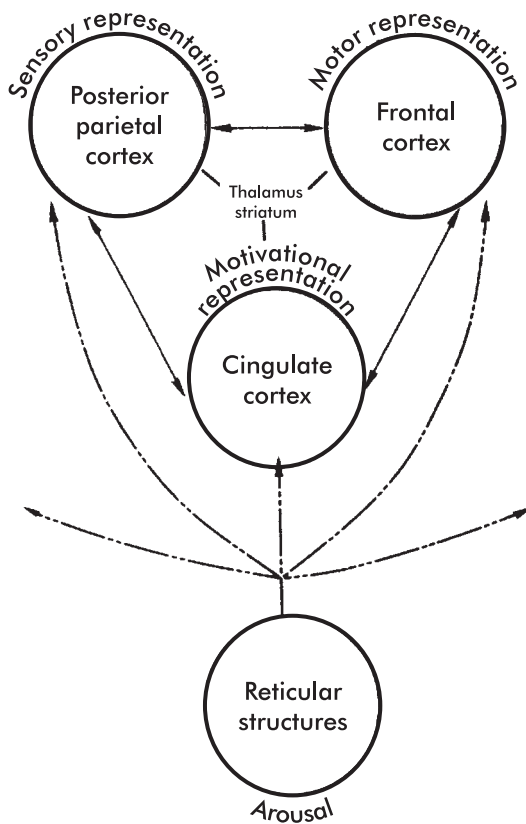

FIGURE 32-1. Neural network subserving neglect.

The patient with neglect will continue to avoid the left side of the page regardless of where the target stimulus is in their field of view. Unfortunately, some patients with extensive right hemisphere damage will demonstrate both neglect and a visual field deficit. In these patients, it may be impossible to disentangle these two phenomena.

Another important point for clinicians is that neglect may not be limited to the visual modality. When visual stimuli are presented simultaneously in opposite visual fields, patients with neglect will extinguish stimuli presented in the left visual field. That is, patients will fail to acknowledge stimuli in the left field only under simultaneous conditions, not during single presentation in the left field. This same phenomenon can occur with simultaneous presentation of auditory or tactile stimuli. The most common site of damage causing attentional neglect is in the posterior parietal lobe (Heilman et al. 1983). However, attentional neglect can also occur after subcortical lesions such as in the posterior thalamus (Watson and Heilman 1979).

A second type of neglect is called *representational* neglect. This type of neglect is manifested as a loss of the internal mental representation of the space opposite the side of the lesion. For example, when a group of patients with right hemisphere lesions were asked to imagine that they were facing a well-known cathedral in a square in Milan, they were unable to recall details regarding the left side of the square. However, when they were asked to imagine themselves facing away from the cathedral (i.e., their backs toward the cathedral), they were able to recall those left-sided details that were now on their right (Bisiach and Luzzatti 1978). Like patients with attentional neglect, patients with representation neglect also tend to have posterior lesions.

A third type of neglect, *action-intentional* neglect, is a unilateral deficit of motor program activation that causes reduced and delayed movements to the contralesional side (Coslett et al. 1990). Thus, despite being aware of stimuli in the left side of space, patients will fail to respond to stimuli on the left side. For example, if patients were blindfolded and asked to find all the items that were spread across a table, they would be reluctant to move their right hand into the left side of the table for exploration. Intentional neglect is most common after frontal (or anterior) lesions.

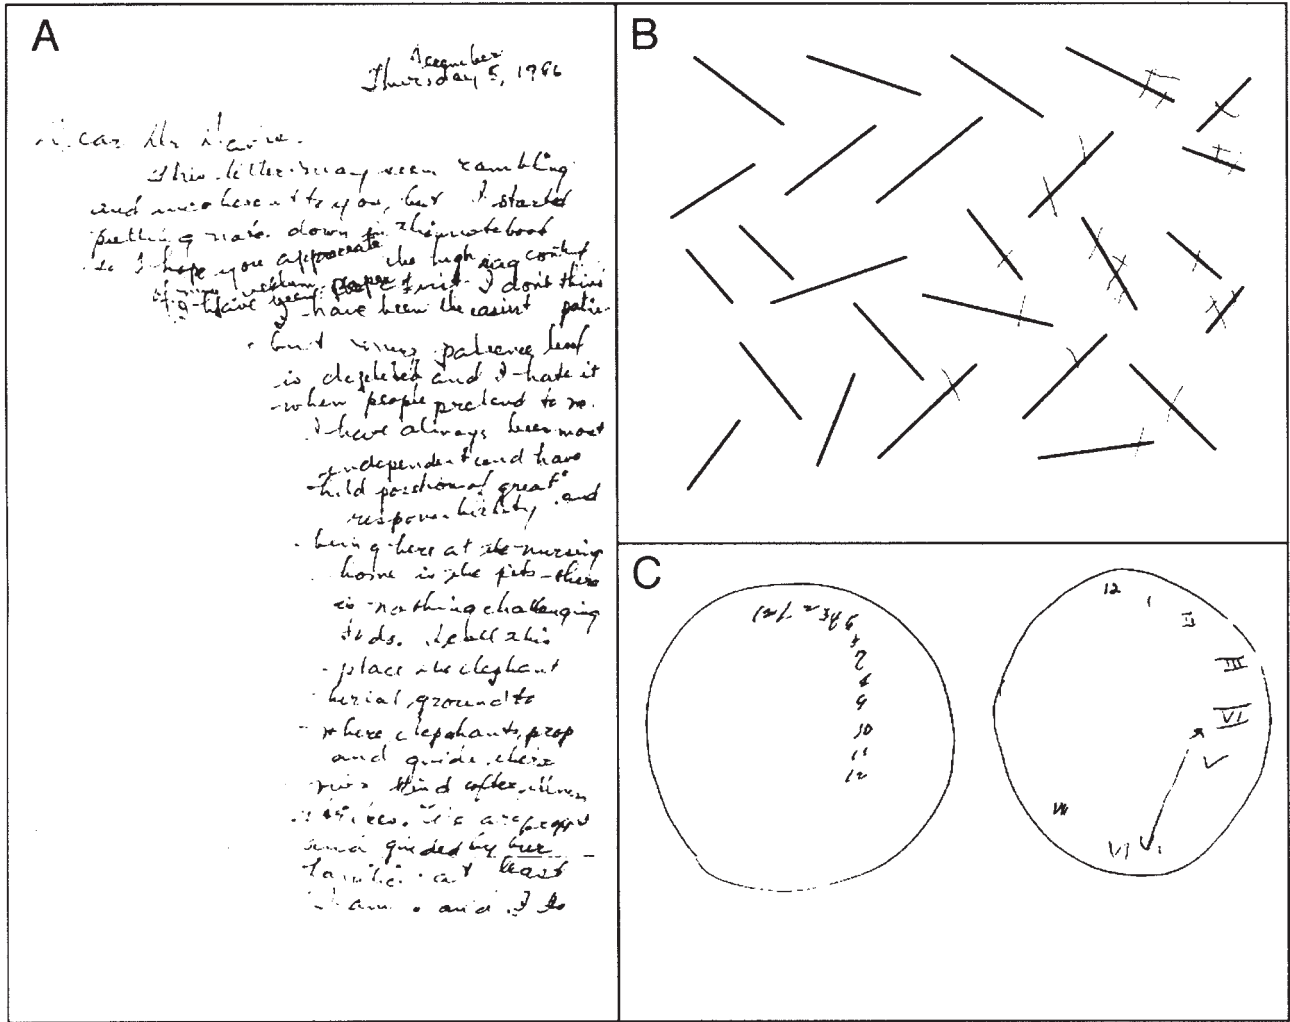

## Disorders of Language

### Distinction Between Speech and Language

Damage to the frontal, temporal, and/or parietal cortex will usually cause aphasia (Alexander and Benson 1991). *Aphasia* is defined as a disturbance of language, that is, the set of symbols that humans use as a means for communication. In contrast, speech is defined as the mechanical processes of language production, such as articulation and phonation. The major difference in the neural substrate for these disorders is that a lesion in the left hemisphere generally causes impairments in language, whereas damage to any component of the motor system for vocalization can cause impairment in speech. For example, a motor neuron disease such as amyotrophic lateral sclerosis or a muscle disease such as myasthenia gravis can cause a speech disturbance leaving language completely intact. A language disturbance, or aphasia, is specifically a result of cortical or subcortical brain damage.

### Left Hemisphere Is Dominant for Language—With a Few Exceptions

It is believed that in as many as 99% of right-handers and 70% of left-handers, language is subserved by the left

**FIGURE 32-2.** Examples of performance of a patient with neglect from right hemisphere lesions on handwriting sample (panel A), line cancellation test (panel B), and clock drawing (panel C). In each of the samples, the left side of the page is ignored.

hemisphere and brain injury on that side will cause aphasia (Benson and Geschwind 1985). Because more than 90% of the population reports themselves as right-handed, the vast majority of patients encountered with aphasia will have left hemisphere damage. In contrast, a very small percentage of right-handers, less than 1%, and up to 30% of left-handers have language subserved by the right hemisphere and can develop an aphasic syndrome from damage to the right hemisphere. Because aphasias resulting from right hemisphere lesions are fairly uncommon, they have not been studied extensively, but a few clinical observations have been made (Alexander et al. 1989). First, right-hemisphere lesions can cause two types of aphasia. In the first situation, the aphasia appears to manifest the identical clinical manifestations as if it were a result of damage in the left hemisphere. For example, right anterior lesions will cause a

nonfluent aphasia. Alternatively, aphasia resulting from a right hemisphere lesion can appear quite anomalous. For example, anterior lesions may cause a fluent aphasia. Second, although the right hemisphere, especially in left-handers, sometimes subserves language, right hemisphere functions such as directed attention and visuospatial skills often can be retained on that side. As one can envision, a large lesion in the right hemisphere in some left-handers can cause a profound cognitive disorder.

**Anatomy of Language**

The left hemisphere contains an organized distributed network for language function. Lesions in anterior portions of the brain, or in the frontal cortex, will cause impairments in the ability to produce fluent output, yet auditory compre-

hension of language is relatively preserved. The classic anterior aphasia is Broca's aphasia. Alternatively, damage to posterior portions of the brain, in the temporal and parietal lobes, will not cause a problem with producing fluent output but will cause a significant deficit in auditory comprehension of language. The classic posterior aphasia is Wernicke's aphasia. Large lesions that extend both anteriorly and posteriorly result in global aphasia, that is, that demonstrated in patients who are nonfluent and have a significant comprehension impairment. Damage to the arcuate fasciculus, the white matter bundle connecting Wernicke's and Broca's areas, will cause deficits in repetition of spoken language, called a conduction aphasia. Each of these aphasias is usually a result of occlusion of branches of the middle cerebral artery that supplies the lateral surface of the cerebral hemispheres. Damage in watershed territories of the brain (borderzones between the middle cerebral artery and the anterior or posterior cerebral artery), which leaves Broca's area, Wernicke's area, and the arcuate fasciculus intact, will cause transcortical aphasias, which are characterized by a perseveration of the ability to repeat spoken language. Damage almost anywhere in the left hemisphere will cause anomia, or a word-finding deficit. Also, many aphasic syndromes will recover into an anomic aphasia. These clinicoanatomical relationships are illustrated in Figure 32–3. It is also important to note that isolated subcortical lesions involving the striatum or the thalamus can cause each of the principal aphasic syndromes (D'Esposito and Alexander 1995; Mega and Alexander 1994). The characteristic features of each of the classic aphasic syndromes are presented in Table 32–2.

### Aphasic Syndromes: Nonfluent Versus Fluent

**Nonfluent aphasic syndromes.** *Broca's aphasia* is a result of a lesion in the posterior portion of the inferior frontal gyrus, or frontal operculum. The most common cause of Broca's aphasia is a stroke in the territory of the superior division of the middle cerebral artery. Poor fluency, good comprehension, and poor repetition define it. These patients use short phrases (less than four to five words), have reduced grammatical form, poor articulation, and prosody. It is important to know that even though these patients have good functional comprehension, they may have problems understanding syntactically complex utterances such as interpreting the following sentence: The boy was chased by the girl who was fast. Who is being chased?

Broca's aphasia is usually accompanied by a right-sided sensorimotor deficit as well as buccofacial and left limb

ideomotor apraxia. Ideomotor apraxia is defined as the inability to produce a learned motor activity in the absence of sensorimotor impairments or a failure to understand the task (Geschwind 1975). Most patients will perform better when they are asked to carry out whole-body or eye movements. Buccofacial apraxia usually suggests damage to frontal opercular cortex in the left hemisphere, whereas limb apraxia usually suggests left parietal damage (Alexander and Benson 1991).

*Global aphasia* is a result of a large lesion that includes both Broca's and Wernicke's areas and is usually caused by a complete middle cerebral artery territory stroke. Poor fluency, poor comprehension, and poor repetition define it. Patients' deficits may range from a complete lack of output and understanding to the ability to produce a few stereotyped phrases that carry no meaning and understanding of some gestures. Interestingly, even patients with aphasia with severe comprehension deficits may understand an examiner's gestures. These preserved abilities can sometimes lead to an underestimation of the severity of their comprehension deficit. Also, the patient may retain many pragmatic skills that are involved in everyday conversation, such as knowing when to speak and when to pause and listen. Global aphasia is usually accompanied by a right-sided sensorimotor deficit, as well as a visual field deficit.

*Transcortical motor aphasia* is a result of a lesion in the watershed territory between the anterior and middle cere-

**FIGURE 32–3.** Schematic diagram of the anatomical location of lesions that cause each of the classic aphasic syndromes. Combined damage to Broca's and Wernicke's area = global aphasia; damage to arcuate fasciculus = conduction aphasia; 4 = transcortical motor aphasia; 5 = transcortical sensory aphasia; 6 = anomic aphasia.

**TABLE 32-2. Characteristic features of classic aphasic syndromes**

Aphasia syndrome	Fluency	Comprehension	Repetition
Anomic	Good	Good	Good
Conduction	Good	Good	Poor
Transcortical sensory	Good	Poor	Good
Wernicke's	Good	Poor	Poor
Transcortical motor	Poor	Good	Good
Broca's	Poor	Good	Poor
Global	Poor	Poor	Poor

bral artery or to a medial left frontal lesion. Poor fluency yet good comprehension and repetition define it. The striking finding in these patients, in contrast to patients with Broca's aphasia, is their ability to repeat phrases that they cannot produce spontaneously, called echolalia. Patients often repeat the examiner's utterance. Transcortical motor aphasia is usually accompanied by right hemiakinesia, that is, a lack of initiation of movement of the right side despite adequate strength.

**Fluent aphasic syndromes.** *Wernicke's aphasia* is a result of a lesion that causes extensive damage to the posterior region of the left superior temporal gyrus (Wernicke's area). The most common cause is a stroke in the territory of the inferior division of the middle cerebral artery. Good fluency, poor comprehension, and impaired repetition define it. These patients have normal articulation and prosody and can produce sentence-length phrases effortlessly. Their spontaneous speech can be filled with phonemic paraphasias, semantic paraphasias, or neologisms. Paraphasias are substitutions for or within words. Semantic paraphasias are substitutions of words of similar meaning (e.g., "knife" for "spoon"). Phonemic paraphasias are sound substitutions (e.g., "scoon" for "spoon"). A neologism is a nonsense word such as "platin." Comprehension deficit can be mild, as when the patient has difficulty only at the sentence level, or severe, as when the patient is impaired even at attempting to understand single words. These patients may have similar impairments in reading and writing. Unlike many patients with nonfluent aphasia, patients with fluent aphasia may have several profound behavioral impairments such as anosognosia (unawareness of one's illness), perseveration, and agitation. Because the lesion is in posterior portions of the brain, a sensorimotor deficit is rarely found. Visual pathways are usually interrupted as they course through the temporal lobe on their way to the visual cortex, manifesting as a visual field deficit in the right upper quadrant of space.

*Conduction aphasia* is a result of a lesion that causes

damage to the arcuate fasciculus as it courses through the left inferior parietal lobe (supramarginal gyrus). Good fluency, good comprehension but poor repetition define it. The output of patients with conduction aphasia consists of abundant phonemic paraphasic errors especially during repetition. These patients often do not have any other neurological deficits.

*Transcortical sensory aphasia* is a result of a lesion in the watershed territory between the posterior and middle cerebral artery. It is defined as good fluency, good repetition, but poor comprehension. This syndrome is similar to Wernicke's aphasia with spared repetition. These patients usually do not have a sensorimotor deficit but may have a visual field cut.

*Anomic aphasia* is usually a result of a small lesion in the temporoparieto-occipital junction. It is defined as good fluency, repetition, and comprehension, but with a word-finding deficit. Essentially all patients with aphasia are anomic, but anomic aphasia refers to a syndrome in which word finding is the only deficit. It is also important to realize that many aphasic syndromes can recover into an anomic aphasia.

## Related Syndromes

*Aphemia* refers to an isolated speech (not language) disturbance resulting from a cortical lesion restricted to the lower motor cortex (Schiff et al. 1983). Another term that is used is cortical dysarthria. *Gerstmann syndrome* is a clinical concept of limited usefulness but is commonly referred to in the clinical world. It refers to the tetrad of agraphia, acalculia, right-left disorientation, and finger agnosia (Strub and Geschwind 1974). Finger agnosia generally refers to the inability to name fingers. Damage to the inferior parietal lobule can cause this syndrome. However, because many of these signs are seen in many types of aphasia, its utility in clinicoanatomical correlation is limited. *Alexia* refers to acquired inability to read; *agraphia* refers to the inability to write. Most aphasic syndromes with a deficit in

spoken language also have a similar deficit in reading and writing. Alexia without agraphia refers to the syndrome in which patients cannot read despite the preserved ability to write. Alexia results from a lesion in the left posterior cerebral artery territory, which includes the left occipitotemporal lobe and splenium of the corpus callosum (Damasio and Damasio 1983). Alexia is accompanied by a right hemianopia and, because of the splenial lesion, visual information projected to the right occipital cortex is cut off from the left hemisphere language center.

## Disorders of Memory

### Theoretical Model of Memory

A better understanding of memory disorders can be derived from a proper understanding of the theoretical distinctions of memory that have been developed by psychologists studying healthy humans. Such work has led to the proposal of several subdivisions of *long-term memory* (Squire 1987). One of the most widely accepted is a dichotomous classification of *declarative* versus *procedural* memory as illustrated in Figure 32–4.

*Declarative memory* represents memories of episodes and facts that can be consciously accessed, and *procedural memory* represents memory for skills. Unlike declarative memory, procedural memory is not available to our consciousness. Procedural memories can be either motor skills or mental procedures such as performing complex arithmetic. Declarative memory can be further subdivided into *episodic* and *semantic* memory (Tulving 1985). *Episodic memory* represents memories for specific personally experienced episodes. In contrast, *semantic memory* represents memories of facts, principles, and rules that make up our

general knowledge of the world. It is proposed that semantic memories have evolved from specific episodes when such information was first encountered, but with the passage of time these episodes lose their temporal context (Cermak 1984). An illustration of these distinctions is that you may recall when you last rode your bicycle (episodic memory), know what a bicycle is (semantic memory), or know how to ride a bicycle (procedural memory) (Parkin 1993).

Another proposed classification of memory is a division between *explicit* and *implicit* memory (Schacter 1987). *Explicit memory* includes conscious recollection of any type of memory encompassing both episodic and semantic memories. *Implicit memory* does not require conscious recollection and would include procedural memory, but the implicit memory domain would also account for the phenomena of priming and classical conditioning. Priming is the phenomenon that previously encountered information has an increased probability of being recalled later even if there is no explicit recall of the earlier (“priming”) experience (Tulving and Schacter 1990). For example, in a prototypical priming experiment, the subject is first presented with a list of words to read (e.g., motel, abstain, house). Subsequently, the subject is given three-letter stems (e.g. mot-) and is asked to produce the first word that comes to mind. The probability of generating a previously encountered word (e.g., motel) is increased compared with the probability of generating words not on the original list.

In clinical practice, the usage of the terms to describe memory processes has become imprecise and has not always followed these theoretical constructs. Many clinicians use the terms short-term memory to refer to learning new episodic information and long-term memory to refer to remote memories. This clinically sensible distinction does not, however, conform to experimental models of memory structure and only creates confusion when used in clinical reports. *Short-term memory* is properly defined as a system that temporarily (for seconds) stores information before becoming consolidated into long-term memory. Short-term memory (or working memory) can be tested with a span task such as digit span or pointing span, and long-term memory is tested by asking the subject to learn items that must be retrieved after an interval with distraction. The term *amnesic syndrome* properly refers to the loss of long-term memory only. *Remote memory* is information that has been consolidated in the past and may now be considered episodic, semantic, or procedural, depending upon its structure. Each of these systems (short-term memory, long-term memory, and remote memory) has a distinct anatomical basis.

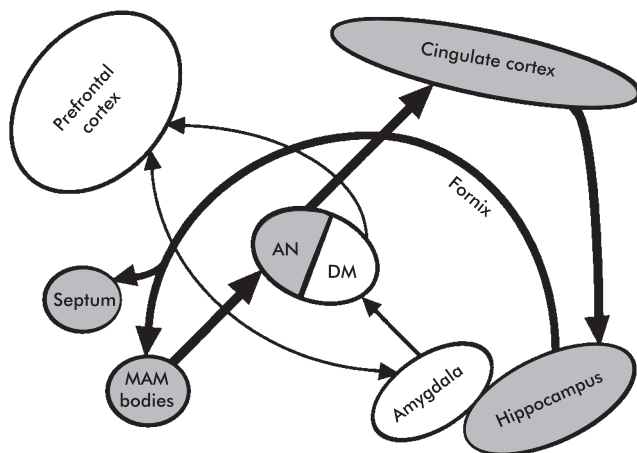

FIGURE 32–4. Proposed divisions of long-term memory.

## Anatomy of Memory

The report of the patient H.M. in 1957 demonstrated conclusively that the hippocampus was critical for long-term memory (Scoville and Milner 1957). H.M. had intractable epilepsy and underwent bilateral surgical excision of the hippocampus and amygdala. After surgery, H.M. was left with a dense and isolated amnesia that has not changed in severity to this day. Anatomical studies in nonhuman primates with experimental lesions of the medial temporal lobe support the importance of this region in declarative memory (Squire and Zola-Morgan 1991). These studies and correlative lesion studies in humans have shown that the hippocampus and amygdala are part of a critical neural network that exists to subserve memory functioning (Zola-Morgan and Squire 1993). The anatomical structures supporting memory are illustrated in Figure 32-5.

This memory network has two anatomical loops or circuits (Mishkin 1978, 1982). The first circuit, called the Papez circuit, includes the hippocampus that projects via the fornices to the mammillary bodies. Via the mammillothalamic tract, the mammillary bodies project to the anterior nuclei of the thalamus, which in turn send projections to the posterior cingulate cortex. The circuit is completed by projections from the cingulate back to the hippocampus. Within this circuit are also important reciprocal connections between the hippocampus and basal forebrain, via the fornix. The basal forebrain is a term that includes the septal nucleus, diagonal band of Broca, and nucleus basalis of Meynert. The second circuit includes the

**FIGURE 32-5.** Neuroanatomical structures involved in memory function. *Gray-shaded* structures are part of the hippocampal circuit; *white* structures are part of the amygdala circuit. AN = anterior nucleus of the thalamus; DM = dorso-medial nucleus of the thalamus; Mam bodies = mammillary bodies.

amygdala that projects to the dorsomedial nucleus of the thalamus via amygdala fugal pathways. The dorsomedial nucleus sends projections to the prefrontal cortex that has direct reciprocal connections with the amygdala, completing the loop. In nonhuman primates, damage to either pathway alone does not result in amnesia, but damage to both of these two memory circuits will produce profound amnesia (Mishkin 1978). Memory deficits may be caused by a lesion anywhere within this neural network, including pathways that connect critical structures (e.g., the fornix) (D'Esposito et al. 1995; Gaffan and Gaffan 1991).

Thus, three main regions with critical pathways that interconnect them form a network for memory functioning. These are the medial temporal lobes, the diencephalon, and the basal forebrain. Human studies have consistently supported this anatomical model. For example, H.M. demonstrates the classic example of damage to medial temporal lobes. The best-studied example of amnesia resulting from damage of the diencephalon is Korsakoff's syndrome (KS), which causes damage to both the mammillary bodies and the dorsomedial nucleus of the thalamus (Victor et al. 1971). Isolated lesions of the basal forebrain occur most commonly after anterior communicating artery aneurysm rupture and can result in dense amnesia (Alexander and Freedman 1984; D'Esposito et al. 1996). This region has strong reciprocal connections with the medial temporal lobe. Also, the nucleus basalis projects widely to the cortex and is the primary source of cortical cholinergic input. Patients with Alzheimer's disease have early and profound memory loss and a marked reduction of neurons in this region (Whitehouse et al. 1981). Thus, damage to the medial temporal lobes, diencephalon, basal forebrain, or the pathways that interconnect these regions can cause severe impairments in long-term memory, also called anterograde amnesia. An important target of the medial temporal lobes and the diencephalon is the prefrontal cortex, which has emerged as an important region that also contributes to long-term memory function, but its main function is to subserve short-term memory.

Other types of memory processes are not dependent on these circuits. For example, isolated impairments in remote memory, also called retrograde amnesia, are caused by extensive damage to the anterior temporal lobes and not the medial temporal lobes (Kapur 1993). Procedural memory impairments are found in patients with damage to the basal ganglia and cerebellum (Gabrieli 1998).

## Patterns of Amnesia

Specification of lesion sites associated with amnesia has led to investigation of possible differences in the pattern of

memory loss with different lesion sites. Although each of the regions that, when damaged, cause amnesia is part of the same functional network subserving memory, it is possible that damage to different regions in the network affects different stages of memory processes, leading to different patterns of deficits (Parkin 1984).

Amnesia produced by *bilateral medial temporal amnesia* has the following characteristics. Short-term memory is normal. Long-term memory is severely impaired (anterograde amnesia). Once learned, information in long-term memory is very rapidly forgotten. Semantic memory is generally preserved, although acquisition of new semantic knowledge is deficient (Gabrieli et al. 1988) and retrieval of general semantic knowledge can be subtly defective after medial temporal damage (Barr et al. 1990). Remote memory of personal events (retrograde amnesia) is variably affected, but in cases with damage limited to the hippocampus the retrograde deficit is usually restricted to a brief period (weeks to a few years) before the injury (Corkin 1984). All implicit memory tasks are performed normally (Corkin 1968).

The classic contrasting example of *diencephalic amnesia* has been KS. Patients with KS have many similarities to patients with medial temporal damage (Butters and Stuss 1989). They also have normal short-term memory, severe anterograde amnesia, rapid rates of forgetting, normal semantic memory, and normal implicit memory. The major differences between KS and medial temporal lesions are in retrograde amnesia. Patients with KS have a more severe retrograde amnesia, often showing a temporal gradient with better recall of more remote information (Albert et al. 1979).

Patients with *frontal lobe damage* have long-term memory impairments. They differ from those with medial temporal damage in obvious ways; they are not amnesic as defined above. The impairments in memory seem to be a result of inefficiencies caused by poor attention or poor executive function (Hecaen and Albert 1978). The most consistent finding in patients with frontal lesions is impairment in multiple-trial list learning tasks (Janowsky et al. 1989). On this task, they fail on recall measures but have generally normal performance on recognition measures. This has been interpreted as defective retrieval, a function that requires strategy and effort, as opposed to normal storage, a function that is more passive. Patients with frontal lesions also have a number of specific impairments in memory (Shimamura 1995). They are defective in recall of temporal order, that is, recalling the context of learned items, even when they can remember these items. Finally, they have defective metamemory, that is, they are poor judges of knowing what they remember and how well their

memory functions. Damage to the prefrontal cortex will also cause a severe deficit in working memory (or short-term memory), which refers to the ability to temporarily store and manipulate information (Baddeley 1986). Elegant investigations in monkeys have shown that the prefrontal cortex is critical for the formation and storage of representations for short periods of time (Fuster 1997; Goldman-Rakic 1987).

## Disorders of Visuoception

The visual system extends from early striate and extrastriate cortex within the occipital lobe to the temporal and parietal association cortex. The visual system is organized into two streams, dorsal and ventral. The dorsal stream includes posterior parieto-occipital regions, whereas the ventral stream includes inferior medial temporo-occipital regions (Figure 32–6). Connections among these visual streams allow for progressively more complex processing of visual stimuli. Nonhuman primate lesion studies (Ungerleider and Mishkin 1982) as well as studies of patients with focal brain injury (Newcombe et al. 1987) have supported the notion that the dorsal stream supports spatial processing of stimuli (“Where is it?”), whereas the ventral stream supports the recognition of stimuli (“What is it?”). Bilateral damage to the earliest stages of visual processing within striate cortex will cause cortical blindness. Sometimes accompanying cortical blindness is Anton’s syndrome, which is characterized by a patient’s unawareness and denial of visual loss. This phenomenon is similar to the unawareness of left hemiplegia that is seen in patients with neglect resulting from right hemisphere lesions.

FIGURE 32–6. Dorsal and ventral visual streams.

## Dorsal Visual Systems

Damage within the posterior parietal cortex will cause deficits in spatial processing. Patients with right hemisphere damage perform more poorly than those with left hemisphere damage on tests of spatial processing such as judgment of line orientation (Benton et al. 1975) or mental rotation (Ditunno and Mann 1990). However, there is evidence that the left hemisphere also plays a role in spatial processing (Mehta and Newcombe 1991). A common way at the bedside to demonstrate the spatial deficit in patients with brain damage is to ask them to copy a drawing. Damage to either the left or right parietal lobe can cause a patient to produce an accurate copy of a figure, but the nature of the impairment differs. For example, a patient with left hemisphere damage will likely produce a figure that lacks details and is oversimplified but that retains its overall spatial configuration. In contrast, a patient with right hemisphere damage will likely produce a figure that is disorganized, possibly with parts in isolation but without an appropriate overall spatial configuration (Patterson and Zangwill 1944). An example of a copy of a drawing by a patient with focal injury is shown in Figure 32-7.

*Balint's syndrome* is a striking example of a disorder of spatial processing and refers to the triad of optic ataxia, ocular apraxia, and simultagnosia (Pierrat-Deseilligny et al. 1986). This syndrome typically occurs after bilateral damage to the parieto-occipital junction as a result of a watershed infarction between the middle and posterior cerebral arteries. Inferior visual field deficits can accompany these deficits. Optic ataxia is the inability to reach for a target under visual guidance. Ocular apraxia is the inability to visually scan one's environment by shifting gaze toward new visual stimuli. Simultagnosia refers to the inability to perceive the environment as a whole (Coslett and Saffran 1991). For example, if a patient was shown a complex scene in a magazine, he or she would be able to point out the details or parts of the scene (e.g., a bicycle) but would be unable to describe the entire scene (e.g., a bicycle race up a large hill in the mountains). In severe forms of this syndrome, patients are functionally disabled and essentially act as if they are blind.

## Ventral Visual Systems

Damage within inferomedial temporo-occipital cortex will cause deficits in recognition of stimuli. *Visual object agnosia* refers to the inability to recognize objects through the visual modality despite intact elementary visual perception and other cognitive abilities (Farah 1990). This rare and unusual disorder has been further subdivided into

apperceptive and associative types. Patients with apperceptive agnosia cannot "see" objects (Benson and Greenberg 1969). They cannot describe, match, or draw a picture of an object. Patients with associative agnosia can "see" the object but cannot recognize it (Rubens and Benson 1971). These patients can make perfect copies of the objects that they are unable to recognize (Figure 32-8). Presumably, in apperceptive agnosia, the visual image has been processed within striate cortex to extract the most elementary features, but a useful visual image cannot be formed because of a failure at the perceptual level. In associative visual agnosia, damage to the visual system presumably occurs after a stable visual image has been formed, but this percept cannot be used to access the knowledge of the object. Associative agnosia is caused by bilateral temporo-occipital damage typically a result of basilar

**FIGURE 32-7.** Illustration of impaired Rey figure copy (*bottom panel*) as compared with the target figure (*top panel*) from a patient with a right parietal lesion.

artery occlusion or embolic events to both posterior cerebral arteries, although visual agnosia can occur after unilateral damage to either hemisphere (Levine 1978; McCarthy and Warrington 1986). In addition to object agnosia, these patients usually have bilateral upper visual field deficits and can also have prosopagnosia, alexia, achromatopsia (i.e., inability to perceive color), or topographical disorientation. Apperceptive agnosia more typically occurs after diffuse injuries, such as cerebral hypoxia.

Patients with visual agnosia can recognize an object by other modalities such as touching it or from its spoken definition, demonstrating that they have not lost the meaning of the object. The deficit in visual agnosia is also not merely a deficit in naming the object since patients cannot identify the object by nonverbal means such as pantomiming its use. Alternatively, optic aphasia refers to a syndrome that occurs when a patient cannot name an object when presented only visually but can clearly identify it through another means (Coslett and Saffran 1989).

*Prosopagnosia* refers to the selective inability to recognize faces and can be considered a distinct form of visual agnosia. Patients are able to recognize familiar faces such as relatives via other means such as their voice, clothes, or

body shape. In some patients the impairment has not been limited to human faces in that patients can have difficulty recognizing other classes of visually similar objects such as specific types of cars or cows in a dairy herd (Damasio et al. 1982). Prosopagnosia arises after lesions of the infero-medial temporo-occipital lobe develop, usually as a result of a posterior cerebral artery infarction. Most early, large clinical surveys of prosopagnosia have concluded that bilateral lesions are necessary (Damasio et al. 1982), but more recent reviews have demonstrated that prosopagnosia can occur with damage confined to the right hemisphere (De Renzi et al. 1994).

## Disorders of Executive Function

### Anatomy of Executive Function

The frontal lobes can be divided into three major subdivisions: the motor/premotor cortex, the limbic cortex, and the prefrontal cortex. The prefrontal cortex, which is multimodal association cortex, has afferent and/or efferent connections to practically all areas of association cortex in the parietal, temporal, and occipital lobes (Fuster 1997). In addition, there are connections to the premotor cortex (and therefore indirect connections to primary motor cortex); the limbic cortex (including the cingulate gyrus, amygdala, and hippocampus); the basal ganglia (the caudate and putamen); the thalamus (predominantly the dorsomedial nucleus); the hypothalamus; and the brainstem. Also, a number of connections exist within the frontal cortex, but these pathways are still poorly understood. Therefore, it is clear that the prefrontal cortex is in direct communication with almost every area of the brain (sensory, motor, and limbic systems) and plays a vital role in almost every function of the brain. Damage to prefrontal cortex causes impairment in behavior as well as high-level cognitive abilities, which have collectively been called executive function (Stuss and Benson 1986).

### Behavioral Deficits After Prefrontal Damage

A number of behavioral alterations can occur as a result of damage to prefrontal cortex. Such damage usually results in socially inappropriate behavior and difficulty in performing actions that require appropriate decisions and planning. Of course, the normal variation and range of human behavior must be taken into account when making any determination of impairment. The patient's age, educational level, social and cultural group, and previous

**FIGURE 32-8.** Copies of various figures from a patient with apperceptive agnosia. Each of these figures, which were copied accurately, could not be recognized visually.

achievements are important factors to consider. Many of the alterations in behavior overlap with the range of normal behavior, and big lesions may appear silent unless a comparison is made to the patient's previous state. It is also important to keep in mind that any combination of these behaviors can be observed in any single patient.

Patients with prefrontal damage can show a lack of appreciation for and disregard of social rules and restrictions. Patients can appear impulsive, disinhibited, or, in the extreme, out of control, exhibiting short periods of anger or rage. An example of this behavior was the change noted in the famous patient Phineas Gage. Before his accident, he was a religious, family-loving, honest, and hardworking man who was described after his frontal injury as "fitful, irreverent, indulging at times in the grossest profanity . . . impatient of restraint or advice when it conflicts with his desires . . . obstinate, devising many plans of operation, which are no sooner arranged than they are abandoned in turn for others appearing more feasible" (Harlow 1868). In contrast, patients with prefrontal damage may show a flat affect, blunted emotional response, and decrease in drive. An example of this behavior is evident in the following description of a different patient with a frontal injury: "He was quiet, did not initiate conversation, and appeared remote and withdrawn. Although frequently incontinent, he was unconcerned and almost never initiated an attempt to remedy the status" (Benson 1994). Self-awareness may be considered one of the highest cognitive attributes of the frontal lobes.

Although patients with frontal damage have little impairment of basic cognitive functions such as language and visuoperception, they can have difficulty using these skills. This problem is illustrated in the following case history: "While being evaluated for the presence of diabetes insipidus, the patient was instructed, 'Don't drink any water; don't go near the water fountain.' Within a few minutes he was observed having a drink at the water fountain. When asked by the examiner what he had just been told, he immediately replied: 'Don't drink any water; don't go near the water fountain.' " He had understood and remembered the instructions, but this knowledge could not be used to control his actions (Benson 1994). His actions were clearly separated from his knowledge.

### **Cognitive Deficits After Prefrontal Damage**

Interestingly, extensive frontal lobe damage may have little impact on the abilities measured by standardized intelligence tests or other neuropsychological tests (see Chapter 7 in this volume), but these findings are in marked contrast

to the way that these patients perform in unintelligent ways in real life (Shallice and Burgess 1991). Based on this observation, it is obvious that neuropsychological tests designed for the laboratory do not always capture the abilities that are necessary for success in real life. For example, "real-life behavior requires heavy time processing demands (working memory) and a core system of values based on both inherited (drives, instincts) and acquired (education, socialization) information that is probably not necessary for most artificial problems posed by neuropsychological tasks" (Damasio and Anderson 1993).

Executive function, which is used to describe the type of abilities that are impaired after prefrontal damage, is difficult to conceptualize and difficult to develop tasks to examine directly, especially at the bedside. The following impairments are characteristic of executive dysfunction:

1. *Inability to initiate, stop, and modify behavior in response to changing stimuli.* An impairment of this type is illustrated when patients with frontal injury perform the Wisconsin Card Sorting Test (Heaton 1985). In this test, a deck of cards is presented one at a time to a patient who must sort each one according to various stimulus dimensions (color, form, or number). Each card from the deck contains from one to four identical figures (stars, triangles, crosses, or circles) in one of four colors. The patient is told after each response whether the response is correct or not and must infer from this information only (the sorting principle is not given by the examiner) what the next response should be. After 10 correct sorts, the sorting principle is changed without warning. During this test, patients with frontal injury usually understand and can repeat the rules of the test but are unable to follow them or use knowledge of incorrect performance to alter their behavior (Milner 1963).
2. *Inability to handle sequential behavior necessary for organization, planning, and problem solving.* Patients with frontal injury often have no difficulty with the basic operations of a given task. For example, when performing complex mathematical problems requiring multiple steps, the patient may initially respond impulsively to an early step and will be unable to string together and execute the component steps required for solving the problem (Stuss and Benson 1984). However, the ability to perform each of the mathematical operations in isolation (e.g., adding and subtracting) required to complete the complex task might be intact. The problem "The price of canned peas is two cans for 31 cents; what is the price of one dozen cans?" is almost impossible for patients with

frontal damage even though these patients perform the direct arithmetical task of multiplying 6 times 31 with ease (Stuss and Benson 1984).

3. *Inability to inhibit responses.* This impairment can be demonstrated with a measure called the Stroop paradigm (Stroop 1935). It is based on the observation that it takes longer to name the color of a series of conflicting color words (e.g., “red” printed in blue ink) than to name the color of a series of color blocks.

This phenomenon is exaggerated in patients with frontal lesions (Perret 1974). A related phenomenon is that these patients may display a remarkable tendency to imitate the examiner’s gestures and behaviors even when no instruction has been given to do so, and even when this imitation entails considerable personal embarrassment. The mere sight of an object may also elicit the compulsion to use it, although the patient has not been asked to do so and the context is

inappropriate—as in a patient who sees a pair of glasses and puts them on, even though he is already wearing his own pair (Figure 32–9). These symptoms have been called the “environmental dependency syndrome.” It has been postulated that the frontal lobes may promote distance from the environment and the parietal lobes foster approach toward one’s environment. Therefore, loss of frontal inhibition may result in overactivity of the parietal lobes. Without prefrontal cortex, our autonomy from our environment would not be possible. A given stimulus would automatically call up a predetermined response regardless of context (Lhermitte 1986; Lhermitte et al. 1986).

4. *Perseveration.* This is defined as an abnormal repetition of a specific behavior. It can be present after frontal damage in a wide range of tasks including motor acts, verbalizations, sorting tests, drawing, or writing (Figure 32–10).

**FIGURE 32–9.** A photograph of a patient with utilization behavior. On the left is the physician and on the right is the patient. A pair of glasses were placed on the table in front of the patient without any instructions from the physician to do anything with them. Nevertheless, the patient put the glasses on his face even though he had another pair of glasses already on.

**FIGURE 32-10.** Several examples of perseverative behavior from patients with frontal pathology.

### Frontal Lobe Syndromes

At least three signature behavioral/cognitive syndromes (Cummings 1993) occur after damage to different regions of the prefrontal cortex (Figure 32-11). These syndromes reflect separable circuits of connection of the prefrontal cortex with subcortical structures (see Chapter 4 in this volume). First, damage to the dorsolateral prefrontal circuit causes executive dysfunction. These patients have difficulty generating hypotheses and flexibly maintaining and shifting sets as required by changing task demands. Second, damage to the orbitofrontal circuit causes disinhibited, irritable, and labile behavior. This type of lesion also results in imitation and utilization behavior. Unlike patients with dorsolateral damage, these patients may not have significant executive impairments. Third, damage to the medial frontal/anterior cingulate circuit causes akinesia, apathy, and unconcern. Of course, patients may have damage to more than one of these frontal circuits that can lead to a mixture of clinical deficits.

### ■ Summary

Injury to the cerebral cortex can cause a wide range of neurobehavioral syndromes with a characteristic profile of deficits in attention, language, memory, visuosperception, or executive function. These syndromes can occur in isolation as a result of a stroke causing very focal damage (e.g., posterior cerebral artery infarction causing alexia) or combinations of each of these syndromes can be seen in more

**FIGURE 32-11.** Functional subdivisions of the frontal lobes corresponding to dissociable behavioral syndromes.

widespread damage to the brain (e.g., Alzheimer's disease causing amnesia, aphasia, and visuospatial deficits). Knowledge of the clinicoanatomical relationships described in this chapter is critical for diagnosis, treatment, management, and rehabilitation of patients with injury to the cerebral cortex.

## *Why Does Age Matter?*

George S. Zubenko, M.D., Ph.D.

Trey Sunderland, M.D.

Older adults respond less predictably to most medications than younger adults, typically requiring lower daily doses to achieve desired therapeutic effects while minimizing adverse effects and toxicity. This unpredictability is particularly evident among the frail elderly who carry a significant burden of comorbid medical problems and central neurodegenerative disorders or are at the upper extreme of the life cycle. Yet this population has a burgeoning need for clinical services and in recent years has become an increasingly important focus of attention for practitioners. Our goal with this chapter is to provide clinicians with a conceptual framework for understanding and responding to aging and age-related events that influence pharmacotherapeutic

in older patients with neuropsychiatric disorders. Limitations and gaps in our knowledge base are also highlighted. This chapter includes a phenomenological overview of the aging process, a consideration of age-related factors that influence the pharmacokinetic and pharmacodynamic properties of psychotropic drugs, methods of enhancing medication compliance, and a brief conclusion.

### ■ Phenomenological Overview

Although aging is most easily defined by the passage of time, the number and extent of physiological changes asso-

---

Helpful comments provided by Dr. James M. Perel are gratefully acknowledged. This work was supported by Research Grants MH43261 and MH/AG47346, and Independent Scientist Award MH00540 for the National Institute of Mental Health and the National Institute on Aging.

ciated with aging are complex and highly variable among individuals. Moreover, within individuals, decrements in physiological functions often do not develop at the same rate or extent across all tissues and organ systems. When they do emerge, functionally significant changes occur predictably in the directions of decreased efficiency and decreased maximal capacity. Useful general relationships have emerged between chronological age and physiological variables that are relevant to assessments of health and the practice of pharmacotherapeutics. However, intra-individual and interindividual heterogeneity limits the informativeness of chronological age alone as an indicator of physiology. A complete history, physical and mental status examinations, functional assessment, and appropriate laboratory testing can provide a more accurate and comprehensive picture in this regard.

Age-related medical disorders, whether a reflection of a pathological acceleration of the normal aging process or novel derangements, often have an important impact on the pharmacotherapy of neuropsychiatric disorders in the elderly. In fact, the consequences of age-related illnesses often overshadow those of normative aging by rendering patients less responsive to treatment, less tolerant of adverse medication effects, or both. For example, even when adequate treatment is provided, comorbid medical burden is a predictor of poorer response of major depression to acute treatment (Katz et al. 1990; Popkin et al. 1985; Zubenko et al. 1994). This phenomenon also contributes to suboptimal responsiveness of patients with neuropsychiatric disorders by limiting the spectrum of medications and other treatment modalities that can be employed. Moreover, the medical disorders of late life are often chronic, contributing to an accumulating burden of medical problems with advancing age. Finally, complex relationships of chronic illness, pain, disability, and depression lead to the co-occurrence of these conditions at rates that are greater than expected from chance alone.

As a consequence of this age-related increase in medical comorbidity, older Americans fill an average of 13 prescriptions each year, greater than twice the national average and nearly three times that of individuals under 65 (Baum et al. 1988; Chrischilles et al. 1992). The use of prescription medications continues to further increase with age within this segment of the population. In a rural community survey, 13% of those between 65 and 70 took no medications compared with 7% of those 85 and older (Helling et al. 1987). Nonprescription drug use also increases with age with about two-thirds of seniors using over-the-counter medications (Lamy 1980). These values underestimate the use of medications by hospitalized patients and those in residential settings such as personal care

or nursing homes. In a study of 868 older psychiatric inpatients with a mean age of 62, this population had an average of six active ICD-9-CM (International Classification of Diseases, 9th Revision, Clinical Modification, 4th Revision 1993) medical problems and were taking an average of three to four nonpsychotropic prescription medications (Zubenko et al. 1997).

The common use of multiple prescription and nonprescription drugs by older Americans may contribute significantly to reduced effectiveness and increased toxicity of medications in this population by multiple interacting mechanisms. Reduced rates of metabolism and excretion of drugs among the elderly place them at risk for adverse effects if daily dosages are not adjusted accordingly. The use of multiple medications increases the likelihood of adverse drug interactions. Furthermore, the greater number of medications increases the likelihood of an adverse reaction with age-associated physiological changes or age-related medical conditions. Finally, polypharmacy invites non-compliance with prescribed medications. Increasing the number of medications and overall complexity of the medication regimen decreases the likelihood that any of the medications will be taken as prescribed. The result is reduced overall therapeutic effectiveness, greater burden of adverse effects, and greater likelihood of discontinuation of prescribed medications altogether.

## ■ Aging and the Pharmacokinetic Properties of Psychotropic Drugs

A rich literature describes numerous physiological changes that accompany normative aging and their impact on the pharmacokinetic properties of psychotropic drugs. A general summary of these physiological alterations and their effects on drug absorption, distribution, plasma protein binding, hepatic metabolism and clearance, and renal clearance is presented in Table 33-1. Common clinical implications of these relationships for pharmacotherapeutics are also described.

### Absorption

Aging and age-related alterations occur throughout the gastrointestinal tract. Difficulties with swallowing are relatively common among elderly patients with neuropsychiatric disorders, especially those that are associated with neurodegenerative or cerebrovascular diseases (Jost 1997; Ribeiro et al. 1998; Sonies 1992; Zubenko et al. 1997). Dysphagia complicates the administration of medications, often rendering the dosing schedule erratic and necessitat-

**TABLE 33-1. Age-related physiologic changes that influence the pharmacokinetics of psychotropic drugs**

	<b>Pharmacokinetic effects</b>	<b>Clinical implications</b>
<b>Absorption</b>	Decreased rate of absorption, especially when compounded by anticholinergic effects, antacids, or coadministration with food. May reduce bioavailability in some cases.	Delayed onset of action and reduced clinical effect if incomplete absorption occurs. Minimize factors that reduce absorption.
<ul style="list-style-type: none"> <li>↓ Swallowing</li> <li>↑ Gastric pH</li> <li>↓ Gastric emptying</li> <li>↓ Intestinal motility</li> <li>↑ Transit time</li> <li>↓ Absorptive surface area</li> <li>↓ Mesenteric blood flow</li> </ul>		
<b>Distribution</b>	Increased total body fat leads to the increased volume of distribution of most (lipophilic) psychotropic drugs, resulting in increased half-life without change in steady-state plasma concentration. Effect of decreased total body water on decreased half-life for lithium is outweighed by age-associated reduction in renal clearance.	Increased treatment interval is required to reach steady-state plasma concentrations of psychotropic drugs. Decreased duration of action of single doses of these agents as a result of redistribution into fat stores.
<ul style="list-style-type: none"> <li>↓ Muscle mass</li> <li>↓ Total body water</li> <li>↑ Total body fat</li> </ul>		
<b>Plasma protein binding</b>	Effects on the plasma concentration of free drug vary, depending on whether the drug is protein bound (all but lithium), whether it binds preferentially to albumin (benzodiazepines and neuroleptics) or $\alpha_1$ -acid glycoprotein (heterocyclic antidepressants), and whether hepatic clearance is restricted to unbound drug (sedative hypnotics) or not (most heterocyclic antidepressants, selective serotonin reuptake inhibitors, and neuroleptics). Competition for protein binding site by coadministered drugs can produce transient increases in the plasma concentrations of free drug.	On average, modest increase in the potency and toxicity of neuroleptics can result along with modest decrease in the potency and toxicity of heterocyclic antidepressants. Greater effects can occur in malnourished patients or those with comorbid medical illnesses. Increase surveillance for adverse effects when adding new medications to regimen.
<ul style="list-style-type: none"> <li>↓ Albumin (↓ ↓ malnutrition)</li> <li>↑ <math>\alpha_1</math>-acid glycoprotein (↑ ↑ illness)</li> </ul>		
<b>Hepatic metabolism and clearance</b>	Decreased metabolism of many psychotropic drugs results in increased peak and steady-state plasma levels. Increased ratios of parent drug to demethylated (often active) derivatives can occur. Modest effect of age on biotransformation by glucuronide, sulfate, or acetyl conjugation.	Reductions in the specific activities of cytochrome P450 isoenzymes can result from genetic polymorphism, age-related diseases, and inhibition by coadministered medications. Modest if any effects of age alone. Anticipate the need for reduced dosages of psychotropic drugs, especially on initial administration, to avoid excessive peak and steady-state plasma concentrations that produce toxicity. Advance dosages and introduce additional medications with caution. Monitor carefully for the emergence of adverse effects and toxicity. When indicated, employ benzodiazepines cleared by glucuronide conjugation (oxazepam, lorazepam, temazepam).
<ul style="list-style-type: none"> <li>↓ Liver volume</li> <li>↓ Hepatic blood flow</li> <li>↓ Oxidative metabolism</li> <li>↓ N-Demethylation</li> <li>→ Conjugation</li> </ul>		

*(continued)*

**TABLE 33-1. Age-related physiologic changes that influence the pharmacokinetics of psychotropic drugs (continued)**

	Pharmacokinetic effects	Clinical implications
<b>Renal clearance</b>		
↓ Renal blood flow	Decreased renal clearance leads to increased half-life and increased steady-state plasma concentration for lithium and active water-soluble metabolites of other psychotropic drugs.	Evaluate renal function before initiating therapy with lithium or other drugs cleared primarily by the kidneys. Age-related decrements in renal clearance can be worsened by common chronic diseases, including hypertension, congestive heart failure, and diabetes. Initiate lithium therapy at a reduced daily dosage and titrate dosage cautiously using plasma levels while monitoring for adverse effects.
↓ Glomerular filtration rate	Diuretics and nonsteroidal anti-inflammatory drugs may further increase half-life and steady-state plasma concentration for lithium.	Toxicity can occur in elderly patients at plasma lithium levels at or below the usual therapeutic range (0.8–1.2 mEq/L). Diuretics and nonsteroidal anti-inflammatory drugs may lead to lithium retention. Monitor potential toxicity in patients with renal failure who may retain water-soluble active metabolites such as cardiotoxic metabolites of heterocyclic antidepressants.

ing the coadministration of medications with food substances that may alter absorption. Most studies have documented age-associated decreases in gastric emptying and intestinal motility, although some reports suggest that these functions are preserved in healthy elders in the absence of intercurrent illness or medication effects (Altman 1990; Annesley 1989; Pilotto et al. 1995; Russell 1992; Schmucker 1985). Increases in gastric pH can also delay absorption by altering the ionization of drugs and further retarding gastric emptying (Altman 1990; Annesley 1989; Russell 1992; Schmucker 1985; Trey et al. 1997). These factors along with reductions in absorptive surface area and mesenteric blood flow may contribute to a reduced rate of drug absorption (Altman 1990; Annesley 1989; Holt and Balint 1993; Pilotto et al. 1995; Russell 1992; Schmucker 1985; Trey et al. 1997). This outcome can be compounded by anticholinergic drug effects, the administration of antacids, and the ingestion of food. Diseases of the liver, pancreas, and intestine are more common in the elderly and may also lead to impaired absorption (Altman 1990; Annesley 1989; Holt and Balint 1993; Pilotto et al. 1995; Russell 1992; Schmucker 1985; Trey et al. 1997). The clinical result of incomplete absorption is a delay in the onset of action and reduced clinical effect.

### Distribution

Age-related alterations in drug distribution result from reductions in lean muscle mass and total body water, along with an increase in total body fat (Borkan et al. 1983; Forbes and Reina 1970; Novak 1972). Because most psychotropic drugs are lipophilic, their volumes of distribution increase commensurate with their degree of lipophilicity and the increase in body fat that occurs with aging. This pharmacokinetic effect leads to increased drug half-lives without changing steady-state plasma concentrations. The clinical consequence is that a longer treatment interval is required to reach steady-state plasma concentrations of most psychotropic drugs, which are typically administered regularly over months to years. In contrast, a reduced duration of action of single doses of these agents can result from redistribution into fat stores. Intermediate effects of these age-related changes in body composition can occur for drugs that have water-soluble metabolites that are pharmacologically active.

In contrast to most psychotropic drugs, lithium is not lipophilic and distributes into total body water. However, the potential reduction in half-life for lithium as a result of an age-related reduction in total body water is outweighed by decreases in renal clearance.

The blood-brain barrier partitions the brain paren-

chyma from substances in the systemic circulation, including medications. Although lipophilic psychotropic drugs distribute into the brain by passive diffusion, the blood-brain barrier is likely to regulate the passage of drugs that contain charged moieties, drugs that are protein-bound, and active hydrophilic drug metabolites into the brain. The contribution of this phenomenon to the distribution of centrally acting drugs to their sites of action remains a potentially important but understudied area of investigation. Available evidence suggests that the integrity of the blood-brain barrier decreases with age, especially in the context of central neurodegenerative disorders such as Alzheimer's disease (AD) (Kalaria 1996; Kleine and Hackler 1994; Shah and Mooradian 1997; Skoog et al. 1998). Such age-related changes may contribute to increased sensitivity to psychotropic medications.

### Plasma Protein Binding

After absorption in the blood, virtually all psychotropic medications with the exception of lithium bind at least partially to plasma proteins, chiefly albumin and  $\alpha_1$ -acid glycoprotein. This phenomenon is important because only unbound drug is able to cross the blood-brain barrier and interact with its intended target in the brain. Unbound drug may also interact with peripheral sites of action that result in unwanted side effects.

Protein binding characteristics of psychotropic drugs are largely determined by their chemical and structural properties (Loi and Vestal 1988). Although heterocyclic antidepressants bind to both albumin and  $\alpha_1$ -acid glycoprotein, the free fractions (concentration of free drug/total drug concentration) of these agents in plasma depend primarily on the concentration of  $\alpha_1$ -acid glycoprotein. In contrast, the free fractions of benzodiazepines and most neuroleptics depend primarily on albumin levels.

Aging is typically associated with modest reductions in plasma albumin levels (Adir et al. 1982; Greenblatt 1979; Loi and Vestal 1988). However, chronic debilitation from medical problems including dementia often results in malnutrition, with more significant reductions in plasma albumin levels. In contrast, most studies suggest that aging is accompanied by moderate elevations in plasma  $\alpha_1$ -acid glycoprotein levels (Abernathy and Kerzner 1984; Amitai et al. 1993; Loi and Vestal 1988). Because  $\alpha_1$ -acid glycoprotein is an acute-phase reactant, illnesses that are accompanied by inflammation and activation of the immune system produce greater elevations in the levels of this protein. On average, moderate age-associated changes occur in plasma albumin (decreased) and  $\alpha_1$ -acid glycoprotein levels (increased), along with increased

age-related variance that is attributable in part to an accumulating burden of medical illness.

Protein binding has a variable effect on hepatic metabolism and clearance that is also drug specific (von Moltke et al. 1998). For several commonly prescribed sedative-hypnotics (chlordiazepoxide, diazepam, lorazepam, alprazolam), hepatic clearance is restricted by protein binding. As a result, increases in the free fractions of these compounds that are attributable to age-associated reductions in albumin result in proportionate increases in their hepatic clearance and only a minimal increase in the concentration of free drug under steady-state conditions. However, for many psychotropic medications (most tricyclic antidepressants, selective serotonin reuptake inhibitors [SSRIs], neuroleptics), hepatic clearance is unaffected by protein binding.

The extent and characteristics of protein binding, and their clinical significance, are highly variable. They depend in important ways on the age, gender, health, and specific medications taken by each patient. On average, modest increases in the potency and toxicity of neuroleptics and modest decreases in the potency and toxicity of antidepressant medications would be expected from age-associated changes in the levels of albumin and  $\alpha_1$ -acid glycoprotein because the hepatic clearance of these compounds is unrestricted by protein binding. Increased sensitivity of the elderly to the sedating effects of benzodiazepines depends to a greater extent on age-related reductions in hepatic and renal clearance as well as on increased tissue sensitivity.

Although significant clinical manifestations of altered protein binding appear to be uncommon, they are more likely to occur among the frail elderly who manifest the greatest perturbations in the levels of albumin and  $\alpha_1$ -acid glycoprotein as the result of extreme age or comorbid medical burden. Competition for protein binding sites by coadministered drugs can also produce transient increases in the free concentrations of the competing compounds. These considerations warrant greater surveillance for adverse effects, especially when adding new medications to a regimen.

### Hepatic Metabolism and Clearance

Most psychotherapeutic drugs other than lithium are cleared by hepatic biotransformation. After oral administration and intestinal absorption, these medications are transported to the liver through the portal and hepatic veins before entering the systemic circulation. Drug metabolism that occurs in the intestinal mucosa and during the first pass through the liver substantially reduces the bioavailability of many orally administered psychotropic drugs.

Biotransformation in the liver is most commonly accomplished through a series of oxidative reactions. The first step in this process is often demethylation, which typically produces an active metabolite. As an example, the tricyclic antidepressants amitriptyline and imipramine are demethylated to nortriptyline and desipramine, respectively. Subsequent oxidative conversions yield progressively more water-soluble compounds with varying degrees of pharmacological activity that are more readily excreted by the kidneys and gut. A second mechanism of biotransformation relies on the conjugation of drugs or their metabolites with glucuronide, sulfate, or acetyl moieties. Such conjugation reactions produce more polar, hydrophilic compounds that are usually devoid of pharmacological activity.

These oxidative reactions are catalyzed by the cytochrome P450 (CYP 450) family of isoenzymes that are localized to hepatic microsomes. They are divided into several subfamilies: CYP 1A2, CYP 2C9/10, CYP 2C19, CYP 2D6, and CYP 3A3/4. Subfamilies CYP 1A2, CYP 2D6, and CYP 3A3/4 account for the metabolism of most psychotropic drugs. A list of commonly prescribed psychotropic drugs and the CYP 450 isoenzymes that contribute to their metabolism is presented in Table 33–2. Not surprisingly, the substrate specificity of these isoenzymes often overlaps. When more than one isoenzyme family is involved, the predominant route of metabolism is indicated by the boldface drug name.

Aging is accompanied by reductions in the rate of metabolism of many psychotropic drugs by the liver. This decreased metabolism results in higher peak and steady-state plasma drug levels compared with those of younger patients receiving the same dosing regimen. Reduced hepatic metabolism associated with normative aging in humans appears to result, at least partially, from reductions in total liver volume and hepatic blood flow (Le Couteur and McLean 1998; Woodhouse and James 1990; Yuen 1990). Reduced uptake into hepatocytes as well as functional shunting as a result of the saturation of particular isoenzymes remain potential, but largely unexplored, contributors as well. Age-related diseases such as congestive heart can further reduce hepatic metabolism by compromising hepatic blood flow.

Most studies of humans have revealed little or no reductions in the specific activities or substrate affinities of the CYP 450 isoenzymes with advancing age in the absence of histopathological changes in the liver (Hunt et al. 1992; Le Couteur and McLean 1998; Pollock et al. 1992; Schmucker et al. 1990; Woodhouse and James 1990; Yuen 1990). However, reductions in the activities of these isoenzymes can result from genetic polymorphisms (e.g.,

CYP 2D6), age-related diseases, and inhibition by coadministered medications. Aging has only a modest effect on biotransformation by glucuronide, sulfate, or acetyl conjugation. Rather than age-related factors, an inherited polymorphism that affects the rate of acetylation accounts for more of the population variance in this phenotype.

Because the elderly often take multiple medications, they are at risk for the development of drug interactions that arise from the inhibition of one or more of the CYP 450 isoenzymes. Such interactions do not necessarily result in significant clinical consequences, especially when modest initial doses are employed and cautiously adjusted to achieve the desired therapeutic effect. A list of common or clinically significant inhibitors of CYP 450 isoenzymes is presented in Table 33–3. As an example, the comparison of Tables 33–2 and 33–3 reveals that both paroxetine and fluoxetine inhibit CYP 2D6. As a result, they would be expected to increase the steady-state plasma levels of tricyclic antidepressants in patients receiving stable doses of the latter. Paroxetine and fluoxetine also inhibit their own metabolism. Therefore, increases in the oral dosages of paroxetine and fluoxetine produce disproportionately larger increases in the corresponding steady-state plasma levels of these agents.

So far, these pharmacokinetic considerations have focused on the effects of coadministered drugs on the metabolism of psychotropic agents. In turn, psychotropic drugs can slow the metabolism of nonpsychotropic medications through their inhibitory effects on CYP 450 isoenzymes. As shown in Table 33–4, inhibitors of CYP 1A2 such as fluvoxamine can interfere with the metabolism of acetaminophen, propafenone, propranolol, warfarin, and theophylline. Inhibitors of CYP 2D6 such as paroxetine can slow the metabolism of several narcotic analgesics, antiarrhythmics, and  $\beta$ -blockers. Inhibitors of CYP 3A3/4 such as nefazodone may result in increased plasma levels of many drugs including narcotic and nonnarcotic analgesics, antibiotics, antihistamines, antitumor agents, antiarrhythmics, calcium channel blockers, immunosuppressants, steroids, and agents used to treat gastroesophageal reflux. All of these classes of drugs are commonly prescribed for age-related medical conditions.

Less commonly, some agents induce increases in hepatic enzyme activity, potentially resulting in subtherapeutic plasma levels of medications (see references for Tables 33–2 through 33–4). For example, cigarette smoking is an inducer of CYP 1A2 activity, whereas phenobarbital and phenytoin induce CYP 3A3/4. Carbamazepine induces its own metabolism (CYP 3A3/4; Table 33–2) and that of haloperidol, requiring upward adjustment of dosages to maintain therapeutic plasma levels. Some evidence

suggests that the capacity for CYP 450 isoenzyme induction may be blunted in late life (Pearson and Roberts 1984; Schmucker 1979; Vestal 1989).

Tables 33–2 through 33–4 do not include comprehensive lists of medications. Instead, they are intended to illustrate common or clinically important drug properties and interactions that occur at the level of hepatic metabolism. This topic is currently receiving considerable attention, leading to a rapidly growing number of drugs whose metabolic profiles have been examined. Furthermore, published studies of drug metabolism performed using animal models of aging may not always provide data that are relevant to humans. When discrepancies were identified, we relied on results from human studies for inclusion in this section. Finally, the results of human *in vitro* studies of drug metabolism have not always been readily reconcilable with the results of human studies performed *in vivo*, reflecting the limitations of experimental designs and our current understanding of this complex topic.

## Renal Clearance

Renal blood flow and glomerular filtration rate decline with age (Annesley 1989; Pollock et al. 1992; von Moltke et al. 1998; and see references to Tables 33–2 through 33–4). As a result, the renal clearance of lithium as well as active water-soluble metabolites of lipophilic parent compounds is reduced. Elevated and potentially toxic steady-state levels of lithium and cardiotoxic metabolites of tricyclic antidepressants may develop in elderly patients if doses that are used in younger adults are not adjusted downward.

Clinically, it is important to recognize that plasma creatinine concentrations overestimate the actual glomerular filtration rate in elderly subjects as a result of the reduction in muscle mass that occurs with aging. Congestive heart failure can further impair renal clearance by reducing renal blood flow, and hypertension and diabetes reduce glomerular filtration rate by producing microvascular damage. Moreover, the treatments for hypertension and congestive heart failure often include sodium-depleting diuretics. These agents along with nonsteroidal anti-inflammatory drugs are commonly prescribed for the elderly, further inhibit lithium excretion, and thereby enhance the potential for toxicity.

## ■ Aging and the Pharmacodynamic Properties of Psychotropic Drugs

Reports of increased susceptibility of the elderly to the adverse effects of psychotropic medications are commonplace in the literature. A list of some of these common adverse effects is presented in Table 33–5. However, the relative contributions of age-dependent changes in tissue sensitivity to the action of a drug (pharmacodynamics) and those that arise from alterations in pharmacokinetic characteristics are often difficult to determine unambiguously, especially in humans. Paradigms for simultaneously measuring pharmacokinetic variables while monitoring clinical effects have been developed for this purpose. However, these approaches do not readily lend themselves to the repeated dosing strategies that are typically used for psychotherapeutic drugs over weeks, months, and years. Moreover, such studies relate clinical effects to plasma levels of active drugs and metabolites that may not always reflect the concentrations of these compounds at their sites of action in the central nervous system.

The capacity for the brain to remodel itself at intercellular, cellular, and subcellular levels in response to endogenous and external stimuli appears to diminish in late life, especially among individuals who have central neurodegenerative disorders (Zubenko 1997) (Tables 33–6

*Source.* Adapted from Gelenberg 1995; Intek Labs 1999; Michalets 1998; Micromedex 1999; Nemeroff et al. 1995–1996, 1996; Patel and Salzman 1998; Pollock 1994.

through 33–9). This age-associated reduction in plasticity can account for the decreased average rate of response of depressed elders to antidepressant therapy compared with that of younger adults. It can also account for the association of cognitive impairment with a somewhat poorer acute response to antidepressant treatment among elderly patients with major depression. Recovery from drug-induced toxicity also appears to be slower in this segment of the population. As an example, residual symptoms of lithium-induced encephalopathy can persist for a substantive period after drug discontinuation when lithium levels are no longer detectable in plasma.

### **Benzodiazepines**

The elderly fill more prescriptions for benzodiazepines (Balter et al. 1974; Baum et al. 1986) and experience more

adverse effects from these drugs than their younger counterparts (Boston Collaborative Drug Surveillance Program 1973; Castleden et al. 1977; Cook et al. 1984; Giles et al. 1978; Greenblatt et al. 1991; Pomara et al. 1984; Ray et al. 1989; Reidenberg et al. 1978; Thompson et al. 1983). The increased magnitude of pharmacological effects in the elderly, including sedation as well as memory and psychomotor impairment, is partially attributable to age-related reductions in the rates of clearance and elimination that predispose the elderly to the development of elevated plasma levels of these compounds (Greenblatt et al. 1991; Herings et al. 1995; Kroboth et al. 1990; Pomara et al. 1984). However, the increased sensitivity of the elderly to these effects remains evident even when similar plasma concentrations are maintained in younger and older individuals (Bertz et al. 1997; Castleden et al. 1977; Cook et al. 1984; Greenblatt et al. 1991; Herings et al. 1995; Kroboth

**TABLE 33–5. Common adverse effects of psychotropic drugs in the elderly**

- Central nervous system (sedation, confusion, disorientation, memory impairment, delirium)
- Anticholinergic, peripheral (constipation, dry mouth, blurred vision, urinary retention)
- Motor (extrapyramidal symptoms, tremor, impaired gait, increased body sway, falling)
- Cardiovascular (hypotension, cardiac conduction delay)
- Other (agitation, mood and perceptual disturbances, headache, sweating, sexual dysfunction, gastrointestinal disturbances [nausea, anorexia, changes in weight or bowel habits], hyponatremia)

et al. 1990; Nikaido et al. 1990; Pomara et al. 1985; Reidenberg et al. 1978; Swift et al. 1985). The elderly can also experience paradoxical excitement from benzodiazepines, a qualitatively different effect. Although the mechanisms that underlie these age-dependent pharmacodynamic alterations have not been elucidated, age-associated reductions in the numbers of GABAergic neurons (Allen et al. 1983) and the specific activity of the biosynthetic enzyme glutamic acid decarboxylase in selected brain regions (McGeer 1981) have been reported from autopsy studies, along with lower  $\gamma$ -aminobutyric acid (GABA) levels in cerebrospinal fluid (Bareggi et al. 1985; Hare et al. 1982). Together, these pharmacokinetic and pharmacodynamic changes render elderly patients who take benzodiazepines more vulnerable on average to excessive sedation, to memory and psychomotor impairment, and to falls and resulting skeletal fractures.

## Lithium

Unlike dosages of most other psychotropic drugs, oral dosages of lithium salts are typically adjusted to achieve target plasma levels of lithium ion in the range of 0.8–1.2 mEq/L. This approach should minimize the contributions of age-related pharmacokinetic changes (chiefly reduced renal clearance) to the development of therapeutic or adverse effects. Yet, at this relatively narrow range of plasma lithium levels, elderly patients develop adverse effects more commonly, and those adverse effects that develop tend to be more debilitating than those experienced by younger patients (Satlin and Liptzin 1998). These effects include cognitive impairment, tremor, muscle rigidity, abnormalities of gait, gastrointestinal distress (nausea, diarrhea), polydipsia, polyuria, and electrocardiogram changes. In fact, it is not uncommon to encounter elderly patients who develop intolerable adverse effects, including delirium, at steady-state plasma levels below 0.8 mEq/L. It is unclear

whether aging is associated with increased risk of lithium-induced hypothyroidism or renal disease that occur with longer-term treatment.

These common clinical observations strongly suggest that aging is accompanied by sensitization of target tissues to the adverse effects of lithium. However, the neurobiological substrates and mechanisms that are responsible for this phenomenon are unknown. Whether the age-associated increase in the sensitivity of the elderly to the adverse effects of lithium is likewise accompanied by increased therapeutic potency is uncertain.

## Cholinergic Antagonists

Many psychotropic drugs have significant anticholinergic (antimuscarinic) potency, especially antidepressant and antipsychotic medications. Less appreciated is that numerous medications prescribed for indications other than behavioral disorders among the elderly also possess clinically meaningful anticholinergic potencies (Tune et al. 1992). Some common examples include cimetidine and ranitidine; dipyridamole, warfarin, isosorbide, nifedipine, and digoxin; codeine, theophylline, and prednisolone. Over-the-counter medications taken by the elderly for various indications also frequently include ingredients that have significant anticholinergic properties (e.g., diphenhydramine hydrochloride [Benadryl]). These agents alone and in combination contribute to the development of clinically important anticholinergic effects both centrally and in the periphery (Table 33–5).

The relative contributions of pharmacokinetic and pharmacodynamic phenomena to the increased vulnerability of the elderly to the anticholinergic effects of medications have not been clearly defined and probably differ in relative importance depending on the particular drug(s) involved. Challenge studies employing single intravenous doses of the antimuscarinic agent scopolamine have demonstrated greater cognitive impairment with aging (Table 33–6). These results suggest that aging is associated with greater intrinsic sensitivity of the central nervous system to cognitive impairment induced by anticholinergic agents.

Numerous age-related neurobiological changes in the central cholinergic nervous system can contribute to the increased sensitivity of the elderly to the anticholinergic effects of psychotropic and other medications. As shown in Table 33–6, all of these effects of aging are in the direction of decreased cholinergic function. Advancing age is accompanied by a reduction in the number of cholinergic neurons in the basal forebrain that innervate the cortex. The basis for this selective loss of cholinergic neurons in aging individuals is unclear. One factor may be related to

*Source.* Adapted from Allen et al. 1983; Court et al. 1993; Cutler et al. 1994; Flynn and Mash 1986; Lee et al. 1996; Mesulam et al. 1987; Molchan et al. 1992; Muller et al. 1991; Nakano et al. 1986; Nordberg et al. 1992; Suhara et al. 1993; Sunderland et al. 1995.

their need to draw on a limited supply of choline for multiple purposes, including the synthesis of structural components of cell membranes, second-messenger molecules, and the neurotransmitter acetylcholine. Despite its key role of choline in neuronal metabolism, brain cells lack the capacity to synthesize choline *de novo*. The significant decline in the uptake of circulating choline into brain that develops with age can disproportionately compromise cholinergic neurons whose need for choline is the greatest (Cohen et al. 1995).

Aging is also associated with a decrease in the specific activity of the biosynthetic enzyme choline acetyltransferase in the cortex and an increase in the activity of the catabolic enzyme acetylcholinesterase in cerebrospinal fluid. These biochemical changes can reduce the synthesis of acetylcholine while enhancing its rate of degradation once released into the synaptic cleft. Studies of age-related changes in the densities of muscarinic receptors have yielded inconsistent results, possibly because reduced numbers of presynaptic muscarinic receptors are accompanied by a compensatory increase in the density of postsynaptic muscarinic receptors. Reductions in the density of nicotinic receptors in the brain have been reported with aging, although the functional significance of these receptors is unclear.

AD is the most common cause of mental impairment among the elderly (Bachman et al. 1992; Evans et al. 1989; Jorm et al. 1987) (see Chapter 24 in this volume). The pathophysiology of this disorder is complex, and numerous neuronal types and neurotransmitter systems are affected (Zubenko 1997). One of the most consistently reported and profound pathological changes in AD is the loss of cholinergic neurons from the basal forebrain that innervate the neocortex and hippocampus (Arendt et al. 1983; Saper et al. 1985; Whitehouse et al. 1982). This process substantially exceeds that expected for age and is reflected in a loss of choline acetyltransferase as well as decreases in acetylcholinesterase, choline uptake, and the synthesis and release of acetylcholine from cortical tissue slices (Bird et al. 1983; Bowen et al. 1983; Davies and Maloney 1976; Pope et al. 1964; Rossor et al. 1982; Sims et al. 1983). Because the cholinergic system plays an important role in memory and learning (Drachman and Leavitt 1974), its degeneration in AD seems likely to contribute to the development of dementia.

Inconsistent changes or only modest reductions in total,  $M_1$ , and  $M_2$  muscarinic receptor binding have been reported in neocortical, hippocampal, and subcortical brain regions from patients with AD (Greenamyre and Maragos 1993). As with normative aging, these inconsistencies in autopsy findings can result from a complex sequence of

events including the progressive loss of presynaptic cholinergic afferents accompanied by the transient upregulation of cholinergic receptors or postsynaptic neurons. Some studies also suggest reduced coupling of the  $M_1$  receptor to its corresponding G protein (Flynn et al. 1991; Smith et al. 1987). Altered regulation of muscarinic binding and cerebral perfusion after low-dose chronic scopolamine administration has been demonstrated *in vivo* by single photon emission computed tomography (SPECT) scans of patients with AD and elderly control subjects (Sunderland et al. 1995). Nicotine receptor binding has consistently been reported to be substantially reduced in the cortices of patients with AD (Araujo et al. 1988; Flynn and Mash 1986; Perry et al. 1987; Rinne and Myllykylä 1991; Shimohama et al. 1986; Whitehouse et al. 1986), although the functional significance of this finding is unclear.

These findings are consistent with the common observation that patients with AD are even more sensitive to the central effects of anticholinergic and other drugs than older adults who have normal cognition (Molchan et al. 1992). The subgroup of patients with AD with Lewy body pathology (AD Lewy body variant, ADLBV) have been reported to have even greater cholinergic and dopaminergic deficits and can be the most prone to central toxicity from anticholinergic and antidopaminergic drugs (Förstl et al. 1993; Hansen et al. 1990; Langlais et al. 1993; Lippa et al. 1994; Perry et al. 1990, 1991, 1993) (see Chapter 24 in this volume).

## Dopaminergic Antagonists

The elderly are at increased risk of developing extrapyramidal symptoms from the antidopaminergic actions of psychotropic drugs, chiefly the conventional antipsychotic medications. These adverse effects typically consist of parkinsonian symptoms (rigidity, tremor, bradykinesia), akathisia, and tardive dyskinesia (Kalish et al. 1995; Sweet et al. 1995). For reasons that are unclear, neuroleptic-induced dystonic reactions appear to be less common in the elderly than in younger patients. The coadministration of heterocyclic antidepressants or lithium may exacerbate neuroleptic-induced extrapyramidal symptoms by an unknown mechanism.

The relative contributions of pharmacokinetic and pharmacodynamic phenomena to the increased susceptibility of the elderly to extrapyramidal symptoms have not been clearly delineated. However, numerous age-related neurobiological changes can render the central dopaminergic system more sensitive to pharmacological antagonists in later life. As shown in Table 33-7, the number of

<sup>b</sup>Dopamine is metabolized by both MAO-A and MAO-B.

*Source.* Adapted from Bannon et al. 1992; Bareggi et al. 1985; DeKeyser et al. 1990; McGeer 1981; Morgan et al. 1987; Oreland and Gottfries 1986; Rinne et al. 1993; Robinson et al. 1977; Roth and Joseph 1994; Van Dyck et al. 1995; Volkow et al. 1994, 1998; Wang et al. 1995.

neurons in the substantia nigra, the largest collection of dopaminergic nerve cell bodies in the brain, declines with age. Reduction in the specific activity of the biosynthetic enzyme tyrosine hydroxylase, along with increased activity of the catabolic enzyme monoamine oxidase B, can result in reduced synthesis and steady-state levels of dopamine in the dopaminergic neurons that remain. Reductions in the density of dopamine D<sub>2</sub> receptors, at least some of which are located on presynaptic neurons, may reflect the same age-related cell loss. In contrast, the density of D<sub>1</sub> receptors may increase with age as a compensatory mechanism. Age-related reductions in the activity of the dopamine transporter, which serves to recover and inactivate dopamine that is released into the synaptic cleft, may also facilitate dopaminergic neurotransmission across the synapses that remain or may simply reflect the loss of presynaptic dopaminergic neurons. The concentration of homovanillic acid, a major metabolite of dopamine, has been reported to increase in cerebrospinal fluid with age. The last finding may reflect a compensatory increase in the firing rates of surviving dopaminergic neurons.

Postsynaptic denervation supersensitivity has been suggested as a mechanism that contributes to the sensitivity of some patients with Parkinson's disease to dopaminergic agents, including L-dopa preparations ((+)-carbidopa) used to treat this condition. In such cases, psychotic symptoms (delusions, hallucinations) can emerge alone or in the context of delirium. If the use of other antiparkinsonism drugs is not a viable alternative, this clinical scenario can often be managed by reducing the dosage of L-dopa to the extent possible while adding an atypical antipsychotic medication with reduced tendencies to worsen extrapyramidal symptoms and hypotension.

The mechanism of action of L-dopa in the treatment of Parkinson's disease appears to depend on the conversion of this precursor to dopamine in surviving dopaminergic neurons. The progressive degeneration of these neurons that occurs in Parkinson's disease may contribute to the loss of efficacy of L-dopa in the late stages of this disorder.

### Noradrenergic Effects

Age-related changes in the central noradrenergic system are summarized in Table 33–8. Consistent with observations from the cholinergic and other aminergic systems, the transition into late life is accompanied by neurobiological changes that tend to reduce central noradrenergic tone. These changes include a reduced number of cells in the locus ceruleus, the largest collection of noradrenergic nerve cell bodies in the brain, along with a decrease in the specific activity of the biosynthetic enzyme

tyrosine hydroxylase. Unlike dopamine, norepinephrine is preferentially metabolized by monoamine oxidase A, whose activity does not appear to increase with age. These changes are accompanied by decreases in the densities of  $\alpha_2$ ,  $\beta_1$ , and  $\beta_2$  receptors in the projection areas of the locus ceruleus. Moreover, signal transduction across these receptors may be reduced as a result of less efficient G-protein coupling. In spite of these changes, the concentration of methoxyhydroxyphenylglycol, a major metabolite of norepinephrine, appears to increase with age in cerebrospinal fluid. This may result from a compensatory increase in the firing rate of the reduced number of noradrenergic neurons whose postsynaptic sites include fewer, less efficient receptors.

These age-related changes in the central aminergic nervous system may contribute to the vulnerability of older adults to the development of neuropsychiatric syndromes, especially when the degree of neurodegeneration is marked, as occurs in AD and Parkinson's disease (Zubenko 1996; Zubenko and Moossy 1988; Zubenko et al. 1990, 1991). Moreover, these changes can result in a blunted acute response of such patients to antidepressant medications, prolong the time required for a therapeutic response, and contribute to relapse as degenerative changes progress (Zubenko et al. 1994).

### Selective Serotonin Reuptake Inhibitors

As a drug class, the SSRIs have a more benign side-effect profile than the heterocyclic antidepressants and monoamine oxidase inhibitors (MAOIs). Their common adverse effects include headache, gastrointestinal disturbances (chiefly nausea, anorexia, and diarrhea), increased sweating, and sexual dysfunction. Their lack of significant anticholinergic (except paroxetine) and adverse cardiovascular effects has increasingly led to their preferred use in depressed patients who have a significant burden of comorbid medical problems, including the neurodegenerative disorders (see Chapter 13 in this volume). The SSRIs have become especially popular as first-line antidepressants in primary care settings.

Evidence of increased sensitivity of the elderly to the effects of SSRIs is largely limited to interactions with other drugs through inhibition of the CYP 450 isoenzymes (see section on hepatic metabolism and clearance). Little direct evidence implicates age-dependent pharmacodynamic changes in this regard. Instead, age-associated decreases in function of the central serotonergic nervous system may predispose elderly patients to behavioral syndromes, especially in the context of the neurodegenerative diseases. These pathological changes may also contribute to a

blunted response to short-term treatments for these behavioral syndromes, delay the rate of recovery, and contribute to relapse as progression occurs.

Age-related changes in the central serotonergic system are presented in Table 33–9. These changes include reductions in the numbers of serotonergic nerve terminals in the neocortex, as reflected by the decreased density of the serotonin transporter. The specific activity of the biosynthetic enzyme tryptophan hydroxylase has also been reported to decline with advancing age. Age-related changes in central serotonergic receptors are complex as a result of differential effects reported for various characteristics of multiple receptor subtypes. Decreased densities of the serotonin transporter may reflect the age-related reduction in the number of serotonergic neurons. The level of 5-hydroxyindoleacetic acid, the major metabolite of serotonin, increases with age. The last finding may reflect a compensatory increase in the firing rates of surviving serotonergic neurons.

### Cardiovascular Effects and Orthostatic Hypotension

The prevalence of orthostatic hypotension increases with age to become a common condition in late life, where it affects as many as 30% of community-dwelling elders (Patel et al. 1993). Its clinical importance is reflected by its link to syncope, recurrent falling, skeletal fractures, and related sources of morbidity and mortality.

The etiology of orthostatic hypotension among the elderly is typically multifactorial (Mets 1995; Verhaeverbeke and Mets 1997). Although age-related autonomic dysfunction plays an important role in the pathogenesis of orthostatic hypotension, this condition is often induced by the use of psychotropic or other medications in the elderly. Perhaps even more commonly, subclinical cases of orthostatic hypotension are rendered symptomatic by the administration of drugs that aggravate the underlying pathophysiology of this condition. This latter observation highlights the predictive value and clinical importance of pretreatment measurements of postural changes in blood pressure and heart rate before administering medications whose side-effect profiles include postural hypotension.

The pathophysiology of orthostatic hypotension is complex and incompletely understood (Abernathy 1990; Feely and Coakley 1990; Hämmerlein et al. 1998; Mets 1995; Verhaeverbeke and Mets 1997). Common factors that contribute to the development of orthostatic hypotension are listed in Table 33–10. As described in previous sections, aging is associated with functional decrements in several central aminergic systems that participate

in the regulation of blood pressure and other fundamental processes. In the periphery, aging is also associated with a decrease in the baroreceptor reflex response to reductions in blood pressure. Reductions that occur in arterial compliance (elasticity) with aging may contribute to the decreased sensitivity of the baroreceptor region to changes in blood pressure. Decreased compliance of the arterial wall may also render the systemic circulation more vulnerable to changes in blood pressure that result from small reductions in circulating blood volume. In addition to these effects, aging is associated with decreased responsiveness of the heart and vasculature to the chronotropic and inotropic effects of adrenergic stimulation, especially those mediated through  $\beta$ -adrenergic receptors. Finally, reduced activity of the renin-angiotensin-aldosterone system becomes manifest in the elderly. These physiological changes that occur during the course of normative aging contribute to the increased prevalence of orthostatic hypotension in the elderly and to their sensitivity to this common adverse effect of psychotropic and other medications.

Age-related diseases also predispose the elderly to orthostatic hypotension. Heart disease can lead to reduced cardiac output both at rest and in response to exercise or other stimuli. Diabetes mellitus often causes disturbances of fluid and electrolyte balance as well as impairments of the peripheral autonomic nervous system that produce or worsen orthostatic hypotension. Parkinson's disease can lead to peripheral manifestations of autonomic dysregulation, including orthostatic hypotension, that result from the degeneration of central aminergic systems (see Chapter 26 in this volume). Orthostatic hypotension is also commonly associated with dehydration, immobility, or prolonged bedrest, which accompany chronic, debilitating medical disorders in late life. Eating, urination, and defecation all transiently worsen orthostasis.

Not surprisingly, drugs used to lower blood pressure in the treatment of hypertension or congestive heart failure aggravate orthostatic hypotension. These agents include calcium channel blockers,  $\alpha$ - and  $\beta$ -adrenergic blockers, angiotensin-converting enzyme inhibitors, and nitrates. In addition, many psychotropic drugs induce or worsen postural hypotension. Their hypotensive actions reflect their potency as  $\alpha_1$  antagonists and to a lesser extent their antimuscarinic potency. These effects can be magnified by age-related decreases in metabolism, clearance, and elimination if dosing is not adjusted accordingly.

Heterocyclic antidepressants typically produce some degree of orthostatic hypotension at the usual doses used to treat elderly patients with depression. The tertiary amines (amitriptyline and imipramine) are the worst, whereas nortriptyline produces less of this adverse effect. Tricyclic

antidepressants also prolong cardiac conduction, another adverse effect that worsens with age, to a varying degree among individual patients and may preclude their use in predisposed patients. Although MAOIs may be better known for hypertensive crises that result from interactions with tyramine-containing foods, sympathomimetic drugs, and meperidine, treatment with MAOIs typically produces some degree of hypotension, especially among the elderly. This adverse effect is shared by selegiline, which is relatively selective for the B form of monoamine oxidase that is preferentially localized to the brain. By contrast, the SSRIs do not induce significant hypotension or prolongation of cardiac conduction, a feature that has contributed to their popularity in the treatment of depression in the elderly.

Orthostatic hypotension is also a common adverse effect of antipsychotic medications. The phenothiazines with the lowest antipsychotic potency possess the greatest  $\alpha_1$ -antiadrenergic and antimuscarinic potency (e.g., chlorpromazine, thioridazine). These properties make them unsuitable for the treatment of most elderly patients. Higher potency neuroleptic agents such as haloperidol produce less hypotension and are better tolerated by elderly patients at modest doses (usually less than 4 mg/day). However, at higher doses, significant parkinsonian symptoms usually emerge. Newer atypical antipsychotic drugs that possess fewer hypotensive and extrapyramidal effects

are likely to play an increasingly important role in the pharmacotherapy of neuropsychiatric disorders in the elderly (see Chapters 14 and 34 in this volume).

Lithium can contribute to postural hypotension by inducing diuresis through direct effects on the kidney (diabetes insipidus). As already discussed, the degeneration of central aminergic systems that occurs in Parkinson's disease may be accompanied by manifestations of autonomic dysregulation in the periphery, including orthostatic hypotension (among others). Moreover, the common treatments for Parkinson's disease, that is, L-dopa ((+)-carbidopa), bromocriptine, selegiline, and anticholinergic agents, all share hypotension among their side-effect profiles.

### Drug-Related Falls

Aging is an important risk factor for accidental falls (Cumming 1998). About one-third of community-dwelling individuals over 65 fall at least once each year and nearly 10% have recurrent falls (Tinetti et al. 1988). The incidence of falling increases progressively in this population after the age of 65, nearly doubling by age 90 (Campbell et al. 1989, 1990). Not surprisingly, the risk of accidental falls is greater among nursing home residents and hospitalized patients than community-dwelling individuals of similar age (Tinetti and Speechley 1989).

Hip fractures are among the most common consequences of falling, and the incidence of hip fractures also increases with age. Among women over age 80, the annual incidence of hip fractures is about 3% per year, nearly twice that for men (Cummings et al. 1985). This gender difference may reflect greater osteoporosis and lower bone density among women compared with that of men. Hip fractures are often important harbingers of functional decline. The majority of people who have hip fractures never return to their previous level of physical functioning. About a fifth of such individuals die within a year of the hip fracture and another fifth transition to a residential care setting (Cumming et al. 1996; Katelaris and Cumming 1996). Sequelae of hip fractures can also include myocardial infarctions, strokes, excessive bleeding in patients taking anticoagulants, and pneumonia during the recovery phase. Other fall-related fractures can involve the wrist, humerus, ankle, and other bony structures that contribute to disability but typically have less serious consequences than hip fractures (Ray et al. 1987).

Patients who take psychotropic medications, including antidepressants, benzodiazepines, and antipsychotic drugs, are at increased risk of falling and having hip fractures. The evidence implicating antidepressants is the most

compelling. Antidepressant medications have been associated with falls and hip fractures among elderly individuals who reside in a variety of settings (community, nursing homes, and acute care and rehabilitation hospitals), and this association remains robust in studies that controlled for numerous potentially confounding variables (Lipsitz et al. 1991; Ray et al. 1987, 1991; Ruthazer and Lipsitz 1993). Interestingly, SSRIs have been reported in one study to be more strongly related to falls than were tricyclic antidepressants (Ruthazer and Lipsitz 1993). Although this result is somewhat surprising, it may result from impairments in balance produced by some SSRIs or may reflect the use of SSRIs in patients with greater medical comorbidity. Heterocyclic antidepressants have several pharmacological effects that probably contribute to accidental falls. These effects include sedation, psychomotor retardation, postural hypotension, and anticholinergic properties that may cause blurred vision and cognitive impairment. The risk of falling appears to be the greatest during the first 90 days of antidepressant treatment (Ray et al. 1991), when initial dosages are being adjusted and before physiological adaptation to these adverse effects has fully occurred.

Although sedative/hypnotic/anxiolytic agents have been reported to increase the risk of falling, the most convincing evidence involves the use of benzodiazepines (Aisen et al. 1992; Cumming and Klineberg 1993; Cumming et al. 1991; Gales and Menard 1995; Lord et al. 1995; Luukinen et al. 1995; Ray et al. 1987, 1989; Rynnänen et al. 1993; Sorock and Thimkin 1988; Yip and Cumming 1994). The level of increased risk of falling is related to the use of elevated dosages, long-acting agents, and the coadministration of more than one benzodiazepine. Patients taking excessive doses of benzodiazepines are at substantially greater risk of hip fracture regardless of the benzodiazepine prescribed (Herings et al. 1995). The increased risk of falling associated with benzodiazepine usage appears to result from sedation and related psychomotor retardation.

Antipsychotic drugs, chiefly phenothiazines, also increase the risk of falls (Mion et al. 1989; Prudham and Evans 1981; Ray et al. 1987; Sorock 1983; Yip and Cumming 1994). Most of this evidence has resulted from studies of patients in nursing homes and rehabilitation settings. Little evidence exists on the relative risk of falling associated with specific antipsychotic drugs. These agents may increase the risk of falling by producing sedation, orthostatic hypotension, extrapyramidal gait disturbances, and anticholinergic effects that impair cognition or vision. If so, the risk of falling would be expected to be lower among patients receiving modest doses of high-potency neuroleptics or atypical antipsychotic drugs that produce fewer of these adverse effects.

Evidence for the role of cardiovascular medications in contributing to falls is less conclusive than for psychotropic medications. This may be a result of the common practice of grouping various cardiovascular medications together into a single classification rather than analyzing their individual contributions. Some studies have reported an association of the use of antihypertensives with falls (Campbell et al. 1989; Lord et al. 1994; Wells et al. 1985), an effect that may be a result of symptomatic postural hypotension (Ensrud et al. 1992). However, thiazide diuretics have the potential to confer a protective effect against fractures through a positive effect on bone density (Jones et al. 1995; Middler et al. 1973). The use of digoxin, nitrates, and calcium channel blockers have also been reported to be associated with falls (Cumming et al. 1991; Gales and Menard 1995; Koski et al. 1996; Luukinen et al. 1995).

Several studies have reported that analgesics and nonsteroidal anti-inflammatory drugs (NSAIDs) are associated with an increased risk of falling (Cummings et al. 1991; Lipsitz et al. 1991; Myers et al. 1991). The extent to which potential confounding effects of arthritis contributed to these findings is uncertain. NSAIDs have also been reported to cause cognitive dysfunction (Hoppmann et al. 1991), but they also increase bone density and may confer some degree of protection against hip fractures (Bauer et al. 1996). Narcotic analgesics can increase the risk of fall-related hip fractures by producing sedation, cognitive impairment, and postural hypotension (Shorr et al. 1992).

Table 33-11 includes a variety of additional risk factors for falls that result from aging, age-related diseases, medications, or environmental conditions (Robbins et al. 1989; Thapa et al. 1995). Many of these risk factors are influenced by contributions from multiple sources. The elderly often take multiple medications, which increases the risk of adverse effects, including falls. Lower extremity weakness and pain may result from a variety of common medical conditions of the elderly including arthritis, heart failure, vascular insufficiency, and stroke, as well as decreased activity itself. Decrements in gait and balance occur with aging, medication exposure, and many of the same medical conditions that produce weakness of the lower extremities. Neurodegenerative conditions such as AD and Parkinson's disease may likewise contribute to disturbances of gait and balance. Symptomatic postural hypotension is also an important risk factor for falls, and its evolution is addressed in the previous section. Cognitive impairment and depression contribute to the risk of falling through multiple mechanisms. Cognitive impairment often involves impairments of memory, planning, visuospatial function, judgment, and praxis and the development of extrapyramidal symptoms, all of which predispose to falling. Depression

slows cognitive and motor skills; antidepressant medications further increase the risk of falling. Impairments in vision and hearing occur with normal aging and can be exacerbated by conditions such as cataract formation, glaucoma, macular degeneration, and diabetes, as well as medications with anticholinergic properties. Also, proprioceptive and other sensory deficits can arise from B<sub>12</sub> deficiency and diabetes (peripheral neuropathy). The development of functional impairment is usually related to the multiple risk factors and conditions listed in Table 33–11. Finally, environmental hazards such as stairs and poor lighting increase the risk of falling among the elderly. Assessments of such environmental hazards often identify risks that are readily eliminated.

## ■ Therapeutic Compliance

Ensuring patient adherence to a prescribed treatment plan (medication compliance) is a complex longitudinal task that is influenced by many factors (Table 33–12). Estimates of the extent of medication noncompliance among the elderly have ranged from 40% to 75% (Cooper et al. 1982; Jackson et al. 1989; Lamy et al. 1992; Ostrum et al. 1988). Inappropriate discontinuation of prescribed medications may occur in as many as 40% of older adults, usually within the first year of treatment (Cooper et al. 1982; Jackson et al. 1989; Lamy et al. 1992; Ostrum et al. 1988).

Effective ongoing communication is essential for the

development of a successful doctor-patient relationship. For older individuals who live independently, this dyadic relationship does not differ significantly from that developed between younger adults and their physicians. However, much of the practice of geriatric neuropsychiatry requires broadening the conceptualization of the doctor-patient relationship to include a spouse or other family member who serves as the primary caregiver, as well as the patient's primary care physician. For patients in residential care settings, this collaboration best includes a clinician from the facility. Although the geriatric psychiatrist must remain mindful of confidentiality issues, the short-term and sustained effectiveness of neuropsychiatric interventions is dependent on the successfulness of these collaborators in implementing a consensual treatment plan.

Guided by the diagnostic assessment, a clearly articulated treatment plan, including what medications are being prescribed for specific indications, the dosing regimen, and a review of potential side effects, must be discussed with the patient and relevant caregivers. In general, in-person or verbal communications are superior to written materials alone in encouraging compliance. Sensitivity to ethnic and cultural diversity also enhances compliance. Formulation of the medication regimen should include attention to the age-related pharmacokinetic and pharmacodynamic principles described in this chapter including complications that might arise from the use of over-the-counter medications. Because increasing numbers of medications and daily doses of medications discourage compliance (Col et al. 1990; Lamy 1986; Lamy et al. 1992), efforts should be directed at arriving at the simplest regimen possible without sacrificing effectiveness. Issues of cost are also important for elderly patients who are often supported by fixed incomes.

These efforts should also include a follow-up plan for

assessing treatment response and monitoring for the potential development of adverse effects. Office calls by the patient or his or her caregivers to clarify questions or to address newly emergent adverse effects should be encouraged, especially at times of medication changes or dosage adjustments. This approach reduces anxiety in the patient and other caregivers, reduces adverse outcomes, provides an opportunity to respond to emergent adverse reactions at the earliest time, builds trust in the doctor-patient-family relationship, and enhances both compliance and positive outcomes.

Elders who live independently and lack a network of family or social supports are at increased risk of missed doses and irregular dosing schedules. Unfortunately, this results in decreased therapeutic efficacy and can lead to increased side effects. Incorrect guesses about the source of particular side effects that are made without consultation with the physician can result in alterations in the dose or schedule of the wrong drug. When memory or other cognitive impairment is among the side effects that develop, compliance is further compromised. As a result, this pattern of partial compliance often progresses to complete discontinuation of medications. Discontinuation can include medications used to treat general medical conditions along with psychotherapeutic agents, a circumstance that can further compromise the health of the patient. Abrupt discontinuation can also precipitate toxic withdrawal states, including delirium.

For patients with cognitive impairment or who have disturbances of mood, thought, or behavior, the importance of family or other caregivers in encouraging treatment compliance is essential. Memory and other impairments of cognition can lead to underdosing and subtherapeutic responses, as well as overdosing and toxicity. Major depression is often associated with excessive guilt or therapeutic nihilism that undermines compliance, as well as increased somatic complaints that are often difficult to distinguish from drug-induced adverse effects. In contrast, mania and elated mood may preclude accurate self-perception and the need for treatment altogether. Paranoid delusions that frequently accompany mood and neurodegenerative disorders often lead to medication refusal, at least intermittently. The participation and encouragement from family members or other trusted caregivers who support the treatment plan is indispensable in these circumstances.

The burden of comorbid medical problems also threatens compliance. Greater numbers of medical problems complicate and can limit the effectiveness of psychotherapeutic drugs, lead to the need for more prescribed medications, and increase the risk of adverse ef-

fects. All of these factors highlight the importance of optimizing the patient's complete medication regimen in consultation with his or her primary care physician. This should include an ongoing dialogue between the psychiatrist and primary care physician as the health care needs of the patient evolve with time.

## ■ Conclusion

Neuropsychiatric syndromes are common disorders among the elderly that produce suffering, functional disability, and loss of independence and hasten death. This burden is born not only by older individuals who have these syndromes, but also by the families who care for them and the substantial health care resources that are consumed in the process. Pharmacotherapy can play an important role in ameliorating these maladies along with the increases in morbidity and mortality that they cause.

In this chapter, we illustrate various mechanisms that contribute to the increased variance and decreased predictability in the responses of older adults to medications, with a focus on psychotherapeutic drugs. These mechanisms are numerous, complex, interactive, and drug-specific. Moreover, the picture is incomplete. Much remains to be learned about the age-related metabolism, clearance, and excretion of these agents and metabolites, as well as their accessibility to their presumed sites of action in the brain. Even less systematic information is available about the organismal, systemic, cellular, subcellular, and molecular mechanisms that contribute to age-related alterations in tissue sensitivity to the pharmacological actions of psychotropic drugs. Although the increased sensitivity of the elderly to the adverse effect of psychotherapeutic drugs is well-established, little evidence exists to demonstrate that aging is accompanied by a similar increase in the therapeutic potency of these agents. This last observation can result in a reduced margin of safety.

The difficulty in carrying out experiments designed to elucidate these areas of human biology has been limiting. Animal paradigms have not always accurately modeled their human counterparts, and the results of human *in vitro* and *in vivo* studies have not always been easily reconcilable. Furthermore, adults over 65 have been underrepresented in clinical studies. Clinical and preclinical data on elderly individuals over 75, the most rapidly growing segment of the United States population, are especially lacking.

The recommendation to "start low and go slow" remains sound practical advice, while monitoring therapeutic response and potential adverse effects in collaboration with the patient and other caregivers. Newly emergent signs and symptoms that correspond temporally to the ini-

tiation of medications or changes in dosage are often medication related, even if they seem to be outside of the usual spectrum of side effects for the particular drugs being manipulated. They may indeed represent unusual side effects or they may represent more common adverse effects of coadministered medications whose previously stable plasma levels were altered as the result of a drug interaction.

To this appropriate recommendation of caution, one might add the virtues of patience and persistence. Once initiated, the physician should be patient and resist the urge to rapidly increase low starting doses of medications in the elderly. Unlike most medications used in general medical practice whose peak actions occur in hours or a few days, the peak therapeutic effects of most psychotropic drugs typically occur over weeks to months. This interval is longer for the elderly than for younger adults. Overly rapid advancement of dosages, in response to unrealistic expectations that this will hasten therapeutic response, often results in excessive drug levels in plasma and tissue, with associated toxicity.

The consequences of aging and age-related factors, including medical comorbidity, can blunt therapeutic responses and restrict the spectrum of psychotherapeutic agents that are appropriate for use in particular elderly patients. Persistence in the pursuit of therapeutic response and willingness to try alternative pharmacological strategies is often rewarded by remarkable clinical responses that surprise even family members. The continual development of novel efficacious psychotherapeutic medications with increasingly benign side-effect profiles will also contribute to the successful treatment of neuropsychiatric disorders in the elderly.

Finally, the achievement of an optimal acute therapeutic response of neuropsychiatric disorders as well as the maintenance of this response over time may require different pharmacological agents or combinations of agents, different treatment modalities (e.g., medications, electroconvulsive therapy, psychotherapy), and combinations of these modalities over the remaining life-span of older adults. These issues are the appropriate subject of future controlled studies of efficacy as well as intervention studies that evaluate their effectiveness in nonpsychiatric specialty and primary care settings.

# Psychopharmacology

Steven L. Dubovsky, M.D.

Randall Buzan, M.D.

Accounting for 11% of the population, elderly individuals take 20%–25% of all prescribed medications (Sargenti et al. 1988). The average nursing home patient takes 9.3 medications (Pollock et al. 1992), at least 1 of which is likely to be a psychotropic medication (Avorn et al. 1992). Patients may continue for many years to take medications that contribute to neuropsychiatric morbidity (Salzman 1992).

A number of factors complicate the prescription of psychotropic medications for geriatric patients with neuropsychiatric illnesses (Ahronheim 1992; Salzman 1992; Sargenti et al. 1988). Adding these drugs to medications the patient already is taking—including over-the-counter substances that may not be reported to the physician—not only increases the risk of interactions but makes it difficult for a patient with memory impairment to keep track of which pills must be taken when. Further, patients with tremors, arthritis, visual problems, or confusion find it difficult to open the childproof containers that pharmacists are required to dispense medications in unless directed otherwise.

In this chapter, we review the pharmacological treatment of neuropsychiatric conditions in elderly patients. To

facilitate an understanding of parameters that affect pharmacotherapy in older patients with neuropsychiatric disorders, we briefly review general principles of pharmacology and physiology applicable to geriatric neuropsychiatry. We then review the use of the major classes of psychotropic medications and the treatment of special problems such as agitation and dementia. Electroconvulsive therapy (ECT), which is clearly effective and well tolerated in geriatric patients (Philibert et al. 1995), is considered in detail in Chapter 35.

## ■ Changes in the Aging Nervous System Relevant to Psychopharmacology

Even in the absence of frank neurological disease, changes in brain structure and function as the nervous system ages make older patients more vulnerable to side effects of psychotropic medications (Ahronheim 1992; Rovner 1990; Salzman 1990; Sargenti et al. 1988) (see also Chapter 3). Loss of neurons in the cortex, locus coeruleus, and hippocampus makes sedative and psychomotor side effects

more pronounced. A gradual decline in central cholinergic transmission increases sensitivity to anticholinergic side effects such as confusion and amnesia, which are even more marked in the presence of dementia. Reduced sensitivity of baroreceptors in the carotid artery and of hypothalamic blood pressure regulatory centers, along with decreased numbers of  $\alpha_1$ -noradrenergic receptors, make it difficult to maintain blood pressure in the face of the hypotensive effects of antidepressants and neuroleptics. A decline in the number of neurons in the substantia nigra and dopamine receptors in the corpus striatum increases sensitivity to extrapyramidal side effects, which is usually a limiting side effect in the presence of Parkinson's disease.

Although it is clearly established that elderly patients are more sensitive to side effects of psychotropic medications, especially sedation, psychomotor impairment, orthostatic hypotension, and anticholinergic side effects (Abernathy 1992), there is no empirical support in most cases for the common assertion that geriatric patients are also more sensitive to therapeutic actions (Abernathy 1992; Young and Meyers 1991). Indeed, reduced sensitivity of  $\beta$ -adrenergic (Ahronheim 1992; Rovner 1990), benzodiazepine (Young and Meyers 1991), and other receptors may make some drugs less efficient in elderly patients. This issue is considered in more detail in discussions of specific medications.

The response to psychotropic medications in older patients with neurological illness changes as the disease evolves. For example, loss of dopaminergic neurons reduces the capacity of the parkinsonian brain to synthesize dopamine from L-dopa, resulting in reduced benefit from treatment as the disease progresses. Similarly, progressive loss of cholinergic neurons in Alzheimer's disease makes drugs that prolong the action of acetylcholine (e.g., cholinesterase inhibitors) less effective in the later stages of Alzheimer's disease. Loss of postsynaptic dopamine receptors with age makes agitated patients with neuropsychiatric illness more vulnerable to extrapyramidal side effects of neuroleptics. These issues are discussed when specific medications and illnesses are considered.

## ■ Psychopharmacological Principles

A few basic concepts are helpful in predicting medication actions in elderly patients with neuropsychiatric illness (Abernathy 1992; Ahronheim 1992). *Pharmacokinetics*, or what the body does to a drug, refers to factors influencing drug disposition, including absorption, distribution, metabolism, and excretion. *Pharmacodynamics*, the processes influencing the action of drugs at tissue sites, describes

what the medication does to the body. The *volume of distribution* is the hypothetical volume in which a medication is in equilibrium, reflecting how widely a drug is distributed throughout the body.

The *elimination half-life* is the time required to eliminate half the amount of medication in the body. It takes four to five half-lives, which for many drugs administered to elderly patients is more than 2 weeks (Abernathy 1992), to eliminate about 90% of a drug. When the interval between doses is less than the elimination half-life, the medication accumulates until the amount entering the plasma equals the amount being cleared (Abernathy 1992). This resulting concentration is the *steady state concentration*, which is directly proportional to the dose and inversely proportional to the clearance (Young and Meyers 1991). It takes four to five half-lives to achieve about 90% of a steady state (Abernathy 1992).

Although gastrointestinal absorption is essentially unchanged in elderly patients (Abernathy 1992; Young and Meyers 1992), anticholinergic drugs and antacids frequently taken by older neurological patients delay absorption of other medications (Abernathy 1992). Once a medication is absorbed, its metabolism is altered in elderly individuals in several ways (Abernathy 1992; Sargenti et al. 1988; Young and Meyers 1991). First-pass metabolism, which occurs when a drug is carried from the gut to the liver after absorption, is slowed because hepatic blood flow decreases with age. As a result, the blood level and therefore the effect of drugs with extensive first-pass metabolism (e.g., triazolam, midazolam, calcium channel blocking agents, neuroleptics, and all antidepressants except trazodone) can be increased.

After entering the circulation following first-pass metabolism, medications undergo another series of metabolic transformations (Ahronheim 1992; Salzman 1990). Phase I (oxidative) metabolism is mediated by the cytochrome P450 oxidase system and produces demethylated biologically active metabolites. For example, diazepam is metabolized to desmethyldiazepam, desmethyldiazepam is metabolized to oxazepam, amitriptyline is metabolized to nortriptyline, and nortriptyline is metabolized to 11-hydroxynortriptyline. Because phase I metabolism slows with aging, blood levels and half-lives of parent compounds of many tricyclic antidepressants (TCAs), benzodiazepines, neuroleptics, and anticonvulsants tend to increase, causing more toxic, as well as therapeutic, effects at the same dose. On the other hand, individuals who are slow oxidative metabolizers when they are younger remain slow metabolizers as they age (Pollock et al. 1992). Phase II metabolism, which through glucuronidation, acetylation, or sulfation produces inactive water-soluble

metabolites that are excreted by the kidney, is not altered by the aging process.

Slowed oxidative metabolism should result in a lower dose of most psychotropic medications being necessary to achieve the same blood level. However, metabolic rates vary substantially from person to person, and the number of individuals with slow metabolism by the P450 system does not increase with age (Pollock et al. 1992). Further, the age-associated decline in P450 activity that has been observed in animals may not be true of humans (Pollock et al. 1992). Some older patients therefore will continue to have rapid phase I metabolism and will need the same medication doses as those required by younger patients to achieve a therapeutic level (Pollock et al. 1992). In addition, many studies of pharmacokinetics and drug dosing in geriatric patients are complicated by the use of mixed-age samples, different age ranges, and older methodology, making application of findings to clinical practice difficult (Salzman 1992).

The distribution of psychotropic drugs changes substantially with age. Because all of these drugs—with the exception of lithium—are lipid soluble, they distribute into fatty tissue, which increases as a percentage of total body weight from 19% at age 25 to 35% at age 70 (Young and Meyers 1991). As a result, psychotropic medications distribute more widely in peripheral tissues and remain in the body longer, and the proportion diffusing into the brain diffuses more slowly because of increased distribution elsewhere (Abernathy 1992). Because equilibration in the body takes longer, it takes more time to reach a steady state and thus the onset of therapeutic effect may be delayed. Side effects and drug accumulation may also begin later than anticipated (Abernathy 1992). The reverse effects occur with lithium, which, being hydrophilic, has a decreased volume of distribution in elderly patients (Abernathy 1992).

All psychotropic medications except lithium are extensively bound to plasma protein, and only the unbound fraction is available both for pharmacological action and for metabolism (Abernathy 1992; Young and Meyers 1991). Changes in protein binding do not produce noticeable changes in drug action in healthy geriatric patients, but those with marked decreases in serum albumin concentration (e.g., because of inanition) may develop elevated levels of free benzodiazepines and anticonvulsants (Young and Meyers 1991). Acutely ill geriatric patients may have elevated levels of  $\alpha_1$ -glycoprotein, which binds heterocyclic antidepressants (HCAs) and neuroleptics, leading to reduced therapeutic effects of these drugs at the same total blood level (Sargenti et al. 1988).

All psychotropic drugs are excreted by the kidneys, lithium directly and other medications after metabolic

transformation in the liver to hydrophilic metabolites (Abernathy 1992; Young and Meyers 1991). As a result of reduced renal blood flow, creatinine clearance falls by as much as 60% in elderly patients (Abernathy 1992; Young and Meyers 1991). Reduced renal lithium clearance, combined with lithium's smaller volume of distribution, leads to higher lithium levels and a half-life that is increased by up to 50% (Abernathy 1992; Young and Meyers 1991). Diminished clearance of toxic water-soluble metabolites of TCAs (e.g., 11-hydroxynortriptyline) can enhance cardiac and other toxic effects of these drugs.

Longer half-lives, longer times to reach a steady state, larger volumes of distribution of lipid-soluble drugs, and slower elimination, along with hypersensitivity of the central nervous system (CNS) to many toxic effects, necessitate changes in prescribing practices for elderly neuropsychiatric patients. Initial doses should be lower than for younger patients, and more time should elapse between dose increases. Some patients may achieve therapeutic levels at lower final doses, but others may ultimately require the same or even higher doses as those required by younger patients. The appearance of toxicity, especially in the CNS, as well as therapeutic effects, may be delayed longer than in younger adults. Approaches to these problems are outlined in the following discussions of specific medication categories.

## ■ Omnibus Budget Reconciliation Act and Prescribing Practices

Concerns that 33%–74% of nursing home residents were receiving psychotropic medications led to regulations—outlined in the Omnibus Budget Reconciliation Act of 1987 (OBRA-87)—limiting the use of these medications in long-term care facilities (Hawes et al. 1997; Lantz et al. 1996). These regulations have been in effect since 1990 for Medicare- and Medicaid-certified nursing homes (Hawes et al. 1997). Among the changes instituted by OBRA-87 was regular functional assessment of nursing home patients using the Resident Assessment Instrument (RAI), which measures physical functioning, mood, behavior, activities of daily living, and other basic functions. Mandating use of the RAI tripled the amount of accurate patient data in nursing home charts, although data in the charts of 51% of residents are still incomplete (Hawes et al. 1997). Prescriptions of antipsychotic and antianxiety drugs declined after institution of OBRA regulations, although this decrease may have been related as much to changes in standards or practice as to OBRA (Hawes et al. 1997; Lantz

et al. 1996). At the same time, antidepressant prescriptions increased, which suggests that depression is being treated more appropriately (Lantz et al. 1996). Formal educational programs reduce the inappropriate use of psychotropics in nursing homes, without producing more disruptive behavior or distress (Avorn et al. 1992).

Despite these advances, many older residents of nursing homes and elderly patients in general hospitals continue to receive one or more psychotropic medications, and for questionable indications (Avorn et al. 1992; O'Reilly and Rusnak 1990). For example, amitriptyline—which has anticholinergic, sedative, and hypotensive side effects that can be dangerous to older patients—and long-acting benzodiazepines—which increase the risk of falls—are still prescribed frequently (Avorn et al. 1992). A community survey in Australia indicated that 40% of elderly people who complained of insomnia were receiving hypnotic medications, but so were 10% of elderly people living at home and more than one-third of older people living in institutions who did not have trouble sleeping (S. Henderson et al. 1995).

## ■ Heterocyclic Antidepressants

Depression, the most common psychiatric disorder in elderly patients, is often a neuropsychiatric condition in this population in that it is more likely than other psychiatric problems in the same age group to be associated with cognitive complaints (McMahon and DePaulo 1992), cortical and subcortical atrophy and basal ganglia lesions (Coffey et al. 1993; Rabins et al. 1991), and treatment resistance (Coffey et al. 1991; Rabins et al. 1991) (see also Chapter 13). Disruption of systems for affective expression caused by brain lesions can result in atypical presentations of depression that may include unusual course of the neurological illness, lack of initiative, pseudodementia, and toothache and other odd forms of pain (Ruegg et al. 1988; Salzman 1985).

The three best-studied forms of geriatric depression illustrate principles that apply to the general use of antidepressants in geriatric neuropsychiatry. Poststroke depression (see Chapters 13 and 27) is more likely to occur in patients with left-sided lesions; enlarged ventricles and poorer functioning on mental status examination are additional risk factors (Dagon 1990; Robinson et al. 1984). Further, depression following stroke may represent an interaction between premorbid risk factors such as previous depressive episodes, side of lesion, and location of lesion (frontal vs. nonfrontal and dorsal vs. ventral) (C. A. Ross 1992). No matter what the pathophysiology, poststroke

depression may respond to antidepressants (Lipsey et al. 1984; Robinson et al. 1984).

The second common neuropsychiatric presentation of major depression occurs as a complication of Parkinson's disease. This syndrome also may respond to antidepressant therapy (Cummings 1992). In the third variety of neuropsychiatric depression, patients with dementias or other illnesses affecting the right side of the brain do not appear depressed because the full depressive syndrome is masked by aprosodia; such patients may nevertheless benefit from antidepressants (E. D. Ross and Rush 1981). Antidepressants appear to be less useful in elderly patients with dysphoria not meeting criteria for major depression (Salzman 1990).

Antidepressants produce about a 60% remission rate in elderly patients with depression, compared with a 13% rate of remission with placebo (Georgotas et al. 1986). However, relapse is common (Georgotas et al. 1988; Zis and Goodwin 1979), especially in patients with an incomplete remission, chronic depression, and three or more previous depressive episodes (Georgotas et al. 1988). Continuation therapy for 8 months to 2 years has been found to decrease relapse rates substantially, compared with placebo, in geriatric patients with unipolar depression (Flint 1994; Young and Meyers 1991).

## Neurological Uses

Heterocyclic antidepressants (HCAs) include the tricyclic antidepressants (TCAs) and the tetracyclic antidepressant maprotiline. Second-generation antidepressants with diverse structures, such as trazodone, bupropion, venlafaxine, nefazodone, and mirtazepine, are the oldest and best studied of the antidepressants. Although the HCAs are still prescribed frequently, geriatric patients with CNS disease often cannot tolerate the anticholinergic, antihistaminic, and antiadrenergic side effects of these medications, which cause memory loss, sedation, weight gain, and postural hypotension. As a result, the HCAs have largely been replaced as treatments for primary depression in neurological patients by newer and better-tolerated antidepressants, discussed in subsequent sections of this chapter. However, HCAs and related antidepressants continue to have applications in some neurological and neuropsychiatric conditions and still play a major role in the treatment of psychotic depression.

HCAs have been used as primary treatments for some neurological disorders, but these applications have not been studied formally in elderly neuropsychiatric patients. Amitriptyline, imipramine, desipramine, doxepin, and trazodone have been found to reduce chronic pain in both

the usual antidepressant doses and in lower doses (Hoogiverf 1985; Rosenblatt et al. 1984). Rectal doxepin at dosages of 25–150 mg/day has been found to ameliorate chronic pain in terminally ill cancer patients too weak to take the medication orally (Storey and Trumble 1992). Even though many patients with chronic pain are depressed, the antinociceptive effect does not seem to be dependent on an antidepressant action, in that one state may improve with an antidepressant but not the other. The finding that desipramine but not fluoxetine was as effective as amitriptyline for neuropathic pain suggests that a serotonergic mechanism may not be essential for pain relief by antidepressants, as is commonly assumed (Max et al. 1992).

In younger patients, amitriptyline is frequently used as a prophylactic agent for migraine headaches (Mathew 1981), and other TCAs are probably effective as well, although propranolol may be a more reliable antimigraine drug (Goodman and Charney 1985). Many patients find that migraine headaches become less frequent and less severe with age, permitting a reduction in migraine prophylaxis. Highly serotonergic antidepressants such as fluoxetine and sertraline often make migraine headaches worse or increase their frequency. On the other hand, the capacity of trazodone and nefazodone to antagonize 5-HT<sub>2</sub> receptors on blood platelets in a manner similar to that of antimigraine drugs such as the ergotamines may

make these medications more useful for migraine headaches (Dubovsky 1994). Fluoxetine (Lauterbach and Schiveri 1991) and amitriptyline (Schiffer et al. 1985) have been noted to ameliorate pseudobulbar affect in some patients with cerebral disease. In addition to 5-HT<sub>2</sub> antagonist properties that can be helpful for patients with migraine headaches, mirtazepine has 5-HT<sub>3</sub> antagonist properties that can be useful for patients with intractable nausea. Dopamine reuptake inhibition may make venlafaxine, which is effective for refractory depression, a potential treatment for depression in patients with dementia.

### Available Preparations

HCAs (Table 34–1) have different structures containing rings composed of carbon, nitrogen, and/or oxygen with varying side chains. Tertiary amine TCAs such as amitriptyline and imipramine are used as reference antidepressants in many studies, but they are poorly tolerated by older patients with organic brain disease. Secondary amine congeners of these drugs such as nortriptyline and desipramine, which have the additional advantage of demonstrated correlations between blood level and clinical response, are better choices for older patients (Young and Meyers 1991). Newer antidepressants are no more effective than the TCAs for nonpsychotic depression and may be less effective for psychotic depression (Rockwell et al.

**TABLE 34–1. Heterocyclic and related antidepressants in use in the United States**

Medication	Trade name(s)	Starting dose (mg) <sup>a</sup>	Daily dose (mg) <sup>a</sup>
Amitriptyline <sup>b</sup>	Elavil	10	25–100
Nortriptyline <sup>b,c</sup>	Pamelor, Aventyl	10	10–50 <sup>d</sup>
Protriptyline <sup>b</sup>	Vivactil	5	5–20
Imipramine <sup>b</sup>	Tofranil	10	25–100 <sup>d</sup>
Desipramine <sup>b,c</sup>	Norpramin, Pertofrane	10	25–100 <sup>d</sup>
Trimipramine <sup>b</sup>	Surmontil	10	25–100
Clomipramine <sup>b</sup>	Anafranil	10	50–150
Doxepin <sup>b</sup>	Sinequan, Adapin	10	10–75
Amoxapine <sup>b</sup>	Asendin	10	25–300
Maprotiline	Ludiomil	10	25–75
Trazodone	Desyrel	25	25–200
Bupropion	Wellbutrin	75	75–450
Nefazodone	Serzone	50	200–600
Venlafaxine	Effexor	25	125–300
Mirtazepine	Remeron	7.5	15–30

<sup>a</sup>Geriatric dose.

<sup>b</sup>Tricyclic antidepressant.

<sup>c</sup>Secondary amine.

<sup>d</sup>Dose adjusted according to blood level.

1988), but they have fewer sedative, anticholinergic, cardiotoxic, and psychomotor side effects (Gottfries and Hesse 1990; Roose et al. 1991).

## Metabolism and Dosing

Certain aspects of antidepressant metabolism that change with aging must be taken into consideration in prescribing these drugs to older neuropsychiatric patients (Abernathy 1992; Alexopoulos 1992; Cohn et al. 1990; Rockwell et al. 1988). Tertiary amine antidepressants are demethylated to secondary amines, and these and other antidepressants are hydrolyzed by the P450 system to water-soluble hydroxy metabolites that are cleared by the kidneys. Some of these metabolites (e.g., 10-hydroxynortriptyline, 2-hydroxydesipramine) have been linked to cardiac conduction defects and some (e.g., 2-hydroxydesipramine) may have antidepressant properties.

Because the efficiency of demethylation diminishes with age, conversion of tertiary amines to secondary amine metabolites is slower and the parent compounds, which have more adverse effects, tend to accumulate. In addition, reduced renal clearance of cardiotoxic hydroxy metabolites enhances cardiac side effects at therapeutic doses. These changes make tertiary amine TCAs poor choices for most elderly patients. Phase I clearance of newer antidepressants such as fluoxetine, sertraline and bupropion is also impaired by age, but less so than that of the TCAs. However, even in younger patients the half-life of fluoxetine is 1–3 days and the half-life of its active metabolite, norfluoxetine, can increase from 9 days to 3 weeks with chronic use (Pato et al. 1991). Slower metabolism of antidepressants results in longer half-lives, more time to reach a steady state, and higher blood levels of the parent drug. These factors are not affected by brain disease.

Although therapeutic and toxic blood levels may be achieved with lower antidepressant doses in elderly patients, the same blood levels and even the same doses as those in younger patients may be necessary for an antidepressant effect. Young et al. (1985) found a mean dose of 75 mg of nortriptyline per day to be effective for the treatment of geriatric depression. Roose et al. (1987) administered nortriptyline at dosages of 87–92 mg/day with mean serum nortriptyline levels of 92 ng/mL, and imipramine at dosages of 240–280 mg/day with mean serum imipramine plus desipramine levels greater than 300 ng/mL. Nortriptyline levels of 50–150 ng/mL and desipramine levels above 125 ng/mL have been found necessary for antidepressant efficacy in elderly patients in other reports (Dagon 1990; Young and Meyers 1991), and Georgotas et al. (1986) confirmed that the range of nortriptyline levels was roughly

the same in elderly patients (50–180 ng/mL) as that usually reported in younger adults (50–150 ng/mL [Rubin et al. 1985]).

In a study of desipramine in unipolar nonpsychotic depression in patients over age 60 (Nelson et al. 1985), the minimum effective desipramine level was 115 ng/mL, the same value found in a comparison group of patients under age 60. Dosages of 125–350 mg/day were necessary in this study, and geriatric patients who did not initially respond improved when the dose was increased until the blood level was in the therapeutic range. These findings suggest that although lower doses and blood levels might be used initially, the dose should be increased in nonresponding patients until the serum level is in the therapeutic range for imipramine, desipramine, nortriptyline, and possibly amitriptyline or until the patient responds. However, side effects are more likely to occur at higher doses, and adverse effects are not correlated with blood levels, especially of parent compounds.

## Neuropsychiatric Side Effects

Some side effects of HCAs are particularly problematic in the neuropsychiatric setting. Examples are summarized in Table 34–2 (Ahronheim 1992; Alexopoulos 1992; Baldessarini and Marsh 1990; Bryner and Winograd 1992; Davidson 1989; Demuth et al. 1985; Flint 1994; Herman et al. 1990; Jick et al. 1992; Paradis et al. 1992; Rizos et al. 1988; Rockwell et al. 1988; Roose et al. 1987, 1991; Yassa et al. 1987; Young and Meyers 1991; Young et al. 1985).

## Special Considerations

Before depression is treated in elderly patients with brain disease, an attempt should be made to discontinue medications and treat underlying illnesses. When antidepressants are indicated, tertiary amine TCAs should be avoided. Secondary amine TCAs and newer antidepressants such as bupropion, venlafaxine, and the selective serotonin reuptake inhibitors (SSRIs) are better tolerated. Whereas all TCAs can impair cognitive performance in elderly patients (Flint 1994), the dopaminergic effect of bupropion and venlafaxine may enhance cognition in some patients.

**Dementia.** Patients with diffuse brain disease or with dysfunction of the right hemisphere may lose the capacity to express affect directly and may express coexisting depression as negativism, emotional lability, hostility, catatonia, or cognitive disturbance out of proportion to the actual lesion (E. D. Ross and Rush 1981) (see also Chapter 24). Although there is some controversy (discussed later in this

**TABLE 34–2. Some neuropsychiatric side effects of heterocyclic and related antidepressants**

Side effect(s)	Manifestations and comments	Medication(s)
Cardiovascular side effects	Orthostatic hypotension; may cause falls when patient goes to bathroom in middle of night. Type I antiarrhythmic effect causes suppression of ventricular arrhythmias and slowing of conduction. Conduction-repolarization abnormalities with nortriptyline correlated with concentration of E-10-hydroxynortriptyline. Tachycardia not as marked in older patients as in younger patients. Aggravation of ventricular tachyarrhythmias.	TCAs, trazodone, maprotiline; less marked with secondary amines and newer antidepressants TCAs
Sedation	Histamine, subtype 1 (H <sub>1</sub> ), receptor blockade causes oversedation, impaired memory and cognition, worsening of organic mental syndromes, and reduced new learning.	Imipramine, amitriptyline, clomipramine, trimipramine, doxepin, maprotiline, mirtazepine Trazodone, ?other serotonergic antidepressants
Psychomotor impairment	Impaired driving. Tolerance may not develop.	Amitriptyline, imipramine, trimipramine, doxepin, clomipramine, trazodone
Central anticholinergic syndrome	Anxiety, agitation, confusion, restlessness, disorientation, assaultiveness, and psychosis.	Amitriptyline, imipramine, clomipramine, trimipramine, doxepin, maprotiline, paroxetine
Lowered seizure threshold	Usually involves aggravation of preexisting seizure disorders. Incidence of seizures probably <4 per 1,000 in nonepileptic patients taking therapeutic doses. Dose-related phenomenon for all antidepressants.	Bupropion, maprotiline, amoxapine, tertiary amine TCAs, but not sertraline
Extrapyramidal side effects	Parkinsonism caused by dopamine receptor blockade by amoxapine and inhibition of dopamine release resulting from serotonergic action of SSRIs. Akathisia has mechanism similar to parkinsonism. Tardive dyskinesia: orofacial dyskinesia reported in 18 patients, only 6 of whom were taking antidepressant > 4 months, suggesting chance association except for amoxapine.	Amoxapine, fluoxetine, ?other SSRIs, high doses of imipramine and amitriptyline Amoxapine, fluoxetine, ?other SSRIs
Falls	Caused by sedation, orthostatic hypotension, and impaired balance.	Amoxapine, imipramine, amitriptyline, nortriptyline, clomipramine, trazodone, doxepin, nomifensine, tranylcypromine
Neuromuscular side effects	Tremor and myoclonus. Peripheral neuropathy. Proximal myopathy.	Imipramine, amitriptyline, doxepin, trazodone, clomipramine, SSRIs TCAs, maprotiline Amitriptyline Imipramine
Sleep disorders	Vivid dreams, nightmares, and insomnia.	Desipramine, nortriptyline, protriptyline, fluoxetine
Auditory disturbance	Tinnitus.	Most TCAs
Urological side effects	Urinary retention. Priapism not yet reported in elderly patients. Sexual dysfunction may respond to yohimbine, cyproheptadine, trazodone.	Amitriptyline, imipramine, trimipramine, doxepin, maprotiline Trazodone SSRIs

Note. SSRI = selective serotonin reuptake inhibitors; TCA = tricyclic antidepressant.

chapter) about whether antidepressants can improve cognition and behavior in patients with dementia, a trial of an antidepressant or ECT may be the only means of determining how much disability may be attributable to unrecognized depression in these patients (see also Chapter 35). Antidepressants that should be considered first under these circumstances are those that might enhance cognition, such as bupropion and venlafaxine. Other antidepressant classes should be considered before the TCAs. Acute confusion after ECT may be greater in some patients with dementia, but the underlying dementia is not exacerbated (Dubovsky 1993).

**Parkinson's disease.** The anticholinergic properties of tertiary amine antidepressants such as imipramine and amitriptyline could be useful in the treatment of Parkinson's disease; however, the same properties aggravate the cognitive deficits that are often present and have additive side effects with other anticholinergic drugs that patients with Parkinson's disease may be taking (see also Chapter 26). Because of its dopaminergic properties, bupropion improves parkinsonian symptoms in about one-third of patients (Cummings 1992). Venlafaxine could be useful in the treatment of the same group of patients, although its efficacy in parkinsonism has not been studied. The monoamine oxidase inhibitor (MAOI) L-deprenyl (selegiline), which is used as a primary treatment for Parkinson's disease, is also an appropriate choice. Stimulants have dopaminergic properties that could benefit some parkinsonian patients. The neuroleptic attributes of amoxapine contraindicate its use in the presence of Parkinson's disease. The use of SSRIs is discussed in a later section. Independent of its impact on depression, ECT has been shown to improve signs and symptoms of Parkinson's disease, especially in patients with the on-off phenomenon (Cummings 1992; Dubovsky 1993) (see also Chapter 35). Bromocriptine, an antiparkinsonian dopamine agonist, may have antidepressant effects in some patients, but this and other antiparkinsonian drugs also may cause depression.

**Seizure disorders.** In sufficient doses, all antidepressants have the potential to lower the seizure threshold (Davidson 1989), an effect that only rarely causes spontaneous seizures in patients without neurological predisposing factors (Jick et al. 1992). For most antidepressants, the dose at which seizures may occur is considerably higher than the usually therapeutic range, but in the cases of bupropion and maprotiline, doses that can produce seizures (greater than 450 and 225 mg/day, respectively, in younger adults) overlap therapeutic doses (Davidson 1989). Doses of these drugs at which epilepsy may be ag-

gravated in older patients are not known, but because they may be close to the geriatric therapeutic range, it is wise to avoid prescribing bupropion and maprotiline to older patients with epilepsy. Amoxapine, which can cause intractable seizures in elderly patients and which has extrapyramidal side effects, should not be taken at all by these patients (Litovitz and Troutman 1983). Doxepin, secondary amine TCAs, and MAOIs are safer in epileptic patients, but trazodone, nefazodone, and the SSRIs are the best initial choices. In one study of younger adults (Cohn et al. 1990), sertraline at a mean dose of 117 mg/day did not lower the seizure threshold.

## Interactions

HCAs interact with many other medications that are prescribed in geriatric neuropsychiatry. Some important examples are listed in Table 34-3 (Bailey et al. 1992; Dagon 1990; Rizos et al. 1988; Sargenti et al. 1988; Young and Meyers 1991).

## Selective Serotonin Reuptake Inhibitors

Ease of use and lack of anticholinergic, cardiotoxic, and hypotensive side effects have made the selective serotonin reuptake inhibitors (SSRIs) the preferred initial treatment for primary geriatric depression. The SSRIs have been found to be as effective as the HCAs in the treatment of geriatric major depression (Flint 1994; Mendels 1993; F. T. Miller and Freilicher 1995).

## Neurological Uses

SSRIs have been used to reduce the frequency of migraine headaches, although their tendency to increase serotonergic transmission may increase migraine frequency in some patients (Dubovsky 1994). A capacity to reduce dopaminergic transmission could be useful for some patients with tics.

## Available Preparations and Dosing

Five SSRIs are available in the United States: fluoxetine, sertraline, fluvoxamine, paroxetine, and citalopram. Fluoxetine has a long elimination half-life and has an active metabolite with an even longer half-life (Dubovsky and Thomas 1995), making it a better choice for treatment in older patients. Paroxetine has slightly more anticholinergic properties than do other SSRIs and would not be

**TABLE 34-3. Some potential tricyclic and heterocyclic antidepressant interactions**

Medications	Interacting medication(s)	Interaction(s)
Tricyclic antidepressants (TCAs)	Anticholinergic drugs	Additive anticholinergic effects
	Tranquilizers, sedatives, low-potency neuroleptics	Increased sedation
	Low-potency neuroleptics, antihypertensive drugs	Increased orthostatic hypotension
	Antihypertensives (clonidine, guanethidine, bethanidine, and debrisoquin)	Decreased effect of both classes
	Antihypertensives	Hypertensive crisis
	Type I antiarrhythmics	Additive antiarrhythmic effect, prolonged QT, widened QRS, increased risk of bundle branch block
	Directly acting sympathomimetics	Potential of sympathomimetic
	Disulfiram	Increased activity of both classes
	Cimetidine	Increased TCA levels
	All heterocyclic antidepressants	Neuroleptics other than flupenthixol
Stimulants		Increased antidepressant levels
Anticonvulsants		Decreased antidepressant levels
Cholestyramine		Decreased antidepressant levels

used first in patients with dementia. Initial and final doses for elderly patients are summarized in Table 34-4 (Flint 1994).

### Neuropsychiatric Side Effects

Stimulation of serotonin 5-HT<sub>2</sub> heteroreceptors by increased synaptic serotonin with SSRIs reduces release of dopamine, producing extrapyramidal side effects (Dubovsky 1994). Stiffness, tremor, bradykinesia, and akathisia caused by SSRIs can be particularly troublesome for patients with Parkinson's disease (Dubovsky and Thomas 1995). A few cases of tardive dyskinesia have been reported in younger patients taking SSRIs (Dubovsky and Thomas 1996). The syndrome of inappropriate secretion of antidiuretic hormone (SIADH), which can present as confusion or seizures, has also occasionally been reported (Flint 1994). SSRI-induced nausea, which can be a limiting side effect, can be treated with fresh gingerroot or a serotonin receptor 5-HT<sub>3</sub> antagonist such as ondansetron.

### ■ Monoamine Oxidase Inhibitors

Currently undergoing a renaissance, monoamine oxidase inhibitors (MAOIs) are as effective as TCAs in the treat-

**TABLE 34-4. Selective serotonin reuptake inhibitors in use in the United States**

Medication	Trade name	Starting dose (mg) <sup>a</sup>	Daily dose (mg) <sup>a</sup>
Fluoxetine	Prozac	10	10-40
Sertraline	Zoloft	25	50-200
Paroxetine	Paxil	10	10-40
Fluvoxamine	Luvox	25	50-200
Citalopram	Celexa	10	10-40

<sup>a</sup>Geriatric dose.

ment of geriatric depression (Georgotas et al. 1986). Indeed, because activity of the B form of monoamine oxidase (MAO) increases with aging and is even higher in Alzheimer's patients and patients with Parkinson's disease (Alexopoulos 1992; Danielczyk et al. 1988; Flint 1994), MAOIs may be particularly appropriate choices in geriatric neuropsychiatry (Rockwell et al. 1988), especially in the presence of apathy and low motivation (Salzman 1990). Patients with depression and physical symptoms of anxiety that mimic symptoms of neurological disease, such as light-headedness, dizziness, numbness, and paresthesias,

may be candidates for treatment with MAOIs, especially in the presence of rejection sensitivity, mood reactivity, and intolerance of or lack of response to HCAs (Pare 1985).

### Neurological Uses

L-Deprenyl (selegiline) given at dosages of 5–10 mg/day is a treatment for Parkinson's disease. At these dosages, selegiline does not usually interact with other antiparkinsonian drugs or tyramine-containing foods, because it is selective for the A form of MAO. Increased MAO levels in Alzheimer's disease and other dementias may be an indication that MAOIs could be useful in these conditions, and selegiline was found in several open studies and one single-blind investigation to improve anxiety, depression, and cognitive dysfunction in patients with Alzheimer's disease (Schneider and Sobin 1992) (discussed later in this chapter). Because they suppress rapid eye movement (REM) sleep and have alerting properties, MAOIs can be used to treat narcolepsy.

### Available Preparations

Three classes of MAOIs (Alexopoulos 1992) are now in use in the United States (Table 34–5). Tranylcypromine has amphetamine-like properties and is the most stimulating of the MAOIs. Inhibition of MAO does not persist as long after tranylcypromine is discontinued as it does after withdrawal of other MAOIs. The antidepressant dose of L-deprenyl (20–40 mg/day) is higher than the antiparkinsonian dose. However, side effects may be less troublesome than with other MAOIs. Moclobemide, a reversible inhibitor of MAO-A that at moderate doses does not interact with tyramine or serotonin reuptake inhibitors, has been found to be effective in the treatment of geriatric depression (Flint 1994). Because it does not cause postural hypotension or have anticholinergic side effects, moclobemide is an appropriate choice for older patients; however, because it was not deemed to be profitable in the United States, it will not be released here.

### Metabolism and Dosing

MAOIs are metabolized by acetylation, which is not affected by aging; however, plasma levels in elderly patients are usually higher with a given dose, probably because of slowing of additional metabolic steps (Alexopoulos et al. 1992). Initial doses, rate of dose increment, and final doses therefore are lower for geriatric patients than for younger patients. However, the dose of MAOI necessary to inhibit MAO is not always lower than in younger patients (Alexopoulos 1992), and some elderly depressed patients

require the same MAOI doses as do younger patients (Young and Meyers 1991). In addition, rapid acetylation of MAOIs is not attenuated by age. Patients who are “rapid acetylators” may require higher doses than those recommended by the manufacturer, which by and large are not based on prospective dose-response studies.

### Neuropsychiatric Side Effects

MAOIs produce more side effects in elderly patients than do HCAs (Georgotas et al. 1988). Some examples are listed in Table 34–6 (Alexopoulos 1992; Georgotas et al. 1986, 1988; Lawrence 1985; Lieberman et al. 1985; Meyler and Herxheimer 1968; Pare 1985; Sargenti et al. 1988).

### Special Considerations

Although seizures have occurred in nonepileptic patients after overdose of MAOIs, at therapeutic doses these drugs are safe for patients with epilepsy. Patients with carcinoid or pheochromocytoma should not be given MAOIs because of the risk of fatal serotonergic or hypertensive reactions. Selegiline is an appropriate first choice for the treatment of depressed patients with parkinsonism, although at higher doses (see the following section) it may interact with levodopa, bromocriptine, and dietary substances. Elderly patients often do not consider over-the-counter preparations to be medications, and therefore they do not necessarily avoid such drugs when warned about potential MAOI interactions. The major risk of MAOIs in dementia is that patients will not remember the dietary restrictions (Young and Meyers 1991). On the other hand, in a study of older patients with depression, Pancheri et al. (1994) found

<sup>b</sup>Higher doses may be necessary.

<sup>c</sup>Experience in elderly patients limited.

<sup>d</sup>Withdrawn due to poor sales.

<sup>e</sup>Antiparkinsonian dose = 5–10 mg.

**TABLE 34–6. Some neuropsychiatric side effects of monoamine oxidase inhibitors**

Side effect	Manifestations	Comments
Altered brain function	Sedation, activation, headache, paradoxical reactions, memory loss, confusion, ataxia, irritability, insomnia, mania, psychosis	Abrupt withdrawal can cause insomnia, nightmares, mania, psychosis, and delirium.
Autonomic dysfunction	Postural hypotension, anticholinergic side effects, sexual dysfunction	Phenelzine and isocarboxazid most anticholinergic.
Peripheral nervous system dysfunction	Peripheral neuropathy, paresthesias, gait disturbance, falls	Caused by direct neurotoxicity or interference with B <sub>6</sub> metabolism. Pyridoxine replacement may be helpful.
Neuromuscular irritability	Twitching, myoclonus, muscle tension, tremor, muscle and joint pain	May reflect mild serotonin syndrome. Nocturnal myoclonus occurs in 10%–15% of patients taking phenelzine. No tolerance.
Sexual dysfunction	Anorgasmia, impotence	Cyproheptadine occasionally helpful. Avoid yohimbine.

that even though more patients stopped taking moclobemide than stopped taking imipramine, moclobemide but not imipramine produced improved cognition as well as improvement of anxiety and depression. MAOIs do not aggravate cardiac conduction delays (Young and Meyers 1991).

## Interactions

MAOIs have two potentially dangerous interactions. The first is the hypertensive reaction that occurs with foods that are high in tyramine content and with certain adrenergic medications. Hypertensive reactions occur because MAOIs irreversibly inhibit both MAO-A, which is found in the gut and the brain, and MAO-B, which is found in the brain but not the gut. Because gastrointestinal MAO-A metabolizes ingested tyramine (a pressor amine found in many foods) before it can be absorbed into the bloodstream, inhibition of the enzyme results in increased intestinal absorption of tyramine and an amplified pressor response that is augmented by decreased tyramine metabolism in sympathetic nerve ganglia. Hypertensive crises are no more common in elderly patients than in other patients (Georgotas et al. 1986), but they are more dangerous in patients with fragile cerebral vasculature. Because selegiline is selective for MAO-B at antiparkinsonian doses and therefore does not inhibit intestinal MAO, tyramine in the gastrointestinal tract is degraded normally. However, at doses greater than 10 mg/day selegiline loses its selectivity and inhibits MAO-A, producing tyramine reactions.

In a study of traditionally proscribed foods, K. I. Shulman et al. (1989) found that the tyramine content of most of them is so low that massive amounts (e.g., 50 glasses of wine) would have to be ingested to produce a hypertensive reaction. The investigators suggested that a more real-

istic list would include all cheese except cottage cheese and cream cheese, concentrated yeast extract, sauerkraut, broad bean pods, aged meats, salami, air-dried sausage, old chicken liver, protein extracts, spoiled protein-containing foods, and pure soy products. Patients should refrain from taking sympathomimetic drugs, including most cold preparations, decongestants, and anorectics. Antihistamines, acetaminophen, Cepacol, Sucrets, and plain Alka Seltzer are safe, but Alka Seltzer Plus is not. Dextromethorphan, which has serotonergic properties, should be avoided because of the risk of serotonin syndrome (described shortly).

Experience with younger patients suggests that a 10-mg tablet of nifedipine chewed and placed under the tongue for rapid absorption can blunt the severity of hypertensive reactions (Clary and Schweitzer 1987) until the more definitive treatment of 2–5 mg of intravenous phentolamine can be administered. However, nifedipine is poorly absorbed from the buccal mucosa, and dangerous hypotension may occur. Chlorpromazine should not be used to treat hypertensive reactions in geriatric neuropsychiatric practice because of the risk of dangerous hypotensive and anticholinergic side effects.

Because serotonin is metabolized by MAO-A, the second type of dangerous MAOI interaction is with serotonergic substances such as L-tryptophan, meperidine, dextromethorphan, imipramine, clomipramine, SSRIs, and possibly buspirone (Salzman 1992; Sargenti et al. 1988). TCAs other than imipramine and clomipramine can be safely combined with MAOIs if the TCA is started first and low initial doses of each medication are used. Serotonin syndrome is a neurotoxic condition characterized by ataxia, hyperreflexia, myoclonus, excitation, diaphoresis, dysarthria, paresthesias, fever, confusion, delirium, seizures, coma, hypotension, and fatal cardiac arrhythmias (Lieberman et al. 1985).

MAOIs interact with a number of other kinds of compounds, some of which are listed in Table 34–7 (Lieberman et al. 1985; Meyler and Herxheimer 1968; Pare 1985; Salzman 1992; Sargenti et al. 1988).

## ■ Stimulants

Stimulants increase central release of norepinephrine, dopamine, and serotonin and may have direct dopamine agonist properties (Hoffman and Lefkowitz 1990). Stimulants, available preparations of which are listed in Table 34–8 (Alexopoulos 1992; Salzman 1992), have been found superior to placebo in some double-blind studies of geriatric depression and depression in patients with dementia, especially those who are apathetic and unmotivated (Chiarello and Cole 1987; Rockwell et al. 1988; Warneke 1990). In addition, stimulants can improve negative symptoms such as apathy and withdrawal in geriatric patients with dementia (Galynker et al. 1997). Chiarello and Cole (1987) suggested that a preference for coffee may be an indication of a good response to a stimulant.

Depression in neurologically ill patients may respond within a few weeks to stimulants, although dose-finding studies have not been conducted. In one study (Holmes et al. 1989), cognitive deterioration was found to improve along with depression when human immunodeficiency virus (HIV) encephalopathy was treated with stimulants. Tolerance to the antidepressant effect generally has not been noted in older neuropsychiatric patients (Kaufman et al. 1984), and appetite and sleep improve when the depression remits. The medication can sometimes be withdrawn after a few months without return of symptoms (Kaufman et al. 1984), especially if the underlying neurological illness

improves, but chronic treatment has been successful in some instances (Chiarello and Cole 1987).

Stimulants can also be used to augment HCA therapy in treatment-resistant geriatric depression (Warneke 1990). One strategy for patients who cannot tolerate therapeutic doses of HCAs is to administer a lower dose of HCA and increase the blood level of the HCA with a stimulant (discussion follows), avoiding side effects associated with products of first-pass metabolism. Intermittent treatment of bipolar depression with a stimulant can reduce the risk of antidepressant-induced hypomania or mood cycling. The major neurological uses of stimulants are in the treatment of narcolepsy and of apathy and cognitive deterioration in dementia.

## Metabolism and Dosing

Until formal data have been collected concerning stimulant metabolism in elderly patients, low initial doses and gradual increments (e.g., in the case of methylphenidate, by 2.5 mg/day every week) are recommended (Table 34–8). Dosages of 5–15 mg/day are often successful in antidepressant augmentation, and administration of 10–40 mg/day is successful as primary treatment for depression in elderly neurologically ill patients. Adderall, a proprietary combination of *l*- and *d*-amphetamine used to treat attention-deficit disorder in children, has not been studied in elderly patients with neuropsychiatric illness.

## Neuropsychiatric Side Effects

Stimulant side effects are usually dose related, toxicity being rare at doses less than 15 mg/day (Hoffman and Lefkowitz 1990). Many of the adverse effects noted in Ta-

**TABLE 34–7. Some potential monoamine oxidase inhibitor interactions**

Medication(s)	Interaction(s)
Hydrazine <sup>a</sup> plus nonhydrazine <sup>b</sup> MAOI	Fever, hypertension, convulsions, stroke, coma
Levodopa	Hypertension; less with carbidopa
Amantadine	Hypertension
General anesthetics, sedatives, narcotics, antihistamines, neuroleptics, antiparkinsonian drugs	Potential of central nervous system depression due to inhibition of hepatic metabolism
Antihypertensive drugs	Increased hypotension
Insulin	Increased hypoglycemic effect
Reserpine, tetrabenazine	Excitation
Aspartane	Headache, diaphoresis
Bupropion	Increased bupropion toxicity, serotonin syndrome

<sup>a</sup>Geriatric dose.

ble 34–9 represent excessive CNS and cardiovascular stimulation (Ahronheim 1992; Hoffman and Lefkowitz 1990; Rockwell et al. 1988; Young and Meyers 1991).

### Special Considerations

The dopaminergic properties of stimulants could be useful for patients with depression and parkinsonism, but the same effect aggravates chorea and psychosis and may lower the seizure threshold. As discussed later in this chapter, a trial of stimulants in patients with dementia may help to identify the component that is attributable to depression.

### Interactions

Stimulants increase blood levels of TCAs, neuroleptics, and other medications metabolized by the P450 system. Therefore, stimulants can be used to raise serum levels of another medication, with no dose increase of that drug required.

## ■ Nonpharmacological Antidepressant Treatments

When interactions, side effects, or lack of efficacy limits the usefulness of antidepressants, or when the patient is se-

**TABLE 34–9. Some neuropsychiatric side effects of stimulants**

Side effect	Manifestations
Central nervous system stimulation	Agitation, restlessness, tremor, diaphoresis, hyperreflexia, confusion, cognitive deterioration, paranoia, hallucinations, suicidal and homicidal behavior, convulsions
Cardiovascular stimulation	Tachycardia, hypertension, hypotension, headache, palpitations, arrhythmias, angina, circulatory collapse, cerebral hemorrhage

verely ill, ECT is an obvious consideration, even in the presence of epilepsy, dementia, or delirium (see Chapter 35). Stimulants (discussed in the previous section) are useful in treating apathetic depression associated with neurological illness. At dosages of 40–90 mg/day, buspirone has antidepressant effects in younger patients (Rickels et al. 1991), and augmentation of HCAs with buspirone at dosages of 10–60 mg/day can be as effective as lithium augmentation, with fewer side effects in older patients with brain disease.

Exposure to 2,500–10,000 lux of light for ½–2 hours has been found to be an effective treatment for seasonal affective disorder and some cases of nonseasonal depression. Like any antidepressant, artificial bright light can induce hypomania. The incidence of seasonal affective disorder and the effectiveness of bright light in the geriatric population have not been studied formally, but consideration of this treatment is warranted in patients with a seasonal variation of mood who cannot tolerate antidepressant side effects. The use of artificial bright light to treat abnormalities of the sleep-wake cycle is discussed later in this chapter. Medications that sensitize the lens and retina of the eye to phototoxicity—including imipramine, fluoxetine, lithium, chlorpromazine, thioridazine, and propranolol—should be used with great caution, if at all, in elderly patients who are exposed to bright light or who spend much time in the sun (Roberts et al. 1992).

Repetitive transcranial magnetic stimulation (rTMS) is a method of regional magnetic stimulation of the brain that produces localized subconvulsant electrical discharges and that has been found to have antidepressant effects in a few animal studies, as well as in some pilot studies and small controlled comparisons to sham treatment (George et al. 1997; Markwort et al. 1997; Zyss et al. 1997). In a study in which subjects were informed of their treatment (Tom and Cummings 1998), rTMS produced temporary relief of depression in patients with Parkinson's disease. Like ECT, rTMS may improve the movement disorder of parkinsonism itself, separate from its antidepressant effect (Brandt et al. 1997). An advantage of rTMS is that it does not require the presence of seizures or high doses of electrical energy to be effective, and therefore it should be better tolerated by patients with dementia. A few patients with refractory depression have responded to rTMS to the left frontal cortex (Post et al. 1997). However, improvement of depression with rTMS is only transient, and relapse occurs as soon as the treatment is discontinued (Markwort et al. 1997; Post et al. 1997). Seizures and myoclonus have sometimes occurred in patients receiving rTMS (Jaggy and Koch 1997).

## ■ Antimanic Drugs

The risk of mania does not increase with age (Young and Klerman 1992), but bipolar disorder does not “burn out” with age either (K. I. Shulman et al. 1992; Snowdon 1991; Young and Meyers 1991) (see also Chapter 13). Between 5% and 10% of elderly patients undergoing treatment for mood disorders have episodes of mania or hypomania (Young and Klerman 1992), and 5%–10% of bipolar patients become ill for the first time after age 50 (Yassa et al. 1988). Even in the geriatric population, having had previous episodes of depression without mania is no guarantee of a unipolar illness, because up to 25 years may elapse between the onset of depression and the first manic episode (Snowdon 1991).

As is true of depression, late-onset mania in elderly patients is frequently an expression of underlying neurological disease (Snowdon 1991). In addition, manifestations of early-onset primary bipolar disorder can be modified later in life by coexisting brain disease (Young and Klerman 1992). In various reports, 24%–36% of cases of late-onset bipolar disorder have been associated with overt neurological disease (K. I. Shulman et al. 1992; Young and Meyers 1991), which is often present before the onset of mania (Snowdon 1991). The severity of the neurological component is indicated by a retrospective study (K. I. Shulman et al. 1992) in which half of 50 elderly manic patients were dead from medical causes after 6 years of follow-up.

One common neurological precipitant of mania is stroke, especially in association with right-sided lesions of the frontal cortex, basal ganglia, thalamus, or basotemporal cortex or in association with preexisting subcortical atrophy. Other neurological causes of late-onset mania include adrenal steroids, calcium replacement, levodopa, antidepressants, bronchodilators, decongestants, vitamin B<sub>12</sub> deficiency, hyperthyroidism, epilepsy, trauma, and degenerative, vascular, or neoplastic disease of the right hemisphere (Dagon 1990; Snowdon 1991; Yassa et al. 1988; Young and Klerman 1992).

The frequent association of geriatric mania with neurological disease leads to a high frequency of cognitive dysfunction (Young and Klerman 1992) and resistance to lithium (Hardy et al. 1987; Young and Klerman 1992). Treatment of neurological causes and withdrawal of medications that cause mania may lead to improvement, but additional antimanic treatments are often necessary.

### Lithium

Lithium is the best-studied medication for the treatment and prophylaxis of mania in elderly patients. Lithium aug-

mentation can be useful in bipolar and, to a lesser extent, unipolar depression (Jefferson 1990; Roy and Pickar 1985); obsessive-compulsive disorder (Jefferson 1990; Jenike 1990); and schizophrenia (Jefferson 1990).

**Neurological uses.** Lithium has been noted in uncontrolled reports to ameliorate cluster headaches, Huntington’s disease, and spasmodic torticollis. Lithium-induced leukocytosis is a treatment for leukopenia caused by chemotherapy for cancer and autoimmune disease. Reduced renal water conservation caused by lithium therapy may counteract the syndrome of inappropriate secretion of antidiuretic hormone (SIADH), which can complicate some tumors and infections of the CNS.

**Metabolism and dosing.** Because of age-related reduction of renal clearance and volume of distribution, only one-half to two-thirds of the usual adult doses are necessary to achieve the same plasma level as that in younger patients (Liptzin 1992; Young and Meyers 1991). In elderly patients, lithium half-life is usually (Ahronheim 1992; Liptzin 1992), but not always (Hardy et al. 1987), increased to about 40 hours, resulting in a longer time to reach a steady state (Liptzin 1992), with a corresponding delay in onset of therapeutic action as well as slower elimination after discontinuation. Because of the prolonged half-life, lithium doses should not be increased more frequently than once per week (Ahronheim 1992; Liptzin 1992). The risk of neurotoxic side effects probably warrants even slower dosage adjustments in elderly patients with neuropsychiatric illness.

Clinical lore holds that the therapeutic effect of lithium occurs at lower blood levels as well as lower doses in elderly patients (Salzman 1990). However, there is no empirical evidence for this assertion (Hardy et al. 1987; Young and Meyers 1991). Low starting doses (e.g., 75–150 mg/day) and maintenance doses (e.g., 600–1,200 mg/day) are appropriate (Ahronheim 1992; Liptzin 1992), but the dose should be increased if the patient does not respond and the blood level is not in the usual adult therapeutic range. Single daily doses of lithium enhance compliance, reduce adverse effects, and are safe in elderly patients (Hardy et al. 1987; Mellerup and Plenge 1990).

**Neuropsychiatric side effects.** Lithium toxicity is common at serum levels greater than 1.5–2.0 mEq/L, but toxicity may occur at therapeutic levels, especially in elderly patients with CNS disease (Hardy et al. 1987; Liptzin 1992). Toxicity produces a coarse tremor, ataxia, vertigo, dysarthria, disorientation, nausea, and vomiting. Severe

intoxication is associated with muscle fasciculations, hyperreflexia, confusion, delirium, seizures, and coma. Irreversible memory loss, brain damage, cerebellar symptoms, and motor deficits may occur following lithium intoxication (Saxena and Maltikarjuna 1988).

Lithium side effects, which occur at therapeutic levels, are more frequent at blood levels above 0.8 mEq/L, although lithium is more reliably prophylactic at higher levels, at least in younger adults (Gelenberg et al. 1989; Vestergaard et al. 1988). As many as 50% of lithium-treated patients develop reversible impairment of memory and concentration, which is problematic for patients with dementia. Hypokalemia increases the risk of neurological side effects (Jefferson and Greist 1977). Common CNS side effects are summarized in Table 34–10 (Griffin 1992;

**TABLE 34–10. Some neuropsychiatric side effects of lithium**

Type of side effects	Manifestations and comments
Neuromuscular	Tremor, ataxia, dysarthria, incoordination, and myoclonus. Falls may result from ataxia and incoordination. Elderly patients more prone to tremor and myoclonus.
Mental	Impaired memory, concentration, and consciousness; anterograde amnesia; aphasia; confusion; dazed feeling; and flat affect.
Extrapyramidal	Parkinsonism.
Degenerative	Parkinsonism and Creutzfeldt-Jakob–like syndrome.
Intracranial	Pseudotumor cerebri.
Electroencephalographically demonstrated	Generalized slowing, disorganization of background rhythm, discharges, rapid eye movement (REM) sleep suppression, and seizures.
Endocrinological	Hyperparathyroidism may produce mental and neuromuscular symptoms, especially depression or mania. Hypothyroidism may initiate rapid cycling or confusion.
Renal	Polyuria and polydipsia not more common in elderly patients. Lithium does not cause or accelerate renal failure in elderly patients. Nephrogenic diabetes insipidus may be reduced by amiloride, which reduces lithium transport into collecting duct.

Liptzin 1992; Rizos et al. 1988; Salzman 1990; Saul 1985; Schneider and Sobin 1992; Young and Meyers 1991).

**Special considerations.** Lithium can lower the seizure threshold and induce seizures in nonepileptic patients (Massey and Folger 1984). However, in one study (Shukla et al. 1988), lithium at therapeutic levels did not increase seizure frequency or anticonvulsant requirement in a small group of patients with epilepsy and bipolar disorder. The use of lithium in elderly patients with seizure disorders has not been investigated formally, but anticonvulsants with antimanic properties (discussed later in this chapter) should be considered for such patients.

Because lithium occasionally causes extrapyramidal side effects, it can be problematic in parkinsonian patients. Cognitive side effects of lithium are poorly tolerated by patients with dementia. Because lithium slows the rate of depolarization of the sinus node and conduction through the atrioventricular node, electrocardiograms should be obtained with dosage increases and cardiac function should be followed closely in elderly patients with heart disease who take lithium.

**Interactions.** Neurotoxic interactions between lithium and neuroleptics, which consist mainly of extrapyramidal and neuromuscular syndromes or delirium (F. Miller and Menninger 1987), may represent aggravation of lithium neurotoxicity by the neuroleptic, additive neurotoxic effects or a true interaction between the two classes of medication. Neurotoxicity is more common with higher neuroleptic doses and higher lithium levels and may be irreversible in a few cases (W. J. Cohen and Cohen 1974; Izzo and Brody 1985). A neurotoxic interaction of lithium with clozapine that included confusion, delirium, incoordination, dystonias, and myoclonus has also been reported (Blake et al. 1992). Because neuroleptics are mainly used to control agitation and psychosis until the antimanic action of lithium occurs, it has been recommended that the risk of neurotoxicity could be lessened by deferring lithium therapy until the patient's behavior is under control, at which point the neuroleptic can be gradually withdrawn (Chou 1991). Other interactions of lithium with drugs used in geriatric neuropsychiatry are summarized in Table 34–11 (Abernathy 1992; Ahronheim 1992; Chou 1991; Jefferson 1990; Liptzin 1992; P. J. Perry et al. 1984; Rizos et al. 1988; Salzman 1990; Young and Meyers 1991).

**Alternatives to lithium.** ECT is clearly effective for mania in elderly patients (Black et al. 1987; Dubovsky and Buzan 1997) (see also Chapter 35). None of the medications that have been used in younger patients with mania

**TABLE 34–11. Some potential lithium interactions**

Medication(s)	Interaction(s)
Neuroleptics, carbamazepine, clonazepam, calcium channel blockers	Neurotoxicity, increased extrapyramidal side effects
Thiazide diuretics, angiotensin-converting enzyme (ACE) inhibitors	Increase in serum lithium concentration by 35%
Furosemide, amiloride	No effect on lithium clearance
Theophylline, aminophylline, ?caffeine	Increased lithium clearance, decreased lithium half-life
Nonsteroidal anti-inflammatory drugs	Increase in serum lithium concentration by 50%
Tetracyclines, spectinomycin, metronidazole	Increased serum lithium concentration
Iodine	Increased risk of hypothyroidism
$\beta$ -Blockers	Increased serum lithium concentration
Fluoxetine	Increased serum lithium concentration

as alternatives or adjuncts to lithium have been studied systematically in elderly patients for this indication (Young and Meyers 1991), but some anecdotal evidence exists.

Carbamazepine, the best studied of the alternatives to lithium, may be particularly useful in mixed, rapid-cycling, and lithium-resistant bipolar disorders, although tolerance to prophylaxis of mood disorders may develop (Post 1990). Carbamazepine is an obvious choice for bipolar patients with epilepsy or electroencephalograms (EEGs) showing nonspecific abnormalities, and the drug is better tolerated than lithium in elderly patients with brain damage. However, carbamazepine can cause confusion and neurotoxicity in some of these patients, especially when combined with other antimanic drugs or neuroleptics, and older patients may be unable to tolerate the sedation it causes. Carbamazepine can also be useful in trigeminal neuralgia but is less reliably effective for other kinds of neuropathic pain (Ahronheim 1992).

Because carbamazepine induces its own metabolism, the half-life tends to decrease over a month or so from 36 to 10–20 hours (Ahronheim 1992). Some therapeutic, as well as some toxic, effects of carbamazepine can be attributed to an active epoxy metabolite (Ahronheim 1992). The initial dose of carbamazepine in elderly patients should be 50–100 mg (Ahronheim 1992; Salzman 1990). The therapeutic

dosage for epilepsy, and presumably for mood disorders, in older patients is thought to be 300–1,200 mg/day (Liptzin 1992; Salzman 1990); higher doses may be necessary for pain control (Ahronheim 1992). Side effects and interactions are noted in Tables 34–12 and 34–13 (Ahronheim 1992; Liptzin 1992; Salzman 1990; Thomas 1997).

Valproic acid appears to be a most useful agent for some bipolar patients with EEGs showing abnormalities, rapid cycling, mixed affective states, and resistance to other medications (Chou 1991). In a few studies, valproate was found to be effective in elderly patients with bipolar disorder (Liptzin 1992). Starting dosages of 125 mg/day and total daily doses of 125–1,800 mg, with blood levels around 100 ng/mL, have been recommended (Bowden et al. 1994; Liptzin 1992; Salzman 1990), but these can only be considered estimates in neurologically ill geriatric patients. Some valproate side effects and interactions are noted in Tables 34–12 and 34–13.

Verapamil at dosages of 240–480 mg/day has been used in several elderly patients with dementia and bipolar disorder, with good results and minimal side effects (Dubovsky and Buzan 1997; Dubovsky et al. 1986). Nimodipine, which is used to treat some forms of stroke and which may have applications in dementia, has antimanic properties (Dubovsky and Buzan 1997) and could also be useful in geriatric bipolar illness complicated by dementia or cerebrovascular disease. It has also been observed (but not demonstrated in controlled studies) that nimodipine may be a useful antidepressant in patients with dementia (Riekkinen et al. 1997; Vry et al. 1997). Side effects and interactions of calcium channel blockers are included in Tables 34–12 and 34–13.

The anticonvulsants lamotrigine and gabapentin have recently been used as antimanic and mood-stabilizing drugs. However, there are as yet no published controlled studies of such indications (Dubovsky and Buzan 1997). Both medications are well tolerated by elderly patients, the primary interactions being reduction of the drugs' serum levels by carbamazepine and increase of serum levels by valproate (Thomas 1997). Lamotrigine may have neuroprotective properties related to reduction of excitatory amino acid transmission, making it potentially useful for bipolar patients with cerebrovascular disease (Thomas 1997).

In addition to being used as antimanic and mood-stabilizing medications, anticonvulsants are used to treat seizure disorders, the incidence of which increases between age 60 and 75 (see also Chapter 29). Most new episodes of epilepsy in elderly patients are secondary to cerebrovascular disease, brain tumors, neurodegenerative disease, and toxic-metabolic conditions (Thomas 1997). Certain

**TABLE 34–12. Some neuropsychiatric side effects of alternatives to lithium**

Alternative	Side effect/type of side effects	Manifestations
Carbamazepine	Neurotoxicity	Ataxia, dizziness, sedation, lethargy, diplopia, cognitive impairment, irritability, confusion, restlessness, seizures
	Neuroendocrinological	Syndrome of inappropriate secretion of antidiuretic hormone (SIADH), hypocalcemia
	Hematological	Transient leukopenia
	Hypersensitivity	Agranulocytosis, aplastic anemia, thrombocytopenia, rash, hepatitis, pneumonitis
Valproic acid	Neurotoxicity	Sedation, ataxia, tremor, impaired memory
	Dermatological	Rash, alopecia
	Gastrointestinal	Weight gain, anorexia, nausea, vomiting; hepatitis in 1 in 50,000 adults
Verapamil	Neurological	Sedation, dizziness, headache, occasional extrapyramidal symptoms

**TABLE 34–13. Some potential interactions of alternatives to lithium**

Alternative	Medication(s)	Interaction(s)
Carbamazepine	Lithium	Neurotoxicity
	Anticonvulsants, neuroleptics, benzodiazepines, warfarin sodium	Decreased blood level of other medication, caused by enzyme induction
	Fluoxetine	Increased carbamazepine levels
	Neuroleptics	Neurotoxicity
	Cimetidine, erythromycin, isoniazid	Increased carbamazepine levels
Valproic acid	Aspirin	Increased valproate levels
	Other anticonvulsants	Increased levels of other anticonvulsant
	Clonazepam	Absence status epilepticus
Verapamil	Carbamazepine, lithium	Increased carbamazepine and lithium levels, neurotoxicity
	Lithium, $\beta$ -blockers	Additive cardiac slowing

adverse effects of antiepileptic drugs are more common in elderly patients (Table 34–14) (Thomas 1997).

## ■ Antianxiety Drugs

Benzodiazepines and azapirones are the primary treatments for generalized anxiety in elderly patients (see also Chapter 15). Benzodiazepines are most appropriately used to treat acute anxiety or insomnia in response to a discrete stress (Salzman 1990). Because generalized anxiety disorder is chronic and recurrent, ongoing treatment is often necessary. Azapirones are better tolerated by chronically anxious patients with brain disease, because these drugs do not impair higher cortical function, but their delayed onset

of action makes them ineffective when used on an as-needed basis.

Alprazolam has been the most thoroughly studied as a treatment for panic disorder, but other benzodiazepines appear to be effective if administered in equivalent doses. Clonazepam has been used to treat mania (Chouinard and Penry 1985), although some of its apparent antimanic effect could be secondary to sedation, which is difficult for many older neuropsychiatric patients to tolerate. Alprazolam and perhaps other benzodiazepines may have antidepressant effects in mixed anxiety-depression, but antidepressants and azapirones have a wider margin of safety for this indication in neurologically ill elderly patients. Azapirones can be used to augment antidepressants in the treatment of depression and obsessive-compulsive disorder.

**TABLE 34-14. Some side effects of anticonvulsants**

Adverse effect	Comments
Megaloblastic anemia	Greater incidence of folate deficiency increases risk of anemia
Osteomalacia	Decreased calcium and vitamin D intake increases risk
Cognitive impairment	Reduced memory and aggravation of dementia
Depression	Anticonvulsants may precipitate or aggravate symptoms of depression
Falls	Especially with sedating anticonvulsants
Cardiac conduction defects	Carbamazepine and oxycarbamazepine can worsen conduction defects and bradycardia

## Benzodiazepines

**Neurological uses.** Clonazepam is used to treat generalized, myoclonic, and absence seizures (Chouinard and Penry 1985) (see also Chapter 29). Clonazepam may also be useful in pain syndromes such as trigeminal neuralgia that are associated with paroxysmal dysesthesias, burning sensations, and hyperesthesias (Bouckonis and Litman 1985) (see also Chapter 18) and with choreoathetosis and neuroleptic-induced akathisia (Chouinard and Penry 1985). Intravenous diazepam is a well-known treatment for status epilepticus. Intravenous midazolam is used for severe agitation in delirium patients.

**Available preparations.** Benzodiazepines can be divided into short- and long-half-life preparations. As a general rule, the long-half-life drugs are poorly tolerated by elderly patients with neuropsychiatric illness because accumulation leads to sedation, amnesia, psychomotor impairment, ataxia, and falls (Mustard and Mayer 1997; Ray 1992). Properties of benzodiazepines used to treat anxiety are summarized in Table 34-15 (Abernathy 1992; Ahronheim 1992; Regestein 1992; Salzman 1992; Salzman et al. 1983). (Benzodiazepine hypnotics are discussed in a later section.)

**Metabolism and dosing.** Unlike antidepressants, anticonvulsants, and low-potency neuroleptics, benzodiazepines do not induce their own metabolism (Salzman 1992). Diazepam, chlordiazepoxide, clorazepate, praze-

pam, halazepam, and flurazepam have long elimination half-lives that are prolonged two to three times in elderly patients (Regestein 1992), resulting in a longer time to reach a steady state and drug accumulation over time (Salzman et al. 1983). Long-half-life benzodiazepines also have a complex hepatic oxidative metabolism that produces desmethyl diazepam, an active metabolite with a half-life in elderly patients of 80–130 hours (Salzman 1990, 1992; Salzman et al. 1983).

Hydroxylated benzodiazepines such as oxazepam, lorazepam, alprazolam, triazolam, and temazepam have intermediate and shorter half-lives and simpler metabolic pathways that are not affected as much by aging (Salzman 1990, 1992; Salzman et al. 1983). Such medications do not accumulate in elderly patients and are quicker to reach a steady state. Despite long half-lives in elderly patients, benzodiazepines are often given in divided doses to minimize periods of intoxication caused by blood level peaks. Recommended dose ranges for geriatric neuropsychiatry are noted in Table 34-15.

**Neuropsychiatric side effects.** The older CNS may be more prone to benzodiazepine toxicity, perhaps because of increased sensitivity of the benzodiazepine receptor (Salzman 1992). Patients with disease of the brain may be even more vulnerable to adverse effects of CNS depression caused by benzodiazepines, such as excessive sedation, memory impairment, confusion, falls, or paradoxical reactions. As they grow older, geriatric patients may develop benzodiazepine toxicity at doses that were previously well tolerated (Regestein 1992). Common benzodiazepine side effects are presented in Table 34-16 (Ahronheim 1992; Hart et al. 1991; Ray 1992; Regestein 1992; Salzman 1991, 1992; Salzman et al. 1983; Young and Meyers 1991).

**Dependence and withdrawal.** Physical dependence on benzodiazepines can occur after treatment for months with therapeutic doses, especially with shorter-half-life compounds (Salzman 1991). On abrupt discontinuation, three kinds of syndromes may occur, all of which are more severe and prolonged in elderly patients with impaired central nervous systems (Busto et al. 1986; Noyes et al. 1988; Salzman 1991). Relapse (return of the original anxiety symptoms) occurs gradually over weeks to months in 60%–80% of chronically anxious patients. Rebound (an intensification of the original symptoms, lasting several days) occurs within hours to days in 25%–75% of patients. Withdrawal, which occurs within hours to a day or two of stopping short-half-life benzodiazepines and within days to weeks of discontinuing longer-half-life preparations,

**TABLE 34–15.** Some benzodiazepine anxiolytics in use in the United States

Medication	Starting dose (mg) <sup>a</sup>	Therapeutic dose (mg) <sup>a</sup>	Half-life (hours)	Comments
Midazolam	2.5	5–15	1–3	Used intravenously for agitation and orally for sleep. Use for anxiety in elderly patients not studied.
Lorazepam	0.5	0.5–4	12–18	Does not accumulate in elderly patients.
Alprazolam	0.25	0.25–2.0	17–24	Increased half-life in elderly patients. Has 2 active metabolites.
Oxazepam	10	10–90	10–14	Active metabolite of diazepam with no active metabolites of its own. Slow onset of action due to slow absorption.
Clonazepam	0.125	0.25–2	>100	Very sedating. Accumulates with long-term use.
Diazepam	2	2–10	75–90	Metabolized to desmethyldiazepam, active metabolite with half-life of 194 hours.
Chlordiazepoxide	5	20–40	30	Metabolized to desmethyldiazepam and desmethylchlordiazepoxide, both active.
Prazepam	5	10–15	} See diazepam	These 3 prodrugs (precursors) are demethylated to desmethyldiazepam, the major active metabolite.
Clorazepate	3.75	7.5–30		
Halazepam	5	10–40		

<sup>a</sup>Geriatric dose.**TABLE 34–16.** Some neuropsychiatric side effects of benzodiazepines

Side effect	Manifestation(s)	Comments
Central nervous system depression	Sedation, paradoxical excitement, disinhibition, suspiciousness, agitation, aggression, wandering, ataxia, falls, delirium	Sedation persists up to 2 weeks after discontinuation of long-half-life benzodiazepines. Tolerance may develop with careful dosage increases. Long-acting benzodiazepines are most likely to produce falls, the most common cause of injury in elderly patients.
Cognitive dysfunction	Confusion, anterograde amnesia, dementia-like syndrome, aggravation of dementia	Rebound insomnia more common with triazolam and other very short half-life benzodiazepines; less common with alprazolam.
Psychomotor impairment	Impaired driving	Elderly neuropsychiatric patients more vulnerable to psychomotor impairment. Benzodiazepines implicated more frequently than alcohol or other medications in accidents involving elderly patients. Automobile accidents second most common cause of injury in elderly patients.
Electroencephalographic changes	Decreased alpha, increased low-voltage fast activity, especially in frontal regions	Depressed patients with increased REM density may develop nightmares or vivid dreams due to further increased REM by benzodiazepines.

Note. REM = rapid eye movement.

adds to anxiety autonomic symptoms and new CNS symptoms such as confusion, tremor, and myoclonus. Withdrawal symptoms may be even more delayed and prolonged in older patients who continue to take benzodiazepines or other CNS depressants intermittently. Withdrawal after a single dose of a benzodiazepine with a very short half-life such as triazolam and midazolam may produce rebound anxiety, confusion, and amnesia, especially in patients with brain disease (Regestein 1992; Salzman 1992).

**Special considerations.** Benzodiazepines are obvious choices for treatment of anxious patients with epilepsy, but many geriatric patients with dementia, cerebellar disease, or psychomotor impairment tolerate these drugs poorly. Benzodiazepines are often more effective for and better tolerated in neuroleptic-induced akathisia than are antiparkinsonian drugs.

Chronic use of benzodiazepines can aggravate existing cognitive deficits in patients with dementia and cause dementia in neurologically intact patients. The use of these and all CNS depressants should, therefore, be reviewed before diagnosis or treatment of primary dementia.

Withdrawal from benzodiazepines and other CNS depressants can produce a variety of neuropsychiatric syndromes (Table 34–17) that are easily mistaken for neurological illness in elderly patients. These syndromes often appear when a new physician becomes concerned about a patient's use of tranquilizers and discontinues them, when the patient runs out of medication, or when the medication is abruptly discontinued after admission to a hospital or other facility. The latter problem often develops because a patient does not consider use of the benzodiazepine important enough to report it to the physician or conceals use of the drug out of shame or fear of the physician's disapproval. The doctor then underestimates the patient's drug intake.

**TABLE 34–17. Manifestations of central nervous system depressant withdrawal**

Anxiety, panic, insomnia, agitation, restlessness, irritability
Hypersensitivity to light and noise
Headache, dizziness, diaphoresis
Myalgia, tremor, muscle twitching
Fever
Tinnitus, seasickness
Amnesia
Psychosis
Delirium
Seizures

Family members can be important sources of information about the patient's use of medications prescribed by other doctors or obtained over the counter. Toxicology screening is usually negative when an abstinence syndrome is present, but it may reveal unsuspected use of other substances.

Withdrawal from any combination of CNS depressants can be diagnosed with the barbiturate tolerance test (D. E. Smith and Wesson 1970); however, experience with this test in elderly patients has not been reported in the literature. Specific dosage guidelines have not been formally addressed in studies involving geriatric patients, but one recommendation would be that if phenobarbital is used, 45- to 60-mg doses should be taken on an empty stomach once signs of withdrawal appear. These doses should be repeated every 2–6 hours until intoxication begins to develop. Signs of withdrawal and/or intoxication (e.g., decreased level of consciousness, dysarthria, postural hypotension, hyperreflexia, hyporeflexia, and nystagmus) should be recorded before and 1 hour after each dose to determine the next dose. Once definite intoxication occurs, or when 300–500 mg of phenobarbital has been administered in a 24-hour period, the total amount is divided into four doses, given every 6 hours, and the phenobarbital is withdrawn by about 10% per day. Each specific dose is determined by the patient's overall course and the patient's response to the last dose. Phenobarbital often begins to accumulate after 4–8 days, and it may be necessary to withdraw the drug more rapidly at this point. A pentobarbital withdrawal protocol can also be used in elderly patients (Dubin et al. 1986), although seizures are more likely if an individual dose is missed.

**Interactions.** As indicated in Table 34–18, benzodiazepines have pharmacokinetic as well as pharmacodynamic interactions with medications in common use in neuropsychiatry (Salzman 1992).

**Alternatives to benzodiazepines.** The only currently available azapirone is buspirone, which is effective

**TABLE 34–18. Some benzodiazepine interactions**

Medication(s)	Interaction(s)
Central nervous system depressants	Increased sedation, confusion, amnesia, and psychomotor impairment
Opioids	Increased respiratory depression
Cimetidine	Increased benzodiazepine levels
Anticonvulsants, adrenal steroids	Decreased benzodiazepine levels

for generalized anxiety in older as well as younger patients (Salzman 1992). Because buspirone does not impair cognition or psychomotor function (Hart et al. 1991), it is preferable to benzodiazepines for treating anxiety in patients with dementia. However, buspirone is not effective when given intermittently. The use of buspirone to reduce agitation in patients with dementia is discussed in a later section.

Buspirone, gepirone, and ipsapirone have been shown to have primary antidepressant properties in younger patients, but the high doses that are necessary (40–90 mg/day) are difficult for many geriatric patients to tolerate. More moderate doses (e.g., 10–40 mg/day) may augment the antidepressant or antiobsessional effect of antidepressants, the only adverse reactions of concern being headache, nausea, dizziness, and mild serotonin syndrome when azapirones are combined with highly serotonergic antidepressants such as fluoxetine. Because buspirone inhibits presynaptic dopamine autoreceptors, it may enhance dopaminergic transmission and therefore could be useful for some parkinsonian patients. The same effect could produce abnormal movements, but there is no reason this drug should cause tardive dyskinesia, given that it does not block postsynaptic dopamine receptors.

TCAs, even if they are not sedating, have been found to be as effective as benzodiazepines in the treatment of generalized anxiety disorder; in many studies it was not clear whether patients might also have been depressed, but depression was excluded in at least one study (Hoehn-Saric et al. 1988). Because relatively high doses of benzodiazepines may be necessary to treat panic disorder, antidepressants other than bupropion are more appropriate choices for patients with panic disorder complicated by neurological syndromes who would be expected to be sensitive to benzodiazepine adverse effects and discontinuation syndromes. Venlafaxine and the SSRIs can be effective for generalized anxiety and are better tolerated by older patients than are benzodiazepines and TCAs. All other antidepressants except bupropion have also been noted to have anxiolytic properties.

Antihistamines (e.g., hydroxyzine or diphenhydramine, at a dose of 10–25 mg one to four times per day) are frequently used as anxiolytics or sleeping pills in elderly patients with dementia (Ahronheim 1992; Salzman 1992). However, the antianxiety effect is unpredictable, and tolerance to the sedative effect usually occurs rapidly. In addition, anticholinergic side effects aggravate memory loss. The most appropriate use of antihistamines in geriatric neuropsychiatry may be for sedating a patient for electroencephalography, because they have minimal effects on this measure.

## ■ Antipsychotic Drugs

Antipsychotic drugs are effective for all forms of psychosis. Well-established indications include schizophrenia, bipolar disorder, and psychotic unipolar depression. In low doses, antipsychotic drugs can be helpful in psychiatric syndromes commonly encountered in geriatric neuropsychiatry such as hallucinations and delusions caused by neurological factors, paraphrenia, and late-onset paranoia (Young and Meyers 1991). Pimozide with or without antidepressants has been found effective for monosymptomatic hypochondriacal delusions and delusions of parasitosis (Dagon 1990). The use of antipsychotic drugs to control agitation in patients with neurological illness is discussed later in this chapter.

### Neurological Uses

Antipsychotic drugs can be used to treat interictal psychoses (Dagon 1990), as can ECT (Dubovsky 1993). Low doses of most neuroleptics other than thioridazine can ameliorate nausea and vomiting caused by cancer chemotherapy, autonomic dysfunction, vestibular syndromes, and related conditions (Richelson 1985), although serotonin 5-HT<sub>3</sub> receptor antagonists such as ondansetron and granisetron are more effective and have fewer adverse effects (Dubovsky 1994). Low doses of chlorpromazine can stop intractable hiccups, and the phenothiazine trimiprazine, which does not have antipsychotic properties, is an antipruritic agent. Haloperidol and pimozide are often used to control chorea and other involuntary movements in Huntington's disease and Tourette syndrome. (The uses of neuroleptics in delirium and dementia are discussed later in this chapter.)

### Available Preparations

The older antipsychotic drugs are neuroleptics (from the Greek for “to clasp the neuron”) in that they control psychosis and produce neurological side effects. In neuropsychiatric practice, antipsychotic drugs do not differ in efficacy. Older patients with schizophrenia, like their younger counterparts, seem to respond better to lower than to higher neuroleptic doses (Weisbard et al. 1997). However, older patients with schizophrenia may have a different pattern of response to neuroleptics than younger patients, with more improvement of negative symptoms (Weisbard et al. 1997). Regardless of diagnosis, older patients with neurological illnesses have a greater risk of neurological side effects from neuroleptics. These adverse effects are less problematic with the newer atypical antipsychotic

medications such as clozapine, risperidone, olanzapine, quetiapine, and ziprasidone because 5-HT<sub>2</sub> receptor antagonism ameliorates the motor effects of dopamine, subtype 2 (D<sub>2</sub>), receptor blockade. Like younger patients, older patients tolerate the atypical antipsychotic drugs better and those patients with schizophrenia have greater improvement of negative symptoms with these drugs (Tamminga and Lahti 1996). Some characteristics of antipsychotic drugs as used in geriatric neuropsychiatry are summarized in Tables 34–19 and 34–20 (Ahronheim 1992; Lohr et al. 1992; Salzman 1990).

## Metabolism and Dosing

As with other lipid-soluble medications in elderly patients, the volume of distribution of neuroleptics is increased and metabolism is slowed, resulting in a longer time to reach steady state and prolonged therapeutic as well as toxic effects (Lohr et al. 1992; Wragg and Jeste 1988). Reduced dopaminergic transmission in elderly patients may contribute to the development of neurological and antipsychotic effects at lower blood levels (Lohr et al. 1992). Some low-potency neuroleptics (e.g., chlorpromazine and

**TABLE 34–19. Neuroleptic medications in use in the United States**

Medication (by class)	Starting dose <sup>a</sup>	Usual dosage <sup>a</sup>	Comments
<b>Phenothiazines</b>			
Chlorpromazine	10 mg	10–300 mg/day	Many active metabolites from complex hepatic and gastrointestinal metabolism. Hypotension prohibits parenteral use in elderly patients.
Thioridazine	10 mg	10–300 mg/day	Use in elderly patients limited by anticholinergic and cardiac side effects.
Triflupromazine	10 mg	10–75 mg/day	Moderate sedation, hypotension, and extrapyramidal side effects.
Acetophenazine	10 mg	10–100 mg/day	Moderate sedation, hypotension, and extrapyramidal side effects.
Mesoridazine	10 mg	10–200 mg/day	Thioridazine metabolite. May be useful in some treatment-resistant psychoses.
Perphenazine	2 mg	4–20 mg/day	Midrange in potency and side effects.
Trifluoperazine	1 mg	2–15 mg/day	More extrapyramidal side effects than with perphenazine
Fluphenazine	0.25 mg	0.5–6 mg/day	Most potent phenothiazine.
Fluphenazine decanoate and enanthate	0.25 ml	0.25–0.5 ml every 2–3 weeks	Erratic absorption due to decreased muscle mass in elderly individuals.
<b>Thioxanthenes</b>			
Thiothixene	1 mg	1–15 mg/day	Similar to trifluoperazine in potency and side effects.
Chlorprothixene	10 mg	10–100 mg/day	Similar to chlorpromazine in potency and side effects.
<b>Butyrophenones</b>			
Haloperidol	0.25 mg	0.25–8 mg/day	Intramuscular dose poorly tolerated by elderly patients.
<b>Diphenylbutyl-piperidines</b>			
Pimozide	0.25 mg	0.25–4 mg/day	Calcium channel and dopamine, subtype 2 (D <sub>2</sub> ), receptor blocking properties. Useful for atypical psychoses, but high incidence of cardiotoxicity.
<b>Dihydroindolones</b>			
Molindone	5 mg	10–100 mg/day	Not associated with weight gain or seizures.
<b>Dibenzoxazepines</b>			
Loxapine	10 mg	10–100 mg/day	Metabolized to amoxapine. May have special applications in psychotic depression and schizophrenia with secondary depression.

<sup>a</sup>Geriatric dose/dosage.

**TABLE 34-20. Atypical antipsychotic medications in use in the United States**

Medication	Starting dose (mg) <sup>a</sup>	Usual daily dose (mg) <sup>a</sup>	Comments
Clozapine	12.5	50–450	Sedation, salivation, and weight gain difficult to tolerate. Neuroleptic malignant syndrome occasionally reported.
Risperidone	1	2–6	Extrapyramidal side effects more common than with clozapine.
Quetiapine	25	50–100	Unclear risk of eye damage.
Olanzapine	0.5	5–15	Weight gain in 50% of patients

<sup>a</sup>Geriatric dose.

thioridazine) induce their own metabolism and have complex metabolic pathways with many active metabolites, making them problematic in older patients. Butyrophenones and thioxanthenes appear to have only inactive metabolites (Ko et al. 1985). In a few studies of patients with Alzheimer's disease, the effective plasma concentration of haloperidol to control agitation and psychosis was less than the 4–18 ng/mL range thought to represent the therapeutic range for schizophrenia, although most patients with Alzheimer's disease cannot tolerate higher levels (Devanand et al. 1992).

In acutely ill younger patients, intramuscular injection of neuroleptics avoids first-pass metabolism and increases bioavailability. However, this form of administration is usually too painful and absorption of drugs administered by this route is too unpredictable in older patients, who have decreased muscle mass (Lohr et al. 1992; Wragg and Jeste 1988). (Intravenous use of neuroleptics is discussed later in this chapter.)

### Neuropsychiatric Side Effects

Antipsychotic drugs are frequently prescribed for older patients with agitation or psychosis, but these patients are particularly vulnerable to neurological side effects, summarized in Table 34-21 (Ahronheim 1992; Almeida 1991; Lohr et al. 1992; Satlin et al. 1992; Wragg and Jeste 1988; Yassa et al. 1991; Young and Meyers 1991). Elderly patients with dementia are at increased risk for extrapyramidal side effects, possibly as a result of degenerative changes in nigrostriatal pathways, higher blood levels with a given dose, and longer duration of treatment with greater cumulative neuroleptic exposure (Young and Meyers 1991). Tremor, rigidity, and bradykinesia are more common side effects in older patients, whereas dystonia occurs less frequently than in younger patients (Young and Meyers 1991). Acute and chronic extrapyramidal side effects are less frequent with risperidone, olanzapine, quetiapine, and

zaprasidone and are almost unheard of with clozapine.

Tardive dyskinesia occurs in 20%–40% of elderly patients taking neuroleptics (Ereshefsky et al. 1989; Saltz et al. 1991; Yassa et al. 1991). The risk of tardive dyskinesia in older patients is higher in women and in patients with a history of acute extrapyramidal side effects, brain damage, longer neuroleptic exposure, mood disorder, medical illness, concurrent use of antiparkinsonian drugs, and drug holidays (Almeida 1991; Lohr et al. 1992). Tardive dyskinesia in elderly patients must be distinguished from oral movements due to loose dentures and from spontaneous dyskinesias, which occur in 0.22%–5% of elderly individuals who have not been exposed to neuroleptics (Green et al. 1993; Yassa et al. 1991), the higher prevalence occurring in patients with brain disease.

Whereas tardive dyskinesia eventually resolves after drug discontinuation in 80% of younger adults, remission after the neuroleptic is withdrawn occurs in only one-third to one-half of geriatric patients (Almeida 1991; Yassa et al. 1991; Young and Meyers 1991). The best strategy for dealing with tardive dyskinesia in older neurologically ill patients, therefore, is to reduce the risk of its occurrence. Useful approaches to achieving this goal include using the lowest possible dose and avoiding drug holidays, antiparkinsonian drugs, and rapid dose escalations (Wragg and Jeste 1988). Compared with traditional neuroleptics, the atypical antipsychotic drugs clozapine, risperidone, olanzapine, and quetiapine all have a lower incidence of extrapyramidal side effects and tardive dyskinesia in older as well as younger individuals (Casey 1997).

Several experimental treatments for tardive dyskinesia have been introduced, with variable success. Calcium channel blockers ameliorate dyskinetic movements in animals and humans but have not been studied extensively (Dubovsky 1986). Vitamin E has been thought to improve tardive dyskinesia in 21%–45% of patients in whom symptoms have been present for less than 5 years (Egan et al. 1992). However, in a 6-week double-blind, pla-

**TABLE 34–21. Some neuropsychiatric side effects of antipsychotic drugs**

Side effect	Manifestations	Comments
Central nervous system depression	Sedation, confusion, and memory impairment.	Tolerance may develop within 1–3 weeks if dose is increased slowly.
$\alpha$ -Adrenergic blockade	Orthostatic hypotension.  Priapism.	May produce falls, especially in patients with extrapyramidal side effects.  Especially with chlorpromazine and thioridazine. Not yet reported in elderly patients.
Akathisia	May be acute or tardive. Subjective report of restlessness may be impaired in elderly patients.	Most common neuroleptic-induced movement disorder. Treat with decreased neuroleptic dose or addition of $\beta$ -blocker or benzodiazepine.
Parkinsonism	Tremor, rigidity, bradykinesia, stiffness, shuffling gait, salivation, and loss of postural reflexes.	Occurs in 75% of elderly patients. May cause falls. Try to decrease dose before adding antiparkinsonian drug. Amantadine may produce less anticholinergic toxicity than other antiparkinsonian drugs.
Dystonia	Spasm of face, neck, and extraocular muscles. Less frequent in elderly than in younger patients. Not dose related in elderly patients.	Treat with lower neuroleptic dose, anticholinergic drug (e.g., benztropine 0.5–1 mg), or diphenhydramine 25 mg.
Pisa syndrome	Dystonic reaction in which body is flexed to one side.	Responds to same treatment as for dystonia.
Rabbit syndrome	Tardive orofacial dyskinesia with 5-Hz lip movements resembling rabbit chewing.	Responds to anticholinergic medications.
Tardive dyskinesia	Orofacial movements most common in elderly patients. Next in order of frequency are movements of feet, neck, shoulders, trunk, diaphragm, pharynx, and intercostal muscles. May be associated with cognitive impairment in elderly schizophrenic patients.	Acute extrapyramidal side effects may predict later tardive dyskinesia in geriatric patients. Tardive dyskinesia is more frequent and more persistent in elderly patients.
Catatonia	Waxy flexibility, catalepsy, negativism, mutism, staring, echolalia, and echopraxia.	Responds to withdrawal of neuroleptic and to amantadine or antiparkinsonian drugs.
Neuroleptic malignant syndrome	Extrapyramidal signs and dysfunction. Rigidity, dystonia, tremor, fever, tachycardia, unstable blood pressure, diaphoresis, increased serum creatine phosphokinase and white blood cell count, and myoglobinuria.	Has been reported in elderly as well as in younger patients.
Seizures	Spontaneous seizures or lowered seizure threshold.	Most frequent with clozapine, loxapine, and low-potency neuroleptics. Older patients more susceptible to seizures, especially patients with history of seizures, central nervous system disease, or recent electroconvulsive therapy.
Photosensitivity	Increased sensitivity of skin and eyes to sun. May persist for months after drug is discontinued.	May sensitize eyes to toxic effects of sun or bright light.
Pigmentary retinopathy	Irreversible pigment deposition in retina.	With daily doses of thioridazine of > 800 mg.
Syndrome of inappropriate secretion of antidiuretic hormone (SIADH)	Hyponatremia may produce confusion or seizures.	Water retention may be aggravated by additional direct effect of neuroleptic on kidney.
Hypothermia	Temperature dysregulation that does not progress to neuroleptic malignant syndrome.	Especially with clozapine and phenothiazines in hypothyroid patients.
Electrocardiographically demonstrated side effects	Electrocardiographic changes, sudden death rare.	Thioridazine and pimozide.

cebo-controlled study of the effects of 1,600 IU of vitamin E daily in 18 patients, one-third of whom were older than 53 years, meaningful improvement was found in only a few (Egan et al. 1992). Clozapine, which is technically not a neuroleptic, reduced tardive dyskinesia by 50% or more in 43% of cases, with the greatest efficacy occurring in tardive dystonia and severe tardive dyskinesia (Lieberman et al. 1991). This effect does not appear to represent temporary masking of tardive dyskinesia with eventual exacerbation of the syndrome, as occurs with neuroleptics.

Neuroleptic malignant syndrome, which has been reported in 0.5%–1.0% of patients taking neuroleptics (Guze and Baxter 1985), has been associated most frequently with high-potency neuroleptics but has also been reported with low-potency neuroleptics, clozapine, metoclopramide, carbidopa-levodopa, and withdrawal of amantadine and carbidopa-levodopa (Mueller 1985; Pelonero et al. 1985). Older patients seem to be somewhat less vulnerable to neuroleptic malignant syndrome, but the risk is increased in the elderly population by brain damage, other forms of neurological disease, and debilitation (Mueller 1985). Waiting more than 2 weeks before re-administering neuroleptics after an episode of neuroleptic malignant syndrome, using low doses of low-potency neuroleptics of a different class, and carefully monitoring vital signs, mental status, and extrapyramidal side effects may decrease the risk of another episode of neuroleptic malignant syndrome (Rosebush and Stewart 1989).

Although neuroleptic malignant syndrome can occur with clozapine, it is much less frequent than it is with neuroleptics (Kane et al. 1988). However, clozapine is difficult to administer to elderly patients with neuropsychiatric illness for several reasons. The risk of agranulocytosis may increase with age, especially in Ashkenazi Jews (Gelenberg 1992). In addition, sedation, orthostatic hypotension, hypersalivation, hyperthermia, and akathisia are common side effects (Wilson 1992). The manufacturer-reported incidence of seizures with clozapine is 1%–2% at doses less than 300 mg/day and 4%–6% at doses of 300–600 mg/day. The manufacturer has reported 9 (incidence of 1 in 3,000 patients) nonfatal cases of respiratory or cardiac arrest with clozapine, in some instances in patients who were also taking benzodiazepines. Slower dose titration of clozapine is associated with better long-term results (Chengappa et al. 1995).

### Special Considerations

Treatment with neuroleptics of behavioral problems associated with delirium and dementia are considered in later sections of this chapter (see also Chapters 19, 23, and 24).

Clozapine, loxapine, and low-potency neuroleptics should not be administered to patients with seizure disorders; haloperidol and molindone may be safer for such patients (Fenwick 1989). Because dopamine blockade by neuroleptics increases prolactin levels, great caution is necessary when these medications are administered to patients with prolactin-secreting pituitary tumors or, possibly, a history of breast cancer. Prolactinemia occurs more frequently with risperidone than with olanzapine.

Agitation and psychosis in patients with Parkinson's disease may be related to dementia or to toxicity of dopaminergic drugs (see also Chapter 26). If changing the medication does not relieve psychosis, administering clozapine at dosages of 6.25–275 mg/day can be effective (Bajulaize and Addonizio 1992; Lohr et al. 1992), even if dopamine agonists are continued (Wolk and Douglas 1992). Patients with Parkinson's disease tolerate neuroleptics poorly, but atypical antipsychotic drugs are sometimes useful. ECT may improve the neurological illness as well as the psychosis (Dubovsky 1993) (see also Chapter 35).

### Interactions

Antipsychotic agents interact with many neurological and cardiovascular drugs. Some examples are listed in Table 34–22 (Ayd 1986; Bailey et al. 1992; Dagon 1990; Kahn et al. 1990; D. D. Miller 1991; Rizos et al. 1988; Sargenti et al. 1988; Sassim and Grohmann 1988).

### Alternatives to Antipsychotic Drugs

In neurologically ill patients with catatonia; mania; depression; schizoaffective, schizophreniform, or some schizophrenic psychoses (Van Valkenberg and Clayton 1983); or delirium (Dubovsky 1993), ECT can be more rapidly effective and better tolerated than neuroleptics (see also Chapter 35). When neuroleptics are necessary, benzodiazepines, reserpine, baclofen, or droperidol may augment the antiagitation (but not the antipsychotic) effect, reducing the amount of neuroleptic needed for behavioral control (Bodkin 1990; Richelson 1985). Benzodiazepines alone may ameliorate catatonia (Fricchione 1989).

### ■ Treatment of Insomnia

Complaints of disturbed sleep are more common in elderly patients than in younger patients (Spiegel 1990). Some complaints reflect diminished efficiency and more frequent interruptions of sleep (see also Chapter 17). A Dutch

**TABLE 34–22. Some antipsychotic drug interactions**

Medication(s)	Interaction(s)
Central nervous system depressants	Increased sedation, confusion, falls
Guanethidine	Decreased antihypertensive effect
Lithium	Increased extrapyramidal side effects
Anticholinergic antiparkinsonian drugs, cimetidine, antacids	Decreased neuroleptic levels caused by inhibition of gastrointestinal absorption
Anticonvulsants	Decreased neuroleptic levels caused by increased metabolism
Tricyclic antidepressants	Increased levels of both; clinically significant only for tricyclic antidepressant
Levodopa	Decreased antiparkinsonian effect due to dopamine receptor blockade
Propranolol	Increased levels of both classes
Benzodiazepines	Physical collapse with clozapine
Carbamazepine	Increased risk of fatal bone marrow suppression with clozapine

study of 1,485 elderly individuals (Middelkoop et al. 1996) found that women had more trouble getting to sleep, had more interrupted sleep, and used sedative-hypnotics more frequently, whereas men complained of more daytime sleepiness. Worrying and nocturia were the most common causes of insomnia in this study. In other cases, neurological or medical disorders disrupt sleep (Regestein 1992; Salzman 1992; Spiegel 1990). Dementia and delirium are associated with reversal or fragmentation of the sleep-wake cycle, more awakenings, and decreased total, stage 4, and REM sleep. These changes are aggravated by sleeping pills and other CNS depressants but may be corrected by entrainment to normal light-dark cycles. Alzheimer's disease is associated with reversal of the sleep-wake cycle, and residence in long-term care facilities increases the risk of disordered sleep in older patients (Gottlieb 1990). Grief, depression, and anxiety are common causes of disturbed sleep in elderly patients that respond to specific therapies. Medical and neurological causes of insomnia in elderly patients include dementia with sundowning, chronic pain, nocturnal myoclonus, restless legs syndrome, sleep apnea, and gastroesophageal reflux. Many psychoactive substances

used by geriatric patients can produce insomnia (Table 34–23).

Although geriatric patients often request a drug for insomnia, frequently the best approach is to stop medications the patient is already taking, especially sleeping pills. Up to one-third of elderly people and 20%–40% of patients in intermediate care facilities take benzodiazepine sleeping pills regularly. However, these drugs lose their effectiveness after 20–30 days, after which time they are taken to prevent withdrawal insomnia. Sleep architecture may remain abnormal for some time after the hypnotic is withdrawn.

The initial approach to geriatric insomnia should include discontinuing substances such as caffeine and alcohol that disrupt sleep and treating illnesses that cause insomnia. Patients should improve sleep hygiene through such measures as increasing daytime activity, arising at the same time each morning, keeping the room at a comfortable temperature, setting aside a time to review the day's activities before getting into bed, and not spending time in bed when not asleep.

When these measures are not effective, a hypnotic medication may be appropriate. Benzodiazepine sleeping pills are best used for time-limited insomnia in reaction to identifiable stress; when these medications are to be given chronically, intermittent dosing may prolong their effectiveness. Short-half-life benzodiazepines (Table 34–24) (Greenblatt et al. 1991; Johnson et al. 1990; Regestein 1992; Salzman 1990; Spiegel 1990) do not accumulate in elderly patients, but they may produce early-morning awakening and rebound insomnia when used for more than 1–2 weeks. Longer-half-life preparations are more likely to produce daytime sedation and psychomotor impairment (Dubovsky 1993). In the standard geriatric dose (0.125 mg) triazolam does not appear to aggravate memory loss in patients with Alzheimer's disease, but it also seems not to be effective for disrupted sleep in these patients (McCarten et al. 1995).

Quazepam, a new hypnotic that is selective for the

**TABLE 34–23. Substances that cause sleep disturbances in elderly individuals**

Caffeine (stimulant effect lasts 12–20 hours)
Nicotine
Alcohol
Activating antidepressants
Diuretics
Antiarrhythmics
β-Blockers
Chronic use of sleeping pills

**TABLE 34-24. Benzodiazepine hypnotics**

Medication	Dose (mg)	Half-life (hours)	Comments
Triazolam	0.125 <sup>a</sup>	2–5	Clearance reduced in elderly. Even lowest dose may produce next-day anxiety, agitation, anterograde amnesia, irritability, and insomnia.
Midazolam	5–15	1–3	Minimal psychomotor impairment.
Temazepam	10–30	10–20	Higher doses occasionally helpful for some treatment-resistant patients. Peak plasma levels occur 1 hour after ingestion.
Flurazepam	15	100–200	Not recommended for elderly patients because of accumulation and central nervous system depression.
Quazepam	7.5–15	Not studied in elderly patients	Parent drug is selective for benzodiazepine type 1 receptor but desalkylflurazepam metabolite is nonselective and has long half-life.
Estazolam	0.5–1	Not studied in elderly patients	Similar to other high-potency benzodiazepines (e.g., triazolam).
Zolpidem	5–10	3–6	Nonbenzodiazepine structure but acts on benzodiazepine type 1 receptor. Less cognitive impairment than with benzodiazepines.

<sup>a</sup>This dose effective in older but not younger adults.

benzodiazepine type 1 receptor, should not produce as much daytime sedation, as much impairment of memory and psychomotor function (attributed in part to benzodiazepine type 2 receptors), or as many withdrawal syndromes (attributed in part to peripheral-type benzodiazepine receptors) as nonselective benzodiazepines. However, quazepam is metabolized to desalkylflurazepam, a nonselective flurazepam metabolite that accumulates with chronic treatment. Zolpidem, a benzodiazepine type 1 receptor selective agonist sleeping pill, has not yet been found to have a nonselective metabolite that might complicate continued treatment. In a study of zolpidem in geriatric insomnia, 5- and 10-mg doses were found to be equally effective, and both doses were as effective as 0.25 mg of triazolam (Roger et al. 1993). Given that confusion occurred only in patients taking triazolam and additional experience supports the finding of a lack of cognitive impairment with zolpidem (Scharf et al. 1991), zolpidem may be the first choice among medications acting on benzodiazepine receptors for geriatric insomnia.

Of the available alternatives to benzodiazepines for the treatment of insomnia in geriatric neuropsychiatry (Regestein 1992; Spiegel 1990; Salzman 1990), sedating antidepressants (e.g., trazodone or nefazodone, in doses of 25–75 mg) are most reliable, even in patients who are not depressed. However, these drugs may cause daytime hangover and sedation in older patients with neuropsychiatric illness. Antihistamines (e.g., diphenhydramine, in doses of 25–50 mg) can be useful sedatives in patients with pruritis, but in patients with brain disease, they may produce both-

ersome anticholinergic side effects and daytime sedation that increase impairment of memory and psychomotor performance. Aspirin at dosages of 325–650 mg/day can have mild hypnotic effects in some patients and may counteract sleep disruption caused by adrenal steroids and bronchodilators. In contrast, over-the-counter sleeping pills, which are frequently used by elderly patients, are not particularly effective and cause daytime sedation and have anticholinergic effects (Balter and Uhlenhuth 1991).

## ■ Treatment of Delirium

Agitation due to delirium in elderly patients requires urgent intervention when the patient is at risk of injury, dehydration, cardiovascular collapse, or gross noncompliance with essential medical therapy (see also Chapter 19). Emergency pharmacotherapy in such situations has never been the subject of controlled studies, but clinical experience has accumulated with a number of intravenous medications, particularly haloperidol, benzodiazepines, and droperidol. As discussed in Chapter 35, one to four ECT treatments can rapidly ameliorate delirium of virtually any etiology (Dubovsky 1995). The barbiturate tolerance test discussed earlier should be considered before any other treatment when delirium could be the result of withdrawal from CNS depressants.

Intravenous haloperidol can be useful for treating severe agitation in delirium patients. Therapy is started with a 1- to 5-mg dose. For patients of mixed ages on a coronary

care unit, Tesar et al. (1985) recommended increasing haloperidol doses rapidly to 30–75 mg and administering them as frequently as necessary to control agitation. In patients who are unresponsive to repeated intravenous doses of haloperidol, an intravenous haloperidol drip at 5–25 mg/hour may be effective (Fernandez et al. 1988). Although extrapyramidal side effects are common with intramuscular administration of haloperidol, they are relatively rare with the intravenous route (Fernandez et al. 1988).

In their work with delirium patients with metastatic cancer of the brain, many of whom were elderly, Adams et al. (1986) first administered 3 mg of intravenous haloperidol and then followed with 0.5–1.0 mg of lorazepam. If the patient did not improve within 20 minutes, 5–10 mg of haloperidol was combined with or followed by 2–10 mg of lorazepam; individual doses of haloperidol did not exceed 10 mg. When pain was believed to contribute to delirium, Fernandez et al. (1988) added 0.5–4.0 mg of hydro-morphone to each dose of the other intravenous medications. Patients unresponsive to other treatments have had amobarbital added to intravenous haloperidol and lorazepam, surprisingly without disinhibition or respiratory suppression (Adams et al. 1986). Hypercortisolemia, hypoxemia, and hypothyroidism may contribute to resistance to intravenous haloperidol or lorazepam (Adams et al. 1986).

According to these investigators, one of these regimens usually ameliorates severe agitation within 90 minutes. Many patients need no further treatment, whereas some require additional intravenous or oral doses of 5–10 mg of haloperidol, possibly augmented with 0.5 mg of lorazepam (Adams 1988; Fernandez et al. 1988). The longest reported duration of intravenous therapy was 3 months, in a terminally ill patient with an intractable behavioral disorder.

Through a survey of British practitioners, Pilowsky et al. (1992) found that initial intravenous doses of 10–60 mg of haloperidol per day or 10–80 mg of diazepam per day, followed by 20–40 mg of haloperidol and/or 10–40 mg of diazepam, respectively, were used most frequently for uncontrollable agitation in neurological and primary psychiatric illness. Intravenous droperidol, a butyrophenone used as an anesthetic, has also been found to be an effective antiagitation agent in delirium (Pilowsky et al. 1992; Szuba et al. 1992). Droperidol, which is associated with an 8% incidence of extrapyramidal side effects in emergency dosing, has higher potency, more rapid onset of action, and a shorter half-life than does haloperidol (Szuba et al. 1992). In an average dose of 7 mg, droperidol is equally effective intramuscularly with an equally low incidence of extrapyramidal syndromes, making it an appealing choice for patients who are so agitated or have such fragile veins

that intravenous dosing is not practical.

The tranquilizing effect of midazolam, a lipophilic high-potency benzodiazepine, occurs quickly with intravenous doses of 5–15 mg, and rapid elimination prevents accumulation and excessive sedation (Bond et al. 1989). Intravenous midazolam controls violent and self-destructive behavior in mentally retarded younger patients (Bond et al. 1989) (see also Chapter 21) but has not been studied in the geriatric population. Amnesia after a single intravenous dose is common, but this is not an issue for delirious patients.

## ■ Treatment of Lethal Catatonia

ECT is the treatment of choice for lethal catatonia, an unusual syndrome of catatonia, neurological signs, and fever (Mann et al. 1986) (see also Chapter 35). Intravenous dantrolene was helpful for two elderly patients taking imipramine or diazepam who developed catatonia, leukocytosis, and fever (Pennati et al. 1991). Because of the possible relationship of lethal catatonia to extrapyramidal syndromes, neuroleptics should not be administered.

## ■ Treatment of Problem Behaviors in Dementia Patients

*Agitation* is a nonspecific term for a group of disruptive behaviors that range from verbal perseveration, yelling, cursing, biting, and screaming to wandering, pacing, disinhibition, sexually inappropriate behavior, property destruction, and unpredictable attacks on self and others (Lantz and Marin 1996) (see also Chapter 22). The incidence of agitation in elderly residents of nursing homes and among patients with Alzheimer's disease ranges from 32% to 85% (Chandler and Chandler 1998; Yudofsky et al. 1997). More than half of a community sample of patients with dementia were verbally disruptive, and 45% were physically aggressive (Cohen-Mansfield 1989). The onset of agitation frequently leads to nursing home admission (Cohen-Mansfield 1995).

OBRA mandated that specific target behaviors be documented when neuroleptics are used for agitation in elderly patients (Yeager 1995). These behaviors must be dangerous or functionally impairing if they are to be treated pharmacologically, and attempts should be made at least every 6 months to taper medications unless there are compelling clinical reasons not to attempt drug withdrawal. Documenting agitation and its response to treatment can be difficult because agitation is often intermittent and sub-

ject to numerous environmental variables (Cohen-Mansfield 1995; Cohen-Mansfield et al. 1992). Obtaining 1-month baseline scores on an agitation scale (Overt Agitation Scale; Yudofsky et al. 1997) and then quantitatively tracking response over time permits clinicians to determine whether there is any measurable correlation of symptoms with intervention (Mulsant et al. 1997). The Overt Agitation Severity Scale is a reliable and valid instrument that can be easily and effectively used over a 15-minute observation period (Yudofsky et al. 1997). Some clinicians prefer individualized instruments using target symptoms developed in concert with staff members or family members who will be applying the ratings. However, global scores are less accurate than specific behavioral ratings in estimating the benefits of an intervention (Mulsant et al. 1997).

Before instituting drug therapy for agitation, it is important to address physiological, environmental, and psychiatric factors (Malone et al. 1993) that may cause or contribute to agitation (Table 34–25). It is particularly important to withdraw medications that may be disinhibiting, especially benzodiazepines. In addition to aggravating confusion, these medications cause hypotension, falls, and withdrawal syndromes and are poor choices as treatments for agitation in elderly patients (Mustard and Mayer 1997; “Practice Guideline” 1997). Useful behavioral interventions include keeping a clock and calendar in the room; providing a predictable routine; regular reorientation of the patient; encouraging concrete, repetitive conversations; reducing complex tasks like bathing to a series of steps; not confronting memory lapses and delusions; and installing locks that are difficult to operate, so that wandering is reduced. An ingenious approach was used with one patient who kept pulling fire alarms in her nursing home, apparently responding to the word *PULL* printed on the switches in bold type. Putting signs that said “Not You, Gladys!” on all alarms stopped this behavior (L. Robbins, personal communication, February 1998).

### Neuroleptics

Molchan and Little (1995) reviewed 24 studies involving 2,200 patients with dementia and found that delusions were present in 11%–73% of patients, hallucinations occurred in 3%–67%, misidentifications of persons or places occurred in 5%–30%, and unspecified psychotic features were present in 5%–50%. However, psychosis is an uncommon cause of aggressive behavior in this population (Deutsch and Bylsma 1991). Most of the time, nonspecific sedative effects of antipsychotic drugs result in, at best, a modest and transient reduction in agitation and aggression

in patients with dementia who do not have a comorbid primary psychosis (Risse and Barnes 1986; Schneider and Sobin 1992).

In a review of 20 controlled studies of neuroleptics that included a total of 1,207 patients with dementia, Sunderland and Silver (1998) found that 60% of patients had positive short-term clinical outcomes; no neuroleptic appeared more efficacious than any other. However, after conducting a meta-analysis of all double-blind, placebo-controlled, parallel-group studies of neuroleptics in dementia from 1960 to 1982, Schneider and Pollock (1990) concluded that the benefit from neuroleptics was only 18% greater than that from placebo. In more recent double-blind comparisons in agitated patients with dementia, improvement with haloperidol, the most frequently ad-

**TABLE 34–25. Common causes of agitation in patients with dementia**

---

#### Medications

- Sedative-hypnotics
- Anxiolytics
- Antihistamines
- Antibiotics
- Antihypertensives
- Any medication, including aspirin

#### Intercurrent medical disorders

- Sleep deprivation
- Delirium
- Urinary tract infection
- Pneumonia
- Hypoxemia
- Sleep apnea
- Subdural hematoma
- Chronic pain

#### Intercurrent psychiatric disorders

- Major depression
- Bipolar disorder
- Panic disorder
- Psychotic disorders
- Accentuation of maladaptive character traits

#### Environmental factors

- Change of surroundings or roommate
  - Power struggles with family or staff
  - Frustration (catastrophic reaction)
  - Change of staff or personnel
  - Overstimulating or understimulating environment
  - Abuse by caretakers
-

ministered neuroleptic, was no greater than with oxazepam, diphenhydramine, or trazodone (Coccaro et al. 1990; Sultzer et al. 1997). Such results suggest that any benefit from neuroleptics may be attributable to nonspecific sedating and tranquilizing actions. In addition, the best results with neuroleptics have been obtained in shorter studies (R. Levy 1996), which conclude before there has been a chance for tolerance to the sedative effect to develop. In the long term, neuroleptics do not even influence the course of psychotic symptoms in patients with dementia, probably because such symptoms fluctuate spontaneously over time (Ballard and O'Brien 1997). Further, more than 20% of neuroleptic-treated dementia patients exhibit increased confusion and motor symptoms (Goldstein and Birnbom 1976; G. R. Smith et al. 1974).

The risk of tardive dyskinesia is five to six times greater in older individuals with dementia than in younger dementia patients (Jeste et al. 1996). In addition, neuroleptics may have adverse effects on cognitive function. In a prospective 2-year study of 71 patients with dementia, the mean decrease in cognitive scores was twice as great among the 16 patients who took neuroleptics as it was among patients not treated with these drugs ( $P = .002$ ), and the rate of cognitive decline increased after neuroleptic therapy was begun (McShane et al. 1997). Cortical Lewy bodies on autopsy did not explain the differences between neuroleptic-treated and non-neuroleptic-treated patients. Although another autopsy study showed no correlation between neuroleptic use in 7 schizophrenic patients and the development of Alzheimer's pathology (Niizato and Ikeda 1996), additional clinical experience has reinforced the impression that neuroleptics can impair cognition as well as motor function (Ahronheim 1992; Risse and Barnes 1986; Wragg and Jeste 1988). Even if neuroleptics do not hasten cognitive deterioration, the risks of chronic neuroleptic therapy outweigh the benefits for most patients with dementia without comorbid primary psychotic illnesses.

Is it possible to withdraw neuroleptics in some patients as OBRA mandates and scientific data warrant? In a double-blind study of 22 patients with dementia, neuroleptic withdrawal was possible without any significant increase in aggression (Bridges-Parlet et al. 1997). Werner et al. (1994) performed a retrospective review of psychotropic medication use in 88 nursing home residents ages 66–102 years whose physical restraints were removed. These investigators found that neuroleptic use decreased, probably as a result of closer observation and interaction with the patients. Agitation has been shown to decrease and cognitive function to increase in nursing home patients in whom neuroleptic therapy was discontinued after educational interventions with the staff (Rovner et al. 1996).

## Atypical Antipsychotic Drugs

Unlike the typical neuroleptics, atypical antipsychotic drugs with serotonin 5-HT<sub>2</sub> receptor antagonist properties have a specific antiaggressive effect that can be useful in patients with dementia, even if they are not psychotic (Dubovsky 1994). A lower incidence of extrapyramidal side effects makes these medications better tolerated by psychotic or agitated patients with Parkinson's disease because they are not as likely to cause extrapyramidal side effects. Because patients with parkinsonism and hallucinations have lower Mini-Mental State Exam (MMSE) scores and are more likely to require nursing home placement (Klein et al. 1997), finding a medication to manage agitation in these patients is a common and important challenge.

Risperidone is the best studied of the atypical antipsychotic drugs in elderly patients. Of 26 elderly patients without dementia (mean age, 70.4 years), 24 of whom had psychotic disorders and two of whom had bipolar disorder, 77% had moderate or marked improvement with a mean risperidone dose of 3.8 mg/day (Sajatovic et al. 1996). Extrapyramidal side effects occurred in only 4 patients. In a review of the use of risperidone in 122 hospitalized elderly patients, 53% of whom were treated for agitation or psychosis associated with dementia, Zarate et al. (1997) found the mean dose to be 1.6 mg/day. The drug appeared to be effective in 85% of cases. Patients undergoing rapid dose increases were more likely to discontinue risperidone because of adverse effects. Although 11% of patients developed extrapyramidal side effects with risperidone, 40% of patients experiencing preexisting extrapyramidal side effects with other neuroleptics were able to discontinue their use of antiparkinsonian agents after risperidone therapy was started.

In other case series, dosages of risperidone have ranged from 0.5 to 6 mg/day, for treatment of various forms of agitation, aggression, and screaming in patients with dementia due to Alzheimer's disease, cerebrovascular disease, and Lewy body dementia (Goldberg and Goldberg 1997; Herrmann et al. 1997; Jeanblanc and Davis 1995; Kopala and Honer 1997; Madhusoodanan et al. 1995; Raheja et al. 1995). In a double-blind, placebo-controlled trial of risperidone (Marder 1998), 625 dementia patients with Alzheimer's disease, vascular dementia, or mixed dementia were randomized to treatment with risperidone (0.5, 1, or 2 mg/day) or placebo (at the same dosages) for 12 weeks. Patients receiving 1 or 2 mg of risperidone per day showed significant improvement in psychosis as well as in severity and frequency of aggressive behaviors. Side effects were no more frequent than with the 1-mg dose of placebo but were significantly more frequent than with placebo at the 2-mg

dose. Although risperidone is more expensive than conventional neuroleptics per dose, decreased hospital costs may make it a cost-effective treatment, at least in the treatment of schizophrenia (Aronson 1997).

It has been suggested that olanzapine, whose side effect profile is similar to that of risperidone, will be equally well tolerated and effective in patients with dementia or parkinsonism (Fava 1997; Glazer 1997). Although there are no published controlled studies of olanzapine in psychotic or agitated patients with dementia or Parkinson's disease, clinical experience suggests that this medication may be a reasonable alternative to risperidone in such patients. An advantage of olanzapine is that it has few interactions with other medications often prescribed for elderly patients (Ereshefsky 1996).

Despite the increased risk of confusion and orthostatic hypotension in elderly patients (Lake et al. 1997; Thorpe 1997), clozapine has been found to be useful for older patients with psychosis (Frankenburg and Kalunian 1994) or mania (R. W. Shulman et al. 1997). Patients ages 55–64 years may have a greater likelihood of benefit than patients 65 and over (Sajatovic et al. 1997). Clozapine at dosages of 6.25–75 mg/day has also been found to be effective in a number of patients with dementia or Parkinson's disease without increasing movement disorders (Pitner et al. 1995; Valldeoriola et al. 1997). In a prospective open-label study of 12 patients with psychosis associated with Parkinson's disease, Chacko et al. (1995) found significant improvement in psychosis and behavior in all patients and sustained improvement in 10 patients. Probably as a result of slow dose titration, clozapine was well tolerated in this study. In another prospective open trial of clozapine (Factor et al. 1994), involving administration to 17 patients with Parkinson's disease and psychosis at dosages ranging from 6.25 mg every other day to 150 mg/day, marked improvement of psychosis was observed during the first year, without any increase in the severity of the movement disorder. Improvement was not statistically significant during the second year of treatment, possibly because the benefits of clozapine were obscured by the effects of increasing doses of levodopa and by progression of dementia, part of the natural course of the illness. Agitated patients with dementia or parkinsonism and prominent psychosis or aggression that has proven nonresponsive to other interventions are appropriate candidates for treatment with clozapine (Salzman 1996).

### Anticonvulsants

Anticonvulsants may be particularly useful in patients with dementia and comorbid mood disorders or with EEGs

showing abnormalities (Fava 1997). Tariot et al. (1994) studied 17 patients with Alzheimer's disease and 8 patients with vascular dementia in a double-blind crossover study consisting of two 5-week periods of treatment with carbamazepine or placebo, each period separated by a 2-week washout interval. The mean carbamazepine dose was 300 mg/day, with a mean serum level of 5.7 g/mL. The condition of 16 patients taking carbamazepine was considered to have improved, compared with the condition of 4 patients in the placebo group. Carbamazepine was generally well tolerated. Encouraged by their initial trial, Tariot and colleagues (1998) performed a 6-week multisite, randomized, placebo-controlled, double-blind, parallel-group trial involving 51 nursing home patients with agitation and dementia and using similar carbamazepine doses. The study was terminated after a planned interim analysis showed that carbamazepine was more beneficial than placebo (agitation and aggression were reduced in 77% of patients taking carbamazepine and 21% of those taking placebo). Although it is often well tolerated and effective, carbamazepine has the potential for interactions with many of the medications often taken by older patients.

Narayan and Nelson (1997) performed a retrospective chart review and reported that 56% of 25 agitated patients with dementia had improvement of behavioral disturbances with divalproex alone or in addition to neuroleptics (mean divalproex level, 1,650 mg/day). Only 1 patient had an increase in confusion. In a prospective open trial (Mellow et al. 1993), 50 of 88 patients had at least a partial response and 40 patients had moderate to marked benefit. Dosages ranged from 375 to 2,500 mg/day, and side effects were minimal. Although it may help patients sleep, valproate therapy in elderly patients has been associated with oversedation, parkinsonism, and reversible dementia (Walstra et al. 1997). No case series have been reported in which agitated patients with dementia were treated with gabapentin or lamotrigine. Although these new anti-convulsants may prove useful for some patients, experience with younger patients with brain damage suggests that these medications may be overstimulating in older patients with dementia, resulting in aggression (Anderson et al. 1996; Beran and Gibson 1998).

### Antidepressants

In reviewing eight case reports and open trials, Tariot et al. (1997) found that 75–400 mg of trazodone per day improved agitation and aggression in 42 of 56 patients with dementia (44 with Alzheimer's disease and 12 with other causes of dementia). Sultzer et al. (1997) found trazodone to be as effective overall as haloperidol in 28 agitated pa-

tients with dementia. Trazodone caused sedation and balance problems in two patients but was better tolerated than haloperidol. In a placebo-controlled, double-blind trial comparing buspirone at dosages of 30 mg/day with trazodone dosages of 150 mg/day for 4 weeks in 10 patients with Alzheimer's disease, Lawlor et al. (1994) found that trazodone produced greater reductions in agitation, psychosis, and hostility. Experience with trazodone as a hypnotic suggests that it would be an appropriate treatment for agitated patients with dementia and disrupted sleep (Devanand 1997). Nefazodone, whose combined serotonin reuptake and 5-HT<sub>2</sub> antagonist properties might suggest the potential to reduce agitation and psychosis, has not been studied for these indications. Nefazodone shares with trazodone a metabolite that may reduce agitation in some patients with dementia (Lawlor et al. 1991).

Substances that enhance serotonergic transmission dampen unpredictable, impulsive aggressive behaviors of the kind that occur in patients with dementia (Dubovsky 1994). In relatively low doses, SSRIs in open trials have reduced stereotypical and aggressive behavior in elderly patients with dementia (Trappler and Vinuela 1997). Fluoxetine, sertraline, and paroxetine were found to reduce disinhibition, compulsive behavior, and depressive symptoms in patients with frontotemporal dementia (Swartz et al. 1997). Additional case series and open trials have demonstrated improvement in agitation with all available SSRIs, although well-controlled studies are lacking (Flint 1994; Herrmann and Lanctot 1997; Karlsson 1996; Lebert et al. 1994; Omar et al. 1995; Schneider and Sobin 1992). Drug interactions are important considerations. Metabolism of tacrine, which is primarily by cytochrome P450 1A2, may be increased substantially by fluvoxamine, which inhibits 1A2 (Becquemont et al. 1997). On the other hand, levels of donepezil, which is metabolized by cytochrome P450 2D6 and 3A4, may be increased by fluoxetine, paroxetine, and nefazodone.

Selegiline (L-deprenyl), an MAOI with antioxidant properties that may slow cognitive deterioration, has been noted to reduce agitation in some patients with dementia. However, other antidepressants are better tolerated and easier to administer to agitated patients.

## Buspirone

In two open trials, 15–60 mg of buspirone per day significantly improved agitation in 10 of 26 patients with mixed dementias (Herrmann and Eryavec 1993). In a blinded trial comparing 15 mg of buspirone per day with 1.5 mg of haloperidol per day in 26 nursing home patients with Alzheimer's disease, both groups improved, but a greater reduction

of tension and anxiety occurred in the buspirone-treated patients (Cantillon et al. 1996). After a 1-week placebo wash-out interval, 2 weeks of treatment with 30 mg of buspirone per day improved delusions and anxiety as well as agitation in 12 patients with Alzheimer's disease (M. A. Levy et al. 1994). In an open study of 10 Alzheimer's disease patients (Sakauye et al. 1993), reduction of agitation began at a dose of 35 mg of buspirone per day and was maximal at a dose of 60 mg. Buspirone is well tolerated by patients with dementia (Markovitz 1993; Zayas and Grossberg 1996), although patients and their caretakers may find it difficult to keep track of the large number of pills necessary at higher doses.

## β-Adrenergic Blocking Agents

In double-blind and open studies, propranolol at dosages of 10–600 mg/day has been shown to be effective in reducing pacing, assaultiveness, and agitation in elderly patients with dementia (Lohr et al. 1992; Salzman 1990; Schneider and Sobin 1992; Shankle et al. 1995; Weiler et al. 1988). Pindolol and nadolol also reduced impulsivity and assaultiveness in double-blind studies of patients with dementia (Schneider and Sobin 1992). Improvement with β-blockers may occur with 1–2 weeks but can be delayed 4–6 weeks (Risse and Barnes 1986; Silver and Yudofsky 1985). Elderly patients who do not have high levels of vagal tone may tolerate these medications without excessive cardiac slowing, but congestive heart failure, heart block, sinus bradycardia, insulin-dependent diabetes mellitus, asthma, and chronic obstructive pulmonary disease are contraindications (Lohr et al. 1992; Risse and Barnes 1986; Salzman 1990). High doses of β-blockers may cause hallucinations and depression and may aggravate aggression (Parker 1985; Schneider and Sobin 1992). A dementia syndrome may also occur (Fisher 1992). β-Blockers increase blood levels of neuroleptics and anticonvulsants.

## Other Treatments

Some of the behavioral disturbances seen in patients with dementia are associated with fragmentation of sleep-wake and activity cycles (see also Chapter 17). In an innovative study of 22 patients with severe dementia (Van Someren 1997), exposure to bright ambient light (1,136 lux) but not dim light over the course of the day decreased daytime hyperactivity and nighttime wandering in patients without visual impairment. Briefer exposure to morning light of the intensity used to treat seasonal affective disorder (2,500–10,000 lux) might be even more effective in normalizing circadian rhythms and behavioral disorganization in dementia patients.

It appears, based on anecdotal reports, that stimulants sometimes reduce agitation in dementia patients, possibly as a result of paradoxical sedation (Chambers et al. 1982; Schneider and Sobin 1992). The serotonergic effect of dextromethorphan may explain a few reports of a calming effect of this substance in patients with dementia (Coccaro et al. 1990; Risse and Barnes 1986).

## ■ Drug Treatment of Cognitive Deterioration

The most common cause of dementia in elderly patients is Alzheimer's disease (E. Perry and Court 1992) (see also Chapter 24). However, at least 20% of cases of dementia have a reversible cause (Ahronheim 1992), one of the most important of which is depression. The intimate relationship between depressive "pseudodementia" (more accurately the dementia syndrome of depression) and neurological dementia makes it difficult to differentiate them (Christensen et al. 1997; Lundquist et al. 1997; Reifler 1997). Up to 89% of patients with the dementia syndrome of depression eventually develop Alzheimer's or other dementias (Gottfries and Hesse 1990), a far greater percentage than would be expected with the passage of time alone. This observation raises the possibility that in some cases depression may lower the threshold for the expression of cognitive deficits of dementia that later evolve on their own even if they improve temporarily when the depression remits.

Even when dementia is present, depression can make a substantial contribution to cognitive or behavioral decline (E. D. Ross 1981). A trial of an antidepressant may therefore be warranted in patients with dementia in whom other reversible causes are not found, even if a patient does not meet formal criteria for major depressive disorder (Nahas et al. 1997). Because sedating and anticholinergic effects further impair cognitive function (Bressler and Katz 1993), TCAs are less desirable for this indication than is bupropion, venlafaxine, SSRIs, or stimulants. Nefazodone has been reported to improve cognition, but sedation can limit this benefit. As noted earlier, L-deprenyl (selegiline) may improve cognitive function, but dietary restrictions that the patient may not be able to remember are necessary at antidepressant doses.

## Medication Reduction

One of the most important interventions in the treatment of any dementia is to withdraw medications that can impair cognition. In a study of 1,810 residents of a district of

Stockholm who were age 75 years or older, Wills et al. (1997) found that 85% of both dementia patients and individuals without dementia were taking at least one medication and that 34% of patients with dementia were taking four or more agents. Dementia patients took significantly more antipsychotic drugs but notably fewer sedative-hypnotics than did individuals without dementia (Wills et al. 1997). The amount of medication use may have been underestimated in the dementia population, because more of these patients did not know what medications, if any, they were taking.

## Treatment of Associated Factors

Even minor medical problems can aggravate dementia. Treating anemia, hypothyroidism, urinary tract infections, and other conditions often improves cognition. Vascular risk factors such as hypertension often coexist with Alzheimer's disease, and treating these risk factors reduces the risk that Alzheimer's disease will be complicated by a component of vascular dementia (Rockwood et al. 1997). Sleep-related breathing disorders and movement disorders, which can further impair cognition, are more common in elderly dementia patients than in persons without dementia (Bader et al. 1996).

## Cognitive-Enhancing Therapies

Most of the new medications that have been approved for treating the actual cognitive decline of primary degenerative dementia have been studied in Alzheimer's disease, but they may be useful in other dementias. These treatments have been found to produce either modest cognitive improvement (an increase of usually three to four points on the Alzheimer's Disease Assessment Scale [ADAS]) or less decline in cognition compared with placebo. Although this amount of improvement is noticeable to patients and caretakers, in other patients statistically significant improvement or slowing of deterioration may not be clinically meaningful (Bracco and Amaducci 1990), and important symptoms not reflected in rating scales may be unaffected (Gauthier et al. 1991; Lebowitz 1992).

Even though there is no definitive treatment for Alzheimer's disease, anything with even a slight chance of benefit is worth trying, if only for the purpose of providing a concrete representation of hope. In addition, it has been estimated that prevention of a two-point decrease in ADAS scores in patients with severe dementia who are living at home would save \$3,700 per year and that increasing ADAS scores by two points in the same patients would save \$7,100 per year (Ernst et al. 1997). Such savings must be

balanced against the risk of disruption of a family that continues to live with a patient whose dementia is already too severe to permit reasonable functioning but who does not deteriorate enough to justify placement out of the home (Fillee et al. 1996). In such situations, families may undergo more disruption than if deterioration progressed further.

A family member or other authorized agent usually provides informed consent for a patient with severe dementia who has impaired ability to understand the nature of the illness, the risks and benefits of a treatment, reasonable alternatives, and the consequences of consenting to or refusing the treatment (see also Chapter 41). The task of determining whether patients with mild or moderate dementia can provide informed consent can be more difficult. In a study of 17 older patients without dementia and 29 patients with mild Alzheimer's disease (mean MMSE score, 24), five specialists in geriatric medicine, neurology, or psychiatry demonstrated 98% agreement on the competence of the subjects without dementia to consent but only 56% agreement on the competence of the patients with Alzheimer's disease (Marson et al. 1997). The truism that informed consent is a dynamic process is particularly apt in dementia patients, whose capacity to understand their circumstances fluctuates along with their cognition. The validity of consent therefore should be reevaluated periodically in all patients with Alzheimer's disease.

## Cholinergic Therapies

Because of acetylcholine's role as a neurotransmitter of memory, and the cognitive impairment produced by drugs that interfere with central cholinergic transmission, the selective loss of presynaptic cholinergic neurons and muscarinic receptors in Alzheimer's disease has been thought to have etiological importance (Branconner et al. 1992; Bromidge et al. 1997; Farlow et al. 1992; Gauthier et al. 1991; Schneider 1996). Postsynaptic muscarinic M1 receptors remain intact in Alzheimer's disease, making receptor stimulation a potentially feasible approach (Bromidge et al. 1997). Activation of nicotinic receptors may produce a neuroprotective effect and muscarinic receptor stimulation may promote neural regeneration (Schneider 1996). Medications that increase brain acetylcholine levels may hold promise in the treatment of Lewy body dementia (E. Perry and Court 1992) but have produced inconsistent results in many cases of Alzheimer's disease (Bracco and Amaducci 1990; Tariot 1992). The lack of more consistently positive findings may reflect the heterogeneity of Alzheimer's disease, the involvement of other neurotransmitter systems, or perhaps such massive cholinergic neuronal destruction in some patients that the

system is no longer capable of responding to exogenous manipulation (Branconner et al. 1992).

With the exception of lecithin (phosphatidylcholine), which produced positive results in one study, acetylcholine precursors have been found ineffective in Alzheimer's disease (Gottfries and Hesse 1990; Tariot 1992). This is not surprising in view of the loss of neurons capable of utilizing precursors. Even though cholinergic muscarinic receptors are preserved in Alzheimer's disease, trials of bethanechol and arecoline, nonselective muscarinic cholinergic agonists, have not yielded positive results (Gauthier et al. 1991). Xanomeline, a muscarinic agonist, did not improve cognition in one trial but did reduce agitation, delusions, and hallucinations (Knopman and Morris 1997). In a 6-month multicenter study of 343 Alzheimer's disease patients randomized to treatment with placebo or one of three doses of xanomeline, the higher dose was associated with substantially better scores on the ADAS and the Clinician's Interview-Based Impression of Change as well as marked reduction of agitation and psychosis (Bodick et al. 1997). Because efficacy was limited by notable gastrointestinal side effects, a transdermal preparation is being developed (Bodick et al. 1997). A muscarinic M1 agonist, SB202026, which has few peripheral effects, did improve cognition in preliminary trials (Bromidge et al. 1997; Knopman and Morris 1997) and is now in phase 3 trials (Bromidge et al. 1997).

Cholinesterase inhibitors have been more consistently successful in increasing cholinergic tone. Oral physostigmine at a dosage of 8 mg/day for 3 weeks improved performance on a test of auditory learning, but this effect was not clinically meaningful (Sevash et al. 1991). Because physostigmine has a half-life of only 30 minutes, it is not a practical chronic treatment (Bracco and Amaducci 1990). However, extended-release physostigmine has proven effective in double-blind clinical trials (Knopman and Morris 1997; Thal et al. 1996), with higher doses being more effective (Thal et al. 1996). Frequent gastrointestinal side effects may limit the use of extended-release physostigmine in clinical practice.

Tacrine (1,2,3,4-tetrahydro-9-acridinamine monohydrochloride monohydrate [or THA]) is a reversible cholinesterase inhibitor with a duration of action longer than that of physostigmine. Findings of early studies with positive results suggested that 40%–50% of patients with Alzheimer's disease who tolerate tacrine, or 30% of all patients who take it, had some meaningful improvement, although it was not clear whether this improvement would last longer than 3 months (Small 1992). A multicenter phase 3 study supported by the manufacturer of tacrine (trade name Cognex) included 468 patients age 50 or older with

probable Alzheimer's disease. After a 6-week placebo washout period, patients received one of the following treatments: placebo for 6 weeks followed by tacrine 20 mg/day for 6 weeks; tacrine 20 mg/day for 12 weeks; tacrine 20 mg/day for 6 weeks followed by tacrine 40 mg/day for 6 weeks; tacrine 40 mg/day for 12 weeks; or tacrine 40 mg/day for 6 weeks followed by tacrine 80 mg/day for 6 weeks. The longest trial therefore was 12 weeks. Patients taking 80 mg of tacrine per day demonstrated an average increase of 3.7 points on the ADAS, compared with an increase of 0.1 point with placebo. Assessments by physicians and caretakers of patients' cognitive and global functioning also increased with the higher tacrine dose.

Egger et al. (1992) noted a two-point improvement in MMSE scores that was maximal at 4 weeks and sustained over 12 weeks in patients taking 150 mg of tacrine daily. Improvement was more marked when serum tacrine concentrations exceeded 8 ng/mL (Egger and Levy 1992).

Although the clinical importance of findings of the first two studies was not addressed, Davis et al. (1992) did consider clinical correlations of test scores. To maximize the likelihood of finding patients who would respond to tacrine, these investigators enrolled only Alzheimer's disease patients older than 50 who demonstrated improvement in ADAS scores of at least four points after taking 40 or 80 mg of tacrine daily for 6 weeks. During a subsequent 6-week double-blind phase, these patients then received either placebo or the dose of tacrine that had seemed helpful during the preliminary phase. Patients taking tacrine had a smaller decrement of cognitive function than did patients taking placebo, one that was statistically significant mainly for word recognition. The difference could have been explained by a greater decline of cognitive functioning in the placebo group caused by withdrawal from tacrine given during the initial phase. The placebo group returned to previous levels of functioning when tacrine was reinstated. However, none of the differences between tacrine and placebo was detectable clinically.

In an editorial on these studies, Growdon (1992) commented that tacrine probably does have a measurable effect on cognition but it is "clinically trivial." To the degree that tacrine is helpful for some patients, long-term benefits would be expected to be limited by continued degeneration of cholinergic neurons (Ahronheim 1992). Problems with tacrine in clinical practice include the need for dosing four times daily and the fact that 10%–25% of patients taking tacrine develop reversible increases in serum transaminase levels, especially alanine aminotransferase (Farlow et al. 1992; Small 1992), that require discontinuation of the drug. An economic analysis of tacrine, the results of which

are probably applicable to all cholinesterase inhibitors, showed that beginning treatment at an earlier stage of Alzheimer's disease results in more cost savings (because of later institutionalization, for example) than does starting treatment later (Wimo et al. 1997).

A number of second-generation cholinesterase inhibitors have been released that have a simpler dosing regimen, do not affect hepatic function, and are better tolerated because of more selective inhibition of brain cholinesterase. Donepezil (Aricept) has an elimination half-life of 60 hours, permitting once-daily dosing (Schneider 1996). Within the dosage range of 5–10 mg/day, higher doses produce more improvement (Schneider 1996). Because donepezil is metabolized by cytochrome P450 2D6 and 3A4, its levels may be increased by inhibitors of these enzymes such as fluoxetine or nefazodone (Barner and Gray 1998). E2020 (Exelon), which is administered twice a day, is also more effective at higher doses (Schneider 1996); the dosage range is 6–12 mg/day. E2020 enhances release of norepinephrine and dopamine at the same time that it increases cholinergic transmission (Giacobini et al. 1996).

Even though metrifonate has an elimination half-life of only a few hours, its inhibition of cholinesterase lasts up to 6 weeks, making dosing intervals of once a day to once a week possible (Schneider 1996). Metrifonate has been found to be safe as a treatment for schistosomiasis in 30 years of experience in various countries. In two recent placebo-controlled studies involving 888 patients with Alzheimer's disease, doses of 10–60 mg of metrifonate per day improved cognitive as well as behavioral symptoms, with higher doses being more effective (Cummings 1998; Morris 1998). Metrifonate performed significantly better than placebo in a 3-month double-blind study of 50 patients with Alzheimer's disease (Becker et al. 1996). Huperzine A, which is more selective for cerebral cholinesterase than are other cholinesterase inhibitors, has shown promise in animal studies (Cheng et al. 1996).

Given that all cholinesterase inhibitor study findings have suggested better results at higher doses, it seems appropriate to increase the dose to the highest tolerated level within the range that has been studied. A 3- to 6-month trial is indicated to determine whether the medication will slow deterioration and ameliorate behavioral disturbances even if meaningful cognitive improvement does not occur. Because controlled studies of cholinesterase inhibitors have not lasted more than 6 months, the duration of therapy with these medications remains uncertain. However, results of open studies suggest that the medication should be continued until deterioration becomes obvious despite high doses of the medication (Knopman and Morris 1997).

Adverse effects of cholinesterase inhibitors are pri-

marily a result of peripheral cholinergic excess. Nausea, vomiting, and abdominal cramps, the most common of these adverse effects, can often be reduced by fresh ginger-root or over-the-counter antiemetics (e.g., Emetrol). As is discussed later, ondansetron may improve cognition and anxiety in addition to reducing nausea, but phenothiazines such as prochlorperazine have anticholinergic properties that may aggravate dementia. Cardiac slowing can be a limiting side effect. Hepatotoxicity has not been reported with any of the new cholinesterase inhibitors.

### Calcium Antagonists and Antiexcitotoxins

Another promising line of investigation involves the role of the intracellular calcium ion ( $\text{Ca}^{2+}$ ) in neuronal degeneration (Branconnier et al. 1992; Choi 1988). All known cytotoxic processes, including ischemia, toxins, immune mechanisms, and genetically programmed cell death (apoptosis), increase free intracellular  $\text{Ca}^{2+}$  concentration ( $[\text{Ca}^{2+}]_i$ ). Although  $\text{Ca}^{2+}$  stimulates many crucial cellular actions, including learning and gene activation, excessive elevations of  $[\text{Ca}^{2+}]_i$  activate enzymes such as phospholipases, which break down the cell membrane and liberate arachidonic acid and xanthine oxidase, and proteases that degrade structural proteins. Arachidonic acid can be oxidized to cytotoxic free radicals, and xanthine oxidase can facilitate the formation of superoxide radicals.

Elderly patients may be more vulnerable to  $\text{Ca}^{2+}$ -induced neurotoxicity because resting  $[\text{Ca}^{2+}]_i$  increases with age as a result of prolonged calcium influx through potential-dependent channels. As some people age,  $[\text{Ca}^{2+}]_i$  may gradually increase to the point at which apoptotic genes are activated, stimulating pathological processes that further promote the increase in  $[\text{Ca}^{2+}]_i$  until it reaches cytotoxic levels. If progression of the increase in resting  $[\text{Ca}^{2+}]_i$  with age could be delayed,  $[\text{Ca}^{2+}]_i$  might be slower to reach levels that promote neurotoxicity.

Sustained increases of  $[\text{Ca}^{2+}]_i$  can be produced by excitatory amino acids (excitotoxins) such as glutamate (Choi 1988; Garthwaite 1991; Manev et al. 1990). In moderate concentrations, excitatory amino acids facilitate learning and neuronal development; however, excessive release and decreased uptake inhibition of excitotoxins have been implicated in various forms of brain damage, including Alzheimer's disease. In one study, for instance (Pomara et al. 1992), cerebrospinal fluid levels of free glutamate were increased in 10 patients with early Alzheimer's disease compared with control subjects.

Through their interaction with specific receptors, the best studied of which is the *N*-methyl-D-aspartate

(NMDA) receptor, glutamate and other excitotoxins produce sustained influx of  $\text{Ca}^{2+}$  through a receptor-operated calcium channel that persists after the excitotoxin is withdrawn. The NMDA receptor also facilitates translocation of the ubiquitous intracellular enzyme protein kinase C to the cell membrane, where  $\text{Ca}^{2+}$  activates it. Protein kinase C phosphorylates cytotoxic calcium-dependent proteins and enhances further  $\text{Ca}^{2+}$  influx by phosphorylating calcium channels.

One approach to reducing excitotoxicity involves the noncompetitive NMDA antagonists such as MK-801, ketamine, and dextromethorphan. These drugs bind to a phencyclidine (PCP) receptor linked to the NMDA complex to attenuate  $\text{Ca}^{2+}$  influx. In animals with ligated cerebral arteries, MK-801 improves learning and reduces neuronal death in regions such as the hippocampus and neocortex, where high concentrations of NMDA receptors are found and vulnerability to glutamate neurotoxicity seems greatest (Albers et al. 1989). Like all drugs that bind to the PCP receptor, noncompetitive NMDA antagonists could have psychotomimetic effects (Albers et al. 1989).

Another approach to reducing excitotoxicity and  $\text{Ca}^{2+}$ -stimulated neurotoxicity is to attenuate elevations of  $[\text{Ca}^{2+}]_i$  by reducing calcium influx through potential-dependent channels. In a 12-week preliminary analysis of a double-blind phase 3 study of Alzheimer's disease (supported by the manufacturer), nimodipine—a lipid-soluble dihydropyridine calcium channel blocking agent—was found to slow progression of memory impairment compared with placebo (Tollefson 1990). However, final results of the study failed to support statistically significant superiority of nimodipine to placebo.

### Vasodilators

Vasodilators do not really increase cerebral perfusion and may even reduce circulation through the brain through a steal effect. Drugs that used to be thought of as vasodilators therefore may be more appropriately classified with the nootropics (metabolic enhancers) (Jenike et al. 1990). The best studied of the vasodilator-nootropics is Hydergine, a mixture of three hydrogenated ergot alkaloids, which was reported to be helpful in 18 studies of mild dementia (Bracco and Amaducci 1990; Gottfries and Hesse 1990; Tariot 1992). In these studies, the measure most consistently improved by Hydergine was mood (Jenike et al. 1990). In a double-blind study (Jenike et al. 1990), no difference was found between treatment with 3 mg and treatment with 12 mg of Hydergine per day over the course of a year, in terms of ratings of dementia and functioning; how-

ever, because there was no placebo control, it was impossible to state whether either dose was actually helpful. On the other hand, in a double-blind, placebo-controlled study, Thompson et al. (1990) found Hydergine to be of no benefit at all to patients with moderate dementia. None of the other available nootropics has been found helpful in Alzheimer's disease (Shrotriya et al. 1996). However, in a 4-month placebo-controlled trial of cyclandelate, a papaverine-like substance, in 127 patients with mixed dementias, slower deterioration was observed with active drug than with placebo (Schellenberg et al. 1997). As yet, there is no convincing evidence of the capacity of any vasodilator-nootropic to slow deterioration of Alzheimer's disease for more than a few months.

Ginkgo biloba is an extract of the ginkgo tree that is thought to have antioxidant properties that might reduce adverse effects of free radicals on the brain. In a 3-month double-blind study involving 20 patients (Maurer et al. 1997), 240 mg of one ginkgo extract (EGb 761) was administered daily. The ginkgo preparation was associated with significantly better improvement on a test of attention and memory compared with placebo, which was associated with decreased scores on the same test. However, the difference in ADAS scores between the ginkgo- and placebo-treated groups was not statistically significant. In a 1-year study of EGb 761 (Le Bars et al. 1997), 327 patients with Alzheimer's disease or multi-infarct dementia were randomly assigned to treatment with ginkgo or placebo. Mean ADAS scores of placebo-treated patients were 1.4 points lower than those of ginkgo-treated patients ( $P = .04$ ). Clinically significant improvement (an increase of 4 points or more) occurred in 27% of patients taking the ginkgo preparation, compared with 14% of patients treated with placebo ( $P = .027$ ). When clinician global assessments of improvement were performed, no differences were found between groups. The large number of dropouts (172 patients) and the mixtures of diagnoses make the results difficult to interpret.

## Estrogen

Estrogen receptors have been identified on hippocampal, hypothalamic, and cholinergic neurons. In addition, estrogen may promote growth and survival of cholinergic neurons and synthesis and release of acetylcholine, promote synaptic plasticity, increase regional cerebral blood flow, decrease apolipoprotein E concentrations, and have antioxidant properties (Birge 1997; Gidal et al. 1996; Knopman and Morris 1997; McBee et al. 1997; Yaffe et al. 1998). Epidemiological study findings suggest that Alzheimer's disease is more frequent in menopausal women than

in men of the same age (McBee et al. 1997) and that estrogen replacement therapy reduces the risk of Alzheimer's disease in postmenopausal women, with increasing estrogen dose and duration of treatment being associated with decreasing risk (Gidal et al. 1996; McBee et al. 1997) (see also Chapter 24). Postmenopausal women taking estrogen had better scores on tests of immediate recall than did women in a placebo-control group (McBee et al. 1997). Yaffe et al. (1998) performed a meta-analysis of 10 studies of risk factors for Alzheimer's disease and other dementias. In two prospective cohort studies and one case-control study, the risk of dementia was significantly lower in postmenopausal women taking estrogen; in the other studies, the risk in the estrogen groups was non-significantly decreased or increased. Overall, the results of the meta-analysis suggested a 29% reduction in the risk of dementia with hormone replacement therapy (HRT) (Yaffe et al. 1998). None of the studies controlled for the possible confounding influence of comorbid depression.

Results of initial trials of estrogen treatment in women with Alzheimer's disease have been contradictory (McBee et al. 1997). The only placebo-controlled trial was a small one in which estrogen therapy was associated with improvement on one of three dementia scales compared with placebo (Yaffe et al. 1998). As of March 1998, only 58 women had been studied in trials of HRT for Alzheimer's disease, and most of these trials were small, brief, or unblinded (Yaffe et al. 1998). However, several prospective double-blind studies of estrogen therapy in women with Alzheimer's disease are currently under way (Knopman and Morris 1997). The largest of these is the Women's Health Initiative-Memory Study, a 6- to 9-year prospective controlled study of HRT involving more than 8,000 women at 39 centers (McBee et al. 1997).

The modest but definite increased risk of breast cancer in women who have taken estrogen within the past 5 years must be taken into account when prescribing estrogen for prevention or treatment of Alzheimer's disease, especially in women with a personal or family history of breast cancer. In a meta-analysis of 51 studies in 21 countries involving a total of 52,705 women with invasive breast cancer and 108,411 women without breast cancer (overall median age at the start of HRT, 48 years) (Collaborative Group on Hormonal Factors in Breast Cancer 1997), the relative risk for breast cancer in women who had ever undergone HRT was 1.14 ( $P = .001$ ). The risk of breast cancer in women who had received HRT for 5 years or more was increased 1.35 times compared with placebo, but the risk of breast cancer was not increased in women who had not undergone HRT for at least 5 years.

## Nonsteroidal Anti-Inflammatory Drugs

Inflammatory processes in Alzheimer's disease have been implicated by findings of activated microglia and reactive astrocytes in neurofibrillary tangles (Lukiw and Bazan 1997). Such findings have promoted the hypothesis that amyloid deposition results in an acute-phase response that leads to the release of inflammatory substances such as prostaglandins, which further injure neurons (Lukiw and Bazan 1997). Prostaglandin synthesis is catalyzed by cyclooxygenase isoenzymes (Jouzeau et al. 1997), the activity of some of which is increased in some patients with Alzheimer's disease (Lukiw and Bazan 1997). Because nonsteroidal anti-inflammatory drugs (NSAIDs) inhibit cyclooxygenase, they could reduce some of the secondary damage in Alzheimer's disease.  $\beta$ -Amyloid peptide stimulates peripheral blood monocytes to release soluble neurotoxic factors that are inhibited by dexamethasone and NSAIDs (Dzenko et al. 1997). Findings of an epidemiological study (Knopman and Morris 1997) suggested that individuals who take NSAIDs have a lower risk of developing Alzheimer's disease than do persons who do not take them, theoretically because inflammatory processes may play a role in the progression of the disease. In a trial of indomethacin, the deterioration of Alzheimer's disease in patients receiving active treatment appeared to be slower than in subjects taking placebo (Schneider 1996). An approach for avoiding the gastrointestinal toxicity of NSAIDs is to develop selective cyclooxygenase-2 inhibitors, which inhibit the inducible enzyme associated with inflammation in the brain and elsewhere while sparing cyclooxygenase-1, which is thought to be responsible for gastrointestinal effects (Knopman and Morris 1997). These substances have not yet been subjected to clinical trials in dementia.

## Antioxidants

Trials of medications with antioxidant properties (Knopman and Morris 1997; Schneider 1996) have been based on evidence of increased oxidative stress in Alzheimer's disease, which can disrupt neuronal DNA and neuronal membranes (Bozner et al. 1997; Schneider 1996), and of the mediation of amyloid neurotoxicity by free radicals (Bozner et al. 1997). In a 2-year placebo-controlled trial of vitamin E and selegiline (both of which are antioxidants) in Alzheimer's disease patients with moderate dementia, both of the active drugs delayed progression of Alzheimer's disease by about 8 months (Sano et al. 1997). For unclear reasons, outcome was worse with a combination of the two medications than with either one alone.

Vitamin E in particular seems to be a benign and possibly useful adjunctive treatment for Alzheimer's disease, although it can exacerbate some coagulopathies (Knopman and Morris 1997).

Selegiline reduces oxidative stress associated with dopamine breakdown and may slow degeneration of neuronal systems in patients with comorbid Parkinson's and Alzheimer's disease (Schneider 1996). In 8 of 11 controlled trials in patients with Alzheimer's disease, improvement of cognition was observed with selegiline, and in 2 of 5 controlled trials, selegiline had a positive effect on agitation, anxiety, and depression (Tolbert and Fuller 1996). In a 14-week randomized comparison of 10 mg of selegiline daily and placebo in Alzheimer's disease, selegiline was found to improve behavior and cognition without significantly affecting mood (Lawlor et al. 1997). In a 14-week randomized trial in 25 outpatients with Alzheimer's disease, significant improvement of agitation, mood, and cognition occurred with selegiline compared with placebo (Lawlor et al. 1997). However, in a 6-month trial, no differences were noted between placebo and selegiline in ratings of behavior or cognitive function (Freedman et al. 1998).

## 5-HT<sub>3</sub> Antagonists

Because serotonergic influences can inhibit some aspects of cognitive function, antagonists of the serotonin 5-HT<sub>3</sub> receptor may prove useful in Alzheimer's disease (Knopman and Morris 1997). A trial of ondansetron is currently under way. Ondansetron and zacopride, a 5-HT<sub>3</sub> antagonist used as an antipsychotic drug, are of particular interest to psychiatrists because they also have antianxiety properties and may be useful in the treatment of substance abuse (Dubovsky 1994). The antiemetic effect of 5-HT<sub>3</sub> antagonists makes these medications appropriate choices for the treatment of intractable nausea caused by cholinesterase inhibitors that does not respond to less expensive treatments.

Of the novel treatments for Alzheimer's disease being studied (Bracco and Amaducci 1990; Crapper McLachlan et al. 1991; Crook et al. 1991, 1992a, 1992b; Gottfries and Hesse 1990; V. W. Henderson et al. 1989; Knopman and Morris 1997; Lindvall et al. 1990; Parnetti et al. 1997; Rainer et al. 1997; Spagnoli et al. 1991; Tariot 1992; Weyer et al. 1997), the most innovative are therapies involving nerve growth factors, substances that inhibit  $\beta$ -amyloid accumulation, or apolipoprotein E analogues and genetic therapies (see also Chapter 38). Such approaches will substantially increase the number of options available for treating dementia.

## ■ Psychiatric Side Effects of Neurological Drugs

Psychiatric syndromes commonly are caused by the many medications taken by elderly neurologically ill patients. Some important reactions are noted in Table 34–26 (“Drugs That Cause Psychiatric Symptoms” 1984; Kulkarni et al. 1992; Lohr et al. 1992). Whenever possible, the offending medicine should be withdrawn before psychiatric treatments are initiated. (Further discussion of these medications can be found in Chapter 31.)

## ■ Summary

Many Axis I disorders in elderly patients are true neuropsychiatric syndromes in that psychiatric symptoms in this population are often produced or aggravated by neurological dysfunction. Treating such syndromes is complicated by the sensitivity of the older nervous system to the toxic but probably not the therapeutic effects of psychotropic medications, as well as by interactions of psychotropic medications with the many neurological drugs taken by elderly patients. Many of the more frequently used medicines for geriatric neuropsychiatric conditions are poorly tolerated, especially the sedating and anticholinergic TCAs and neuroleptics and the long-half-life benzodiazepines. SSRIs and other new-generation antidepressants and atypical antipsychotic drugs are better-tolerated alternatives. Short-half-life benzodiazepines are appropriate choices for some patients with acute anxiety, but anxiety and insomnia in patients with overt brain disease often is better managed with azapirones or antidepressants.

Severe agitation in delirium patients can be treated emergently with ECT or with intravenous haloperidol, droperidol, or benzodiazepines. Intermittent explosive outbursts and other behavioral disturbances can be managed with  $\beta$ -adrenergic blocking agents, buspirone, lithium, anticonvulsants, some antidepressants, cholinesterase inhibitors, and anticonvulsants. Atypical antipsychotic drugs such as risperidone have primary antiaggressive properties. Neuroleptics should be avoided for this indication unless nothing else is effective. There is no proven treatment for dementia itself, but the second-generation cholinesterase inhibitors produce at least some improvement. Selegiline, antioxidants, estrogen, and possibly NMDA antagonists may have some potential.

**TABLE 34–26. Psychiatric side effects of neurological medications**

Syndrome	Medication(s)
Depression	Adrenal steroids
	Amantadine
	Asparaginase
	Cimetidine
	Digoxin
	Indomethacin
	Levodopa
	Methyldopa
	Metoclopramide
	Narcotics
	Procainamide
	Propranolol
	Reserpine
	Thiazide diuretics
Mania	Adrenal steroids
	Baclofen
	Bromocriptine
	Captopril
	Cimetidine
	Dextromethorphan
	Indomethacin
	Isoniazid
	Levodopa
	Confusion
Aspirin	
Cisplatin	
Cyclophosphamide	
Opiates	
Pentazocine	
Ranitidine	
Sulindac	
Any medication in patients with brain damage	
Psychosis	
	Anticonvulsants
	Asparaginase
	Bromocriptine
	Cimetidine
	Cisplatin
	Cyclophosphamide
	Digoxin
	Isoniazid
	Levodopa

(continued)

**TABLE 34-26. Psychiatric side effects of neurological medications (continued)**

Syndrome	Medication(s)
Psychosis (continued)	Lisuride
	Pergolide
	Procainamide
	Propranolol
	Quinidine
	Ranitidine
	Sulindac
	Tocainide
Sleep disorder and bad dreams	Antidepressants
	Baclofen
	Bromocriptine
	Cimetidine
	Levodopa
	Lisuride
	Propranolol

# Electroconvulsive Therapy

C. Edward Coffey, M.D.

Charles H. Kellner, M.D.

If major depression were not a serious public health problem in the elderly population, there would be no need to discuss electroconvulsive therapy (ECT) in this book. Yet, major depression is one of the most common and serious illnesses in the elderly (see Chapter 13). In addition to death from suicide, depressive illness is associated with substantial mortality from medical illness (Avery and Winokur 1976). ECT remains the “gold standard” treatment for serious depression and, as such, requires careful consideration as a therapeutic modality. Such consideration is particularly relevant because there is evidence that ECT is especially safe and effective in elderly patients (Consensus Conference 1985) and because of the sensitivity to the side effects of antidepressant medication experienced by the geriatric population. With the burgeoning of psychopharmacological treatments for depression over the past 35 years, many may have believed that ECT was well on its way to extinction; however, we are now no longer sanguine about the efficacy of antidepressant medications for all patients. Even with the

most sophisticated psychopharmacological treatment combinations, a substantial proportion of patients remains severely ill. For these patients, it is fortunate that ECT is still available.

The case for ECT is strengthened by its remarkable record of safety. ECT compares favorably with any procedure in all of medicine for its low morbidity and mortality. With recent advances in ECT technique, the safety profile of the treatment continues to be refined, and ECT has enjoyed a resurgence as a more mainstream treatment in the psychiatric armamentarium. Furthermore, it has a predictably rapid onset of effect and can be performed in both inpatient and outpatient settings.

It is widely known that ECT is most commonly used for the treatment of severe depression. We will discuss its use for this indication in depth here, but because this is a textbook of neuropsychiatry, we will also evaluate ECT as a treatment for mood disorders due to a general medical condition such as poststroke depression, as well as for neurological disorders such as Parkinson’s disease. As the

mind-body dualism separating the fields of psychiatry and neurology dissolves, investigators and clinicians will have further opportunities to explore the potent effects of ECT on functions of the brain as well as of the mind.

## ■ ECT in Geriatric Practice

Considerable evidence exists to demonstrate that a large proportion of patients receiving ECT is elderly. Kramer (1985) reviewed patterns of ECT use in California between 1977 and 1983 and found that the probability of receiving ECT increased with age of the patient. Patients 65 years and older were given ECT at a rate of 3.86/10,000 population, compared with 0.85/10,000 in those 25–44 years old. In an analysis of the data on ECT use in California between 1984 and 1994, Kramer (1999) found similar patterns. Lambourn and Barrington (1986) surveyed the use of ECT from 1972 to 1983 in a British population of 3 million and found that ECT was more common in patients (especially female patients) 60 years or older. In a study of 5,729 psychiatric admissions over 3 years, Malla (1988) found that patients who received ECT in general hospitals were significantly older than patients who did not receive ECT. Babigian and Guttmacher (1984) reviewed a massive data set from the Monroe County (New York) Psychiatric Case Register over three 5-year periods. They found that among patients who were being hospitalized for the first time, those who received ECT were older than those who did not. Thompson et al. (1994) analyzed data from the National Institute of Mental Health Sample Survey Program for 1980 and 1986, which included representative samples of psychiatric inpatients in the United States. These researchers found that approximately one-third of ECT recipients were 65 years or older, a figure far out of proportion to the representation of that age group in the sample (8.2%). In contrast, Hermann et al. (1995) reported that age was not related to ECT use as estimated from the American Psychiatric Association's 1988–1989 Professional Activities Survey.

Several features of the natural history of major depressive illness help to explain the frequent use of ECT in elderly patients. Post (1992) reviewed data suggesting that major affective disorders increase in both severity and cycle frequency with increasing age. In a review of the course of illness of late-onset depression, Alexopoulos (1990) cited evidence for an association between high relapse rates and later onset of illness (Zis and Goodwin 1979). Thus in the geriatric population, the frequency and severity of depressive illness, its impact on quality of life, and the increased sensitivity of the elderly to adverse effects of antidepressant medications, combine to make ECT an attractive and

often-used treatment option (Benbow 1987, 1989; McCall et al. 1999; Weiner 1982).

## ■ Medical Physiology of ECT in Elderly Patients

The data on the physiology of ECT have been compiled largely from mixed-age samples, and to our knowledge, few data focus specifically on the physiology of ECT in elderly patients. Clearly, the myriad physiological changes that accompany an ECT seizure take on particular importance in elderly individuals, in whom medical illnesses involving multiple organ systems are so common. In a study of 33 elderly patients (mean age, 74 years) receiving ECT, Gaspar and Samarasinghe (1982) found the incidence of major or minor medical risk factors for ECT to be 75%. Of greatest importance are the physiological effects of ECT on the brain and the cardiovascular system. As described later in this chapter, modifications in ECT technique may be required in patients with brain or cardiovascular disease.

### Cerebral Physiology

With ECT, an electrical stimulus is used to depolarize cerebral neurons and thereby produce a generalized cerebral seizure. The mechanism by which ECT seizures are propagated is not well understood. Bilateral ECT appears to lead to seizure generalization through direct stimulation of the diencephalon, whereas seizures induced with unilateral stimulation may begin focally in the stimulated cortex and then generalize via corticothalamic pathways (Staton 1981).

During the initial phase of the induced seizure, electroencephalographic activity is variable, consisting of patterns of low-voltage fast activity and polyspike rhythms. These patterns correlate with tonic or irregular clonic motor movements. With seizure progression, electroencephalographic activity evolves into a pattern of hyper-synchronous polyspikes and waves that characterize the clonic motor phase. These regular patterns begin to slow and eventually disintegrate as the seizure ends, sometimes terminating abruptly in a flat electroencephalogram (EEG) (Weiner and Krystal 1993). The ictal EEG has been the focus of much research, by our group and others, aimed at identifying markers of therapeutic response (discussed in a later section). These studies indicate that age has a major impact on a number of ictal EEG measures and is associated with shorter seizure duration, shorter slow-wave-phase duration, weaker overall strength and patterning, and lower early ictal, midictal, and postictal amplitudes (Krystal et al. 1995, 1998; Nobler et al. 1993).

Transient cumulative changes are also evident on the interictal EEG during a course of ECT. Increased predominance of delta activity on the interictal EEG is seen as a function of the number of ECT treatments given in a course of ECT and their rate of administration (Fink 1979). Asymmetric (left greater than right) decreases in average EEG frequency after a course of ECT have been correlated with increasing age of the patient (Turek 1972; Volavka et al. 1972). (No such relation was reported by Bergman et al. [1953].) Strömngren and Juul-Jensen (1975) found an association between age and postictal slowing with bilateral ECT but not with unilateral nondominant ECT. By 30 days after the ECT course, EEGs resemble baseline EEGs in most patients (Abrams 1997a). The effects of aging on the severity and persistence of interictal electroencephalographic changes have not been extensively studied.

The ECT-induced seizure is also associated with a variety of transient and benign changes in cerebral physiology, including increases in cerebral blood flow, cerebral blood volume (resulting in a transient increase in intracranial pressure), and cerebral metabolism of oxygen and glucose (Bolwig et al. 1977; Brodersen et al. 1973; Prohovnik et al. 1986). The brief increase in intracranial pressure is rarely of clinical consequence, but it is the reason for the well-known proscription against ECT in patients with space-occupying mass lesions. Postictally, cerebral blood flow and metabolism are decreased globally and regionally for at least several hours, and then they return to normal values (Nobler et al. 1994; Rosenberg et al. 1988; Scott et al. 1994; Volkow et al. 1988). Conflicting data exist regarding the interictal effects of ECT, with both reduced (Nobler et al. 1994) and increased (Bonne et al. 1996) cerebral blood flow reported approximately 1 week after a course of ECT. The effects of age on these changes have not been described.

Transient disruptions in blood-brain barrier permeability also occur during the seizure (Bolwig et al. 1977) and may account for the short-lived increase in  $T_1$  relaxation times demonstrated by brain magnetic resonance (MR) imaging after ECT (Mander et al. 1987; Scott et al. 1990). The effects of age and associated brain changes on these blood-brain barrier alterations have not been described in humans, but in animals age is associated with more pronounced blood-brain barrier changes after 10 electroconvulsive seizures (Oztas et al. 1990).

### Cardiovascular Physiology

ECT results in a marked activation of the autonomic nervous system, and the relative balance of parasympathetic

and sympathetic nervous system activity determines the observed cardiovascular effects (Applegate 1997). Vagal (parasympathetic) tone is increased during and immediately after administration of the electrical stimulus, and this may be manifested by bradycardia or even a brief period of asystole. With development of the seizure, activation of the sympathetic nervous system occurs, resulting in a marked increase in heart rate, blood pressure, and cardiac workload. Peripheral stigmata of sympathetic activation may also be observed and include piloerection and gooseflesh. The tachycardia and hypertension continue through the ictus and generally end along with the seizure. Shortly after the seizure, there may be a second period of increased vagal tone that may be manifested by bradycardia and various dysrhythmias, including ectopic beats. As the patient awakens from anesthesia, there may be an additional period of increased heart rate and blood pressure as a result of arousal and further sympathetic outflow (Welch and Drop 1989).

The cardiovascular responses during ECT combine to produce an increase in myocardial oxygen demand and a decrease in coronary artery diastolic filling time. Transient electrocardiographic changes in the ST segment and T waves are seen in some patients during the procedure, but it is unclear whether these findings are related to myocardial ischemia (Gould et al. 1983; McCall 1997; Wesner 1986; Zvara et al. 1997). A direct effect of central nervous system stimulation on cardiac repolarization has been proposed as an alternative mechanism (Welch and Drop 1989). No corresponding increase in levels of cardiac enzymes has been found to accompany these electrocardiographic changes (Braasch and Demaso 1980). In a study of patients receiving ECT, Messina et al. (1992) obtained echocardiograms during and after ECT treatments and found transient regional wall motion abnormalities more often in patients with ST-T changes on electrocardiograms (ECGs), suggesting a period of demand myocardial ischemia. The clinical importance of these findings remains to be evaluated.

The effects of age on the cardiovascular response to ECT have been examined in only a few modern studies. Shettar et al. (1989) randomly assigned 19 patients (mean age [ $\pm$  SD],  $51 \pm 21$  years; range, 19–84 years) to ECT with pretreatment with glycopyrrolate or with placebo, the alternate pretreatment drug being used for the subsequent ECT treatment (i.e., each patient served as his or her own control). For both types of pretreatment, there was no correlation between age and length of poststimulus asystole. In two controlled studies of mixed-age samples that included elderly patients (Prudic et al. 1987; Webb et al. 1990), no relationship was found between age and ECT-induced changes in heart rate, blood pressure, or

rate-pressure product. In a study of relatively younger patients (mean age, 43 years; range, 20–64 years), Huang et al. (1989) noted a significant inverse correlation between age and increases in blood pressure and rate-pressure product.

Although these results suggest that age, per se, is not associated with the extent of the cardiovascular response to ECT, these findings must be interpreted cautiously. Some of the subjects in these studies (especially those who were older) were also receiving antihypertensive drug therapy that may have attenuated their cardiovascular response to the treatments, and (as discussed later in this chapter) other clinical observations suggest that at least some elderly patients with cardiovascular disease may be at risk for marked increases in pulse and blood pressure during ECT (Applegate 1997; Bodley and Fenwick 1966; Gerring and Shields 1982; Zielinski et al. 1993).

## ■ Diagnostic Indications and Efficacy

### Major Depression

The most common indication for ECT in the elderly population remains depression, both unipolar and bipolar. In elderly patients with depression, ECT is typically used as a second-line treatment, after patients have failed to respond to a trial of medication or have exhibited intolerance of the side effects of medication. ECT should be considered a first-line intervention, however, in certain situations: severe suicidality, inanition and malnutrition, history of previous response to ECT, or patient preference (American Psychiatric Association 2000).

Several clinical studies involving mixed-age samples and various diagnoses have found increasing age to be associated with a favorable outcome from ECT (Black et al. 1993; Carney et al. 1965; Coryell and Zimmerman 1984; Folstein et al. 1973; Gold and Chiarella 1944; Kahn et al. 1959; Mendels 1965; Roberts 1959; Strömngren 1973). Investigators in other studies involving older patients have reported a diminished response to unilateral but not bilateral ECT (Heshe et al. 1978; Pettinati et al. 1986; Strömngren 1973) or a requirement for longer courses of treatment (Ottosson 1960; Rich et al. 1984b).

The effects of ECT in elderly patients with depression have been directly examined in a small number of studies, but results are somewhat difficult to compare because of differences in patient samples (e.g., size and diagnosis), ECT technique (e.g., stimulus waveform and dosage and electrode placement), and assessment methodology (Table 35–1). Nevertheless, reported response rates range from

63% to 98%, clearly demonstrating that increasing age, per se, does not have a negative impact on the effectiveness of ECT for depressive illness. Indeed, other data (although uncontrolled) indicate that ECT is associated with reduced chronicity, decreased morbidity, and decreased mortality (Avery and Winokur 1976; Babigian and Guttmacher 1984; Wesner and Winokur 1989).

There are no controlled, prospective, randomized studies comparing the efficacy and side effects of ECT versus drug therapy for treatment of depression in elderly patients. In a retrospective chart review of 112 consecutive geriatric hospital admissions, Meyers and Mei-Tal (1985–1986) compared outcome in depressed patients who had received ECT with outcome in those who had received tricyclic antidepressants (nonrandom assignment) and found that ECT was associated with a better response rate (81% versus 62%) and a lower morbidity rate (0% versus 27%).

Because major depression in elderly patients appears to respond well to ECT, there may be little need to correlate specific clinical features with ECT response. However, in the case of data derived largely from mixed-age samples, a particularly good response to ECT has been associated with the presence of psychosis, catatonia, pseudodementia, pathological guilt, anhedonia, agitation, and neurovegetative signs (Greenberg and Fink 1992; Hickie et al. 1996; Salzman 1982; Zorumski et al. 1988). In a prospective study involving 29 elderly patients (Fraser and Glass 1980), guilt, anhedonia, and agitation were identified as positive prognostic signs. In multiple studies, response to ECT has been particularly good in patients with delusional depression, compared with a nonpsychotic group (Hickie et al. 1996; Mulsant et al. 1991; Pande et al. 1990; Wilkinson et al. 1993), although other studies have found no difference (O’Leary et al. 1995; Rich et al. 1984a, 1986; Sobin et al. 1995; Solan et al. 1988). The use of ECT in agitated or psychotic elderly patients may spare them exposure to neuroleptic agents. This consideration is important, given the high risk of tardive dyskinesia and drug-induced parkinsonism in elderly patients (Jenike 1985; see also Chapter 25).

Several authors have also attempted to identify predictors of nonresponse to ECT. In a retrospective study, Magni et al. (1988) compared elderly patients who responded to ECT and those who did not respond and found that physical illness during the index episode, fewer negative life events preceding the onset of the index episode, and prior depressive episodes of long duration were predictive of nonresponse to ECT. Other investigators have found that longer duration of the index episode predicts poorer outcome (Fraser and Glass 1980; Karlinsky and

**TABLE 35-1. Studies of electroconvulsive therapy (ECT) as a treatment for geriatric depression**

Study	Subjects	Methods	Findings
Fraser and Glass 1980	29 patients (8 men, 21 women) Age 64–86 years Depressive illness by Feighner criteria <sup>a</sup>	Prospective ECT two times/week; chopped sine wave; randomized assignment to bilateral ( <i>n</i> = 16) or right unilateral ( <i>n</i> = 13) electrode placement Blinded outcome rating	Both groups had significant reductions in HRSD scores 3 weeks after last treatment, at which point 28 patients (97%) showed “satisfactory” clinical outcome. No group differences in therapeutic response. Average time to reorientation after fifth ECT treatment was 32.8 minutes for bilateral ECT and 9.5 minutes for right unilateral ECT. WMS scores improved during ECT, and 3 weeks after ECT all scores were normal. No group differences.
Gaspar and Samarasinghe 1982	33 patients (9 men, 24 women) Age 66–88 years (mean ± SD, 73.9 ± 5.7 years) Depression in 28 (85%) of 33 patients; diagnostic criteria unspecified	Prospective ECT two times/week for 3–4 weeks, then one time/week; mean number of ECT treatments, 8.7 (range, 2–29); bilateral Outcome rated as good, intermediate, poor	Good outcome in 26 patients (79%), intermediate outcome in 3 (9%), poor outcome in 4 (12%).
Karlinsky and Shulman 1984	33 inpatients (11 men, 22 women) Age 62–85 years (mean ± SD, 73.2 ± 5.0 years) DSM-III major depression, single episode, in 12 patients (36.4%); major depression, recurrent, in 18 (54.5%); bipolar disorder in 3 (9.1%)	Retrospective ECT two or three times/week; sine wave; unilateral ( <i>n</i> = 23, 69.7%), bilateral ( <i>n</i> = 3, 9.1%), or both ( <i>n</i> = 7, 21.2%) Nonblinded outcome rating by author consensus from clinical progress notes Follow-up at 3 and 6 months	Immediate “good” response in 14 patients (42.4%), “moderate” response in 12 (36.4%), “poor” response in 7 (21.2%). During 6-month follow-up, 23 patients (69.7%) remained out of hospital and 6 (18.2%) received more ECT. Only one complication (pneumonia), and even this patient was able to complete ECT course.
Burke et al. 1985	30 patients (7 men, 23 women) Age 60–82 years (mean, 72 years) DSM-III major depression in 24 patients, bipolar disorder in 5	Retrospective Average number of ECT treatments, 9 (range, 1–25); brief pulse; bilateral in 70% Outcome rating (four-point scale) determined by review of medical records	92% of patients with major depression improved, and 69% showed complete symptom resolution.
Burke et al. 1987	136 patients (39 men, 97 women) Mean age of total sample, 48 years; 96 subjects < 60 years (mean ± SD, 39 ± 12.19 years), 40 subjects > 60 years (mean ± SD, 69 ± 6.43 years) 81% of total sample had a major affective disorder; diagnoses of elderly subgroup unspecified	Sine wave; bilateral in 87%, unilateral in 73%; mean number (± SD) of ECT treatments, 9 ± 3.6	70% of total sample had complete resolution of affective symptoms (61% < 60 years, 75% > 60 years). Complication rates increased with age (35% in older group, 18% in younger group).
Kramer 1987	50 inpatients (9 men, 41 women) Age 61–88 years (mean, 74.1 years) DSM-III major depression in 49 patients, schizophrenia in 1	Retrospective ECT three times/week; brief pulse; bilateral all patients Nonblinded assessment by author’s chart review	46 patients (92%) “much improved” after ECT. No serious medical complications.
Godber et al. 1987	163 patients (43 men, 120 women) Mean age, 86 years; all > 65 years Primary depression by Feighner criteria <sup>a</sup> in 153 patients (94%), psychotic symptoms in 80 (49%)	ECT two times/week for most patients, three times/week for those slow to respond; sine wave; right unilateral in 155 patients (95%); mean number of ECT treatments, 11.2	83 patients (51%) “fully recovered,” 37 (23%) “much improved,” 34 (21%) poor response.
Magni et al. 1988	30 patients (14 men, 16 women) Mean age, 73.9 years DSM-III major depression	Retrospective ECT two or three times/week initially, then once weekly; bilateral in all patients; minimum of 7 ECT treatments (range, 7–12) Independent clinical rating by two psychiatrists	19 patients (63%) responded to ECT.

(continued)

**TABLE 35-1. Studies of electroconvulsive therapy (ECT) as a treatment for geriatric depression (continued)**

Study	Subjects	Methods	Findings
Coffey et al. 1988	44 inpatients (18 men, 26 women) with leukoencephalopathy Age 60–86 years (mean, 73 years) DSM-III major depression in all patients	Retrospective ECT three times/week; brief-pulse, “moderately suprathreshold” stimulus; average number of ECT treatments, 9 (range, 6–14) Nonblinded global ratings of clinical response	“Excellent” response in 54%, “good” response in 44%.
Coffey et al. 1989	51 inpatients (15 men, 36 women) Age 60–90 years (mean, 71.3 years) DSM-III major or bipolar depression in 49 patients, organic affective disorder in 2	Prospective ECT three times/week; brief pulse; unilateral ( $n = 38$ ), bilateral ( $n = 3$ ), or both ( $n = 10$ ); mean number of ECT treatments, 9 (range, 5–18) Nonblinded observer and patient self-rating	42 patients (82%) met criteria for full therapeutic response. No association between ECT response and brain white matter abnormalities on magnetic resonance images.
Mulsant et al. 1991	42 inpatients (7 men, 35 women) Age 60–89 years (mean $\pm$ SD, 73.5 $\pm$ 7.3 years) DSM-III major depression	Prospective  ECT three times/week; brief pulse; unilateral ( $n = 29$ , 69%), bilateral ( $n = 3$ , 7%), or unilateral and then bilateral ( $n = 10$ , 24%); mean number of ECT treatments, 8.3 (range, 4–13) HRSD, BPRS, and MMSE scores, used for outcome rating, obtained by research nurses	28 patients (67%) had excellent response to ECT (50% decrease in HRSD score).  38 patients had decrease in BPRS score. No significant change in mean MMSE scores for group.
Rubin et al. 1991	101 inpatients (19 men, 82 women) Mean age ( $\pm$ SD), 76.0 $\pm$ 6.4 years DSM-III unipolar depression	Retrospective 46 patients (46%) received ECT (technique not described), some in combination with antidepressant drug therapy; 65 (64%) received antidepressant drug therapy only; nonrandomized Nonblinded retrospective outcome rating by unit director	Relative to patients treated with drug therapy, those who received ECT had significantly lower final BDI scores, greater reduction in BDI scores, and higher frequency of ratings of “major improvement” (78% vs. 42% for non-ECT group).
Kellner et al. 1992	15 patients (11 men, 4 women) Age 53–87 (mean, 69.9 years) DSM-III major depression	Prospective Blinded rating of outcome measures including cognitive assessment and antidepressant response Randomized assignment to ECT one time/week or three times/week for 3 weeks; brief pulse; bilateral	All patients improved. Mean HRSD scores decreased from 27 to 12 in three times/week group and from 29 to 20 in one time/week group. No difference in cognitive effects between groups.
Wilkinson et al. 1993	78 patients (23 men, 55 women) Four age groups (18–39, 40–64, 65–74, and 75–88 years) 43 patients > 65 years (mean, 68.96 years in age 65–74 group and 79.50 years in age 75–88 group) DSM-III major depression with melancholia or psychosis	Prospective ECT two times/week; right unilateral in 5 patients (6%), bilateral in remainder; mean number of ECT treatments, 7.9 Nonblinded cognitive and affective ratings Positive response to ECT defined as $\geq$ 50% reduction in Montgomery Asberg Depression Rating Scale	Positive response to ECT in 73% of patients $\geq$ 65 years and 54% of patients < 65 years. Age associated with response to ECT, and with more improvement in cognition on MMSE with ECT.
Casey and Davis 1996	19 patients (8 men, 16 women) Mean age 79.5 years DSM-III major depression in 18 patients; bipolar disorder depressed in 1	Retrospective Brief-pulse ECT (22 courses); nonrandomized electrode placement (bilateral, $n = 13$ ; unilateral, $n = 1$ ; both, $n = 8$ ) Nonblinded assessment of “complication,” “confusion,” and clinical response (4-point scale)	Clinical response (rating of $\geq$ 3) achieved in 19 (86.3%) courses. Response associated with younger age, lower ASA rating, and absence of neurological disorder. Complications in 5 patients: dental (1), cardiovascular (2), urinary retention (1), and confusion (1).

**TABLE 35-1. Studies of electroconvulsive therapy (ECT) as a treatment for geriatric depression (continued)**

Study	Subjects	Methods	Findings
Tomac et al. 1997	34 patients > 85 years old (79% female) Mean age 81 years (range 85–96) DSM-III-R major depression (85%), bipolar disorder (9%), depressive disorder NOS (3%), delusional disorder (3%), and dementia NOS (59%)	Retrospective Brief-pulse ECT three times/week (mean, 7 ECTs); nonrandomized electrode placement (unilateral, 65%; bilateral, 18%; and both 17%); stimulus dosage at 150%–200% initial seizure threshold Nonblinded assessment of therapeutic response and treatment complications	Significant increase in GAF (mean, 8.2 points, $n = 30$ ) and significant decrease in HRSD (mean, 5.7 points, $n = 16$ ) and BPRS (mean, 47.2 points, $n = 18$ ). Significant increase in MMSE scores (mean, 2.6 points, $n = 20$ ) Treatment complications in 27 (79%): most common included confusion or delirium (32%), transient hypertension (67%), and arrhythmia (24%)
Gormley et al. 1998	67 patients > 75 years old (73% female) Mean age 79.4 years (range 75–91) ICD-10 recurrent depression (78%), bipolar disorder (15%), or depressive disorder (7%)	Retrospective Brief-pulse ECT twice weekly (mean, 6.7 ECTs); nonrandomized electrode placement (bilateral, 95%; unilateral, 2%; both, 3%) Nonblinded assessment of therapeutic response (4-point scale), “complications,” “confusion,” and “memory impairment”	Marked improvement in 53% and moderate improvement in 32% Complications in 11% (prolonged confusion, 6.5%; hypomania, 4%; hypertension, 2%; headache, 2%)
Tew et al. 1999	268 women Adults (< age 60 years), 133 patients; young-old (age 60–74 years), 63 patients; old-old ( $\geq$ age 75 years), 72 patients DSM-III-R major depression	Prospective Brief-pulse ECT three times/week; nonrandomized electrode placement (bilateral, $n = 22$ ; unilateral, $n = 136$ ; both, $n = 87$ ); stimulus dosage at 2.5 times initial seizure threshold Nonblinded assessment of therapeutic response (HRSD score $\leq 10$ at 3 days post last ECT) and of MMSE scores	Adult group had lower response rate (54%) than young-old group (73%), whereas old-old group had an intermediate rate of response (67%); no relation of response to burden of medical illness. Only adult group showed significant decline in MMSE scores at 3 days post ECT.

Note. BDI = Beck Depression Inventory; BPRS = Brief Psychiatric Rating Scale; DSM-III = Diagnostic and Statistical Manual of Mental Disorders, 3rd Edition (American Psychiatric Association 1980); HRSD = Hamilton Rating Scale for Depression; MMSE = Mini-Mental State Exam; WMS = Wechsler Memory Scale.

<sup>a</sup>See Feighner et al. 1972.

Shulman 1984). Previous courses of ECT and increased age at the time of first treatment with ECT have been linked with a slower response rate to ECT, with no effect on eventual positive outcome (Rich et al. 1984b; Salzman 1982; Shapira and Lerer 1999). These limited data should not discourage the clinician from initiating a trial of ECT in patients with any of the aforementioned predictors of nonresponse. Clinical experience suggests that many elderly patients with these putative predictors of nonresponse often will improve with ECT.

Efforts at using biological markers to predict ECT response in elderly patients have met with equivocal success. A variety of probes have been investigated in mixed-age samples, including the dexamethasone suppression test (DST), the thyrotropin-releasing hormone (TRH) test, and other neuroendocrine tests (Decina et al. 1987; Kamil and Joffe 1991; Kirkegaard et al. 1975; Krog-Meyer et al. 1984; Papakostas et al. 1981; Swartz 1993), as well as polysomnographic studies (Coffey et al. 1988; Grunhaus et al. 1996). None of these laboratory studies appear to be strong “state-specific” markers for major depressive illness, and data are conflicting on whether they can be used serially to follow the course of ECT, predict outcome, or predict early relapse. Nevertheless, a report by Devanand et al. (1991) suggests that consideration of complex technical factors in neuroendocrine testing may enhance the clinical utility of such assessments in ECT.

## Mania

Although extensive clinical experience indicates that ECT is effective for treating both the manic and depressed phases of bipolar illness in elderly patients, formal data for this population are lacking. A small number of controlled studies involving relatively young mixed-age samples have found ECT to be superior to drug therapy (Mukherjee 1988; Mukherjee et al. 1994; Small et al. 1988, 1991). ECT appeared to be particularly effective in mixed bipolar states and agitated mania, conditions that tend to become more prevalent as the illness becomes more chronic and refractory (Calabrese et al. 1993). Many elderly patients with bipolar disorder have reached this more severe phase of the illness and thus may be expected to have a particularly good response to ECT. Anticonvulsant medications are often effective in mixed bipolar disorder (Calabrese et al. 1993), although we are not aware of efficacy studies testing this use of anticonvulsants in elderly patients. ECT itself also has powerful anticonvulsant properties (Coffey et al. 1995b; Sackeim et al. 1983). Whether bilateral ECT is more effective than nondominant unilateral ECT in the treatment of mania remains controversial (Small et al. 1991).

## Schizophrenia and Other Psychotic Disorders

No controlled data exist on the use of ECT in elderly patients with schizophrenia. ECT has been used in relatively younger patients with this illness, and in these patients the presence of affective or catatonic features, an acute onset of illness with relatively brief duration of illness, or a history of response to ECT, correlate with good outcome (American Psychiatric Association 2000). ECT is not very effective for treating the chronic, residual phase of the illness with predominant negative features (Weiner and Coffey 1988). These “deficit” states become more common as the illness progresses (Kaplan and Sadock 1988) and thus should be highly represented in elderly schizophrenic populations, although controlled data on this issue are lacking.

ECT has also been used in elderly patients with other psychotic disorders. Botteron et al. (1991) reported the cases of three elderly patients with late-onset psychosis treated with ECT. None of the patients had major depression or dementia. Two patients with substantial structural brain changes as shown by MR imaging (lateral ventricular enlargement and deep white matter hyperintensities) did not respond to ECT. A third patient with bilateral caudate hyperintensities and normal subcortical white matter did respond to ECT. As will be discussed later, we have noted an excellent response to ECT for major depression in patients with subcortical hyperintensities on magnetic resonance images, including patients with psychotic symptoms and late-age onset (Coffey et al. 1989). To the best of our knowledge, there are no data on the efficacy of ECT in patients with late-onset functional psychoses, such as paraphrenia.

## Concomitant Neurological Disease

There is increasing clinical evidence that ECT may be effective for affective disorders in patients with brain disease (Dubovsky 1986; Hsiao et al. 1987; Krystal and Coffey 1997; Weiner et al., in press; Zvil et al. 1992). In some cases, advantage has been taken of the neurobiological effects of ECT in order to treat the neurological disorder. Issues related to modifications of ECT technique in patients with cerebral disease are discussed later in this chapter.

**Affective disorder in dementia.** Twenty percent to 30% of patients with dementia have marked concomitant depression, and 10%–15% of patients with a diagnosis of dementia actually have the pseudodementia of depression (Price and McAllister 1989; Rummans et al. 1999). Depression may be difficult to diagnose in demented pa-

tients. Some dementia patients may be too ill to generate depressive complaints, with affective disorder manifesting itself chiefly as agitated, screaming behavior with neurovegetative signs. Determining whether there is a personal or family history of affective disorder may be helpful in diagnosing depression in these patients (Fogel 1988). Thorough treatment of depression in patients with dementia often does much to enhance quality of life and functional status. (The effectiveness of drug therapy for depression in patients with dementia is discussed in Chapter 34.)

Fisman (1988) reported the case of a man with major depression and profound pseudodementia whose condition was diagnosed incorrectly for 14 years as Alzheimer's disease before his affective disorder was successfully treated with ECT. In a literature review of the cases of 56 patients with dementia and depression treated with ECT, Price and McAllister (1989) found the rate of response of depression to be 73%. ECT effectively treated depression in several subtypes of dementia, including senile dementia of the Alzheimer's type, multi-infarct dementia, and normal-pressure hydrocephalus, as well as the dementias of Parkinson's disease and Huntington's disease (Price and McAllister 1989). Locations of electrodes were not specified in the majority of cases reviewed. Nearly one-third of patients with dementia also had an improvement in cognition after ECT. Delirium was a relatively infrequent complication of ECT in these patients (overall occurrence, 21%), clearing by the time of discharge in all but one patient.

Dementia does not appear to be worsened by ECT. Still, to minimize cognitive side effects of ECT, physicians of patients with dementia may need to pay special attention to issues of concomitant medications, electrode placement, and frequency of treatments (discussed below). Prospective studies are needed to address the efficacy and side effects of ECT in depressed patients with dementia.

**Parkinson's disease.** As discussed in Chapter 26, depression is common in patients with Parkinson's disease, and treatment of depression with medication may be complicated. Pharmacological treatment of the parkinsonism is also limited. Levodopa therapy for Parkinson's disease often has serious side effects and does little to retard the progression of the illness. Increasing doses of the medication are required to maintain motor function but in turn cause more and more debilitating side effects such as hallucinations, dyskinesias, and the on-off phenomenon. Neuroleptics may improve the psychoses and dyskinesia but increase parkinsonism. This situation has led to recent attempts to graft fetal mesencephalic tissue into the brains of patients with Parkinson's disease (Krauss and Jankovic 1996). Despite some encouraging results, these experi-

ments remain fraught with difficulty at multiple levels (Fahn 1992). Pallidotomy and deep brain stimulation are other neurosurgical procedures that have recently been gaining wider acceptance (Arle and Alterman 1999).

In this setting of limited treatment options, reports of the efficacy of ECT in Parkinson's disease offer the hope of a safe and effective treatment (Table 35-2). Case reports document that ECT is an effective treatment for both the motor manifestations of Parkinson's disease and the commonly associated depression (for a review, see Kellner and Bernstein 1993). Interestingly, some patients experience improvement in motor symptoms but not improvement in mood, or vice versa (Kellner and Bernstein 1993; Young et al. 1985).

A group of Swedish investigators (Andersen et al. 1987) performed the most methodologically rigorous trial of ECT in Parkinson's disease. In this double-blind, controlled, crossover-design comparison of real ECT and sham ECT, 9 (82%) of 11 nondepressed elderly patients with the on-off phenomenon experienced substantial improvement in parkinsonian symptoms with ECT, with the improvement lasting 2-6 weeks. Sham ECT was ineffective. Nine patients received bilateral ECT (8 responded, 1 did not respond) and 2 patients received right unilateral ECT (1 responded, 1 did not respond). A total of five to six treatments was given during the active phase of the trial. The stimulus-dosing strategy was not fully detailed in the report.

In a prospective naturalistic study, Douyon et al. (1989) studied seven patients with both Parkinson's disease and major depression. Major improvement in motor function was noted after only two bilateral treatments. Following an average of seven bilateral ECT treatments with "just above threshold" stimulus dosing, mean New York University Parkinson's Disease Rating Scale scores decreased from 65 to 32 (51% improvement). Patients remained well, without further ECT, for 4 weeks to 6 months. Although initial Hamilton Depression Scale scores were determined for all patients (all scores were greater than 20), follow-up scores were determined for only four. Depression scores decreased by a mean of 50% in these patients. In the report of another prospective naturalistic study, Zervas and Fink (1991) described the successful ECT treatment of four nondepressed elderly patients with severe refractory Parkinson's disease. Three of the four patients received bilateral ECT. Stimulus-dosing strategies were not specified. Improvement in parkinsonism rating scores of 20%-40% was observed. Two patients were successfully treated with ongoing maintenance ECT, but once it was discontinued, both patients relapsed within 4-6 weeks. Finally, ECT has also been found to be effective for neuroleptic-induced

**TABLE 35-2. Electroconvulsive therapy (ECT) for the treatment of Parkinson's disease**

Study	Number of subjects	Diagnosis	ECT course	Treatment response
Fromm 1959	8	Parkinson's disease	5-6 bilateral ECT treatments	Improvement: 5 patients Mild improvement: 2 patients No improvement: 1 patient
Brown 1973	7	Parkinson's disease and major depression	Average of 8 ECT treatments (electrode placement unknown)	No improvement in Parkinson's symptoms No improvement in depression
Lebensohn and Jenkins 1975	2	Parkinson's disease and depression: 1 patient Parkinson's disease and bipolar disorder, depressed: 1 patient	4-6 ECT treatments (electrode placement unknown)	Improvement in Parkinson's symptoms: 2 patients Improvement in depressive symptoms: 2 patients
Lipper and Bermanzohn 1975	1	Parkinson's disease and psychotic depression	7 ECT treatments (electrode placement unknown)	Marked improvement in depression Improvement in Parkinson's symptoms
Dysken et al. 1976	1	Parkinson's disease and depression	12 bilateral ECT treatments	Improvement in Parkinson's symptoms Improvement in depressive symptoms
Asnis 1977	1	Parkinson's disease and psychotic depression	6 bilateral ECT treatments	Improvement in Parkinson's symptoms Improvement in depressive symptoms
Yudofsky 1979	1	Parkinson's disease and psychotic depression	10 ECT treatments (electrode placement unknown)	Improvement in Parkinson's symptoms Improvement in depressive symptoms
Balldin et al. 1980	5	Parkinson's disease: 5 patients Parkinson's disease and depression: 3 patients	4-8 bilateral ECT treatments	Improvement in Parkinson's symptoms: 5 patients Improvement in depressive symptoms: 3 patients
Balldin et al. 1981	9	Parkinson's disease	3-8 bilateral ECT treatments	Marked improvement: 5 patients Slight improvement: 2 patients No improvement: 2 patients
Ward et al. 1980	5	Parkinson's disease	6 bilateral ECT treatments	No improvement: 5 patients
Holcomb et al. 1983	1	Parkinson's disease and depression	14 ECT treatments (electrode placement unknown)	Improvement in Parkinson's symptoms Improvement in depressed mood
Levy et al. 1983	1	Parkinson's disease and major depression	10 ECT treatments (electrode placement unknown)	Improvement in Parkinson's symptoms Resolution of depressive symptoms
Young et al. 1985	1	Parkinson's disease, major depression, and dementia	7 right unilateral ECT treatments	Improvement in Parkinson's symptoms No improvement in depressed mood or cognitive function
Jaekle and Dilsaver 1986	1	Parkinson's disease and bipolar disorder, depressed	9 bilateral ECT treatments	Improvement in Parkinson's symptoms Improvement in depressed mood

Andersen et al. 1987	11	Parkinson's disease	Sham control Bilateral: 9 patients Right unilateral: 2 patients	Improvement: 9 patients
Burke et al. 1988	3	Parkinson's disease and depression	5–8 right unilateral ECT treatments	Improvement in Parkinson's symptoms: 2 patients Improvement in depressed mood: 3 patients
Atre-Vaidya and Jampala 1988	1	Parkinson's disease and mania	12 bilateral ECT treatments	Improvement in Parkinson's symptoms Resolution of manic symptoms
Roth et al. 1988	1	Parkinson's disease and bipolar disorder, manic	10 right unilateral ECT treatments	Improvement in Parkinson's symptoms Resolution of manic symptoms
Birkett 1988	5	Parkinson's disease and major depression	Right unilateral ECT (number of treatments unknown)	Improvement in Parkinson's symptoms: 4 patients Improvement in depressive symptoms: 4 patients
Douyon et al. 1989	7	Parkinson's disease and major depression	Average of 7 bilateral ECT treatments	Improvement in depressed mood: 7 patients Improvement in Parkinson's symptoms: 7 patients
Lauterbach and Moore 1990	1	Parkinson's disease and major depression	9 ECT treatments (electrode placement unknown)	Improvement in Parkinson's symptoms Improvement in depression
Zervas and Fink 1991	4	Parkinson's disease	8–12 ECT treatments Bilateral: 3 patients Right unilateral: 1 patient	Improvement in Parkinson's symptoms: 4 patients
Friedman and Gordon 1992	5	Parkinson's disease and major depression	7–12 ECT treatments Bilateral: 1 patient Right unilateral: 3 patients Electrode placement unknown: 1 patient	Improvement in depressed mood: 4 patients Improvement in Parkinson's symptoms: 3 patients
Holzer et al. 1992	1	Parkinson's disease and major depression	8 right unilateral ECT treatments	Improvement in Parkinson's symptoms Improvement in depressed mood
Oh et al. 1992	11	Parkinson's disease and major depression (10 patients) or mania (1 patient)	3–9 ECT treatments Bilateral: 1 patient Right unilateral: 9 patients Unilateral then bilateral: 1 patient	Minor improvement in Parkinson's symptoms: 2 patients Improvement in psychiatric symptoms: 6 patients Post-ECT delirium: 7 patients

parkinsonism (Hermesh et al. 1992).

Rasmussen and Abrams (1991) suggested that the primary indication for ECT in Parkinson's disease be refractoriness to, or intolerance of, antiparkinsonian medication in patients with severe disability from the disease. They recommended that ECT for Parkinson's disease be initiated with right unilateral placement at substantially suprathreshold electrical dosage, with a switch to bilateral ECT if no response is seen after three right unilateral treatments. However, some patients with Parkinson's disease may be at increased risk of developing delirium during ECT (Figiel et al. 1991), a complication that could be worsened by use of bilateral electrode placement. For patients who have clearly benefited from ECT, Rasmussen and Abrams (1991) recommended maintenance ECT administered just frequently enough to maintain improvement. Recently, Aarsland et al. (1997) reported on two additional patients whose Parkinson's disease was successfully treated with maintenance ECT.

The mechanism by which ECT benefits patients with Parkinson's disease is unclear. Rudorfer et al. (1988) found significant increases in cerebrospinal fluid homovanillic acid, the primary metabolite of dopamine in the central nervous system, after a course of ECT. In addition to these presumed presynaptic effects, Fochtmann (1988) found increased dopamine, subtype 1 ( $D_1$ ), receptor binding in the substantia nigra of rats who had electrically induced seizures. She hypothesized that these changes may be associated with other changes in the dopamine system, including upregulation of postsynaptic dopamine, subtype 2 ( $D_2$ ), receptors in the striatum. Another potential dopamine-enhancing mechanism may be the temporary disruption of the blood-brain barrier seen with ECT (Bolwig et al. 1977), allowing an increase in brain concentrations of levodopa. Whatever the mechanism by which dopamine potentiation may occur, levodopa doses may need to be decreased during a course of ECT to avoid dyskinesia and delirium presumably related to dopamine overactivity.

**Poststroke depression.** As discussed in Chapter 27, approximately one-third of patients develop marked depression in the 2 years after a stroke (Robinson and Price 1982; Rummans et al. 1999). In a placebo-controlled trial, Lipsey et al. (1984) found a statistically significant improvement in poststroke depression treated with nortriptyline. In other uncontrolled studies, the response rate to psychostimulants in this population was 47%–52% (Finklestein et al. 1987; Lingam et al. 1988). However, patients with stroke are often quite medically ill and debilitated and may be intolerant of pharmacotherapy. In the study by Lipsey et al. (1984), 35% of patients assigned to

receive nortriptyline dropped out because of medication intolerance.

Clinical reports suggest that ECT may also be effective for treating poststroke depression. In a retrospective chart review of 14 patients with poststroke depression (mean age, 66 years) treated with ECT at Massachusetts General Hospital, Murray et al. (1986) found that 86% had marked improvement in depression after ECT. Apparently, no patient exhibited any worsening of neurological deficit, and although formal measures of cognitive status were not reported, 5 of the 6 patients with "cognitive impairment" before ECT showed lessening of this deficit after ECT.

Currier et al. (1992) published retrospective data on 20 geriatric patients with poststroke depression treated with ECT at the same hospital, with predominantly non-dominant unilateral electrode placement being used. A "marked or moderate response" to ECT was observed in 95% of patients. No patient experienced any exacerbation of preexisting neurological deficits, but 3 patients exhibited "minor encephalopathic complications" (prolonged postictal confusion and amnesia) and two patients developed "severe interictal delirium requiring neuroleptics." Of note, 7 of their patients (37%) relapsed within a mean of 4 months of discontinuation of ECT, despite ongoing maintenance drug therapy.

Elderly psychiatric patients with no clinical history of stroke often have subcortical white matter hyperintensities on magnetic resonance images, which are believed to be evidence of ischemic cerebrovascular disease. Coffey et al. (1989) found a high rate (82%) of response to ECT in depressed patients with these MRI findings, many of whom had been refractory to antidepressant drug therapy. In addition, the majority of the patients tolerated the course of ECT without major systemic or cognitive side effects. This positive outcome with ECT is especially notable given other data that suggest that subcortical ischemic disease may be associated with depressive illness that is resistant to treatment with antidepressant medications (Fujikawa et al. 1996).

In summary, ECT may be effective for poststroke depression, but controlled prospective data are needed to confirm this clinical impression and to identify patients potentially at risk for the adverse cognitive effects of the treatment.

**Other neuropsychiatric illnesses.** A variety of other mental syndromes secondary to medical conditions in elderly patients may improve with ECT (Hsiao et al. 1987), including catatonia and delirium from many different causes (Fink 1996, 1997; Krystal and Coffey 1997; Strömberg 1997;

Weiner et al. 2000). Indeed, the antidelirium effect of ECT may occur even in the absence of improvement in the conditions that originally caused the delirium. A careful neuropsychiatric evaluation is required in such instances to clarify the etiology, including those conditions that might increase the risk involved in ECT (discussed later in this chapter).

## ■ Issues of ECT Technique Relevant to Elderly Patients

### Pretreatment Evaluation

When a patient is referred for ECT, a focused evaluation of indications and risk factors for the treatment should ensue (American Psychiatric Press 2000; Coffey 1998). The patient's current mental status, neuropsychiatric history (including recent somatic therapies and history of treatment with ECT), and family psychiatric history should be reviewed. In the evaluation of medical risk factors for the treatment, the focus should be on the brain, the cardiovascular system, the musculoskeletal system, and the upper gastrointestinal tract. Any history of head trauma or surgery, seizures, focal or general neurological complaints, angina, congestive heart failure, bony fractures, osteoporosis, spinal disease or trauma, or esophageal reflux should be elicited. Any personal or family history of problems with anesthesia should be noted.

Handedness should be assessed because of its relevance to nondominant unilateral electrode placement (Kellner et al. 1997). Because the hand used for writing is a fallible indicator, patients should be asked which hand they use to throw a ball, cut with a knife, and so on (American Psychiatric Association 2000). A minority of left-handed patients and patients with mixed dominance may have language localized to the right hemisphere. For this reason, if substantial confusion is observed in a left-handed patient after the first right unilateral ECT treatment, consideration should be given to the use of left unilateral electrode placement at the next session. The time required for the patient to become fully oriented after the treatment can be measured for each type of electrode placement, and the treatment series can then be continued using the placement associated with less confusion (Pratt et al. 1971).

A careful documentation of baseline affective and cognitive status is essential in elderly patients before initiation of ECT. In our clinical experience, the Hamilton or Montgomery Asberg Depression Rating Scales and the Mini-Mental State Exam are often helpful standardized instruments that may be used at intervals throughout the ECT course.

A physical examination and basic laboratory tests (e.g., serum potassium assay) should be performed and an ECG obtained before ECT is initiated in elderly patients. Special care should be given to the neurological examination, including the fundoscopic examination to rule out papilledema. Further studies, such as a hemogram, serum chemistries, spine X-rays, EEGs, brain computed tomography (CT) scans or magnetic resonance images, and cardiac functional evaluations (Applegate 1997; Coffey 1998; Rayburn 1997), should be ordered as clinically indicated. Elderly patients have an increased occurrence of clinically important incidental brain findings (e.g., aneurysm, subdural hematoma, undiagnosed primary or metastatic brain tumor, and evidence of increased intracranial pressure), and brain imaging may have predictive value as a tool to detect increased risk for some ECT side effects (discussed in a later section) (Coffey 1996). The EEG can be helpful for differentiating between pseudodementia and dementia in some cases (Leuchter 1991). A baseline EEG to determine background frequency may also be helpful for comparison in cases of prolonged encephalopathy after ECT. Roemer et al. (1990) performed quantitative analyses of pre-ECT EEGs in elderly patients with depression and found that normal anterior interhemispheric coherence in the delta frequency band was associated with more clinical improvement, whereas a poorer clinical response was seen in those patients with lower coherence values.

For patients with serious cardiovascular disease, consultation with a cardiologist is often indicated. Once the decision to proceed with ECT has been made, the cardiologist should be asked how best to maximize the patient's cardiovascular function in preparation for, and during, ECT (McCall 1997).

The patient's medications should be carefully reviewed. Typically, all psychotropics are stopped before ECT, although neuroleptics may be used if necessary (Farah et al. 1995). Lithium taken around the time of ECT has been linked to an increased incidence of delirium and seizures (Weiner et al. 1980). These effects may be related to an increase in brain lithium concentration, due to transient opening of the blood-brain barrier with ECT. Most patients should not receive lithium for several days before or after ECT (Kellner et al. 1991a), although exceptions to this rule should be considered in patients who have demonstrated early relapse when not taking the medication.

Antidepressants are usually stopped to avoid cumulative cardiac and central nervous system side effects (Kellner et al. 1991a), although this practice is now being reconsidered. Studies in the early 1960s found no added benefit with tricyclic antidepressant and ECT combination therapy (Seager and Bird 1962). However, in a retrospective

chart review of 84 geriatric patients with depression, Nelson and Benjamin (1989) found improved outcome (i.e., the need for fewer treatments) with tricyclic antidepressant and ECT combination therapy. No increase in side effects occurred in the group receiving combination therapy. The study was severely limited by its retrospective design and by the fact that the ECT-only group presumably included more medically ill patients, in whom antidepressant drug therapy may have been stopped for fear of complication (Nelson and Benjamin 1989). Recently, Lauritzen et al. (1996) demonstrated the safety of ECT combined with paroxetine or imipramine, as well as the ability of both antidepressants to decrease relapse in the 6 months after index treatment (although paroxetine was more effective for relapse prevention than was imipramine).

Benzodiazepines may impair the intensity of the therapeutic seizure, thereby decreasing treatment response (Kellner 1997b; Pettinati et al. 1986). The use of these agents in elderly patients may also theoretically increase their susceptibility to cognitive side effects from ECT. Benzodiazepine use thus should be minimized or stopped before ECT.

In patients with epilepsy, the anticonvulsant effect of ECT itself may allow for a temporary decrease in anticonvulsant dose. There are few reported data about the effects of carbamazepine and valproate on the efficacy of ECT. However, because anticonvulsant medications could interfere with the induction of adequate ECT seizures, anticonvulsants prescribed for psychiatric indications (i.e., not for epilepsy) should usually be tapered and discontinued before ECT (Kellner et al. 1997).

Several other specific pharmacological issues require attention. Theophylline levels should be monitored closely, because high blood levels during ECT have been associated with status epilepticus (Abrams 1997a). Echthiophate, an organophosphate glaucoma medication that irreversibly inhibits cholinesterase and pseudocholinesterase, may cause prolonged apnea when combined with succinylcholine and should not be given (Zorumski et al. 1988). Likewise, donepezil (Aricept) and tacrine (Cognex), reversible cholinesterase inhibitors used as cognition enhancers in patients with Alzheimer's disease, could increase the duration of succinylcholine muscle relaxation (*Physicians' Desk Reference* 1999). Otherwise, patients should take any required cardiac, antireflux, or other medications with a sip of water the morning of the ECT session.

A final and critically important component of the pre-ECT evaluation is the informed consent procedure. According to the 1999 American Psychiatric Association Task Force report on the practice of ECT, adequately informed consent should involve "1) the provision of adequate information, 2) a patient who is capable of under-

standing and acting intelligently upon such information, and 3) the opportunity to provide consent in the absence of coercion" (American Psychiatric Association 2000). Compared with younger patients, those over 65 appear to be less aware that they can refuse ECT (Malcolm 1989). With the increased prevalence of cognitive impairment in elderly patients, competency to consent becomes a major issue, and the education of both patient and family becomes essential. This is also a time in the patient's life cycle when children are becoming increasingly responsible for their parents, and the patient's children should be involved in the consent process whenever possible. Incompetent patients may require the judicial appointment of a legal guardian for consent. (For a pertinent sample of an informed consent document, see American Psychiatric Association 2000).

Recently, there has been a shift to performing ECT on an outpatient basis. Many centers have found this to be a viable and efficient way to offer the treatment, as long as certain precautions are taken (Association for Compulsive Therapy 1996). First, the patient's psychiatric illness must allow for safe management outside the hospital. Clearly, acute suicidality or agitated psychosis will often require inpatient hospitalization. Second, the patient's medical status should be stable enough for safe outpatient management. Additionally, strong social support is required; family members or others must transport the patient to and from the treatment facility, ensure the patient takes nothing by mouth (NPO) for at least 8 hours before a treatment session, and provide supervision between treatments (with particular attention paid to ensuring that the patient refrains from driving and making important financial or personal decisions while experiencing cognitive side effects) (Fink 1994). For some patients, it is helpful to administer the first (or several initial) ECT treatment on an inpatient basis and then switch to outpatient treatments once it has been established that outpatient treatments can be administered safely and comfortably.

## ECT Technique

In the United States, ECT is commonly given as a series of single treatments on alternate mornings. Elderly individuals typically receive ECT initially in an inpatient setting. Patients have been previously evaluated for coexisting medical conditions and indications for treatment, and the consent process has been initiated. The treatment team consists of a psychiatrist, an anesthesiologist, and specially trained nursing personnel. ECT is typically given in either a special treatment suite or the recovery area of an operating room suite. Patients should have nothing to eat or drink

for at least 8 hours before treatment. Once baseline vital signs and an ECG have been obtained and pulse oximetry has been performed, the short-acting barbiturate methohexital is given at a dosage of approximately 1 mg/kg body weight iv, followed by the depolarizing neuromuscular blocker succinylcholine, given at a dosage of 0.75–1.5 mg/kg body weight iv. Adequacy of neuromuscular blockade is monitored by the use of a peripheral nerve stimulator or by clinical assessment of relaxation, including loss of reflexes and tone.

Throughout the procedure, the patient is ventilated with 100% oxygen and blood oxygen saturation is monitored using a pulse oximeter. Heart rate and blood pressure are also closely monitored. After a specially designed bite block is inserted into the patient's mouth, a predetermined electrical stimulus is delivered across electrodes placed on the patient's properly prepared scalp. Typically, a generalized seizure ensues, lasting from 20 to 90 seconds. The seizure is monitored by electroencephalography and by observation of the motor manifestations of the seizure, a blood pressure cuff having been inflated above systolic pressure on the right ankle to prevent access of the succinylcholine to the right foot. Ventilatory support is continued until the patient emerges from the anesthesia, and further recovery is provided in an environment with as little stimulation as possible. The entire procedure takes about 20 minutes, and patients are often able to have breakfast within an hour of the time of treatment.

A typical course of ECT consists of 6–12 treatments, although occasionally patients may require fewer or more treatments to achieve full response. The treatment schedule is often modified in elderly patients to lessen cognitive side effects, with treatments given once or twice per week rather than three times per week (American Psychiatric Association 2000; Freeman 1995; Lerer et al. 1995; Zervas et al. 1993). ECT is stopped when maximal clinical improvement is thought to have been achieved or when further improvement is not noted between treatments. Special attention is then given to continuation/maintenance treatment with either medication or ECT (discussed in a later section).

## Anesthesia Considerations

Brief, light general anesthesia is used during ECT to render the patient unconscious during (and thus amnesic for) the procedure. Methohexital is the agent of choice because it has rapid onset and a brief duration of action and induces minimal postanesthesia confusion. Methohexital also appears to have a lesser anticonvulsant effect than thiopental, propofol, or alfaxalone with alfadolone (Althesin) (Bergsholm and Swartz 1996). Still, because methohexital

is an anticonvulsant, and because the seizure threshold is often increased in elderly patients (see the following section), the lowest effective anesthetic dose is desirable. Because methohexital dosing is based on lean body mass, the required methohexital dosage in many elderly patients may be less than 1 mg/kg total body weight (Fragen and Avram 1990). In some cases, etomidate is a reasonable alternative to methohexital, but it is more expensive and is associated with pain on infusion, longer cognitive recovery time, and short-term adrenocortical suppression.

The preferred neuromuscular blocking agent for ECT is succinylcholine, primarily because it has rapid onset and a brief duration of action. The use of succinylcholine may require special consideration in the elderly patient. Succinylcholine stimulates muscarinic cholinergic receptors in the sinus node and may cause bradycardia, especially if serial doses are required. This effect may be pronounced in patients receiving  $\beta$ -blockers and those with evidence of preexisting conduction delay on ECGs, both frequently the case among elderly patients. Pretreatment with anticholinergics, such as atropine or glycopyrrolate, will block this bradycardiac effect (the use of anticholinergic premedication is discussed in greater detail later in this chapter). Patients with extensive burns or trauma, or with severe spasticity or paralysis, may have an exaggerated extracellular release of potassium in response to succinylcholine (R. D. Miller and Savarese 1990). Use of a non-depolarizing muscle relaxant should be considered in these patients. Myalgia following ECT may be due to either the fasciculation caused by succinylcholine or excessive motor movement during the seizure. Fasciculation may be blocked in subsequent ECT treatments by administering a small pretreatment dose (e.g., 3 mg) of *d*-tubocurarine.

Intragastric pressure also increases with use of succinylcholine, related to abdominal skeletal muscle fasciculation; however, the risk of gastric reflux and aspiration is reduced by a concomitant increase in esophageal pressure above the lower esophageal sphincter (R. D. Miller and Savarese 1990). Certain groups of elderly patients (e.g., those with hiatal hernia, gastroparesis, or morbid obesity) are at risk for substantial gastroesophageal reflux during the procedure, with subsequent risk for aspiration pneumonia (Zibrak et al. 1988). Smokers are particularly prone to morbidity from aspiration (Lichter 1990). In these patients, additional strategies beyond requiring NPO status before a session may be considered to decrease gastric volume and acidity during ECT. Premedication with histamine, subtype 2 ( $H_2$ ), receptor antagonists or sodium citrate decreases gastric acidity, and metoclopramide increases lower esophageal sphincter tone and promotes gastric emptying (Lichter 1990).

## Stimulus Dosing

Seizure threshold (the amount of electricity required to elicit a seizure) increases with age (Coffey et al. 1995a; Sackeim et al. 1991). This effect is believed to be the result of a decrease in the excitability of the brain but may also be partially due to increases in skull thickness (electrical resistance) with aging. Older patients thus require higher ECT stimulus intensities (doses) than do younger patients, but the optimal stimulus dosage for ECT has yet to be determined. Data from mixed-age samples suggest that barely suprathreshold stimulus intensities may be ineffective (especially for unilateral nondominant ECT), whereas excessive stimulus dosing has been linked to more cerebral toxicity (Sackeim et al. 1993; Weiner et al. 1986). Given these data, our clinical practice is to use stimulus dosing in unilateral ECT that is at least 2.5 times the patient's seizure threshold. This method of stimulus dosing requires a determination of the patient's seizure threshold, which may be done routinely at the first ECT session by increasing stimulus intensity in fixed increments over successive stimulations until a seizure results (Coffey et al. 1995a; Kellner et al. 1997; Sackeim et al. 1987). For bilateral ECT, we use a stimulus dose that is 1.5 times the seizure threshold, because the efficacy of this modality appears to be less sensitive to dosing effects than that of unilateral ECT.

Seizure threshold increases during ECT (the well-known anticonvulsant effect), necessitating increases in stimulus dose during the course of therapy (Coffey et al. 1990, 1995b; Kellner et al. 1997; Sackeim 1991; Sackeim et al. 1991). This effect does not appear to be more pronounced in elderly patients, but because this population has a higher initial seizure threshold, some older patients may eventually require stimulus intensities during their course of treatment that exceed the maximal settings of the ECT device. In such instances, we have found administration of caffeine to be an effective and well-tolerated strategy for augmenting ECT seizures in elderly patients (Coffey et al. 1987, 1990; Lurie and Coffey 1990). Higher-powered ECT devices (available in some European countries) are also helpful. The effects of cerebral disease and age-related changes in brain structure on ECT seizure threshold have not been described but are currently under study in our laboratories.

## Electrode Placement

The choice of unilateral or bilateral ECT in the elderly patient is often a complex one. Studies in mixed-age samples suggest that right unilateral ECT has fewer cognitive side effects (Weiner et al. 1986). Most research has also found

unilateral and bilateral ECT to be equally effective (American Psychiatric Association 2000); however, in those studies in which differences have been noted, bilateral ECT has consistently been found to be more effective (for a review, see Abrams 1997a).

Few studies have addressed the issue of electrode placement specifically in elderly patients. In a meta-analysis of the literature, Pettinati et al. (1986) found a trend for improved efficacy in elderly patients receiving bilateral treatment. In the only reported randomized study, 29 elderly patients with depression were assigned either to unilateral or bilateral ECT two times a week (Fraser and Glass 1980). Stimulus-dosing strategies were unclear. No group differences were observed in terms of therapeutic response or memory performance after ECT, but those subjects randomized to bilateral electrode placement required more time to become reoriented after the fifth ECT treatment (Table 35–1). Whether the effects of cerebral disease or age-related structural brain changes modify the therapeutic or adverse effects of unilateral versus bilateral ECT in elderly patients has not been studied.

Thus, limited data exist to guide the choice of ECT electrode placement in elderly patients with neuropsychiatric illness. Our approach is to begin with right unilateral ECT in elderly patients, switching to bilateral ECT if minimal or no response is seen by the fifth or sixth treatment. Because bilateral ECT may have a more rapid onset of action, it may be considered the treatment of choice in patients in urgent need of care. If intolerable cognitive side effects develop with bilateral ECT, the treatment may be changed to unilateral ECT once the affective disorder has begun to respond. Finally, atypical electrode placements (e.g., left unilateral, right frontotemporal–left frontal, or bifrontal) may be clinically useful in some elderly patients (Kellner 1997a; Letemendia et al. 1993; Manly and Swartz 1994).

## Seizure Monitoring

The seizure may be monitored indirectly by observation of the convulsive motor response of a “cuffed” extremity, but more direct monitoring with ictal electroencephalography is preferred. The ECT seizure is monitored to confirm that a seizure has occurred and to determine when it has ended (Kellner et al. 1997; Weiner and Krystal 1993). More recently, the ictal EEG has been studied using sophisticated computer analysis to determine whether various indices such as amplitude, regularity, or coherence may be predictive of treatment efficacy (Krystal et al. 1995, 1996; Weiner and Krystal 1993). These studies suggest that such measures hold promise for indicating seizure adequacy during treatment sessions.

## Continuation/Maintenance ECT

Major depression is increasingly recognized as a chronic, relapsing condition. Some studies have found 6-month relapse rates as high as 50% for patients initially responsive to antidepressant medications who are then given no form of continuation/maintenance therapy (Prien and Kupfer 1986). Similarly high rates of relapse have been noted after response to ECT if no form of continuation/maintenance therapy is given (Imlah et al. 1965; Jarvie 1954). Frank et al. (1990) found that relapse rates after response to pharmacotherapy can be substantially reduced by continuation of antidepressant medication at full dose.

ECT is one of the few treatments in modern medicine that is commonly stopped as soon as it has proven effective. Usual clinical practice involves administration of continuation/maintenance pharmacotherapy after successful ECT. Because these patients often failed to respond to medication therapy before ECT, it is not surprising that a 50% relapse rate at 1 year was found for patients receiving maintenance pharmacotherapy after response to ECT (Sackeim et al. 1990). In that study, there was a particular propensity to relapse within 4 months after successful ECT.

Results of a growing number of studies involving mixed-age samples indicate that continuation/maintenance ECT is safe and effective for the prevention of depressive relapse, and there are several promising retrospective studies involving elderly patients (for a review, see Monroe 1991). Thienhaus et al. (1990) described the cases of six elderly patients with major mood disorder treated with maintenance ECT for a period of 1–6 years. While receiving maintenance ECT, patients spent significantly fewer days in the hospital per year on average, compared with the interval prior to beginning maintenance ECT.

Dubin et al. (1992) reported the successful use of maintenance ECT for an average of 22 months in a group of eight patients over age 75. The single patient in the case series who required rehospitalization had been previously withdrawn from maintenance ECT by her attending psychiatrist and placed on fluoxetine. No major adverse events were associated with maintenance ECT in this case series.

Loo et al. (1991) described the use of maintenance ECT in seven elderly patients over an average of 3 years. Mean time in the hospital during this 3-year period decreased to 3 weeks, compared with 27 weeks for patients treated during the 3 years before the introduction of maintenance ECT. Patients had 1.4 recurrences of illness during the maintenance ECT period, compared with 4.7 re-

currences for patients during the 3 years preceding maintenance ECT.

In one of the few prospective studies to date, we (Clarke et al. 1989) evaluated 27 patients (mean age, 65 years; range, 26–90 years) not taking psychotropic medications who were assigned to a continuation ECT protocol after initial response to ECT. Only 8% of patients who completed the continuation ECT protocol required rehospitalization, whereas 47% of those who did not complete the protocol relapsed (a statistically significant difference).

Studies comparing continuation/maintenance ECT with continuation/maintenance pharmacotherapy after response to ECT are lacking in the literature. As of this writing, a multisite study comparing treatment with nortriptyline, nortriptyline plus lithium, and placebo after successful ECT is nearing completion (Sackeim 1997) and a second multisite study comparing continuation ECT and treatment with nortriptyline plus lithium has been initiated (C.H. Kellner, A.J. Rush, M. Fink, T. Rummans, unpublished data, 1996). Interim results of the former indicate high relapse rates after ECT for patients (mixed-age group) receiving monotherapy (approximately 75%) compared with patients receiving nortriptyline plus lithium (approximately 40%).

Continuation/maintenance ECT typically involves single treatments given initially at weekly intervals, with the frequency gradually reduced to every 4–8 weeks, as the patient's depressive symptoms allow. The increased interval between maintenance treatments results in fewer cognitive side effects than with an index course of ECT, leading to the suggestion that bilateral treatment may be the modality of choice for continuation/maintenance ECT (Kellner et al. 1991c). Several factors determine whether the treatments can be given on an outpatient basis. Patients must reliably follow NPO orders for 6–8 hours before treatment (patients are permitted only a sip of water to take any required premedications). Patients must also have an adequate support system to assure observation and care for several hours after treatment. If these criteria cannot be met, or if the patient has complex medical or recovery needs, an overnight stay in the hospital may be required.

## Adverse Effects of ECT and Their Management

The safety of ECT compares favorably with that of any treatment requiring general anesthesia. The mortality is

variously reported as approximating three deaths per 100,000 treatments (the same as for general anesthesia for minor surgery) and may actually be decreasing as medical management of underlying illnesses improves (Abrams 1997a). To put these data into perspective, Abrams (1997b) noted that ECT is 10 times safer than childbirth and that the risk of dying from being struck by lightning is 6 times higher than the risk of dying from ECT.

Kroessler and Fogel (1993) compared the mortality during long-term follow-up of 65 depressed patients age 80 or older who had been treated with ECT with that of patients treated with other modalities. The 2-year survival rate was 54% in the group treated with ECT, versus 90% in the group treated with medications. This group difference was related to more severe depression and physical illness in the patients who had received ECT. The course of ECT itself was remarkably well tolerated by these elderly patients, with a median interval between ECT and time of death of 20 months. The authors called for further attention to medical comorbidity as a prognostic factor in future outcome studies of geriatric depression. Abrams (1997b) noted that the estimated mortality rate among community-dwelling elderly patients (approximately 0.26% per each 3 weeks) was an order of magnitude higher than that observed after a 3-week course of eight ECT treatments in elderly patients (approximately 0.016%).

### Cardiovascular Side Effects

A proportion of elderly patients referred for ECT have serious preexisting cardiovascular disease. Common cardiac conditions such as hypertension, angina, previous myocardial infarction, atrial and ventricular arrhythmia, aneurysm, and conduction system disease require evaluation and optimized treatment before ECT, to minimize any adverse effects from the hemodynamic events that occur during ECT.

Uncontrolled retrospective studies comparing the cardiovascular complication rate of ECT in older and younger patients have found an increase in transient and treatable complications in elderly patients. In a non-blinded, retrospective chart review of 293 patients, Alexopoulos et al. (1984) found cardiovascular complications in 9% of the patients age 65 and over, compared with 1% of the patients under 65. Cardiac ischemia, arrhythmia, hypertension, and congestive heart failure were the most common complications, although the vast majority of complications were not clearly temporally related to ECT and did not prevent the completion of treatment. Burke et al. (1987) conducted a similar retrospective chart review of

136 subjects, 30% of whom were age 60 and over. Sine wave bilateral ECT was used in 85% of cases. These investigators found a cardiorespiratory complication rate of 15% in patients age 60 and over, compared with 3% in those under 60. Complications were correlated with the number of cardiovascular medications the patient was receiving, with more medication presumably marking those with more cardiovascular illness. These complications did not affect treatment response. In a chart review of 81 elderly patients, Cattani et al. (1990) found a 36% cardiovascular complication rate with ECT in patients over age 80, compared with 12% in younger geriatric patients. As would be expected, the older patients had notably more medical diagnoses and were receiving more cardiovascular medication than the younger patients.

More recently, two controlled studies of ECT in a total of 66 high-risk patients with cardiovascular disease have demonstrated the safety of ECT in elderly individuals. Zielinski et al. (1993) compared the rate of cardiac complications in a group of 40 depressed patients (mean age, 68.9 years; range, 54–84 years) with serious preexisting cardiac disease (left ventricular impairment, conduction delay, and ventricular arrhythmias) with the rate of such complications in a group of 40 depressed patients (mean age, 68.3 years; range, 55–83 years) without cardiac disease. Not surprisingly, the group with preexisting cardiac disease had more complications. Most of the complications were transient (e.g., brief arrhythmias or increases in ectopy), however, and 38 of the 40 cardiac patients were able to complete their course of ECT. This group of depressed patients with cardiac disease had even more difficulty with adverse cardiac effects from prior trials of tricyclic antidepressants; 11 of 21 patients had been forced to stop tricyclic treatment because of cardiovascular complications. Rice et al. (1994) used a case-control design to compare two groups of patients over age 50 receiving ECT. One group consisted of 26 patients at increased risk for cardiac complications, and 27 patients at standard risk made up the other group. Compared with the patients at standard risk for cardiac complications, patients in the high-risk group were older, had received more pre-ECT medical consultations before ECT, and experienced more minor medical complications from ECT. However, the two groups did not differ in terms of frequency of major medical complications, and no patients died or experienced permanent cardiac morbidity from ECT.

The data just reviewed suggest that ECT is a low-risk procedure, even in elderly patients (Applegate 1997). Still, prospective studies, carefully controlled for severity of cardiovascular and other medical disease, are needed to evaluate the effects of age on cardiovascular complications of ECT.

Increasingly sophisticated medical management during ECT should decrease the cardiovascular risk of treatment in elderly patients (Applegate 1997; Weiner et al., in press). The primary areas of concern are bradycardia, tachycardia, hypertension, and ventricular arrhythmia. Anticholinergic premedications (atropine and glycopyrrolate) may be used to prevent vagally induced bradycardia, but in elderly patients their use may be complicated by confusion, tachycardia, constipation, and urinary retention. We generally reserve the use of anticholinergic premedication for patients who develop unusually prolonged or severe bradyarrhythmias. The method of serial electrical stimulations to determine a patient's seizure threshold (described earlier) may involve administration of subconvulsive stimuli, with a vagal surge unaccompanied by the sympathetic outflow associated with a seizure. The use of this method, as well as the presence of conduction delay on the ECG, may indicate the need for premedication with an anticholinergic, particularly if the patient is also receiving a  $\beta$ -blocker medication.

Hypertension and tachycardia during ECT in elderly patients may be attenuated by short-acting intravenous  $\beta$ -blockers such as labetalol or esmolol (Howie et al. 1990; Stoudemire et al. 1990). It should be kept in mind that  $\beta$ -blockers have anticonvulsant effects, and their use during ECT may limit the intensity of the ECT seizure and, in turn, its therapeutic potency. Kalayam and Alexopoulos (1989) described the safe use of sublingual nifedipine before administration of anesthesia in an elderly patient with a severe hypertensive response to ECT. Hydralazine (an  $\alpha$ -adrenergic antagonist), as well as nitroglycerine (sublingual, transdermal, or intravenous), may also be used when clinically indicated. Trimethaphan produces transient sympathetic and parasympathetic ganglionic blockade and has also been used in this setting (Maneksha 1991). Although the hemodynamic responses to ECT are robust, they are well tolerated by most patients, including elderly individuals (Webb et al. 1990). In addition, indiscriminate use of antihypertensive medication may lead to clinically important hypotension in elderly patients. Therefore, we do not routinely blunt the cardiovascular response to ECT in elderly patients unless such changes are extreme or are clearly associated with evidence of cardiovascular compromise. Finally, in patients receiving adrenergic blockers, anticholinergic premedication should be considered so as to prevent a disproportionate decrease of sympathetic tone below parasympathetic tone, with resultant bradycardia (Abrams 1997a).

Marked posttreatment ventricular ectopy (multifocal premature ventricular contractions [PVCs] or several consecutive PVCs) may be treated with lidocaine (1–1.5 mg/kg

body weight). Because of its anticonvulsant properties, lidocaine should be given after termination of the seizure (Drop and Welch 1989). Stoudemire et al. (1990) found that ventricular ectopy could also be reduced by pretreatment with labetalol.

## Cerebral Side Effects

There is no evidence that ECT causes structural brain damage (Devanand et al. 1994; Weiner 1984). Carefully controlled prospective brain imaging studies in humans reveal no changes in brain structure for up to 6 months after a course of ECT (Coffey 1993; Coffey et al. 1991). Neuropathological studies in animals, including cell counts in regions thought to be at highest risk, reveal no evidence of brain damage when the seizures are induced under conditions that approximate standard clinical practice (i.e., when the seizures are spaced, relatively brief, and modified by oxygenation and muscle relaxation). Furthermore, studies of the pathophysiology of seizure-induced structural brain damage in animals indicate that the conditions necessary for injury do not apply to the modern practice of ECT (Weiner 1984).

The incidence of cerebrovascular complications with ECT is exceedingly rare. ECT has been given successfully to patients with cerebral aneurysms, with close management of blood pressure elevation (Krystal and Coffey 1997). The intracerebral hemorrhage reported in a normotensive patient during ECT was probably related to cerebral amyloid angiopathy (Weisberg et al. 1991). We know of no other reported case of intracerebral hemorrhage with ECT, nor of any documented case of ischemic stroke during the treatment.

The amount of time that must elapse before ECT can be safely administered after an acute cerebral infarction is unclear. Alexopoulos et al. (1984) reported the uneventful delivery of ECT 4 days after a cerebral infarct (whether it was hemorrhagic or ischemic was not specified), and others (Currier et al. 1992; Murray et al. 1986) reported successful ECT 1–2 months after ischemic stroke. Patients with a recent cerebral infarction may have more friable vasculature with a propensity to rebleed. These patients require time for cerebral vessels to heal before ECT, as well as careful management of blood pressure during the procedure. Titratable agents with short half-lives (e.g., esmolol or nitrates) are helpful in this situation. Care must be taken to avoid hypotension in all elderly patients with cerebrovascular disease.

Other intracranial processes are risk factors for ECT. As described earlier, intracranial mass lesions and increased intracranial pressure are among the most serious

risk factors for ECT. In a retrospective literature review, Maltbie et al. (1980) examined 28 patients (mean age, 47 years; range, 20–80 years) with brain tumor who were treated with ECT. Only 34% of patients improved, and 74% showed neurological deterioration, with 29% dying from neurological complications within a month of ECT. This study was flawed by a form of recall bias, with cases involving dramatic outcomes more likely to be reported. As well, a previously undiagnosed brain tumor would more likely be diagnosed during a treatment course involving complications than during an uneventful ECT course. Abrams (1997a) and Kellner (1996) reviewed reports of several cases of safe delivery of ECT to patients with brain tumors, mostly meningiomas, and ascribed the lessened risk to the fact that the tumors were small and slow growing and had no associated increased intracranial pressure. There is no report of safely delivered ECT prospectively given to a patient with documented increased intracranial pressure (Abrams 1997a). Subdural hematomas may require evacuation before ECT (Abrams 1997a).

### Side Effects in Other Organ Systems

Other organ systems that may be impaired in the elderly patient need to be considered before ECT, including the lungs, bones, eyes, and teeth (Weiner et al. 1999). Pulmonary status should be optimized before ECT. Patients with severe chronic obstructive pulmonary disease and carbon dioxide retention may require special ventilatory strategies during the treatment (Abrams 1997a). Pneumonia secondary to aspiration of gastric contents may occur rarely during ECT (Alexopoulos et al. 1989; Karlinsky and Shulman 1984).

Patients with osteoporosis, spinal disk disease, or spondylosis may require increased muscular relaxation during ECT. Such patients should receive succinylcholine doses of at least 1.0–1.5 mg/kg body weight, and they require careful attention to clinical evidence of adequate relaxation (e.g., loss of reflexes or tone, and disappearance of fasciculation) before delivery of the stimulus. Kellner et al. (1991b) reported the safe treatment of a patient with osteoporosis and cervical spondylosis with multiple subluxations of the cervical spine using succinylcholine doses of 1.3 mg/kg weight.

Because ECT produces a transient increase in intraocular pressure, patients with chronic open-angle glaucoma should receive their eyedrops before ECT. As noted earlier, treatment with echothiophate, an irreversible cholinesterase inhibitor, should be stopped several days before ECT. Patients with acute closed-angle glaucoma or retinal detachment should be stabilized before ECT and watched closely by an ophthalmologist during an ECT course.

When a patient's teeth are loose, decayed, or asymmetrical, the risk of dental injury during ECT may be increased. A major proportion of malpractice litigation with ECT is related to dental issues (Slawson 1985). A specially designed bite block must be inserted before delivery of the ECT stimulus. The tongue, cheeks, and lips must be kept clear of the clenching teeth. The bite block should be used even in edentulous patients. Occasionally, upper or lower dentures may be kept in place during the treatment to facilitate airway management. In patients with only a few remaining, and possibly loose, teeth, dental consultation or alternative bite block strategies (with the aim of shifting bite pressure to the molars) may be helpful (Welch 1993).

### Cognitive Side Effects

The cognitive side effects of ECT include acute postictal confusion, impaired retrograde and anterograde memory, and, occasionally, interictal delirium. The severity of these adverse effects is increased with bilateral electrode placement, sine waveform, higher stimulus dose relative to seizure threshold, and more frequent treatments. Conversely, cognitive side effects are reduced with right unilateral electrode placement, brief-pulse waveform, lower stimulus dose relative to seizure threshold, and longer intervals between treatments (American Psychiatric Association 2000). Although it has been suggested that elderly patients may be at greater risk for these cognitive side effects than are younger patients, controlled data on this issue are limited.

**Acute postictal disorientation.** In studies involving mixed-age samples of adults, increasing age has been found to be associated with longer or more severe disorientation immediately after ECT (Burke et al. 1987; Calev et al. 1991; Daniel et al. 1987; M.E. Miller et al. 1986; Sackeim et al. 1987). Additional risk factors for post-ECT confusion in elderly patients may include presence of major medical illness or use of psychotropic medications during ECT.

In one of the studies focusing on elderly patients, Fraser and Glass (1978) measured time to recovery of full orientation in nine elderly patients with depression who received ECT in courses in which electrode placement alternated (i.e., unilateral placement in one treatment followed by bilateral placement in the next treatment, and so on). When comparing these reorientation times with those reported in the literature for younger patients, the investigators observed that recovery in elderly patients took five times as long for unilateral treatment and nine times as long for bilateral treatment. Recovery time after bilateral ECT

increased cumulatively over the course of ECT, and with closer spacing of treatments. No such relationship was found for unilateral ECT. In a subsequent study of 29 elderly patients with depression randomly assigned to courses of either unilateral ( $n = 13$ ) or bilateral ( $n = 16$ ) sine wave ECT, Fraser and Glass (1980) found significantly longer reorientation times after the fifth ECT session among patients receiving bilateral treatments (32.8 minutes) than among those receiving unilateral treatments (9.5 minutes) (Table 35-1). In contrast to the group undergoing bilateral ECT, patients receiving unilateral ECT had a significant reduction in recovery time from the first to the last treatment.

In a study of subjective side effects during ECT, Devenand et al. (1995) found that older patients actually reported fewer severe cognitive symptoms (i.e., confusion/disorientation and amnesia) than did younger patients.

**Agitated delirium on emergence from anesthesia.** Approximately 10% of patients receiving ECT experience an acute agitated delirium on emergence from anesthesia, characterized by restlessness, disorientation, combativeness, and poor response to commands. Age does not appear to be a risk factor for this complication (Devanand et al. 1989). The complication is usually effectively treated with intravenous benzodiazepines (e.g., midazolam or diazepam) or other sedatives (e.g., droperidol or methohexital).

**Interictal delirium.** In a small proportion of patients, ECT is associated with more prolonged disorientation and even frank interictal delirium. Most studies evaluating interictal delirium in elderly patients have used disorientation as a measure, rather than the full DSM-III-R (American Psychiatric Association 1987) or DSM-IV (American Psychiatric Association 1994) criteria for delirium. In a retrospective study involving 136 patients receiving mainly bilateral sine wave ECT, Burke et al. (1987) found disorientation (confusion severe enough to alter the treatment plan) in 18% of patients older than 60 but in 13% of younger patients. This incidence increased to 25% for patients over age 75. In a retrospective study in which mostly bilateral (waveform not specified) ECT was administered, Alexopoulos et al. (1984) found a somewhat greater incidence of confusion (disorientation to time, place, and person) in elderly patients (12.6%) than in younger patients (9.6%). Cattan et al. (1990) conducted a study involving primarily bilateral or combination bilateral-unilateral sine wave ECT and found a nonsignificant trend for more frequent severe disorientation (defined functionally by interference in ward activities) in elderly

patients over 80 (59%,  $n = 39$ ), compared with those patients 65–80 years old (45%,  $n = 42$ ).

In the study of Alexopoulos et al. (1984), elderly patients with a history of underlying organic brain disease were found to have higher levels of severe post-ECT confusion than were the younger patients, suggesting that baseline cerebral impairment may increase the risk of adverse cognitive effects of ECT.

In several studies, subcortical structural disease has been implicated in the development of interictal delirium with ECT. We have found subcortical gray and white matter lesions to be more extensive in elderly patients who developed a prolonged interictal delirium during a course of ECT. The majority of these patients were able to continue ECT, with no decline in expected treatment response. All patients were free of delirium 1 week after ECT (Coffey et al. 1989; Figiel et al. 1990). The specificity of subcortical disease in producing delirium after ECT is further suggested by Martin et al. (1992), who found that patients with ischemic lesions of the caudate nucleus had a 92% incidence of delirium during ECT. Patients with a previous stroke in other brain regions had the same incidence of delirium as did a group of elderly depressed control (no stroke) subjects receiving ECT (Martin et al. 1992). In a prospective study of seven consecutive patients with Parkinson's disease, Figiel et al. (1991) found a 100% incidence of interictal delirium during a course of ECT. The delirium lasted 7–21 days, longer than is typical, but 86% of patients recovered from depression. Whether the delirium was due to subcortical disease or to increased intracerebral concentration of levodopa (due to transient breakdown of the blood-brain barrier with ECT) is unknown.

In summary, although the duration and severity of acute post-ECT disorientation may increase with age, the majority of elderly patients appear to recover their orientation within 60–120 minutes of the treatment. In the small percentage of elderly patients who develop more prolonged confusion or frank delirium, underlying cerebral impairment may be contributory, especially dysfunction of the basal ganglia. Clearly, more research is needed in a larger number of elderly patients to characterize post-ECT confusion and to identify its risk factors, including the effects of preexisting cerebral impairment.

**Amnesia.** A course of ECT is associated with transient disturbances in memory, including both retrograde and anterograde amnesia. Retrograde amnesia (forgetting of material known before the ECT) may extend back to several months before ECT and is more pronounced with bilateral electrode placement, sine waveform, grossly suprathreshold stimulus intensity, and increased treatment

frequency (Abrams 1997a). These same factors also increase anterograde amnesia (forgetting of information acquired after the start of ECT). These side effects subside within weeks of completion of ECT, but some patients may have permanent loss of specific memories for some events that occurred before, during, or shortly after the treatment course. Although some patients may report persistent memory difficulties, objective testing has demonstrated that ECT is not likely to produce persistent impairment in the ability to remember past information or acquire new information (American Psychiatric Association 2000).

Given the large body of data on the amnesic effects of ECT, it is surprising that there has been relatively little controlled research on age as a risk factor (Abrams 1997a; Calev et al. 1993; Fink 1979). Some (Fromholt et al. 1973; Heshe et al. 1978) but not all (d'Elia and Raotma 1977; Strömngren et al. 1976) early studies found that ECT-induced amnesia is worse in older patients.

Zervas et al. (1993) examined age effects on memory in a study comparing twice-weekly and three-times-a-week bilateral ECT administered using contemporary techniques (pulse waveform given at "moderately suprathreshold" stimulus intensity). The sample consisted of 42 inpatients with a mean age ( $\pm$  SD) of  $53.5 \pm 16.1$  years; no patient was older than 65 years, however. Correlations were found between age and decrements in retrograde memory 1–3 days after the end of ECT but not 1 month or 6 months posttreatment. Age was also correlated with decrements in verbal anterograde memory acutely and 1 month after ECT (but not 6 months after ECT) and with changes in figural anterograde memory acutely and 6 months after ECT.

McElhiney et al. (1995) examined autobiographical memory in a mixed-age sample (mean age [ $\pm$  SD],  $54 \pm 13.9$  years) of 75 patients with depression randomly assigned with regard to electrode placement and stimulus intensity. Age was found to be a predictor of lower recall of autobiographical memories after ECT. In a follow-up report on this sample, the pre-ECT modified Mini-Mental State Exam score was predictive of the extent of retrograde autobiographical amnesia both 1 week and 2 months after ECT (Sobin et al. 1995). This study provided evidence in support of the conventional clinical wisdom that preexisting cognitive deficit is a risk factor for more severe ECT-induced amnesia. Work is under way by our group to determine whether age-related structural changes on brain images might also be predictive of cognitive impairment after ECT (Coffey 1996).

Memory performance has been reported to improve in elderly patients with the pseudodementia of depression who are treated successfully with ECT (Reynolds et al. 1987; Stoudemire et al. 1995). In the study of Fraser and

Glass (1980) described earlier (also see Table 35–1), all elderly patients showed impairment of memory function before ECT, but during treatment, memory improved and was normal in all patients by 3 weeks after completion of the ECT course. No group differences were found on the basis of electrode placement.

There has been relatively little research into the effects of age on subjective memory complaints after ECT. As noted previously, Devanand et al. (1995) found that older patients actually reported fewer severe cognitive symptoms (i.e., confusion/disorientation and amnesia) than did younger patients.

In summary, recent controlled data appear to support the clinical wisdom that elderly patients are at greater risk for the amnesic side effects of ECT. More work is needed in a larger number of elderly patients (especially very old patients) to characterize the extent and severity of ECT-induced amnesia and to identify relevant risk factors, including the effects of preexisting cerebral impairment. Recommendations for lessening ECT amnesia in elderly patients include using unilateral electrode placement and brief pulse stimuli, avoiding maximally suprathreshold stimulus dosing, and lessening the frequency of treatments (e.g., giving ECT on Monday and Friday instead of Monday, Wednesday, and Friday). A variety of pharmacological agents have shown anti-amnesic activity in animal models of ECT, but clinical trials in humans have been limited by methodological issues (Prudic et al. 1998).

## ■ Psychosocial Issues

In addition to its myriad biological effects, ECT has important intrapsychic and interpersonal effects. A powerful treatment, during which the patient is put to sleep and has an electrical stimulus delivered to the head, may arouse predictable fears and fantasies in the patient. Issues of trust and autonomy over one's body while in a vulnerable position may predominate, especially in patients with a history of trauma. Patient education—in particular, educational videotapes—may be effective and reassuring for these fears. Patients who are vulnerable to idealized fantasies of a nurturant, all-caring, supportive other may overvalue the ECT procedure and practitioner. Conversely, these patients may excessively devalue the treatment when their distorted expectations are not realized. Such patients may be at increased risk for a bad psychological outcome from the treatment. Overridealization of the treatment should be challenged by the ECT practitioner, and the informed consent process should be firmly grounded in factual information.

Patient attitude surveys indicate that those undergo-

ing ECT typically find the experience no more upsetting than a trip to the dentist (Fox 1993; Hughes et al. 1981; Malcolm 1989). In the only study that has systematically examined the effects of age on patients' perception and knowledge of ECT, Malcolm (1989) found that patients over 65 had less knowledge of the procedure before treatment and were also less fearful of it. In addition, fewer elderly patients viewed the treatment as frightening after completing a course of ECT.

Medicolegal issues surrounding the use of ECT in elderly patients include the informed consent process (discussed earlier in this chapter), do-not-resuscitate (DNR) orders, and consideration of driving after ECT. A patient with DNR status may still experience improved quality of life with aggressive treatment of his or her affective disorder and may still be considered for ECT (Sullivan et al. 1992). In such cases, strategies for the management of major complications that could occur during ECT should be discussed with the patient and the family before treatment. Patients should not drive until that point after a course of ECT when cognitive side effects have substantially resolved (Fink 1994). This issue may be an especially sensitive one for elderly patients who consider driving a means of maintaining their mobility and functional independence.

Financial concerns are of increasing importance in today's cost-conscious health care marketplace. A growing literature suggests that ECT has economic advantages over other forms of treatment for severe mood disorders. The cost-effectiveness of ECT has been demonstrated for both inpatient treatment of the index episode as well as for maintenance therapy on an ambulatory basis (Markowitz et al. 1987; McDonald et al. 1998; Olfson et al. 1998; Steffens et al. 1995). Despite these advantages, there remains much variation in ECT reimbursement patterns, and it is not uncommon to encounter payers who will reimburse only for ECT when it is given on an inpatient basis. In addition, reimbursement rates are very low and thus discourage the use of this safe and highly effective treatment.

## ■ Transcranial Magnetic Stimulation

Transcranial magnetic stimulation (TMS) is a relatively new technology that uses an electrically induced magnetic field to generate small electrical currents that can depolarize brain neurons. Repeated TMS (rTMS) can cause repeated neuronal firing that (depending on a variety of technical factors related to the TMS, as well as possible host factors) can either augment or suppress neuronal network functioning. Many ECT research groups throughout the world are currently investigating rTMS as a possible anti-

depressant treatment. Most studies have been open trials, relatively few elderly patients have been studied, and results indicate that there are minimal side effects but only modest improvements in mood (for a concise review, see George 1998). Although it is unclear what role rTMS will play in the management of elderly patients who are candidates for ECT, rTMS holds great promise as a tool for understanding the neurobiology of mood regulation.

## ■ Conclusions

Sixty years after its introduction, ECT remains a cornerstone of the treatment of severe affective disorder and selected other neuropsychiatric illnesses in elderly patients. Recent modifications in ECT technique have reduced the risk of severe side effects in this population. There is, however, a paucity of controlled studies comparing the efficacy and safety of ECT versus pharmacotherapy in elderly patients. ECT also appears to be an effective treatment in patients with preexisting brain disease and in some cases may even have a beneficial effect on the underlying neurological disorder. Further study is needed to determine the impact of age-related changes in brain structure or function and of preexisting cerebral disease on the beneficial and adverse effects of ECT in the elderly.

# Psychosocial Therapies

Linda Teri, Ph.D.

Susan M. McCurry, Ph.D.

Historically, it was believed that older adults were not good candidates for nonpharmacological, psychotherapeutic interventions. However, in the past several decades, there has been a growing awareness of the psychosocial issues confronting aging adults and of the value of psychotherapy as a tool for managing age-related change and maintaining quality of life. The empirical literature on the treatment of depression in older adults has been summarized in numerous recent reviews (Niederehe 1994, 1996; Scogin and McElreath 1994; Teri et al. 1994). Studies of a number of other treatments related to psychological health in elderly patients have also been reviewed, including behavioral assessment and treatment of anxiety (Hersen and van Hasselt 1992), behavioral management of dementia (C. K. Beck and Shue 1994; Fisher and Carstensen 1990), reminiscence therapy or life review (Haight 1991; Thornton and Brotchie 1987), treatments for sleep and cognitive enhancement (Gatz et al. 1998), and group interventions for family caregivers (Bourgeois et al. 1996; Knight et al. 1993).

In this chapter, we summarize the main psychosocial treatments that have been empirically evaluated in older

adults. The focus of the chapter is on psychosocial treatments designed to improve the emotional status of participants. Therefore, the studies reviewed here had as their primary treatment outcomes psychological variables such as depression, anxiety, and other psychiatric symptoms; life satisfaction; interpersonal skills; coping and stress management; and caregiver burden. The emphasis of the chapter is on controlled clinical trials; individual case studies or treatments conducted using single-case design methodologies are not discussed. The majority of the reviewed empirical psychosocial studies involved cognitive-behavioral, brief psychodynamic, or reminiscence-based interventions. Studies of other forms of treatment for geriatric patients, including interventions for alcohol abuse (e.g., Kashner et al. 1992), behavioral treatments for insomnia (e.g., Bliwise et al. 1995; Morin et al. 1999), and cognitive training or memory-enhancement programs (e.g., Quayhagen et al. 1995; Verhaeghen et al. 1992), were excluded unless they included evaluation of mood or psychosocial status as primary outcomes. Also excluded were studies describing treatment of older patients using somatic therapies (e.g., use of light treatment, exercise, massage, or white noise to reduce agitation in patients with dementia [Burgio et al.

1996; Lovell et al. 1995; Snyder et al. 1995]) and studies describing staff training programs in institutional settings (e.g., Baltes et al. 1994; Blair 1995; Heacock et al. 1997; Lantz et al. 1997). In summary, the focus of this chapter is on controlled clinical trials of psychosocial treatments for older adults in which the primary treatment outcomes were psychological.

## ■ Psychotherapy for Depression in Older Adults

Much of the psychotherapeutic research involving elderly patients has focused on the treatment of depression. Depression is thought to affect approximately 15% of community-dwelling persons over age 65 and up to 25% of nursing home residents (National Institutes of Health 1991). Depressive symptoms are also prevalent among medically or neurologically ill older adults, including those with dementia and their caregivers (Baker 1996; Gallagher et al. 1989; Teri and Wagner 1992). Nevertheless, epidemiological studies indicate that older adults are underserved by mental health care providers. It has been estimated that only 10% of the older population in need of psychiatric treatment receives this care (National Institutes of Health 1991). Because recurrence of depressive episodes is common throughout the life span, and suicide rates for older adults are greater than for younger adults (Bharucha and Satlin 1997; Reynolds 1997), this lack of psychosocial treatment in geriatric patients is a cause of concern. Fortunately, the literature has generally demonstrated that both acute and continuation therapies can be effective with depressed elderly patients (see Chapter 13). In this section, we review empirical studies of psychosocial interventions that were specifically designed to reduce depression in community-dwelling older adults without dementia.

### Cognitive-Behavior Therapy and Psychodynamic Psychotherapy

Cognitive-behavioral approaches have been widely used in the treatment of depression in geriatric outpatients. *Cognitive-behavior therapy* (CBT) refers to an approach that combines the conceptual and applied work of various cognitive and behavioral-social learning theorists such as Beck (see A. T. Beck et al. 1979) and Lewinsohn (see Lewinsohn et al. 1984). In interventions involving CBT, it is generally assumed that psychiatric disturbances are learned and maintained through a combination of cognitive distortions and behavioral or environmental events. Thus, the goal of treatment is to change the cognitive and behavioral context

in which the disturbance occurs, through use of specific techniques such as providing new information, teaching problem-solving strategies, correcting skills deficits, modifying ineffective communication patterns, or changing the physical environment in which problems arise. Homework assignments to supplement in-session interventions are frequently given. Although specific treatment protocols vary, all cognitive-behavioral approaches tend to be active and to be focused on solving specific, current day-to-day problems, rather than on effecting global personality change. In practice, the terms *psychoeducational* and *cognitive-behavioral* are often used interchangeably to refer to similar intervention strategies.

A few controlled studies have compared the use of psychodynamic or insight-oriented approaches with that of either CBT or pharmacotherapy in depressed older subjects. The dynamic approaches used in these studies differ from CBT in their emphasis on the importance of the therapeutic relationship as a mechanism of change and in their focus on historical causes of current patient behavior. Typically, patients are not taught specific skills as a part of therapy, nor is homework outside of session considered an essential aspect of treatment. Rather, greater import is assigned to patients' psychological insight and ongoing emotional experience. Therapeutic techniques such as reflection or interpretation of patient resistance are often used, and the therapist tends to be less directive than in CBT. Brief dynamic or insight-oriented approaches have been developed, however, that emphasize specific problem resolution within a limited number of therapy sessions (Strupp 1982). Among the brief manualized psychodynamic approaches, interpersonal psychotherapy (IPT) (Klerman et al. 1984), has been the most widely used in controlled clinical outcome trials with depressed older patients.

Much of the empirical data on the efficacy of CBT in geriatric subjects have been obtained by L. W. Thompson, Gallagher-Thompson, and their colleagues (Table 36-1). Several of their studies compared cognitive and behavioral treatments with a brief psychodynamic or insight-oriented approach. For example, Gallagher and Thompson (Gallagher and Thompson 1982, 1983; L. W. Thompson and Gallagher 1985) compared the effectiveness of short-term individual cognitive, behavioral, and brief relational-insight therapies in a sample of 30 elderly outpatient volunteers who had no evidence of significant cognitive impairment (Mini-Mental State Exam [MMSE] score of 25 or higher) and in whom a major depressive disorder had been diagnosed. There was a substantial decrease in depressive symptoms in subjects in all three groups by the end of treatment, and this decrease was maintained at 1 year. However, maintenance of treatment gains was not the

Reynolds et al. 1992, 1994, 1995, 1996a, 1996b, 1997, 1999a, 1999b; Dew et al. 1997; Opdyke et al. 1996–1997; Miller et al. 1997; Thase et al. 1997; Wolfson et al. 1997	158 consecutively enrolled elderly patients with recurrent MDD	Range, 60–80	After successful open treatment (nortriptyline therapy plus weekly IPT) of index depressive episode, patients are randomly assigned to one of four maintenance therapies: Nortriptyline therapy Nortriptyline therapy and IPT Placebo and IPT Placebo	Monthly for 3 years or until recurrence of major depressive episode
Mossey et al. 1996	76 medical outpatients (recently hospitalized) with subdysthymic depression	Mean, 71 (range, 60–91)	IPT Usual care	10 sessions in 3 months

*Note.* BT = behavior therapy; CBT = cognitive-behavior therapy; CT = cognitive therapy; IPT = interpersonal psychotherapy; MDD = major depressive disorder.

<sup>a</sup>Studies cited together involved subsamples of the same sample in the larger randomized clinical trial.

<sup>b</sup>A diagnosis of MDD is indicated for subjects in studies in which the diagnosis was specified; other studies may also have included subjects with this diagnosis.

same across the three groups: depressive symptoms increased in subjects in the brief relational-insight therapy group, beginning as early as 6 weeks after treatment, whereas no such relapse was evident in subjects in the other two groups.

Subsequent studies (L. W. Thompson and Gallagher 1984) repeated the comparison of cognitive, behavior, and brief dynamic therapies in elderly patients without dementia and in whom a major depressive disorder had been diagnosed. Significant decreases were noted in depression for all three groups compared to a 6-week, delayed treatment control condition (Gallagher-Thompson et al. 1990; L. W. Thompson and Gallagher 1986; L. W. Thompson et al. 1987). Other research groups have reported similar results. Fry (Fry 1984) found group CBT, both in immediate- and in delayed-treatment form, to be effective in reducing depression in geriatric subjects, although patients were experiencing a wider range of depressive symptoms (including milder symptoms) before treatment than in the studies described previously. Strategies involving CBT have been shown to be effective in treating depression in elderly patients whether such techniques are taught by professional or peer instructors (L. W. Thompson et al. 1983) and through self-paced or time-limited bibliotherapy (Scogin et al. 1987, 1989, 1990).

CBT has also been compared with pharmacotherapy for treating depression in elderly patients. Jarvik, Steuer, and their colleagues (Jarvik et al. 1982; Steuer et al. 1984) conducted two concurrent studies in geriatric outpatients who met DSM-III (American Psychiatric Association 1980) criteria for major depression. In one study (Jarvik et al. 1982), they compared the response of patients who received either imipramine, doxepin, or a placebo. In the other study (Steuer et al. 1984), patients who had no evidence of severe cognitive impairment were assigned to CBT or group psychodynamic therapy. Results indicated that all medication and therapy approaches were better than a placebo in reducing depression, and no significant differences in response between active treatments (imipramine vs. doxepin therapy, CBT vs. dynamic therapy) were observed. Medication therapy initially (at 26 weeks) was associated with a higher full remission rate than was psychotherapy (45% vs. 12%, respectively) (Jarvik et al. 1982). However, in the medication group, the drop-out rate was higher and more subjects showed no improvement by the end of treatment (36 weeks) than in the psychotherapy group. Further, by the end of treatment, 40% of all patients who completed psychotherapy had achieved a full remission in depression, eliminating the early advantage found in medication recipients. Results for the CBT group were slightly better than for the psychodynamic group, but

because subjects were enrolled in an open-trial (nonrandomized) fashion, these conclusions are difficult to interpret (Steuer et al. 1984).

Beutler et al. (1987) compared the relative and combined effectiveness of alprazolam therapy and group cognitive therapy in geriatric patients with major depression. Patients were randomly assigned to a 20-week course of therapy plus medication (alprazolam or placebo) or medication only. Subjects in all treatment groups showed reductions in depressive symptoms (as rated by interviewers using the Hamilton Depression Rating Scale [HDRS]) after 1 month of treatment, and gains were maintained through follow-up sampling (3 months after treatment). However, patient self-reports of depression (as rated using the Beck Depression Inventory [BDI]) and sleep disturbance indicated continued improvement after 1 month and at follow-up only for subjects who received group therapy. Significantly more patients who received cognitive therapy and medication were asymptomatic by the end of follow-up than were those who received medication without psychotherapy. No significant differences were reported for subjects receiving therapy with or without active medication.

More recently, L. W. Thompson and colleagues (1991) compared the efficacy of CBT with that of desipramine therapy, either alone or in combination with CBT, in treating 67 depressed elderly patients. Patients who received combined treatment had significantly greater reductions in depression than did those in the desipramine-only group, but not those who received CBT only. No significant differences in depression measures were observed in subjects who received either desipramine or CBT alone.

IPT has been compared with nortriptyline therapy in some of the most extensive research into psychosocial interventions for treatment of geriatric depression (Table 36-1). Early studies showed that IPT was as effective as nortriptyline therapy at 6 and 16 weeks in the acute treatment of geriatric major depression and that IPT was also associated with lower drop-out rates (Schneider et al. 1986; Sloane et al. 1985). Short-term IPT (six to eight sessions) has also been shown to reduce subdysthymic depression significantly, as evidenced on the Geriatric Depression Scale (GDS), up to 6 months after hospital discharge in elderly outpatients, compared with persons receiving usual medical care (Mossey et al. 1996). In an ongoing double-blind, controlled study, Reynolds and colleagues (1999b) are following a group of cognitively intact elderly individuals who, after successful treatment for recurrent major depression with a combination of IPT and nortriptyline, were randomized to maintenance treatment for 3 years with placebo, nortriptyline, or a combination of

IPT and placebo or IPT and nortriptyline. This study showed that elderly patients are able to benefit from psychological or pharmacological treatment of acute depression, although their rate of response is somewhat slower, and relapse rates appear to be higher, than among younger depressed individuals (Reynolds et al. 1999a).

A variety of factors may influence treatment outcome in studies of CBT and dynamic interventions in older adults. For example, in the Pittsburgh IPT studies, family involvement in educational workshops was linked to improved response to depression treatment and lower drop-out rates (Sherrill et al. 1997). Persons who reported good-quality sleep during the early stages of maintenance therapy have been shown to have significantly lower rates of depression relapse after active antidepressant medication therapy is discontinued and replaced with monthly IPT sessions plus placebo (Reynolds et al. 1997). M.G. Thompson et al. (1995) reported a relationship between major shifts in depressive mood and relapse rate in elderly patients being treated with cognitive, behavioral, or brief psychodynamic therapy. Gallagher-Thompson and Steffen (1994), who treated depressed elderly caregivers with either CBT or brief psychodynamic therapy, reported an interaction between form of treatment and duration of caregiving; individuals who had been caregivers for more than 3.5 years showed greater posttreatment benefit and were less likely to drop out of CBT, whereas those who had been caregivers for a shorter time showed greater improvement with the brief psychodynamic treatment.

Other intra-individual characteristics that have been linked to poor treatment response in elderly patients include endogeneity of depression (Gallagher and Thompson 1983), presence of a personality disorder (L. W. Thompson et al. 1988), and pretreatment defensiveness (Gaston et al. 1988). Commitment to therapy and positive expectations of change have been associated with reductions in depression among elderly patients receiving cognitive therapy but not behavioral or psychodynamic treatment (Gaston et al. 1989; Marmar et al. 1989). Reynolds et al. (1995) outlined many of the logistical challenges of successful depression treatment in this age group, including research recruitment, treatment noncompliance, and selection of appropriate outcome measures. Therapist bias against older adults may be a factor in treatment availability for and outcome with elderly patients (Fry 1986; Lazarus and Weinberg 1982), although few empirical studies have examined the relationship between treatment outcome and therapist variables. Because patients with significant cognitive impairment were generally not enrolled in the existing empirical studies on geriatric depression, there is also little known about the impact of cognitive function (e.g.,

reading ability, conceptualization, or problem-solving skills) on treatment effectiveness or compliance. Future studies are needed to clarify how these or other covariates may influence treatment outcome.

In summary, there is a growing empirical literature showing the effectiveness of CBT and brief psychodynamic therapies in treating depression in physically healthy elderly patients without dementia (studies involving physically frail or cognitively impaired depressed individuals are reviewed later in this chapter). There is evidence that symptom improvements obtained with psychotherapy are equal to those found with pharmacotherapy and that psychotherapy may be associated with lower drop-out rates than pharmacological interventions alone. A wide variety of CBT formats, including individual and group interventions, bibliotherapy, and variants of CBT (cognitive only and behavioral only), have produced reductions in depression. In many studies, treatment gains have been maintained for up to 1 year. The focus of psychotherapy literature has primarily been on community-residing volunteers with a diagnosis of major depression; however, some studies have shown psychotherapy to be effective with milder or chronic depressive symptoms as well. As yet, no empirical studies have examined the efficacy of CBT or psychodynamic treatments in older adults requiring hospitalization for severe depression. However, the research methodologies and standardized assessment instruments that have been used in outpatient studies of CBT and psychodynamic interventions should be applicable in future research with depressed geriatric inpatients as well.

## Reminiscence and Life Review Therapies

There is a growing empirical literature on the effectiveness of reminiscence and/or life review therapy in elderly patients. *Reminiscence* is defined as “the act or process of recalling the past . . . a narration of past experiences” (American Heritage Dictionary 1985). In reminiscence therapy, elderly patients are encouraged to remember the past and to share their memories, either with a therapist or with peers, as a way of increasing self-esteem and social intimacy. It is often highly directive and structured, with the therapist choosing each session’s reminiscence topic. In life review therapy, not only are past experiences recalled, but an effort is made to help patients reexperience old conflicts and rework them so that there is therapeutic resolution. In other words, life review is one form of reminiscence, designed to produce a better understanding and acceptance of past events (Butler 1963). In the clinical intervention literature, however, *reminiscence* and *life review* are often used interchangeably for any individual or group

narrative therapy that encourages patients to remember and describe the past.

Empirical trials have been conducted in which reminiscence and life review were used to reduce depression and anxiety (measured using a variety of self-report measures) and to increase feelings of self-esteem and life satisfaction in older elderly patients (Table 36–2). Although some results have been promising, findings have been inconsistent. For example, Fielden (1990) observed that life satisfaction and socialization increased more among reminiscence group participants than among participants in a “here and now” current events group conducted at a sheltered housing complex. In contrast, Lappe (1987) and Rattenbury and Stones (1989) found that both reminiscence and current events discussion groups were effective in improving elderly patients’ ratings of psychological well-being. McMurdo and Rennie (1993) reported reductions in depression among retirement home residents who were enrolled in either reminiscence or exercise groups, although depression decreased more in persons who exercised twice a week. Arean et al. (1993) found that although both reminiscence therapy and problem-solving therapy led to reductions in depression among older adults compared with wait-list control subjects, subjects who underwent reminiscence therapy were significantly more depressed after the conclusion of treatment and at 3-month follow-up than were those who underwent problem-solving therapy. Still other studies have found that reminiscence activities had no significant effects on depression, anxiety, or self-esteem (Hedgepeth and Hale 1983; Perrotta and Meacham 1981).

A number of variables may contribute to the inconsistent impact of reminiscence on psychological well-being, including cognitive function. In most studies conducted so far, persons with obvious cognitive impairment or dementia were excluded from participation, but in almost none of the studies was a formal cognitive screening tool, such as the MMSE or Mental Status Questionnaire, used to assess cognitive function. Other factors that may affect treatment outcome include intervention frequency and duration (Baines et al. 1987; Lappe 1987), patient age (Youssef 1990), whether reminiscence therapy is conducted in a long-term care or community setting (Lieberman and Falk 1971; Molinari and Reichlin 1985) or directed by peer or professional leaders (Fielden 1990; Lieberman and Bliwise 1985), variability in measures of change used to assess treatment outcome (Berghorn and Schafer 1987), and whether environmental stimuli (such as music) are used to enhance the reminiscence process (Bennett and Maas 1988). The amount of structure provided to the reminiscence activity may also affect treatment outcome. For example, systematic life review techniques may be more ther-

apeutic than simple reminiscence, given that life review encourages a reexamination of the emotional outcomes of past events and may enable an individual to put these events in a different, more positive perspective (Parker 1995). Fry (1983) found that “structured” reminiscence was more successful than “unstructured” reminiscence in lowering depression posttest scores and significantly increased the number of reports of self-confidence and adequacy. Haight (1988) compared the effects of structured life review reminiscing in combination with nonstructured “friendly home visits” with the effects of no treatment. Subjects who engaged in life review reported increased amounts of life satisfaction and increased psychological well-being at 8-week posttest, and life satisfaction ratings remained higher for these individuals than for control subjects at 1-year follow-up; however, improvements in other measures of well-being (e.g., affect balance or depression) were no different from those among controls at 1 year (Haight 1992). Structured life review strategies have been found to be as effective as systematic relaxation training (Ingersoll and Silverman 1978) and CBT (Harp-Scates et al. 1986) in reducing anxiety and improving life satisfaction or self-esteem.

The impact of reminiscence techniques may depend on whether they are used in an individual or a group therapy format. For example, some authors have noted that individual reminiscence has produced positive outcomes less consistently than have group interventions (Watt and Wong 1991). However, other authors have reported improvements in mood after individual reminiscence procedures (Fallot 1980; Fry 1983) and have even suggested that individual interventions may be the treatment of choice for life review with geriatric subjects (Haight 1988). There is also some concern that the terms *reminiscence* and *life review* actually describe distinct psychological processes and that these processes may significantly alter the effectiveness of reminiscence as a therapeutic technique (Watt and Wong 1991). Indeed, the conceptual differences between simple reminiscence and active life review have been considered by a number of authors (see Merriam 1980; Molinari and Reichlin 1985; Watt and Wong 1991). However, to date there has been no empirical attempt to define operationally the processes of reminiscence and life review or to test the impact of each on selected clinical populations.

In summary, a number of empirical studies of reminiscence and life review have indicated that both can help reduce negative mood and improve life satisfaction and self-esteem in geriatric outpatients. However, nonsignificant findings have been reported in several studies, which has led to speculation about factors that increase the efficacy of reminiscence strategies. The approach to remi-

**TABLE 36-2. Empirical studies of reminiscence therapy in depressed older adults**

Study	Subjects	Subject age (years)	Treatment	Treatment duration
Ingersoll and Silverman 1978	17 community residents	Mean, 70	Behavior therapy group Reminiscence/life review group	8 sessions
Fallot 1980	36 female outpatients	Mean, 66 (range, 46–85)	Individual reminiscence Individual current or future events	2 sessions
Perrota and Meacham 1981	21 community residents	Mean, 75–80	Individual reminiscence Individual current life events No treatment (control)	5 sessions
Fry 1983	162 outpatients with depression	Median, 68 (range, 65–82)	Individual structured reminiscence Individual unstructured reminiscence Attention only (control)	5 sessions
Hedgpeath and Hale 1983	60 female outpatients	Mean, 76 (range, 60–98)	Individual reminiscence (past successes) Individual reminiscence (present positive events) No reminiscence (control)	1 session
Harp-Scates et al. 1986	50 outpatients	Mean, 75 (all subjects > 65)	Group cognitive-behavior therapy Reminiscence group Recreational activity	6 sessions in 3 weeks
Lappe 1987	83 NH residents	Mean, 83	Reminiscence group Current events group	10 weeks (half met two times/week, half met one time/week)
Bennett and Maas 1988	26 female NH residents	Mean, 82	Music-based life review group Verbal life review group	6 sessions
Haight 1988, 1992	60 homebound elderly patients	Mean, 76 (range, 61–99)	Individual life review “Individual friendly visits” (control) No treatment (control)	6 sessions
Rattenbury and Stones 1989	24 NH residents	Mean, 83–87	Reminiscence group Current topics group No treatment (control)	8 sessions
Fielden 1990	31 sheltered housing residents	Mean, 74–75	Reminiscence group “Here and now” group	9 sessions
Youssef 1990	66 female NH residents	All subjects > 65	Reminiscence group (65–74 years) Reminiscence group (75+ years) No treatment (control)	6 sessions in 5 weeks

Arean et al. 1993	75 older adults with unipolar, major depressive disorder	Mean, 66–68 (range, 55–80)	Problem-solving therapy Reminiscence therapy	12 sessions
McMurdo and Rennie 1993	49 elderly residents of local-authority residential homes	Mean, 81 (range, 64–91)	Wait list (control) Exercise to music Reminiscence and music	2 sessions/week for 7 months

Note. NH = nursing home or long-term residential setting.

niscence or life review used for the treatment of geriatric depression has not been standardized, and many protocol variations exist that could influence treatment outcome. Although the effectiveness of reminiscence remains inconclusive, studies do suggest that structured life review strategies may be more effective than simple narrative reminiscence. However, the lack of objective cognitive screening procedures may have led to a wide variability in subjects' cognitive status across studies and in subsequent ability to remember and to benefit from the reminiscence process. There is also evidence that life review conducted in different formats (individual or group) may produce different effects, but no well-designed comparison studies have been conducted to evaluate this hypothesis. There has also been no attempt to identify which clinical groups are most likely to benefit from reminiscence therapy or under what circumstances alternative treatments should be considered.

### ■ Psychotherapy for Depression in Elderly Patients With Dementia

There is growing interest in the psychosocial treatment of depression in patients with dementia because depression is commonly associated with dementia, and treatment of depression can have a positive impact on the functional status of cognitively impaired individuals (Teri and Wagner 1992). In this section, we discuss the empirical studies of treatments specifically geared toward reducing depression in cognitively impaired individuals.

Abraham et al. (1992) randomly assigned 76 nursing home residents with mild to moderate cognitive impairment (based on Modified MMSE scores) and depressive symptoms (GDS scores of at least 11) to CBT, focused visual imagery, or education-discussion groups (Table 36–3). No significant reductions in depression, feelings of hopelessness, or life satisfaction scores were observed for any group after completion of the 24-week intervention, although cognitive test scores did improve slightly over the treatment period. The authors suggested that these negative mood findings may have been due to participants' physical frailty and cognitive impairment and to the limited treatment duration.

A subsequent study involving community-dwelling patients with Alzheimer's disease and their caregivers (Teri et al. 1997) showed that behavior therapy can be effective in the treatment of major or minor depression in outpatients with dementia. Treatment was based on a social-learning model in which depression is viewed as a series of behaviors that are learned and maintained through positive and nega-

**TABLE 36-3. Empirical studies with depressed, cognitively impaired older adults**

Study	Subjects	Subject age (years)	Treatment	Treatment duration
Baines et al. 1987	30 NH residents with confusion	Mean, 82 (range, 72-90)	Reality orientation therapy-remembrance group No treatment (control)	40 sessions in 16 weeks (treatment group crossover at 8 weeks)
Goldwasser et al. 1987	27 NH residents with dementia	Mean, 82 (range, 70-97)	Reminiscence group Support (attention/placebo) group No treatment (control)	10 sessions in 5 weeks
Orten et al. 1989	56 NH residents with dementia	Mean, 83 (range, 58-101)	Reminiscence group No treatment (control)	16 sessions
Abraham et al. 1992	76 NH residents with depression and mild to moderate cognitive impairment	Mean, 84 (range, 71-97)	Group cognitive-behavior therapy Visual imagery group Education-discussion group	24 weeks
Baldelli et al. 1993	23 female NH residents with dementia	Mean, 85 (range, 75-94)	Reality orientation therapy No treatment (control)	3 sessions/week for 3 months
Teri et al. 1997	72 outpatients with Alzheimer's disease and major or minor depression	Mean, 76	Behavior therapy-pleasant events Behavior therapy-problem solving Typical care (control) Wait list (control)	9 sessions

Note. NH = nursing home or long-term residential setting.

tive reinforcement contingencies (Lewinsohn et al. 1980). Consequently, the central aim of treatment is to reduce or eliminate depressive behaviors by altering the contingencies that maintain them, as well as by introducing new contingencies to stimulate and maintain nondepressive behaviors. In the study by Teri et al. (1997), caregiver-patient pairs were randomly assigned in a double-blind, controlled clinical trial to one of two behavior therapies (behavior therapy-pleasant events or behavior therapy-problem solving) or one of two control protocols (typical care or wait list). Treatment consisted of nine individual, 60-minute sessions, one per week, with patients and caregivers participating in varying degrees. The goals of active treatment were to teach caregivers behavioral strategies for improving patient depression by 1) increasing the number of pleasant events and decreasing the number of unpleasant events and 2) using behavioral problem-solving strategies to alter the contingencies that relate to depression and associated behavior problems.

Significant reductions in depression on standardized measures (including the HDRS, BDI, and Cornell Depression in Dementia Scale) were noted in patients in the behavior therapy groups but not in those in the control groups (Teri et al. 1997). Fifty-two percent of patients assigned to behavior therapy-pleasant events and 68% of those assigned to behavior therapy-problem solving improved over the course of treatment, compared with 20% of subjects in the control groups. Treatment effects were maintained at 6-month follow-up, and baseline severity of depression was the only patient characteristic that predicted treatment response (more depressed subjects were more likely to benefit from treatment). Interestingly, caregivers of patients assigned to behavior therapy showed significant reductions in depression, whereas caregivers of patients on the wait list did not. This latter finding was unexpected, given that patient depression alone was the treatment target. Increased skill in patient management, availability of regular therapeutic support, and reduced depression in the family member with dementia most likely explain these added benefits. Thus, behavioral treatment of patients with dementia may have the additional advantage of improving caregiver affect and caregiving quality, both of which are important and are often not assessed in typical outcome studies (Teri et al. 1992).

Reminiscence and life review techniques have also been used in studies involving confused, depressed elderly patients in long-term care settings (Baines et al. 1987; Goldwasser et al. 1987; Orten et al. 1989). In these studies, reminiscence storytelling was conducted in a group format (Table 36-3). Specific topics or themes were suggested by staff, sometimes with the assistance of personal artifacts,

newspapers, music, or other memorabilia used to stimulate residents' memories. All three studies found that simple reminiscing led to reductions in depression and improvements in social functioning for the confused participants. However, changes were not maintained over time in all treatment groups. The inexperience of group facilitators and differing levels of patient impairment may have had a negative impact on long-term treatment effects (Goldwasser et al. 1987; Orten et al. 1989), although it may be that treatment based primarily on cognitive effort (e.g., reminiscence) should not be expected to have long-term effects on mood in persons with a progressive dementing illness. Interestingly, Baines et al. (1987) found that reminiscence groups did improve long-term interactions between nursing home staff and patients, perhaps due to increased staff understanding of patient needs and their caretaking roles.

One final approach to treating depression that has been described for use with dementia patients is reality orientation therapy (Baldelli et al. 1993). This form of therapy was designed to stimulate and consolidate cognitive functions that have not deteriorated. Baldelli et al. (1993) found that subjects who participated in a reality orientation therapy group for 3 months also had significantly lower ratings of depression on the GDS after treatment than did subjects who received no treatment. This study had notable methodological problems, including a lack of random assignment into treatment groups, and the report did not include information about group sample size, describe how the GDS was administered to the cognitively impaired participants, or include follow-up data. The study does, however, provide further indication that depression in patients with dementia may be treatable, and additional research regarding potential forms of treatment is warranted.

In summary, behavior therapy that emphasizes specific skills training and behavior change has been shown to be effective in reducing major and minor depression in outpatients with progressive dementing illnesses such as Alzheimer's disease. There is also evidence that treatment for depression in patients with Alzheimer's disease can improve caregivers' mood, even when treatment does not specifically focus on the caregiver. The empirical literature on the use of CBT in patients with dementia and their caregivers is still in its infancy, and such positive early results support further investigation. In long-term residential settings, reminiscence techniques have been used to improve mood and social functioning in severely impaired patients with dementia. However, changes associated with use of reminiscence are not well sustained once treatment is discontinued; therefore, reminiscence therapy may be most appropriate in settings in which reminiscence groups can be

available as needed for an unrestricted period (e.g., as part of an institutional day activity program). Additional information is also needed regarding the individual patient characteristics (e.g., level of cognitive function) that affect treatment effectiveness in patients with dementia. There are at present too few data to draw conclusions about the usefulness of nonbehavioral treatments (e.g., reality orientation therapy) for reducing depression in this group.

### ■ Psychotherapy in Medically Ill Elderly Patients

Elderly patients account for a disproportionately high percentage of the medical illnesses, disabilities, and utilization of health care services in the United States (Keuthen and Wisocki 1991). Because they also represent one of the fastest-growing segments of American society, there is concern that the demand for geriatric medical services will eventually exceed available resources. An increasing number of practitioners have begun exploring the supplemental role of psychosocial interventions in geriatric health care. For example, a number of studies have shown that the use of mental health services leads to a reduction in medical care, particularly in-hospital stays for persons over age 55 (Mumford et al. 1984). Use of behavioral interventions has been shown to improve elderly patients' compliance with difficult medical procedures and their involvement in wellness programs and exercise regimens (Gutman et al. 1977; Kirschenbaum et al. 1987; Matteson 1989). The application and efficacy of psychological interventions in older adults in chronic pain or undergoing medical rehabilitation have been described (Hartke 1991; Saxon 1991).

The majority of controlled experimental studies of psychosocial interventions in medically ill geriatric patients have focused on patients' abilities to cope with chronic or life-threatening illness (Table 36-4). Most of these studies have involved a combination of supportive, educational, and problem-solving strategies drawn from more systematic cognitive-behavioral, insight-oriented, or reminiscence-based approaches. For example, adjustment to declining sensory function has been a focus of some research. Evans et al. (1982) provided problem-solving group therapy by telephone to legally blind elderly patients. Participants showed increases in activity levels and decreases in self-reports of loneliness although no changes in actual social involvement were observed. Andersson and colleagues (1995) taught 12 hearing-impaired elderly patients a combination of relaxation, assertive communication, and problem-solving skills, with the goal of improv-

**TABLE 36-4. Empirical studies with medically ill older adults**

Study	Subjects	Subject age (years)	Treatment	Treatment duration
Godbole and Verinis 1974	61 rehabilitation inpatients with physical disabilities	Mean, 69 (range, 38–82)	Individual confrontational therapy Individual supportive therapy No treatment (control)	6–12 sessions in 2–4 weeks

Greer et al. 1992	156 patients with cancer	Mean, 51–52 (range, 18–74)	Individual CBT No treatment (control)	0–13 sessions in 4 months (median, 5 sessions)
Rice et al. 1993	229 alcoholic patients	Mean, 39 (range, 18–76; 18% of subjects ≥ 50)	CBT Relationship-enhancement therapy Relationship- and vocational-enhancement therapy	1–2 intake sessions; 1 session/week over 16 weeks; 2 booster sessions (3 months and 1 year after treatment)
Andersson et al. 1995	24 hearing-impaired subjects	Mean, 70 (range, 64–72)	Group CBT No treatment (control)	4 sessions in 5 weeks
Andersson et al. 1997	19 hearing-impaired subjects	Mean, 72 (range, 67–75)	Individual CBT bibliotherapy No treatment (control)	1 in vivo relaxation training session and 4 telephone sessions in 4 weeks

Note. CBT = cognitive-behavior therapy.

ing patient adjustment to hearing aids and challenging environmental situations (e.g., group conversation where there is background noise). Group participants scored higher on ratings of relaxation and socially appropriate body posture in posttreatment videotaped role plays and, at 1-month follow-up, reported a significantly better ability to handle difficult communication situations than did patients who received no treatment. In a subsequent study (Andersson et al. 1997), hearing-impaired patients who participated in a 4-week bibliotherapy program supplemented with brief weekly telephone contacts had better scores on the Communication Profile for the Hearing Impaired as well as in interpersonal role plays of difficult social situations (e.g., groups) than did control subjects, which suggests that self-help treatment materials may be of value for improving patient adjustment to hearing loss.

Studies have also examined the use of psychotherapy in elderly patients with cancer. Spiegel et al. (1981) found that patients with metastatic breast cancer who participated in a year-long, nondirective support group reported significantly less anxiety, fatigue, and confusion, as well as improved coping strategies, compared with control subjects. Greer et al. (1992) studied patients with newly diagnosed cancer who attended individual CBT sessions to learn a combination of relaxation techniques, cognitive coping strategies, and communication skills for improving interpersonal relationships. These patients reported significantly less anxiety, helplessness, fatalism, and depression and significantly greater adjustment to their disease than did subjects who received no treatment. Statistical improvements were maintained at 4-month follow-up.

Cardiovascular disease (including stroke and heart disease) is another medical problem in geriatric patients that may be amenable to psychotherapeutic intervention (Cohen-Cole 1989; Lipsey and Parikh 1989). Godbole and Verinis (1974) studied 61 older adults with a variety of physical disabilities, including cardiovascular and respiratory disease. Subjects were randomly assigned to "confrontational therapy," supportive therapy, or no treatment. Patients in both active treatment groups showed significant improvements on measures of depression, anxiety, feelings of hopelessness, and somatic complaints compared with control subjects. A number of authors (e.g., Butcher et al. 1984; Imes 1984) have suggested that group psychotherapy can improve social and psychological functioning in patients with stroke. The utility of various depression treatment measures for assessing poststroke depression in geriatric patients has also been described (Agrell and Dehlin 1989). Surprisingly, no empirical studies have demonstrated the efficacy of psychotherapy in this population. Data are available, however, on the use of psychosocial in-

terventions in patients with heart disease.

Ibrahim et al. (1974) compared elderly cardiac patients assigned to a weekly supportive therapy group and control subjects. Therapy group participants had slightly better survival rates and showed a smaller increase in social alienation than did controls during the study period, although no significant differences on psychological, physical, or social measures were obtained. In contrast, Gruen (1975) found that patients who were seen almost daily for supportive counseling and education while in intensive care after a heart attack scored lower on measures of anxiety and depression during hospitalization than did control subjects. Differences in anxiety between groups were maintained at 4-month follow-up, and subjects in the treatment group also tended to be less restricted in activity at follow-up compared with no-treatment control subjects. Oldenburg et al. (1985) found that patients receiving either brief (6–10 sessions) individual counseling and education or education alone after hospitalization for a heart attack reported better psychological and lifestyle functioning at 3-, 6-, and 12-month follow-up than did subjects who received routine care.

There is a growing literature on the impact of psychosocial treatments on disability, pain, and depression in older adults with rheumatoid arthritis or osteoarthritis (Mullen et al. 1987). Keefe et al. (1990) found that patients with osteoarthritic knee pain who received a combination of training in pain coping skills and arthritis education reported significantly lower amounts of pain and psychological disability (anxiety and depression) than did patients who received only arthritis education or standard medical care. However, earlier intervention studies involving patients with rheumatoid arthritis yielded less promising results. For example, Kaplan and Kozin (1981) found no differences between patients with rheumatoid arthritis who only received information about their disease and those who received information and participated in 12 nondirective group counseling sessions. Shearn and Fireman (1985) also found no significant differences in measures of depression, life satisfaction, or functional disability between patients with rheumatoid arthritis who participated in either stress management or mutual support groups for 10 weeks and control subjects. Thus, the effectiveness of interventions designed to treat psychological disability and pain behaviors in medical patients may be different in select populations. Other factors that may have confounding effects on treatment outcome in medically ill elderly patients include patient age and whether the spouse is involved in treatment (Keefe et al. 1990).

In summary, although the number of existing controlled studies is still relatively small and results are mixed,

there is evidence that psychosocial interventions are valuable adjunctive treatments for some of the medical conditions that affect older adults. Most studies have included medical outpatients, and all have involved some form of psychoeducational, problem-solving, or supportive intervention strategy. Significant improvements in depression, anxiety, feelings of hopelessness, and coping have been reported in patients with vision and hearing impairment, cancer, heart disease, and arthritis. Slight improvements in survival rate and lower risks for rehospitalization have also been described.

## ■ Psychotherapy and Geriatric Caregivers

The American Association of Retired Persons (1986) estimated that more than 5 million community-dwelling elderly people in the United States require some form of assistance to maintain independent living. The vast majority of this assistance comes from family members, usually spouses or grown children who are often themselves elderly or beyond middle age. Caregiving is often a difficult task associated with increased levels of depression, anxiety, insomnia, marital conflict, alcohol and medication use, and medical illness (Cantor 1983; Clipp and George 1990; Coppel et al. 1985; Farkas 1980; Gaynor 1989; Pruchno and Potashnik 1989; Rabins et al. 1982). Research on various psychoeducational, psychotherapeutic, and self-help interventions that have been used with caregivers has been summarized in reviews (Bourgeois et al. 1996; Knight et al. 1993; Toseland and Rossiter 1989; Zarit and Teri 1991). The authors of these reviews noted the lack of methodological rigor in most of these studies and the relatively modest treatment effects reported. They also pointed out the impracticality of expecting short-term supportive or educational interventions to have substantial impact, given the complexity and duration of the caregiving role. Nevertheless, research on the impact of psychosocial interventions with caregivers has rapidly grown over the past decade. This research can be divided into two distinct types: studies of interventions designed to enhance caregiver psychological functioning (here called *caregiver-focused interventions*), and studies of interventions designed to teach family caregivers to alter patient behavior or psychiatric status (here called *patient-focused interventions*).

The majority of the empirical treatment studies involving caregivers have been in the caregiver-focused intervention category. A number of these have included heterogeneous groups of caregivers and patient types (Table

36–5). For example, Greene and Monahan (1987, 1989) recruited community-dwelling caregivers whose levels of stress placed their elderly patients at risk for institutionalization. The majority of patients were living with their care providers (77%) and had at least one major medical illness (89%); Alzheimer's disease had been diagnosed in less than one-fifth (14%). Significant reductions in caregiver anxiety, depression, and burden levels were observed after 8 weeks of group counseling that had supportive, educational, and relaxation components. However, improvements were not maintained at 4-month follow-up, and no caregiver or patient characteristics were associated with any outcome. Lovett and Gallagher (1988) studied 107 family caregivers whose patients had a mixture of moderate to severe memory impairment (40% of patients) and a variety of medical conditions and disabilities. Caregivers who participated for 10 weeks in either a behaviorally based group focusing on increasing the number of pleasant events or a cognitive, problem-solving group experienced decreases in depression and increases in morale that were not observed in wait-list control subjects. Perceived self-efficacy was more strongly associated with improvement on outcome measures than was an abundance of pleasant social events in the caregiver's life.

Other investigators have attempted to control for heterogeneity of care providers by focusing on caregivers of patients with specific disabling conditions rather than on caregivers in general. Evans et al. (1988) studied caregivers of stroke patients and found that patients who either 1) participated in educational classes on the physical and psychosocial consequences of stroke or 2) participated in educational classes plus seven CBT sessions scored significantly higher at 6-month and 1-year follow-up on measures of family functioning, communication, and problem solving than did caregivers who did not receive education or CBT. Families receiving CBT had significantly higher levels of patient adjustment than did those receiving education alone or no education or CBT. This finding is particularly important given that 1) anxiety and depression are common after strokes (Gass and Lawhorn 1991); 2) left untreated, depressive symptoms may not spontaneously resolve over time (Egelko et al. 1989); and 3) level of depression and stroke recovery are strongly related to the quality of patients' family relationships and response to stroke-related disability (Evans et al. 1987; S.C. Thompson et al. 1989).

A large number of studies have focused on caregivers of patients with Alzheimer's disease or related dementias. Many of these studies have shown that although caregivers enjoy participation in supportive and psychoeducational groups, these treatments produce limited treatment

**TABLE 36-5. Empirical treatment studies with caregiving older adults**

Study <sup>a</sup>	Subjects	Subject age (years)	Treatment	Treatment duration
Kahan et al. 1985	40 caregivers of patients with Alzheimer's disease	Range, 16-77 (59% of subjects ≥ 60)	CBT Wait list (control)	8 sessions
Greene and Monahan 1987, 1989	289 caregivers of patients with dementia and medical illnesses (34 groups)	Mean, 58	Group support, education, and relaxation training No treatment (control) (self-selected nonparticipants)	8 sessions
Haley et al. 1987; Haley 1989	54 family caregivers of patients with dementia	Mean, 78	Support group Support and stress management group Wait list (control)	10 sessions in 4 months (7 weekly, 2 every other week, 1 after month delay)
Scharlach 1987	37 daughters (of 24 elderly widowed mothers)	Mean, 50 (range, 38-62)	Group CBT Support/education group Wait list (control)	2 sessions
Zarit et al. 1987	119 family caregivers of patients with dementia	Mean, 62	Support group Individual and family counseling Wait list (control)	8 sessions
Evans et al. 1988	188 caregivers of stroke patients	Mean, 61-63	Education group Education group and individual CBT Standard care (control)	Education group: 2 sessions Education group and CBT: 9 sessions
Lovett and Gallagher 1988	111 caregivers of frail elderly patients	Mean, 59	Behavior therapy group Problem-solving group Wait list (control)	10 sessions
Robinson 1988	20 caregivers of patients with dementia	?	Social skills training group Wait list (control)	8 sessions
Schmidt et al. 1988	20 family caregivers of patients with dementia	Mean, 61-62	Individual problem solving Individual emotional expression and problem solving	4 sessions
Chiverton and Caine 1989	40 spouses of patients with dementia	Mean, 71 (range, 58-87)	Education group No treatment (control)	3 sessions in 4 weeks
Montgomery and Borgatta 1989	541 families caring for 576 elderly persons with physical, functional, or cognitive impairment	?	Full family support services (caregiver seminars, support groups, family consultation services, and respite) Caregiver seminars, support groups, and family consultation only Caregiver seminars and support groups Family consultation services only Respite only No treatment (control)	6 sessions

**TABLE 36-5. Empirical treatment studies with caregiving older adults (continued)**

Study <sup>a</sup>	Subjects	Subject age (years)	Treatment	Treatment duration
Toseland et al. 1989	56 daughter/daughter-in-law caretakers of frail elderly patients	Mean, 50–55 (range, 35–66)	Professional-led support and education group Peer-led support group Respite only (control)	8 sessions
Goodman and Pynoos 1990	66 caregivers of patients with dementia	Mean, 63–66	Peer telephone network Telephone mini-lecture series (12 lessons)	2 supportive telephone calls/week for 12 weeks
Mohide et al. 1990	60 caregivers of patients with dementia	Mean, 66–69	Caregiver support program (home visits, respite care, and support group) Conventional care (home nursing) (control)	6 months
Toseland et al. 1990	154 daughter/daughter-in-law caretakers	Mean, 50–52	Individual supportive therapy Support group Respite only (control)	8 sessions
Toseland and Smith 1990	87 daughter/daughter-in-law caretakers	Mean, 50	Individual “action-oriented” therapy with professional counselor Individual “action-oriented” therapy with peer counselor No treatment (control)	8 sessions
Toseland et al. 1992	89 spouses of frail aging veterans	Mean, 64–68	Support groups (support, education, problem solving, stress reduction) No treatment (control)	8 sessions
Mittelman et al. 1993, 1995, 1996	206 spouse caregivers of patients with Alzheimer’s disease	87% of subjects ≥65	Individual counseling, family counseling, and support groups Usual care (control)	2 individual and 4 family sessions in 4 months; weekly support group sessions thereafter (groups meet indefinitely)
Robinson and Yates 1994	33 caregivers of family members with dementia	76% of subjects ≥60	Social skills development program (group) Behavioral management skills development program (group) No treatment (control)	6 sessions in 12 weeks
McCurry et al. 1998	36 caregivers of patients with dementia	Mean, 69 (range 50–86)	Group behavioral treatment Individual behavioral treatment Wait list (control)	Group treatment: 6 sessions Individual treatment: 4 sessions

Note. CBT = cognitive-behavior therapy.

<sup>a</sup>Studies cited together involved subsamples of the same sample in the larger randomized clinical trial.

effects. For example, Lawton et al. (1989) found that caregivers (of patients with Alzheimer's disease) who were offered a year of formal respite care, and provided with financial assistance as needed as well as education about the purpose and range of respite services available, were no different afterward, in terms of depression, subjective burden, or ratings of affect, from caregivers who received none of these services. Haley et al. (1987) found no improvements in community-dwelling caregivers' self-reports of psychological or social functioning after participation for 10 weeks in either support-only or support-with-skills-training groups. At 2-year follow-up, although caregivers reported high rates of satisfaction with these groups, there was no evidence of group differences in caregiver outcome, with the exception that group participation may have facilitated placement of patients under skilled nursing care (Haley 1989).

Mohide et al. (1990) compared live-in caregivers who received a combination of education, respite, and group support with caregivers who had standard contact with community home nursing services. Although neither group showed improvements in depression or anxiety after 6 months, caregivers who received the combination treatment did report more increases in perceived quality of life and satisfaction with nursing services and their caregiving role than did the conventional care recipients. Zarit et al. (1987) reported reductions in family caregivers' burden level and psychiatric symptoms after participation in an education and problem-solving support group for 8 weeks or 8 weeks of individual and family counseling, reductions that were maintained at 1-year follow-up. However, these treatment effects were no greater than the changes observed in wait-list control subjects. Finally, as already reviewed, Teri et al. (1997) found caregiver depression decreased with a patient-focused depression treatment program.

There are data showing that caregivers can benefit from brief interventions when the treatment focus is on some specific element of skills training. For example, McCurry et al. (1998) taught caregivers of patients with dementia with sleep disturbance a combination of behavioral strategies to improve sleep (sleep hygiene, stimulus control, and sleep compression) and provided education about caregiving resources and management of patient behavior problems. Caregivers who received individual or group treatment ( $n = 21$ ) had significant improvements in self-reported quality of sleep after treatment discontinuation and at 3-month follow-up compared with wait-list control subjects ( $n = 15$ ), but there were no reported improvements in caregiver depression or burden ratings or in patient behavior as a result of the intervention.

Scharlach (1987) examined whether the relationship between adult daughters and their elderly widowed mothers could be improved while the mothers were still functioning independently. Daughters were assigned to either a cognitive-behavioral intervention, which focused on reducing unrealistic feelings of responsibility, or a supportive-educational intervention, in which daughters were encouraged to become more aware of their mothers' needs. Daughters who attended the cognitive-behavioral seminar had greater reductions in feelings of burden than did control subjects or attendees of the supportive-educational seminar. Further, subjects assigned to a cognitive-behavioral intervention reported subjectively greater improvements in their relationships with their mothers, and the mothers reported significantly less loneliness, after the intervention than did subjects in the other two groups. The results of this study introduce the possibility that psychosocial interventions may serve a preventive function in individuals who are likely to become future caregivers.

A fewer number of controlled trials have been patient-focused interventions that examined the effectiveness of caregiver training programs on the behavior and care outcomes of patients with dementia. In an early study, Schmidt et al. (1988) randomized 20 caregivers to two treatment strategies (problem-solving therapy only and problem-solving therapy plus emotional expression group); there was no control group. After 4 weeks, no significant reductions in caregiver life satisfaction, burden, or psychiatric symptomatology were noted for either treatment. However, caregivers who received the combination treatment reported reduction of conflict with their relatives and greater patient trust and submission to caregiver requests compared with caregivers who underwent problem-solving therapy only. Robinson and Yates (1994) randomized 33 caregivers to one of three treatments: social skills development, behavioral management skills development, or no treatment. Caregivers were offered the option of completing a second (alternative) training after the initial 6-week intervention. At posttest, no significant differences were reported for any groups in caregiver ratings of burden or attitudes toward asking for help (including using senior day programs). Patient behavior problems were rated, although no information about method of assessment or outcome was provided in the report; caregivers who completed a second training ( $n = 6$ ) had significantly lower levels of objective burden compared with control subjects, which suggests that some reduction in patient behavior problems occurred.

Recent studies have suggested that significant treatment effects can be achieved when spousal caregivers are offered more intensive or focused programs of education,

individual and family counseling, or ongoing therapeutic support. For example, as reviewed earlier, Teri et al. (1997) found that both outpatients with Alzheimer's disease and their family caregivers experienced significant reductions in depression after completion of a 9-week behavior therapy (focusing on increasing the number of pleasant events or on problem solving) caregiver training program. Mittelman et al. (1993, 1995, 1996) randomly assigned 206 spousal caregivers of patients with Alzheimer's disease to either active treatment or normal care. Caregivers in active treatment received six initial (two individual and four family) psychoeducational sessions over a 4-month period. Caregivers were given information about basic communication, behavior management, and community resources and received a range of emotional and physical support. At the end of the 4 months, caregivers were required to join a support group that met weekly and would continue to meet indefinitely. In addition, caregivers had access to family counselors who were available at any time (including evenings and weekends) for support and assistance. The median time from baseline to nursing home placement was almost 1 year (329 days) longer for spouses of participants in active treatment than for spouses of control subjects, and treatment had the greatest effect when the impaired spouse had mild or moderate dementia.

Regardless of whether the caregiver or the patient is the focus of treatment, a variety of factors may influence treatment effects in caregiver intervention studies. Toseland and colleagues compared the effectiveness of peer-led versus professional-led "action-oriented" support groups for caregivers (Toseland et al. 1989), peer-led versus professional-led individual counseling (Toseland et al. 1990), and group versus individual therapy (regardless of type of leadership) (Toseland and Smith 1990). Significant improvements on measures of well-being and social support and decreases in psychiatric symptoms occurred as a result of both the peer-led and professional-led interventions, regardless of whether caregivers were seen in an individual or group context. However, greater reductions in psychiatric symptoms tended to be associated with individual and professional-led treatment, whereas greater increases in social support were noted with the group and peer-led interventions.

Caregiver relationship to patient may also influence treatment outcome. Montgomery and Borgatta (1989) assigned 541 families caring for impaired elderly individuals to either no treatment or one of five supportive programs with various combinations of education, respite, and family consultation services. After 1 year, they found that adult children caregivers in any of the active treatment groups were less likely than control subjects to have institutional-

ized their impaired parents, whereas spouses in active treatment groups (except for those with access to a family consultant only) were more likely to have done so.

In summary, the empirical literature on psychosocial interventions with caregivers is growing. There is evidence that brief psychosocial interventions can lead to increased caregiver knowledge, social support, feelings of well-being, patient behavior change, and delays in patient institutionalization. However, treatment effects tend to be modest and inconsistent across studies. There is some evidence that interventions that target specific caregiver problems (e.g., depression or sleep disturbance) may be more likely to have measurable effects, but there have been few studies in which caregiver outcome goals were narrowly defined. Unfortunately, follow-up data are still not always obtained in many caregiver studies, treatment tends to be brief, outcome measures are often poorly tied to intervention hypotheses, and study samples are typically small. Given the design limitations in many caregiver studies, the positive findings that have been reported are impressive and support the need for continued research with caregiver populations.

## ■ Psychotherapy and Elderly Patients in Long-Term Care Settings

A move into a long-term care setting can be difficult, or even traumatic, for many older adults. Consequently, there is growing interest in the use of psychosocial interventions to help ease some of the acute adjustment problems associated with long-term residential care. The interventions most commonly used with nursing home residents (Burckhardt 1987; Gugel 1989; Karuza and Katz 1991), the importance of outcome instrument selection in long-term care settings (Rabins et al. 1987), and unique design and administrative issues that affect treatment outcome research (Radebaugh et al. 1996; Rapp et al. 1994; Weiss 1994) have been identified in reviews. As noted at the beginning of this chapter, there are also growing numbers of institutional training programs geared toward teaching staff to manage specific patient behavior problems or improve independence in activities of daily living (Baltes et al. 1994; Blair 1995; Heacock et al. 1997; Lantz et al. 1997). Surprisingly, however, there are few studies that have examined the impact of psychotherapy on patients' psychological well-being and adjustment to nursing home life (Table 36-6).

Dhooper et al. (1993) conducted a pilot project with 16 depressed, cognitively intact nursing home residents. Subjects were randomly assigned to either an active treatment

**TABLE 36-6. Empirical studies with older adults in long-term care**

Study	Subjects	Subject age (years)	Treatment	Treatment duration
Power and McCarron 1975	30 NH residents with depression	Mean, 84 (range, 70–98)	Individual interactive contact (including physical touching and socialization) No treatment (control)	15 sessions
Langer and Rodin 1976	91 NH residents	Range, 65–90	Resident responsibility-induced group Staff conduct (control)	1 session
Schulz 1976	42 NH residents	Mean, 82 (range, 67–96)	Scheduled visits (visit times chosen by subjects) Scheduled visits (visit times not chosen by subjects) Nonscheduled random visits No visits (control)	2 months
Berger and Rose 1977	25 NH residents	Mean, 77 (range, 48–97)	Individual interpersonal skills training Individual discussion (control) Assessment only (control)	3 sessions
Lindell 1978	39 NH residents	Mean, 81–82 (all subjects > 65)	Supportive group therapy Group discussion (control)	Therapy: 16 sessions in 8 weeks Control: 3 sessions in 8 weeks
Langer et al. 1979	54 NH residents	Mean, 79–80	Individual visit (high self-disclosure) Individual visit (low self-disclosure) No treatment (control) Pretest only (control)	4 sessions in 6 weeks
Dye and Erber 1981	52 new NH residents	Mean, 80	Resident-only group Resident-family group No treatment (control)	7 sessions
Hanley et al. 1981	57 NH residents	Mean, 80	Group reality orientation Group reality orientation plus ward orientation No treatment (control)	4 sessions/week for 12 weeks
Hussian and Lawrence 1981	36 NH residents with depression	Mean, 74 (all subjects > 60)	Social reinforcement for activity Individual problem solving Wait list (control) Social reinforcement and problem solving Problem solving plus social reinforcement Education (control)	10 sessions in 2 weeks

TABLE 36-6. Empirical studies with older adults in long-term care (continued)

Study	Subjects	Subject age (years)	Treatment	Treatment duration
Moran and Gatz 1987	59 NH residents	Mean, 76	Task-oriented group Insight-oriented group Wait list (control)	12 sessions
Dhooper et al. 1993	16 NH residents with depression	Mean, 78 (range, 64–94)	Cognitive-behavior therapy and reminiscing Unspecified control	9 sessions
Weiss 1994	48 NH residents	? (“young old,” 55–74; “old old,” 75–100)	Cognitive therapy group Life review group Unspecified (“standard”) control	8 sessions
Lantz et al. 1997	14 NH residents	Mean, 81–82	Wellness group No treatment (control)	10 sessions
Rosen et al. 1997	31 NH residents with depression	Mean, 79 (range, 56–96)	Planned leisure activities Wait list (control)	8 weeks

Note. NHT = nursing home or long-term residential setting.

group (9 weeks of participation in a “Coping Together Group,” which included cognitive-behavioral and reminiscence treatment components) or an unspecified control (presumably no treatment) group. Subjects in the active treatment group reported significantly lower post-treatment levels of depression (as rated using the Zung Self-Rating Depression Scale) than did control subjects, although the fact that the study involved small numbers of subjects, no contact control, and apparently nonblinded raters may have influenced treatment outcome. No follow-up data were included in the report.

Dye and Erber (1981) described a program in which 52 new residents participated in support groups (with or without family members) to discuss the events that led to their move, any problems encountered during the admission process, and problem-solving strategies for coping with institutional life. Patients who participated in the resident-only group had lower levels of anxiety and higher internal locus of control scores than did either control subjects or patients who participated in the resident-family group. However, at 6-month follow-up, participants in the resident-only group were significantly more agitated and had lower health self-rating scores than did participants in the family-resident group and control subjects.

In other studies examining residents' adjustment to institutionalization, problems in generalization and long-term maintenance of treatment effects have been reported. Lindell (1978) reported positive changes in self-concept in long-term residential center and nursing home patients who participated in nondirective support groups; however, changes were maintained only in those subjects who continued to meet with their group regularly after the formal research study ended. Hussian and Lawrence (1981) found that depressed nursing home residents initially showed improvements in mood as a result of systematic increases in daily activity or training in problem-solving skills. However, after 2 weeks, only those subjects who both increased their daily activity and learned new problem-solving strategies continued to show improved mood. At 3-month follow-up, no gains were maintained. Thus, although support at the time of transition into a nursing home appears to enhance patients' immediate functioning, this improvement may not be sustained unless other factors are developed to maintain it.

Interpersonal factors have been shown to be particularly influential in patients' psychosocial functioning in long-term settings. For example, Power and McCarron (1975) found that increasing depressed geriatric patients' physical contact with staff, their verbal conversation, and their social interaction with peers led to reductions in self-reported and observed depression in the patients. Sim-

ilarly, Moran and Gatz (1987) found that nursing home residents who participated in an interpersonal task group (which developed a welcoming project for incoming residents) showed significant improvements in feelings of self-control and increases in scores of life satisfaction. Berger and Rose (1977) found that interpersonal skills could be effectively taught to nursing home residents, although in their study, learned skills were not subsequently used in novel, unpracticed situations. Thus, although increases in quantity and quality of interpersonal contacts may enhance patients' adjustment and functioning in long-term care facilities, it may be necessary for staff to provide ongoing opportunities and assistance if these improvements are to be maintained.

Other studies have suggested that sustained, successful coping in long-term care settings is affected by residents' perception of their autonomy and situational control (Langer and Rodin 1976; Schulz 1976) and that social interaction may be associated with improvements in their immediate memory, alertness, and self-initiation (Langer et al. 1979). Rosen et al. (1997) found that depressed nursing home residents randomly assigned to a control-relevant intervention (in which they were helped to establish an individualized leisure activity program) were more likely to show significant decreases in HDRS scores and to be judged as treatment "responders" by nursing staff than were subjects in a wait-list control group. Responders also showed significant improvements in ratings of community "cohesiveness" or supportiveness after treatment. However, improvements were not maintained once the 8-week intervention was discontinued. Further, the investigators had unexpected problems with recruitment and compliance. Nevertheless, the study provides evidence that interventions designed to empower nursing home residents and to help them reestablish patterns of positive social or recreational activity may be highly effective in ameliorating chronic depression in residential care settings.

In summary, there have been relatively few empirical studies on the use of psychotherapeutic interventions in elderly patients in long-term care settings. A number of those studies are more than 20 years old, and the fact that there are few recent studies is surprising, given the growing number of older adults who are unable to remain independent in their own homes. The existing studies often had small samples and problematic research designs. Nevertheless, the findings do suggest that treatment can improve patient self-concept, reduce depression, and enhance social interaction, although changes may not be well maintained without ongoing therapeutic support. Additional research in this area is clearly needed.

## Other Psychotherapeutic Interventions

In the remaining empirical studies of psychotherapy in older adults, a variety of intervention techniques were used to modify depression, anxiety, and other symptoms of emotional distress (Table 36–7). In several studies, meditation-relaxation and cognitive-change techniques were used, and although samples were small, consistent trends were observed. DeBerry (1982) found that 10 weeks of meditation-relaxation training was effective in reducing the number of self-reports of state and trait anxiety, but not depression, in a group of depressed elderly women. Subjects who were assigned continued posttreatment practice with relaxation tapes maintained improvements, whereas state anxiety scores of those who did not practice showed a drift back toward baseline. In a subsequent comparison of meditation-relaxation and cognitive restructuring (DeBerry et al. 1989), the investigators reported significant reductions in state anxiety but not trait anxiety or depression in subjects trained in meditation-relaxation; however, cognitive restructuring produced no significant changes in either depression or anxiety (state or trait). Scogin et al. (1992) offered training in either progressive relaxation or imaginal relaxation techniques to elderly patients with symptoms of tension or anxiety that were at a "subjectively uncomfortable level." Subjects in both treatment groups showed significantly greater improvements in state anxiety and psychiatric symptomatology (as measured by the Symptom Checklist—90) than did delayed-treatment control subjects, although improvements were not maintained at 1-month follow-up. Interestingly, Alexander et al. (1989) found that both meditation and mindfulness (focused attention) training resulted in improvements in cognitive functioning, blood pressure readings, and 3-year survival rates, despite the fact that no changes in anxiety or depression were associated with either intervention.

In some studies, the focus has been on providing skills training to elderly patients with depression. Participation in assertiveness training has been shown to improve effectiveness in interpersonal situations, as well as ratings of self-acceptance (Franzke 1987). Reich and Zautra (1989) found that four sessions of individual therapy, designed to enhance perceived control, significantly increased participation in positive activities by bereaved and disabled elderly subjects and decreased psychological distress as well. However, these improvements were not maintained after the treatment was discontinued.

Other studies have examined the impact of therapy on

**TABLE 36-7. Empirical studies (miscellaneous) with older adults**

Study	Subjects	Subject age (years)	Treatment	Treatment duration
Nevruz and Hrushka 1969	36 psychiatric inpatients	Mean, 70	Structured therapy group Unstructured therapy group	24 sessions in 12 weeks
Mulligan and Bennett 1977	23 isolated outpatients	Mean, 77 (all subjects > 67)	Social visits (subjects at home) Visit at beginning and end of study (control)	1 hour every 2 weeks for 6 months
Zarit et al. 1981	47 female volunteers	Mean, 64	Memory-training group Personal growth group	7 sessions in 4 weeks
DeBerry 1982	36 women with depression	Mean, 63-79	Relaxation-meditation group Relaxation-meditation group and follow-up tapes Pseudorelaxation group (control)	10 weeks (plus 10 weeks of daily practice for subjects assigned to relaxation-meditation group and follow-up tapes)
Lieberman and Bliwise 1985	108 outpatients	Range, 60-83	Professional-led support group Peer-led support group	36 sessions in 9 months
Franzke 1987	84 community-dwelling subjects	All subjects > 65	Assertiveness training groups No treatment (control)	6 weeks
Ong et al. 1987	20 discharged inpatients (most in day hospital program)	Mean, 74	Support group (psychodynamic and problem solving) No added treatment (control)	Weekly sessions for 9 months
Alexander et al. 1989	73 NH residents	Mean, 81	Transcendental meditation Mindfulness training Mental relaxation No treatment (control)	12 weeks
DeBerry et al. 1989	32 outpatients	Mean, 69 (range, 65-75)	Relaxation-meditation group Cognitive-restructuring group Pseudorelaxation group (control)	20 sessions in 10 weeks
Reich and Zautra 1989	25 bereaved, 25 functionally disabled, and 58 matched control subjects	Mean, 71	Perceived-control intervention Placebo contact No contact (control)	4 sessions in 10 weeks
Viney et al. 1989	30 outpatients with "psychological problems"	Mean, 75	Brief personal construct individual therapy No treatment (control) Criterion group (single contact) (control)	5-13 sessions in 24 weeks

Heller et al. 1991	265 women	Median, 74	Time 1 Friendly staff contacts by telephone Assessment only (control) Time 2 (Time 1 staff-contact group only) Staff telephone contact Peer telephone contact (initiators) Peer telephone contact (receivers) Assessment only (control)	Time 1: 10 weeks (two times/week for first 5 weeks, then one time/week) Time 2: 10 weeks
Scogin et al. 1992	71 community residents with anxiety or tension	Mean, 68–69 (all subjects ≥ 60)	Time 1 Progressive relaxation Imaginal relaxation Delayed training (no relaxation training, outcome measures only) Time 2 (delayed-training group only) Delayed progressive training Delayed passive training	4 training sessions

Note. NH = nursing home or long-term residential setting.

subjects' long-term functioning. For example, isolated community-dwelling elderly people who received regular "social visits" in their home for 6 months were more likely to be living independently in the community at 6-month follow-up than were control subjects (Mulligan and Bennett 1977). Geriatric psychiatric patients who participated in weekly psychodynamic problem-solving groups for 9 months had a lower rehospitalization rate, despite the fact that no changes in depressive symptoms were observed in participants (Ong et al. 1987). Therapy has even been shown to influence geriatric psychiatric patients' willingness to leave state hospital wards and try community placement options (Nevruz and Hrushka 1969).

In summary, a variety of nonspecific psychosocial interventions have been used in geriatric subjects. Although a few studies have included psychiatric inpatients, the majority have been conducted with outpatient volunteers. These studies have shown that different combinations of relaxation, cognitive restructuring, emotional support, and skills training can improve self-ratings of depression, anxiety, and self-acceptance. There is also evidence that psychosocial interventions lead to improvements in long-term survival rates and reduced rates of rehospitalization for chronically ill psychiatric patients. However, long-term maintenance of improvements in mood or generalization of newly learned skills has not been consistently reported after therapy discontinuation.

### Summary and Future Research Directions

Several conclusions can be drawn from the existing literature on the efficacy of psychosocial interventions in older adults. First, a variety of interventions have been studied in physically healthy, community-dwelling older adults. Cognitive-behavioral strategies have been the subject of most empirical research, although psychodynamic, reminiscence, and various supportive techniques have also been studied in this population. Each treatment has been found effective in decreasing depression, and a few studies have shown this treatment effectiveness to be equal or superior to the effectiveness of pharmacotherapeutic interventions. There is some evidence that improvements resulting from CBT are better maintained at follow-up than those from the other treatment forms, but there are too few long-term outcome comparison studies to evaluate the strength of these findings.

Although research is less plentiful, there is also empirical evidence for the efficacy of CBT and its variants in patients with medical illnesses and dementia, elderly care-

givers, and residents of long-term care institutions. A few studies have found that psychodynamic therapy, reminiscence and life review activities, and supportive interventions can also reduce negative mood and improve life satisfaction and self-esteem in disabled or institutionalized older adults and their caregivers. In some cases, long-term improvements (e.g., improved rates of rehospitalization or delayed nursing home placement) were reported even in the absence of reductions in acute depression ratings.

A variety of factors may contribute to differing treatment effects across studies. These factors include patient variables, such as presence or absence of premorbid personality disorders, severity of symptoms at the onset of treatment, cognitive capacity, and patient feelings of commitment to treatment or expectation of change. Specific treatment variables have also been implicated in differing outcomes. For example, structured life review strategies may be more effective than simple reminiscence, participation of family members may enhance treatment impact, and treatment with professional therapists may produce greater reductions in psychiatric symptoms than peer-led interventions. In therapy with patients in long-term settings, and in outpatient therapy with caregivers, maintenance of therapeutic gains appears contingent on ongoing, or at least periodic, therapy. Both group and individual therapies have been successful in older patients.

Although the empirical treatment literature has grown substantially over the past several years, additional research is needed concerning the efficacy of psychosocial interventions in elderly patients. Psychosocial interventions based solely on treatments used in uncontrolled case studies and treatments described in anecdotal reports are still widely used with older adults. The interventions in controlled studies that have been conducted represent a mixture of cognitive-behavioral, psychodynamic, relaxation, supportive counseling, and educational techniques. There are, as yet, no data to indicate which components of particular interventions are efficacious in improving psychological, physical, or social functioning. Although increasing numbers of studies (particularly those focused on depression treatment) now have treatment manuals available, many interventions used with older adults are not manualized or adequately described, making replication or comparison across studies difficult. In these cases, more rigorous treatment definition is needed. There is little empirical research on the impact of therapist or environmental variables on therapy outcome. The cultural, intrapersonal, familial, and health factors that are likely to have an impact on treatment efficacy must be systematically in-

vestigated. The intervention literature has tended to focus primarily on the management of pathological cognitive or emotional disorders. The challenges of normal aging deserve attention, as well.

Additional research is needed to determine how long interventions should be continued for maximal treatment impact and to establish strategies for generalization and maintenance once the active treatment phase ends. In the studies reported here, therapy duration ranged from a single session or a few sessions to months or years; in some studies, subjects were exposed to different numbers of sessions over variable lengths of time. Clarifying the significance of this variable may be particularly important for older adults with chronic physical conditions or social circumstances that have precipitated psychosocial intervention. Because therapy outcome is dependent on how psychosocial functioning is defined and measured, research is also needed to identify assessment instruments with good reliability and validity that are sensitive to expected changes and appropriate for use with various elderly populations and in specialized contexts.

Given the growing number of older adults who are medically ill and living in long-term care settings, it is surprising that there are so few controlled studies examining the psychosocial impact of physical disability and institutionalization on geriatric patients. Additional studies of treatment effectiveness in persons with multiple medical, psychiatric, and social disabilities are needed. The use of single-case research design strategies may allow investigators to gather useful information on small numbers of such individuals with little disruption to medical or residential facilities. Validity of results could be maximized by applying such design strategies to multiple settings and using a broad range of reliable assessment instruments. Single-case research design strategies may also permit evaluation of the conjoint impact of pharmacological and psychosocial interventions on functioning in a range of elderly populations.

In summary, although more research is needed, the existing data available on psychosocial interventions in older adults are surprisingly encouraging. A variety of behavioral and supportive interventions have produced improvements in psychological functioning in physically healthy, depressed older subjects, as well as in institutionalized or medically ill geriatric patients and their caregivers. Gains from psychological interventions are often comparable to gains from medical treatments. Efforts now need to be made to clarify which strategies are most efficacious for which patient groups and to develop effective new interventions for elderly patients in both outpatient and inpatient settings.

# Neuropsychiatry in Nursing Homes

Barry W. Rovner, M.D.

Ira R. Katz, M.D.

Constantine G. Lyketsos, M.D., M.H.S.

Existing research demonstrates that nursing homes are the modern mental institutions for elderly people in the United States. Unfortunately, training of nursing home staff and physicians, processes of care, and the recognition and treatment of mental disorders do not reflect the current level of scientific knowledge in psychiatry (Rovner and Katz 1992). Consequently, the nursing home represents one of the greatest challenges in clinical geriatric neuroscience. Although it is important to recognize the promise of basic and clinical research for developing treatments that may prevent or cure Alzheimer's disease, it is also necessary to apply scientific knowledge about the relationships between brain disease and behavior to develop strategies for caring for patients with dementia on a day-to-day basis.

Although the prevalence of nursing home residency for those over 65 is approximately 5%, 20%–50% of people over 65 will live in nursing homes at some point before

death (German et al. 1992). The cost of their care is enormous:

In 1989 the total cost of nursing home care was \$47.9 billion, or 8% of all health care expenditures. This was a 12% increase from the year before, and exceeded the 9% average increase observed for the 1980s overall. The bulk (64%) of nursing home expenditures are financed by public programs, either directly through Medicaid (43%) or Medicare (about 3%), or indirectly from transfer payments (i.e., the Medicaid mandated contributions from the resident's social security income; 18%). Given the projected considerable increase in the number and proportion of older Americans, the use of and expense associated with nursing homes has become an issue of considerable national concern. (Wolinsky et al. 1992, p. 173)

The extent of this concern became evident in a study of projected nursing home costs. Kemper et al. (1991) esti-

mated that it will cost \$60 billion to pay for future nursing home care for Americans who turned 65 in 1990. This projection is based on data that indicate that 43% of this cohort will enter a nursing home during their lives and will spend an average of 2.8 years there.

Recognizing that the dementia syndrome, so prevalent in this population, is the expression of a brain disease and not the consequence of normal aging has been a major advance, a concept only relatively recently accepted by the nursing home industry and the governmental agencies that regulate it. Gradually, making the diagnosis of dementia (when appropriate) in nursing homes has become an acceptable, indeed a required, practice (e.g., note the PASARR [preadmission screening and annual resident review] regulations of the Omnibus Budget Reconciliation Act of 1987). However, recognizing dementia syndromes as brain diseases has led to a denial, of sorts, of the noncognitive behavioral aspects of these disorders, such as depression, delusions, hallucinations, and states of agitation. Although supervision and provision of assistance in activities of daily living are essential components of care for patients with dementia in nursing homes, these noncognitive psychiatric symptoms frequently accompany the dementia syndrome and determine both the patients' needs for care and the quality of care they receive.

## ■ History

The modern nursing home can trace its origins to the almshouses and mental institutions of the nineteenth century, which, transformed incrementally by public policies, have come to resemble hospital facilities. As such, these once derided places have gained respectability through their identification with more credible medical institutions. Along with that credibility has come the expectation that patients would be cared for using the expertise, knowledge, and technology characteristic of the best hospitals. The policies, procedures, and staffing patterns of most nursing homes are in fact based on this model:

Indeed, nursing homes appear, at first glance, like a patient-care floor in a general hospital. As in a hospital, the center of activity, and often the physical center of the floor, is a nursing home station. A high-fronted desk, wide enough to permit 2 or 3 people to sit at it, looks out onto the corridor. Behind it and to the sides are books and manuals, miscellaneous supplies, racks filled with patients' charts, lockable medicine cabinets, and perhaps doors to a supply room and a staff bathroom or lounge. Not infrequently, diplomas or state licenses hang on the wall behind the nursing station, along with other official-looking documents, all neatly framed. (Vladeck 1980, p. 7)

Like patients in hospitals, most patients in nursing homes have medical disorders such as high blood pressure, stroke, heart disease, arthritis, or diabetes (Johnson and Grant 1985). They are cared for by nurses and seen by physicians, and they receive medications. The patients are expected more or less to lie in bed passively and receive the care given by the nursing staff.

The reality of the nursing home, however, is not reflected by the sterility of the medical model. Patients have been moved from sickbeds to Gerichairs, and the nursing home now echoes the bedlam of the psychiatric hospital in the era before the development of specific treatments:

The characteristic picture is that of a dozen residents arrayed in front of a television or sitting in a hall, each staring ahead. If anyone is talking, it is mostly to herself. (Vladeck 1980, p. 26)

## ■ Epidemiology

The change in the kinds of patients cared for in nursing homes over the past 20 years is related to the aging of the population and the increasing prevalence of dementing conditions. Patients with these conditions, unlike their primarily medically ill counterparts, are in need of medical attention as a result of their mental, rather than their physical, symptoms. These changes are evident in successive nursing home surveys. The 1977 National Nursing Home Survey indicated that approximately 57% of patients had "chronic brain syndrome" or "senility" (National Center for Health Statistics 1979). By 1985, these conditions were diagnosed in 63% (National Center for Health Statistics 1987).

The Medical Expenditure Panel Survey indicated that, in 1996, 1.6 million persons resided in 16,800 nursing homes and approximately 70%–80% of these residents had dementia (Krauss et al. 1997). However, because only 2,100 nursing homes (12.5%) had dementia special care units, the majority of residents with dementia received general custodial care. In addition, the prevalence of behavior disorders among residents with dementia is high. In the 1987 National Medical Expenditure Survey, the characteristics of a national nursing home sample were examined and 11 behavior problems were grouped into four categories: wandering or safety problems, aggressive behaviors, collecting behaviors, and delusions or hallucinations (Jackson et al. 1997). Predictors of these behaviors included male gender, more severe cognitive impairment, dependence in activities of daily living, incontinence, psychiatric history, receptive communication deficits, and im-

paired walking and vision. This finding suggests that biological, psychological, and sociocultural factors all contribute to the development of behavior problems. However, nursing homes are ill equipped to treat these problems effectively.

Treatment of mental disorders in nursing homes is impeded by a variety of obstacles, including a shortage of specialized mental health professionals, lack of knowledge and training among nursing staff, lack of adequate payment for mental health care, and difficulty obtaining psychiatric services.

McGrew (1998) noted that although the traditional United States health care system distinguishes between physical and mental health, such a distinction is not made in nursing homes. Further, dementia, for some reason, has been segregated from other mental disorders in nursing homes. Overcoming the barriers that emerge as a consequence will require the cooperation and collaboration of nursing homes, local service providers, states, and the federal government.

Fragmentation of funding also accounts for limitations in mental health care for residents with dementia. Although the nursing home industry is generally a private enterprise, the public sector, largely through Medicare and Medicaid, contributes approximately half of the costs, roughly \$40 billion annually. However, both the federal government and the states attempt to shift the cost of mental health care to the other. The best example of this cost shifting is the process known as *transinstitutionalization*, the movement of state-hospitalized psychiatric patients to federally supported nursing homes.

National survey findings indicating an increased prevalence of dementia are based on nonclinician reviews of records and interviews with staff rather than on findings obtained by psychiatrists during direct examination of patients. The former methods cannot reveal whether psychiatric or behavior disorders are the cause or consequence of institutionalization. Thus, until relatively recently, no studies had been carried out on the prevalence of mental disorders among new residents of nursing homes, studies in which psychiatrists examined large, systematically ascertained samples and made diagnoses using modern diagnostic criteria. In 1987–1989, as part of a National Institute of Aging Study, we (Rovner et al. 1990a) evaluated 454 residents newly admitted to a total of eight Baltimore area proprietary nursing homes. The overall objective was to analyze mental morbidity among nursing home residents, establish its magnitude and type, and assess its influence on quality of life.

The following list shows the prevalence of psychiatric disorders divided into four mutually exclusive diagnostic

groups on the basis of presence and type of psychopathology:

1. *Dementia complicated*: Patients with dementing disorders complicated by depression, delusions, or delirium ( $n = 123$ , 27.1% of the entire sample; 40.2% of all patients with dementia)
2. *Dementia only*: Dementia patients without delusions, depression, or delirium ( $n = 183$ , 40.3% of the entire sample)
3. *Other psychiatric disorders*: Patients without dementia but with affective disorders or schizophrenia ( $n = 58$ , 12.8% of the entire sample)
4. *No psychiatric disorder*: Residents without any disorder ( $n = 90$ , 19.8% of the entire sample)

Overall, 364 new residents (80.2%) were considered by the examining research psychiatrists to have psychiatric disorders. The most common diagnosis was dementia ( $n = 306$ , 67.4%). Primary degenerative dementia of the Alzheimer's type was the most frequent cause of dementia ( $n = 172$ , 37.9% of the entire sample), followed by multi-infarct dementia ( $n = 81$ , 17.8% of the entire sample). Other dementia syndromes or causes of dementia included the dementia syndrome of depression, Parkinson's disease, and brain tumor. Of the patients without dementia ( $n = 148$ , 32.6%), 58 (12.8% of the entire sample) had psychiatric disorders such as affective disorder ( $n = 47$ , 10.4% of the entire sample; 31.8% of those without dementia) or schizophrenia ( $n = 11$ , 2.4% of the total; 7.4% of those without dementia).

In 1994–1996, a separate study was conducted to assess the morbidity of nursing home patients with dementia (Tariot et al. 1993). This study involved 187 consecutive patients admitted to Copper Ridge, a model nursing home program for patients with memory disorders and dementia, affiliated with the Johns Hopkins Neuropsychiatry and Memory Group. Sixty percent of the new residents had Alzheimer's disease, 16% had dementia due to cerebrovascular disease, and the remainder had dementia due to other causes, including mixed Alzheimer's and cerebrovascular disease, Parkinson's disease, alcohol-related dementia, and anoxic dementia. The average Mini-Mental State Exam score was 9. Patients also had high rates of noncognitive psychiatric disorders, including delusions (40%), major depression (21%), sleep disorder (36%), and hallucinations (15%). In addition, 40% of patients had been physically aggressive and 49% had wandered in the 2 weeks before admission. Ninety-two percent had at least one of the aforementioned disturbances.

There was also considerable medical comorbidity; pa-

tients had a median of five medical disorders. The most common were hypertension, diabetes, heart disease, stroke, eye conditions, and dental problems. Impairment of general health was rated using the Hopkins General Medical Health Rating (Lyketsos et al. 1997). General health was excellent in 12%, good in 42%, fair in 38%, and poor in 8%. It can be concluded, therefore, that on admission to a nursing home, patients with dementia exhibit a substantial degree of medical and psychopathological morbidity in addition to dementia.

These 187 patients were followed for 2 years. There were 47 deaths (mean survival time, 38 months). Cognition steadily declined, with the Mini-Mental State Exam score reaching an average of 5. Rates of behavioral disturbance remained high throughout the 2-year period. Physical aggression was not infrequent: there was a mean of 1.6 incidents per 1,000 resident days. Aggression was most likely to occur on day or evening shifts rather than at night. There was no significant variation in rates of aggression over time, across seasons, or over lunar cycles. Rates of aggression also were not related to resident density nor to the number of recently admitted patients. Therefore, it may be said that dementia patients being admitted to nursing homes exhibit substantially high rates of behavioral disturbance over time, resulting in great demands on staff and other providers of care. These high rates also make necessary an on-site expert psychiatric team to evaluate and treat such disturbances.

We (Katz et al. 1990) reported that the prevalence of major depression in nursing homes was 20% in 1989 and stated that major depression was treatable, even though it was associated with medical disorders that complicated diagnosis and treatment (Parmelee et al. 1989).

In 1991, we (Parmelee et al. 1991) showed that pain was associated with depression in nursing home patients, particularly when a physical problem was present that was a potential source of pain. We hypothesized that either pain causes depression or depression intensifies pain. In 1992, we (Parmelee et al. 1992a) reported an increased mortality rate among nursing home residents with major depression, the increase apparently due to the fact that ill health tends to accompany major depression. In contrast, studying a different sample of nursing home patients and using different methods to control for medical illness, we (Rovner et al. 1991) found that depression was an independent risk factor for mortality over and above severity of medical illness. Depression increased the risk of death in depressed patients by 59%. In 1992, we (Parmelee et al. 1992b) found a 6.6% incidence of major depression over 1 year among nursing home residents and reported that 40% of patients who were depressed at the time of initial evaluation showed

no remission after 1 year.

As high as they are, the rates of diagnosable psychiatric disorders may in fact not reflect the magnitude of the neuropsychiatric problems present in nursing homes. In addition to those patients with major depressive disorder, there are substantial numbers of individuals with less severe but nonetheless clinically significant depressive symptoms, and still others with a persistently flat or blunted affect (Lawton et al. 1996). Moreover, in addition to the large numbers of patients with dementia, there may be others whose more focal deficits in executive functions due to aging (see Chapters 7 and 8 in this volume) or structural brain disease may have contributed to an inability to cope with medical illnesses and function in the community (Royall et al. 1993). Thus, the prevalence and range of nursing home residents with psychiatric disorders requires incorporating basic neuropsychiatric and mental health principles into the design of the care environment.

## ■ The Nursing Home Environment

In spite of these epidemiological and clinical realities, nursing homes continue to model themselves after general rather than neuropsychiatric hospitals. The medical staffs consist primarily of internists, family practitioners, or general practitioners, and the nursing staff consists primarily of individuals trained in medical-surgical nursing. Because neither the training of the nursing or medical staffs nor their approaches to care have changed to match the changes in the population, the original conceptualization of nursing homes as diminutive hospitals is no longer applicable. Furthermore, the fact that the majority of nursing home patients have conditions known to be associated with states of psychopathology including delirium, depression, delusions, and hallucinations and behavior disorders such as agitation, combativeness, and wandering has added an unanticipated sense of acuity and disturbance to the environment. Overwhelmed, nursing home staff have turned to restraints and psychotropic medications—often in an indiscriminate and uninformed way—to manage these psychiatric syndromes and behavior disorders. Ironically, nursing homes have returned to their origins as mental institutions in that most patients have mental disorders or disruptive behaviors that are difficult to manage and these patients are frequently physically and chemically restrained.

The nursing home environment is also notable for four additional features that have an impact on the treatment of neuropsychiatric disorders: extensive regulatory oversight by federal and state agencies, limited research

into treatment, high rates of incapacity to consent to medical care, and special care units. Each feature will be discussed individually here.

## Regulatory Oversight

Since the identification of abuses in nursing homes in the 1980s, these facilities have been subject to strict regulations, spelled out in the 1987 Omnibus Budget Reconciliation Act (OBRA; Omnibus Budget Reconciliation Act of 1987). This legislation has improved identification and treatment of mental disorders and has made mandatory the provision of mental health and activity services to residents. OBRA also raised educational standards for staff and initiated the gathering of clinical data on-line. However, some people believe that patient abuse has been defined very broadly in OBRA and that OBRA has created obstacles to the proper use of psychotropic medications and has perpetuated a view of psychotropic drugs as chemical restraints.

Documentation of specific psychiatric diagnoses and behavioral indications is now required when a psychotropic medication is prescribed. Garrard et al. (1991) estimated that had these regulations been in effect from 1976 to 1985, 50% of neuroleptic use in almost 9,000 nursing home residents would have been out of compliance. We (Rovner et al. 1992) found a 36% reduction in the number of prescriptions for neuroleptics from the 3 months before OBRA went into effect until 3 months afterward, but there was no increase in the number of prescriptions for sedative-hypnotics. The same trends existed 1 year later. Although quality assurance data on the prevalence of medical events such as bedsores, weight loss, falls with fractures, adverse incidents, urinary tract infections, and death revealed small but significant changes, the data were difficult to interpret because comparable data from previous years were unavailable.

Along with the pharmacoepidemiological studies demonstrating a nationwide downward trend in the use of psychotropic medications (except for antidepressants), clinical trials have shown that educational efforts may directly facilitate reduction of medication use. Meador et al. (1997) conducted a randomized controlled trial of an educational program to reduce antipsychotic prescribing for patients in nursing homes and found that use of antipsychotics in the six homes offering the educational program decreased from a frequency of 25.3 per 100 days at baseline to 19.7 per 100 days by month 6, a 23% reduction relative to control homes ( $P = .014$ ). This study showed that focused educational programs may facilitate reduction of antipsychotic prescribing, above and beyond that attrib-

utable to regulatory changes. However, the durability of the changed prescribing practices and the degree to which they increase the quality of life for residents remain uncertain. Other studies have also demonstrated the feasibility of reducing use of these medications (Avorn et al. 1992).

## Limited Research Into Treatment

Before the implementation of OBRA, depression was often unrecognized and untreated in nursing homes. Heston et al. (1992) found that of 868 persons with depression, only 10% were treated with antidepressants. More patients received neuroleptics and benzodiazepines, but most received no treatment at all. Similar findings were obtained by us (Rovner et al. 1991). Educational efforts to increase recognition of depression (the efforts being fueled by awareness of adverse outcomes of depression, such as mortality and disability) and the availability of newer antidepressants have led to increased antidepressant treatment. Lasser and Sunderland (1998) reported that 69% of nursing home patients referred to a geriatric psychiatry service were taking at least one psychotropic medication. Although many of these patients were taking benzodiazepines (32%) or antipsychotics (42%), antidepressants were most commonly prescribed; 61% of patients prescribed psychotropic medications were taking antidepressants, and 53% of this subgroup were taking serotonin reuptake inhibitors.

Llorente et al. (1998) examined the pharmacy records of 1,573 nursing home residents from the period 1994–1996 and found that 17.7% were receiving antipsychotic medications during that time. Seventy-one percent had appropriate diagnostic indications, 90% were receiving doses within recommended limits, and 90% had documented, appropriate target symptoms. Lower rates of use of anticholinergic agents, low doses of tricyclic antidepressants, and low rates of tricyclic antidepressant use were noted in patients with Alzheimer's disease, findings that reflect the fact that anticholinergic medications should be avoided in such patients, given the cholinergic deficit associated with the disease. In addition, all dosages of psychotropic medications were within the ranges given in the Health Care Financing Administration guidelines. The investigators concluded that newer-generation psychotropics have had a substantial impact on the prescribing practices of primary physicians treating nursing home residents.

Inappropriate medication use by nursing home residents is not limited to psychotropic drugs. Beers et al. (1991) reviewed the literature indicating inappropriate use of antihypertensives, nonsteroidal anti-inflammatory

agents, oral hypoglycemics, analgesics, and a variety of other commonly prescribed medications. They proposed explicit criteria for inappropriate use of these medications and also suggested that these criteria might be useful for quality assurance review and clinical practice guidelines.

Borson and Doane (1997) examined psychotropic drug use in 39 skilled nursing facilities during the period 1989–1992 and found that the number of prescriptions for antipsychotics, sedative antihistamines, and sedative-hypnotics decreased significantly and that the prescribing of anxiolytics increased. In addition, they noted that the number of research studies on psychotropic drug use increased after the implementation of OBRA but that few studies focused on the effectiveness of drug treatment. The investigators recommended research into treatment outcomes as the next step to improve the care of this population.

There have been a number of well-designed clinical trials of treatment for agitated nursing home patients with dementia (see also Chapter 22 in this volume). Finkel et al. (1995) found that thiothixene (dose range, 0.25–18 mg) was significantly more effective than placebo in patients who were treated for 11 weeks. There were no notable changes in cognition scores or function. We (Katz et al. 1998) reported the results of a large randomized controlled trial of risperidone in a similar sample. We found that risperidone at 1 mg/day was more effective than placebo in reducing aggression and psychotic symptoms and did not cause significant extrapyramidal symptoms. Treatment at higher doses (2 mg/day) produced marginally better responses but was associated with extrapyramidal symptoms in approximately one-quarter of the patients.

In another study, we (Rovner et al. 1996) evaluated the efficacy of a dementia care program, consisting of activities, guidelines for use of psychotropic medications, and educational rounds. We found that, after 6 months, the program had reduced the number of behavior disorders and the use of antipsychotic medications and restraint, in comparison with the control group. The most important therapeutic element, in our opinion, was the establishment of a safe environment and active routines, to minimize dementia patients' exposure to unstructured situations.

### **Incapacity to Consent to Medical Care**

The Patient Self-Determination Act mandates that federally funded nursing facilities inform patients of their rights under state law 1) to make decisions to accept or refuse medical or surgical treatment and 2) to formulate advance directives (Sabatino 1993). Advance directives allow currently competent patients to record the kind of medical procedures they desire should they become incompetent in

the future. These directives decrease the probability that a guardianship hearing will be necessary. Most states allow two types of advance directives: the living will and the durable power of attorney (see Chapter 41 in this volume).

As previously stated, the prevalence of dementing conditions and other psychiatric disorders in nursing homes is high. This situation suggests that many nursing home patients may not be competent to execute advance directives or to consent to medical procedures. Thus, although the Patient Self-Determination Act may improve autonomy in decision making, its intentions may not be fully realized. We (Janofsky and Rovner 1993) investigated the prevalence of advance directives among 186 nursing home patients. Of 29 residents assessed to be competent, 14 (48%) had a durable power of attorney or a living will. One person (3.5%) had a guardian. The remaining 14 patients (48.5%) had no advance directive. One hundred fifty-seven patients were assessed to be incompetent; 61 (39%) had a durable power of attorney or a living will, 44 (28%) had a guardian, and the remaining 52 (33%) had no form of advance directive. These data showed that substantial numbers of residents lacked either guardians or advance directives.

### **Special Care Units**

Special care units in nursing homes have evolved as potentially innovative approaches to care. The underlying theory of treatment generally is based on the identification and treatment of excess disability, compensation for lost abilities through environmental and social support, and systematic evaluations of residents for potentially reversible medical and neuropsychiatric disorders. These units are usually costly to develop because they require modification of existing designs or creation of new ones, as well as recruitment and training of personnel, to create higher staff-patient ratios. Special care units often charge higher daily rates, and therefore the care may be out of reach for most nursing home patients with dementia.

Ohta and Ohta (1988) were among the first to note the variability among dementia special care units and the heterogeneity of the patients who reside there. Perhaps for these reasons, it has been difficult to assess the effectiveness of special care units. Gold et al. (1991) found that such units appeared to be associated with care of a higher quality than that on traditional units but that the quality of special care units was by no means uniform. Holmes et al. (1990) compared the characteristics of patients with dementia residing on these units with the characteristics of their counterparts on other units within the same facilities and found that the two groups differed in levels of cognitive impairment, behavior, functioning, and physical status. They also found

that despite a higher prevalence of behavior disorders among special care patients, staff caring for these patients did not view the disturbances as more severe, and the investigators suggested that the specialized staff were able to adjust to these behaviors. Sloane et al. (1991) conducted a case-control study involving 625 patients with dementia on 31 dementia special care units and 32 traditional units in five states. They found that special care units were associated with reduced use of physical restraints but not of psychotropic drugs and that different variables determined the use of physical restraints and psychotropic medications on the two types of units.

In another study, Sloane et al. (1998) examined the prevalence of agitated behaviors in a representative sample of Alzheimer's disease special care units, to determine the extent to which agitation is associated with aspects of the treatment environment. They found that the proportion of residents exhibiting agitated behavior varied from 0% to 38%. Independent correlates of low agitation levels included favorable scores on measures of the physical environment and of staff treatment activities, low rates of use of physical restraints, small unit size, low levels of resident functional dependency, and fewer comorbid conditions.

Two single-site studies evaluated the outcome of treatment on special care units. Benson et al. (1987) reported increased levels of mental, emotional, and self-care functioning in patients admitted to special care units, and we (Rovner et al. 1990b) found that the functional capacity of patients on special care units remained stable, whereas that of patients on other units declined.

Phillips et al. (1997) examined Minimum Data Set assessments of 77,337 residents in more than 800 facilities, including 1,228 residents in 48 facilities with special care units. They found no statistically significant difference in the rate of decline (nine outcomes were measured) among residents on special care units and residents on traditional units. They concluded that although special care units may have provided unmeasured benefits to families and residents, those benefits did not include slowing rates of functional decline.

## ■ Principles of Care

In practice, the perceptions of nursing staff are critical in determining whether or not a behavior disorder is present. Different observers may have differing views about whether a particular behavior is an expected and accepted occurrence or a disturbance that offends or threatens caretakers and the homeostasis of the environment. In this light, the definition of a behavior disorder includes ele-

ments of the dispositions of the patient and of the observer and their interaction within the environment. This point underscores the importance of education of caregivers in nursing homes.

The underlying brain disease exists independent of the environment, but how the disease manifests itself (i.e., whether or not a behavior disorder emerges as a symptom of disease) reflects the interaction of a number of processes. A clarifying distinction in this regard is the recognition of *predisposing features* and *precipitating factors*. Patients with dementia are predisposed to behavioral disturbances on the basis of 1) specific syndromes marked by depression, delusions, and hallucinations; 2) delirium; and 3) poor impulse control, impaired judgment, and poor regulation of mood secondary to the brain damage. Precipitating factors may be environmental events such as recent nursing home placement, a change of rooms, changes of caregivers, uninformed approaches to care, or exposure to threatening activities or circumstances that overwhelm cognitive capacities.

This reasoning leads to parallel but distinctive treatment interventions. From the neuropsychiatric perspective, recognizing that a patient's behavior is the reflection of brain disease, rather than of a willful or manipulative nature, and that depression, delirium, delusions, and hallucinations may represent biological aberrations and symptoms of the underlying disease leads to the directing of treatment toward the somatic therapies found to be beneficial in other patients with these neuropsychiatric symptoms.

Although neurological influences are important in the genesis of behavior disorders, psychosocial influences are important as well. Patients are exposed to environments and persons whom they may not fully comprehend or recognize, predisposing them to a sense of uncertainty, frustration, and lack of direction. Because of these predispositions, the provocations or precipitating factors in the environment may lead to behavioral disturbance. It is thus important to understand the behavior in its social context within the nursing home so that interventions can be designed within that context to prevent the emergence of behavior disorders.

Treatment is optimized when it is possible to evaluate and treat patients on site and transfer patients in need of acute care at a psychiatric hospital. The latter is necessary because some residents require brief psychiatric hospitalization for stabilization. Hospitalizations of agitated patients with dementia are associated with reductions in general psychiatric symptoms and agitation and improvements in depression and global functioning, without adverse effects on cognitive states (Kunik et al. 1996).

## ■ Optimizing Care and Related Care Issues

Essential to the success of any psychiatric program in a nursing home is proper education of clinical and administrative staff. This education is an ongoing effort that incorporates use of written material, formal lectures, and hands-on teaching during patient care. Staff should be presented with basic facts and terminology about psychiatric disorders, information about available treatments, and data supporting the efficacy of those treatments. Special attention should be paid to psychopharmacology, electroconvulsive therapy, and the ability to effect change through psychotherapy or environmental and other behavioral interventions.

Staff should learn how to obtain histories from patients and informants, understand the process of neuropsychiatric diagnosis, and develop optimal clinical approaches and environmental modifications. Basic rating scales can be used to facilitate patient evaluation and outcome assessment. We propose the use of the Mini-Mental State Exam (Folstein et al. 1975) or the Severe Impairment Rating Scale (Rabins and Steele 1994) to rate cognition, the Cornell Scale for Depression and Dementia (Alexopoulos et al. 1988) to rate depression and dementia, and the Psychogeriatric Dependency Rating Scale (Wilkinson et al. 1980) or the Neuropsychiatric Inventory (Cummings et al. 1994) to rate behavioral disturbance.

It is also helpful for nursing home staff to develop an accurate understanding of the OBRA regulations. This understanding increases awareness of the restrictions under which nursing homes operate but also clarifies the fact, for example, that any appropriate psychopharmacological treatments are permissible with proper documentation. The intent of the OBRA regulations is not to direct the practice of medicine but rather to ensure the protection of patients. Thus, the practice of neuropsychiatry according to current standards of care is not only possible—it is necessary. Of particular importance in this process is a close alliance with the consulting pharmacists who oversee administration of medications in the nursing home.

Another important aspect of psychiatric practice is patient decision-making capacity. As noted earlier, most patients are not capable of directly providing informed consent and making treatment decisions. It behooves the psychiatrist to involve the patient's family in the clarification of the patient's advance directive soon after the patient has been admitted. The preferred method is to convene a diagnostic conference at which nursing home staff (e.g., a nurse and a social worker) are also present. Such a confer-

ence allows for clear communication between families and staff about treatment preferences, creates rapport between the neuropsychiatrist and the family, and helps the neuropsychiatrist understand how families make health care decisions.

The development of special staff expertise also helps improve care. Given the high volume and complexity of neuropsychiatric disturbances, and the inability of most patients to report response to interventions, the neuropsychiatrist must rely on nursing home staff to appraise a patient's response. This staff can include "psychiatric expert" nurses or aides who understand psychotropic medications and behavioral interventions and who are familiar with standardized rating scales.

The success of a nursing home neuropsychiatric program depends as well on the integration of neuropsychiatric care with all other forms of care, including care by activity therapists, nurses, social workers, occupational and physical therapists, and especially physicians treating the patient's comorbid medical disorders. In addition, the neuropsychiatrist must meet regularly with other health care professionals to evaluate new patients and assess their responses to treatment. At the very minimum, rapid rounds can be conducted each day by nursing staff, with other professionals invited to participate. Such rounds permit identification of patients who are developing new behavioral disturbances or new medical problems. These rounds are best conducted at the change to the evening shift. In addition, a weekly interdisciplinary round is critical, in which all professionals meet to review patient progress and discuss difficult cases. This meeting also serves as a learning opportunity for all professionals in attendance.

Admission evaluations should include a review of the present illness, psychiatric symptoms, family and personal histories, medical history, and current medications. Also at the time of admission, cognitive function, independence in activities of daily living, behavior, and general health should be rated, with input from outside informants taken into account, using standardized scales. An experienced nurse can complete a patient evaluation, rating scales included, in 1–2 hours. The neuropsychiatrist working with the nursing team can review evaluations on rounds, to decide whether further assessment is necessary before treatment is begun. In instances in which patients entering a nursing home are already under psychiatric care by outsider providers, it is important to involve these providers.

In the case of patients who are found not to have neuropsychiatric disorders on admission, reassessment every 6–9 months is useful to detect possible incident changes. Neuropsychiatric reassessment might also be performed in response to a particular change in a patient (e.g., the onset of

significant behavioral or mental disturbances) or to a significant change in score on one of the standardized scales (e.g., a decrease in score of more than three points on the Mini-Mental State Exam in a patient without a previous diagnosis of dementia).

The majority of patients admitted to nursing homes have chronic diseases, many of which are progressive or incurable. Most patients are entering the final residence of their lives. The vast majority of nursing home patients will live in the nursing home for an average of approximately 3–4 years before death. For these patients, the goals of care relate to quality of life (being symptom free and comfortable), functioning (maintaining the highest possible levels), longevity, and maintaining of dignity. It is important that staff adopt a can-do philosophy rather than a nihilistic one. Small improvements are almost always possible and can be of tremendous benefit in terms of boosting staff and patient morale.

Knee-jerk responses or prescribing of medications for poorly defined problems should be avoided. The latter often occurs when there is a crisis after hours: a nurse calls a physician to report an “agitated” patient, and the physician prescribes an antipsychotic medication without carefully assessing the patient. Interventions ought to be evidence based as much as possible. Unfortunately, as indicated earlier, scientific evidence regarding outcomes of treatment for neuropsychiatric disorders in nursing homes is sparse. However, an increasing number of studies have been conducted that can inform neuropsychiatric practice. Overall, treatment in the nursing home requires flexibility, optimism, hope, and willingness to work with an interdisciplinary team on all aspects of care.

By the time of admission to the nursing home, most patients have moderate to severe dementia. The underlying disease causing the dementia is typically incurable (see Chapter 24 in this volume). However, for patients with Alzheimer’s disease, even at moderate to advanced stages, vitamin E at dosages of 1,000–2,000 IU/day may be prescribed, in an attempt to slow disease progression. For postmenopausal women, estrogen replacement therapy should be considered; this treatment prevents heart attacks and osteoporosis and may slow the progression of dementia. There is also evidence that treatment with nonsteroidal anti-inflammatory agents may slow the progression of disease, although this has not been proven conclusively. In treating vascular dementia, persistent efforts should be made to reduce risk factors for stroke (see Chapter 23 in this volume). Good control of diabetes, hypertension, and heart disease, as well as smoking cessation (required in most nursing homes), is necessary. Treatment with low-dose aspirin or an anticoagulant such as ticlopidine or

warfarin may be appropriate.

In addition to treating the disease causing the dementia, the focus of interventions in patients with dementia is on relieving cognitive symptoms and possibly preventing functional decline, using cholinesterase inhibitors.

The use of tacrine and donepezil has been approved for these purposes. The use of other new medications, which are cholinesterase inhibitors as well, appears close to approval. Side effects of treatment with tacrine and donepezil are consistent with those associated with systemic elevations of acetylcholine levels and include increased stomach acid secretion, nausea, vomiting, diarrhea, increased vagal tone with bradycardia and syncope, and muscle cramps. Tacrine also affects the liver; use of the drug requires liver function tests every 2 weeks. The efficacy of treatment with these medications in patients with advanced dementia is not well established. However, because some of these patients may benefit, use of tacrine or donepezil should be considered in all cases.

Perhaps the most important type of care for patients with dementia is supportive care. Stabilization and expert management of comorbid medical conditions are essential. Patients with dementia are vulnerable to delirium, which may manifest itself as uncooperativeness and aggression. Sudden changes in behavior should always be investigated, with the possibility kept in mind that they were caused by a new medical condition (e.g., a urinary tract infection). In addition, patients are vulnerable to the toxic effects of medicines; confirmation, on admission, of medical diagnoses and medications being taken can prevent polypharmacy and the attendant drug interactions.

The three main safety concerns related to patients in nursing homes are falls, wandering, and aggression. Patients should be assessed periodically for gait apraxia and deconditioning, particularly after periods of illness that may have restricted mobility. Physical therapy should be used liberally to improve conditioning. Additionally, in the case of patients who cannot walk, efforts should be made to maintain mobility and independence through the use of devices such as safety chairs that enable walking, wheelchairs, walkers, and canes.

The risk of wandering and leaving the nursing home is high, particularly when a locked unit is not available. Risk factors include sleep disorder, male gender, and advanced dementia. Patients who have a history of wandering benefit from locked units or electronic tags that indicate departure from the nursing home. One of the best ways to prevent wandering is to engage patients in structured activities, so that the boredom and uncertainty that lead to wandering are avoided.

Aggression is a particularly common problem and can

be divided into two types (see Chapter 22 in this volume). The first type of aggression occurs in the context of daily care and is directed at staff attempting to assist the patient. This type of aggression does not respond well to pharmacological therapy and may be best addressed through teaching by staff of practical behavioral management skills. Aggression occurring outside the context of daily care and directed toward other residents or visitors is often unpredictable. Many aggressive patients also have exacerbations of medical problems, delirium, depression, delusions, hallucinations, or very severe dementia. Treatment of other comorbid conditions is important and typically leads to reduced aggression. In rare instances, patients may remain unpredictably aggressive despite environmental and pharmacological interventions. Ongoing trial-and-error approaches, including trials of antipsychotics or benzodiazepines at high doses, may be necessary. Although the use of restraint generally should be avoided, severely aggressive patients require restraint for protection of themselves and others.

## ■ Conclusions

Although many of the clinical observations and recommendations in this chapter may seem obvious, and although they are essential elements of care in other medical and neuropsychiatric settings, they are new to the care of patients in nursing homes. One need only recall that recognizing the high prevalence of dementia and the excessive use of restraints and psychotropic medications is a recent advance. Much remains to be accomplished in the area of care for nursing home patients. The lack of knowledge about, lack of interest in, and lack of resources for such care have all contributed to the maintaining of “warehousing” as the standard of care in nursing homes. Because of this approach to care, few administrators or physicians in nursing homes have emphasized the need for psychosocial rehabilitation for dementia patients or organized a system of care to provide it.

Because of the lack of public awareness as well, and the reluctance of federal agencies to provide reimbursement, psychosocial rehabilitation programs are far from being regular and essential aspects of nursing home care. The chief obstacle is cost; lack of mental health professionals trained in geriatrics is another obstacle. With regard to the former, 82% of nursing home administrators and 73.6% of directors of nursing who participated in the 1992 National Telephone Survey of Nursing Homes said that current reimbursement was insufficient for care of residents with dementia and associated behavior disorders (Lombardo 1994). Access to psychiatrists was considered by survey

participants to be limited significantly by low Medicaid reimbursement rates. The failure to finance mental health services adequately is the consequence of the division of governmental financing between acute and long-term care and the fragmentation of benefits for medical, social, and income needs.

Fifty percent of participants in a survey of long-term care nursing directors reported that an inadequate number of psychiatrists were available, and 66% reported that psychiatrists, though capably providing diagnostic and medication recommendations, were not offering advice on nonpharmacological management techniques, staff support, and family conflicts (Reichman et al. 1998). These concerns were believed by the nursing directors to be highly important in the day-to-day management and maintenance of mental health in nursing home patients and staff. Reichman et al. (1998) also found that a formal contract for psychiatric services increased the frequency of consultation and satisfaction with the service provided. These data demonstrate the importance of reimbursement mechanisms in terms of determining, at the very least, the frequency and quality of psychiatric care. Reichman and colleagues wrote: “This differential outcome is particularly important with respect to aspects of comprehensive care that are currently non-reimbursable, poorly reimbursed, or burdensome to bill under Medicare-fee-for-service rules. These fall mainly in the domain of liaison function such as psychosocial care planning, staff-support, and help with families” (p. 325)

Unfortunately, the prospect for devoting more resources toward improving psychiatric care in nursing homes is doubtful, given the current national emphasis on cost control. Even if costs could be demonstrated to be offset—by showing, for example, that psychiatric services prevent hip fractures due to mismanagement of psychotropic medications—reimbursement reform would not likely be forthcoming. Until patients and their families demand improvements in mental health care, the situation is not apt to improve. Our hope is that indicators of nursing home quality can be developed, to ensure provision of expert psychiatric care and to establish a rational basis on which care is reimbursed.

Psychosocial rehabilitation programs should become an integral part of reasonable and expected care. Mental health programs should prevent behavior disorders and functional decline due to inactivity and thus enable patients to achieve their highest levels of functioning and well-being. As Bachrach (1992) noted:

[Although] the gains that some can make are so small as to seem out of proportion to the effort it takes on the part of

patient and personnel to produce them . . . they are so important that the institution must give each long-term patient encouragement and help to achieve his maximum of restoration. (p. 172)

We are stressing the importance of psychosocial rehabilitation and, even more basically, humanistic treatment of nursing home residents with dementia or other neuropsychiatric disorders. All too often, such appeals set off empty debates about the relative importance of high technology versus highly personal approaches to care. Such debates would be pointless here. There is a need for vigorous approaches to neuropsychiatric diagnosis for all patients with dementia and behavioral disturbances, to identify those with hallucinations, delusions, depression, or delirium. There is also a need for assessment of deficits (e.g., amnesia, aphasia, apraxia, and agnosia) and ensuring that all aspects of nursing home care are carried out with the knowledge of these deficits. Here there must be interactions between clinical neuroscience and front-line staff. If environmental interventions are to prevent or treat behavioral disturbances, they must be more than well-intentioned humanistic endeavors; they must be inferred from what is known about cognitive deficits in dementia, both in general and in the individual patient.

To provide this level of care, a complete revision of the nursing home industry will be required, to meet acceptable standards of neuropsychiatric care for patients in nursing homes. Elon (1993) discussed the disparity between the ideals and the realities of nursing home medical directorship and indicated that to fill the role adequately, greater financial commitment by facilities and reimbursement systems will be necessary. In the absence of such leadership, it will be difficult to implement other promising and innovative efforts, such as enriched educational and practice programs for nursing staff, the use of geriatric nurse practitioners, and collaborative relationships with psychiatrists. Future efforts to improve nursing home care might profitably be modeled on successful approaches already used in modern psychiatric, neuropsychiatric, and rehabilitation hospitals.

## Summary

In this chapter, we reviewed the high prevalence of neuropsychiatric conditions and behavioral disturbances in nursing homes. We discussed how nursing homes currently are based on a medical model that may not be appropriate for the problems of their patients. Nursing homes are staffed by personnel who direct their care toward the treatment of

medical conditions but not neuropsychiatric ones. This situation may lead to inappropriate use of physical and chemical restraints, an inability to reduce behavior disorders, and failure to improve the psychosocial functioning of patients. Improving the care of nursing home patients with neuropsychiatric disorders requires appreciation of the brain disturbances and how environmental circumstances contribute to both the genesis of problems and the potential for maximizing patients' cognitive, emotional, and physical functioning.

# Genetic Interventions

Kirk C. Wilhelmsen, M.D., Ph.D.

**G**enetics, the science that deals with heredity, is having an increasingly pervasive influence on medicine and biological science. This influence is due in large part to the success of genetics in elucidating biological processes in experimental systems and in the identification of genes involved in human disease. Over the last 100 years, investigators have developed the concept of the gene and the chromosomal theory of heredity, which included the elucidation of the structure of DNA (Watson 1987). These developments have resulted in an explosion of information about the organization and structure of genes and their roles in diseases. Genetic analysis is expected to lead to the identification of genes that play key roles in behaviors. The impact of genetics on geriatric neuropsychiatry will be more apparent as DNA analysis is used to predict both favorable and unfavorable responses to medications and establish presymptomatic susceptibility to disease.

Most of the successes of human genetic analysis have been in the identification of rare mutations that produce diseases with simple patterns of inheritance, called *Mendelian traits* (e.g., cystic fibrosis [Kerem et al. 1989a, 1989b; Riordan et al. 1989] and Huntington's disease ["A Novel Gene Containing a Trinucleotide Repeat That Is Expanded and Unstable on Huntington's Disease Chromosomes" 1993]). In Mendelian traits, one-fourth or one-half

of the relatives of affected individuals are affected. Non-Mendelian traits do not have predictable modes of inheritance. The causal mutations for most common genetic diseases with Mendelian inheritance have been identified (McKusick and Almon 1998). But it will be many years before mutations are identified for all of the well-described, rare heritable diseases. New mutations are continually being identified, increasing our understanding of gene structure and function.

The work on Mendelian traits has become the foundation for efforts to identify genes that play roles in common diseases produced by the complex interaction between genes and environment, diseases we refer to as *complex traits*. The vast majority of behaviors and diseases of interest to geriatric neuropsychiatry are complex traits.

Because specific genetic findings relevant to geriatric neuropsychiatry are limited, most of this chapter is of a general nature. It will be important for all caregivers and investigators to understand the meaning and context of genetic findings that are made in the next decade.

## ■ Genes, Expression, and Diversity

Proteins form the scaffold and machinery in cells and are made of chains of amino acids determined by the structure

of DNA. The order of amino acids determines in large part how proteins fold. Some proteins require the assistance of other proteins to adopt the proper three-dimensional structure. The machinery needed to replicate and maintain DNA and to translate its coded information into proteins is made of protein and RNA, a molecule similar in structure to DNA.

DNA is a long macromolecule composed of two paired helical strands of repeating subunits called *nucleotides*. Each nucleotide contains a phosphate group, a five-carbon sugar, and a cyclic nitrogen-containing base. The backbone of each strand is composed of alternating sugars and phosphates with phosphodiester linkages. Cyclic nitrogen bases covalently bond to the sugar group and form hydrogen bonds between the strands, strictly according to base-pairing rules. Thus the bases adenine and thymine are paired, as are guanine and cytosine. RNA differs from DNA in that RNA uses a different sugar and is usually single stranded, and the cyclic nitrogen base uridine replaces thymine.

Cellular machinery replicates DNA by separating its strands and applying hydrogen-bonding rules to reconstruct the paired strands. Similarly, RNA molecules are “transcribed” from one of the temporarily separated DNA strands using base-pairing rules. Elaborate protein- and RNA-containing complexes edit primary RNA transcripts, often “splicing” out internal segments, called *introns*, before making proteins. Proteins are linearly encoded in RNA using a set of three adjacent nucleotides, called a *codon*, to specify the order of polymerization of amino acids in proteins. Additional DNA and RNA nucleotide sequences adjacent to protein coding sequences are used to regulate the timing and level of protein production. The DNA used to encode a protein and its regulatory elements is referred to as a *gene*. Humans have between 50,000 and 100,000 genes encoded in 3.3 billion nucleotide pairs of DNA.

Before cell division, nuclear DNA molecules in cells are replicated. During cell division, nuclear DNA molecules in cells are coiled and condensed into microscopically visible elements called *chromosomes*. One copy of each chromosome ends up in each daughter cell that results from the division of the parental cell. Humans have 22 paired chromosomes and 2 sex chromosomes. One sex chromosome and 1 of each of the 22 paired chromosomes are derived from the chromosomes present in the sperm and oocyte that fuse to form a zygote. Generally speaking, the structure of chromosomes remains intact through the replication of chromosomal DNA, from the time the sperm and oocyte are fused until new sperm and oocytes are produced. During spermatogenesis and oogenesis, the homologous

chromosomes align. They also frequently break and rejoin through a process called *recombination*. Thus a particular maternal chromosome may be derived from both maternal grandparents.

With the exception of genes that are encoded on sex chromosomes, all individuals have two copies of each gene. However, not all genes have identical DNA sequences. Some sequence changes affect how, when, and where genes are expressed, whereas others change the amino acids in the protein product. Common variants in proteins, called *allozymes*, are found throughout the population. However, rare gene variants are frequently referred to as *mutations*, particularly when the DNA changes produce disease or have been the result of recent errors in DNA replication. Sexual reproduction with chromosomal recombination and new mutations creates a limitless variation in genetic constitution. The bulk of human diversity comes from the interaction between common gene variations and environmental factors.

In addition to nuclear DNA, there is also mitochondrial DNA. Mitochondria are intracellular organelles that use oxidation of carbon compounds to produce adenosine triphosphate (ATP), the cellular currency for energy. The mitochondrial genome is a 16,000–base-pair circle of DNA. Each mitochondrion has several genomes that replicate and are divided between daughter organelles as the mitochondrion divides. Most cells have many mitochondria that appear to be divided by chance between daughter cells during division. Rare genetic diseases have been identified with maternal inheritance, a consequence of the fact that all human mitochondria in the zygote come from the oocyte and none come from the sperm. Changes in the sequence of genes also occur during the development and regeneration of tissues in an organism. Some changes stem from errors in DNA replication or repair, called *mutations*, which can cause diseases such as cancer (Hansen and Cavenee 1988; Kinzler and Vogelstein 1996). Other DNA sequence changes in non-germ line cells are the result of cellular processes that affect specific genes. For example, rearrangements in the immunoglobulin gene allow the generation of new types of antibodies (Hayday et al. 1985; Tonegawa 1988).

Processes that do not affect DNA sequence can also affect gene expression. The best studied of these effects are imprinting and X chromosome inactivation. Imprinting is the result of differential expression of maternally and paternally inherited genes (Cassidy and Schwartz 1998; Lewin 1998; Surani 1998). X chromosome inactivation permits balancing of effects of genes on sex chromosomes (Brockdorff and Duthie 1998; Jaenisch et al. 1998). Males have an X chromosome and a Y chromosome, and females

have two X chromosomes. This arrangement could result in twice the amount of expression of some X chromosome genes in females. To compensate for this, each female cell has an inactivated X chromosome. This chromosomal inactivation stops genes from being used to make proteins. Thus a female is a mosaic of cells in which the X chromosome from either the mother or the father is inactivated.

In addition to imprinting and inactivation, there are other mechanisms that modulate gene expression, but these mechanisms are less well understood. For example, exposure to certain stimuli can result in long-term changes in gene expression. Technology to measure gene expression for thousands of genes simultaneously has been developed (Lashkari et al. 1997). This technology has allowed investigators to study the correlation of cellular- and tissue-specific patterns of gene expression for large collections of genes after cells or organisms are exposed to drugs, toxins, or other stimuli such as learning.

## ■ Effects of Aging of the Genome

Changes in DNA occur as we age. Most changes are non-specific mutations (Osiewacz 1997). Aging is the most important risk factor for cancer that appears to be the direct result of mutations. The extent to which accumulation of mutations affects the process of aging is not certain.

One consistent finding in studies of aging is that mutations can be detected with an increasing frequency in mitochondrial DNA. These studies have focused on the accumulation of specific mutations detected by powerful molecular biology techniques. Most experts would argue that because there are many mitochondria per cell and because mitochondria have more than one copy of DNA, the observed mutations would not have a significant effect on function. On the other hand, all of the deleterious mutations combined could have an effect on function. This view is supported by the observation that certain mitochondrial functions (e.g., cytochrome-c oxidase activity) decline in muscle fibers as we age (Brierley et al. 1997).

It has been widely observed that cells from normal tissue can divide only a limited number of times (Berube et al. 1998; Shore 1998). This finding suggests that there is some cellular mechanism that regulates the number of times a cell divides. One candidate for this mechanism is the shortening of telomere length. Telomeres are the ends of a chromosome's arms. The enzyme that synthesizes a new strand of DNA, DNA polymerase, requires a single strand of DNA with a small bound "primer strand" to add new complementary bases. DNA synthesis with DNA polymerase proceeds in only one direction, and the end of a chromo-

some is not replicated by DNA synthesis. Thus without another mechanism to regenerate the ends of chromosomes, such chromosomes would become smaller with each round of DNA replication. Some cells have an enzyme, called *telomerase*, that can increase the length of the telomeres. But in most non-germ line cells, telomerase is not made and telomeres become shorter with each cell division.

Whether telomere length plays a physiological role in human aging is not known. Additional work on model systems suggests that there are other mechanisms that regulate cellular life spans. In addition, mutations in genes that can increase the life span of cells and organisms have been identified (Shore 1998). One of the most interesting examples of a mutation that can affect life expectancy in humans was identified by the positional cloning of the gene for Werner's syndrome (Yu et al. 1994, 1997). Patients with Werner's syndrome have a defect in a putative topoisomerase gene, appear to age rapidly, and have an increased risk of developing cancer. A defect in topoisomerase could be predicted to lead to a rapid accumulation of genetic defects.

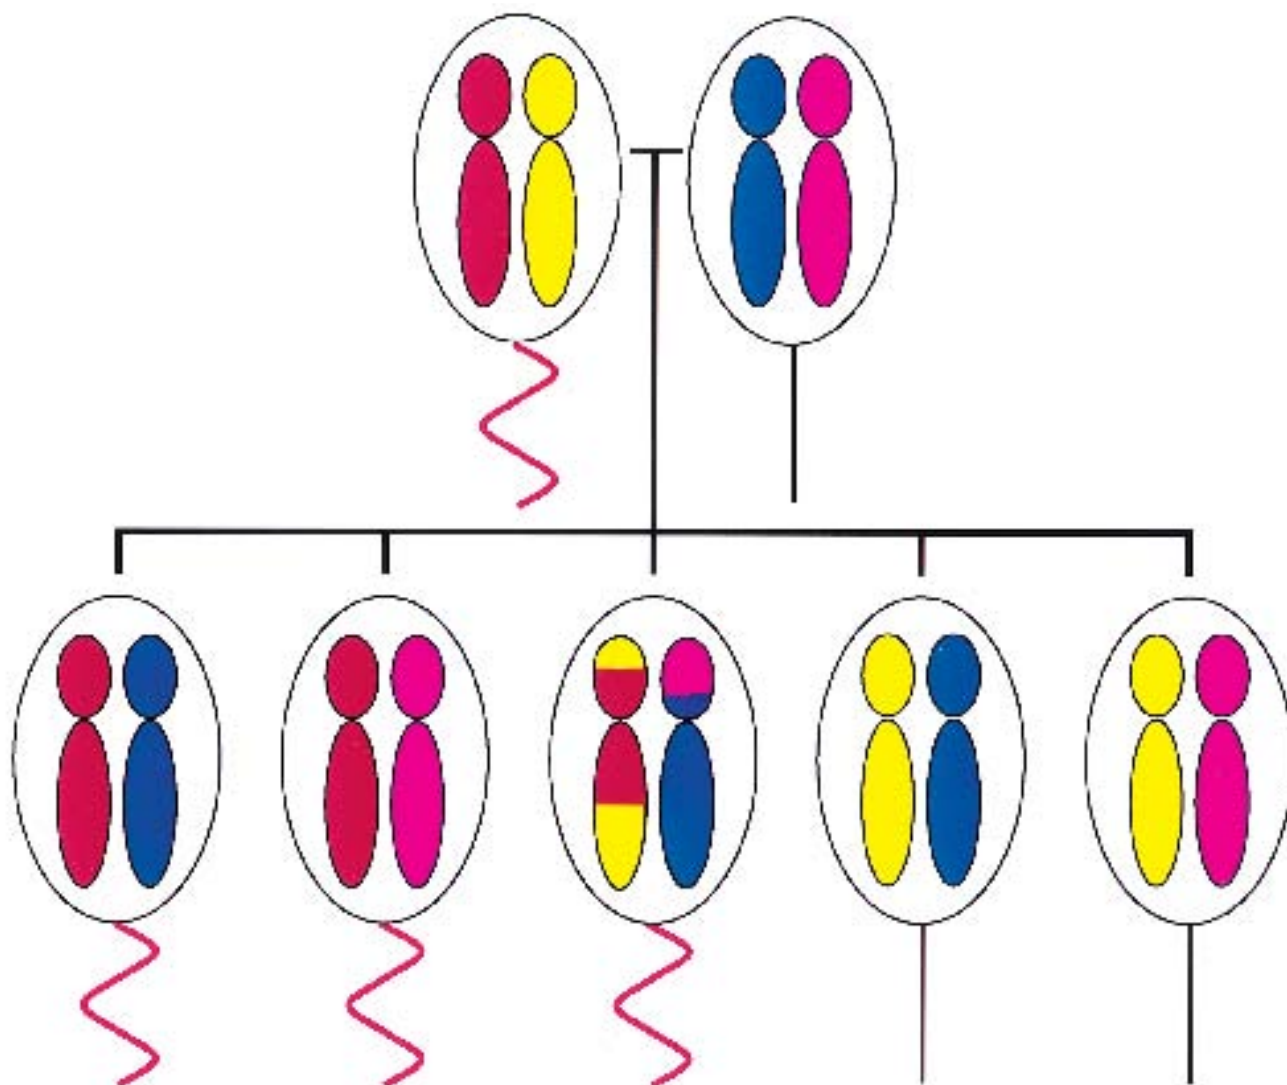

## ■ Molecular Basis of Genetic Analysis

The goal of human genetics is to show that specific gene sequences predispose an individual to specific traits. There are many intermediate observations that can help investigators identify the chromosome location for, and ultimately the genes responsible for, specific traits. This process of using further refinements of the location of a gene to identify a gene is called *positional cloning* (Collins 1995). The positional cloning of the gene for Huntington's disease is an important example.

### Linkage Studies

The focus of most previous positional cloning efforts has been on simple Mendelian traits. To find the genes involved in Mendelian disorders, researchers have studied the outcome of chromosomal recombination events in families. Thinking of a chromosome as color coded (see Figure 38–1) allows one to visualize graphically how a simple Mendelian trait would be localized. One would simply look for a correlation between inheriting a specific color-coded chromosome segment and development of a particular disease in a family.

In practice, markers are used to distinguish chromosomes. Markers are tools for monitoring the inheritance of chromosome segments. A marker is any feature that segregates from generation to generation as a simple trait with a

**FIGURE 38-1.** Each hypothetical organism represented in this diagram has one shared chromosome and a straight or crooked tail. Each homologous chromosome is a different color in the parental generation (*top*). During sexual reproduction, one chromosome from each parent is transmitted to the offspring (*bottom*). In some cases, chromosomes are broken and rejoined, so that an individual receives portions of two grandparental chromosomes. In this example, a red crooked tail is inherited with at least a portion of the red chromosome; individuals with straight tails have inherited the yellow chromosome from their parent with the red tail.

specific chromosome location. The earliest markers were morphological features such as color blindness; these were followed by the more numerous and useful biochemical traits such as ABO blood type. The use of morphological and biochemical markers has largely been supplanted by the study of specific DNA sequence variations (Botstein et al. 1980; Weber and May 1989). Tens of thousands of segments of DNA in which the sequence varies have been identified.

The alternative forms of a marker are called *alleles*. By studying the inheritance of alleles for many different mark-

ers, one can establish the sequence of markers on chromosomes and detect the location of meiotic recombination events. There is usually no direct relationship between the markers used and the trait. In fact, the alleles on the chromosome associated with a disease are often different in different families.

Geneticists have developed mathematical methods to measure the likelihood that a gene for a trait is located at a specific chromosome location given the family structure and the observed marker and clinical data (Ott 1991). Some methods, referred to as *parametric methods*, take into

account the effect of allele number (i.e., whether it takes one or two alleles to cause a trait [dominance]), variable age at onset, the possibility that some gene carriers are unaffected (penetrance), and the possibility that multiple genes can produce the same condition (locus heterogeneity). Because parametric methods require estimates of parameters that are difficult to estimate in advance, there has been a trend toward using nonparametric analyses that rely on simple paradigms, particularly for complex traits.

The simplest form of nonparametric analysis is called the *sib-pair method*, in which excess chromosome sharing is looked for (Blackwelder and Elston 1985). When two siblings (a sib pair) are concordant for a trait, it is more likely that they inherited the same chromosome that has the gene for the trait from both parents. In the case of a random chromosome, siblings are expected to have inherited the same chromosome from both parents, the same chromosome from one of their parents, or different chromosomes from both parents (probability of one in four, two in four, and one in four, respectively). In a population of siblings, the average number of chromosomes shared between siblings is one. In a population of siblings concordant for a trait, there is excess chromosome sharing (an average of between one and two) for the chromosomes containing the responsible genes. It is possible to extend this analysis to include large families and information from both affected and unaffected individuals.

The sib-pair method lends itself to simple parameterization including describing the size of particular gene effects and the effects of gene-environment interactions (Hauser et al. 1996; Risch 1990a, 1990b). The most commonly used parameter to describe the size of effects of a particular gene is analogous to the sibling relative risk ( $\lambda_s$ ).  $\lambda_s$  is the frequency of a sibling of an affected individual being affected, divided by the population frequency for the trait.  $\lambda_s$ , as it is measured in most conditions, in fact indicates both genetic and environmental effects. Ultimately, it should be possible to break down  $\lambda_s$  to recurrence risk for individual genes and recurrence risk for environmental factors. The interaction between these relative risks, be they additive or multiplicative, will tell us much about the biology of underlying disease. Unfortunately, we cannot yet divide recurrence risk into its primary components in advance. The recurrence risk for common genes will not be greater than the total sibling recurrence risk. Estimating the size of the gene-specific recurrence risk allows one to estimate the sample size needed (Hauser et al. 1996).

With enough relatives of individuals who have specific diseases or traits, it is possible to map susceptibility loci. This approach has been strikingly successful for simple traits. As few as 13 individuals in a nuclear family may be

needed to map a susceptibility locus for an autosomal, dominant, simple Mendelian trait. However, it may take several thousand samples to map a susceptibility locus for complex traits.

The key to all genetic studies is the careful definition of a trait that has a significant heritability, along with the collection of the right family members in order to optimize the efficiency of the analysis. In gene mapping studies, a disease susceptibility locus can usually be localized to a broad chromosomal segment that represents approximately  $1/100$ – $1/600$  of the entire human genome. Collection of additional samples can often lead to reduction of this segment to less than  $1/3000$  of the entire genome, but hundreds to thousands of samples are usually required.

### Allelic Association Studies

An approach referred to as *allelic association analysis* has been used to map genes precisely for positional cloning. This approach has been used for many years with the histocompatibility complex, which has as a result been implicated in many diseases, including diabetes, multiple sclerosis, ankylosing spondylitis, and even narcolepsy (Kostyu 1991).

The basis of allelic association studies can be illustrated easily by studying the chromosomes of the descendants of a “founder” with a rare disease (Figure 38–2). The mutation that causes a rare disease in the founder is associated with specific marker alleles along a chromosome. After many generations, all of the individuals who have inherited the founder’s mutation have a portion of the founder’s chromosome. The likelihood that a specific allele will continue to be associated with a disease after many generations depends on the distance along the chromosome between the sequence and the mutation. As the distance between the mutation and the marker increases, it is increasingly likely that recombination events will break the association on the founder’s chromosome.

Allelic association can also be seen with common traits. DNA sequence changes for common traits can either be due to sequence changes that occurred in prehistoric times that have been disseminated throughout the population or be due to the occurrence of many recent mutations. For traits due to ancient mutations, only markers linked extremely closely to the causal sequence variation will show an association because there will have been many opportunities for recombination during the many generations since the founder. Diseases in which there are many new mutations do not show allelic association because there are many founders.

Allelic association studies can be used to localize susceptibility genes precisely. The precision is dependent on

**FIGURE 38-2.** Chromosomes from a “founder” and his progeny who have inherited a mutation. The location of the mutation on the chromosome is indicated by an arrow. Only chromosomes from affected individuals are shown. The founder’s chromosome is in black. Other chromosomes are variegated because there are limitless combinations of possible alleles for each gene and marker. Each meiotic segregation is an opportunity for chromosomes to recombine. With each generation, a smaller portion of the original founder’s chromosome is present in the individuals who carry the founder’s mutation. After many generations, there is essentially a random distribution of colors at any position on a chromosome, except for segments that contain the mutation.

the number of different mutations, the total number of generations since mutations occurred, and the number of individuals with each mutation. With traits that were established thousands of years ago, it is possible to localize disease susceptibility loci to chromosome segments that represent less than  $\frac{1}{5000}$  of a human genome (approximately 1 million base pairs of DNA, or 20–40 genes). Frequently, association studies are used to show that specific DNA sequence variations cause disease. Before strongly associated sequence variations can be considered responsible for a disease, supporting data must usually be obtained.

The most common study design used in allelic association analysis is the case-control design. Use of the case-control design has resulted in the making of spectacular claims that ultimately have not been substantiated. The principal reason for such unsubstantiated conclusions is that there are many reasons an association can be detected, only one of which is significant.

The most common pitfall in case-control designs is population stratification. Case patients and control subjects need to have the same genetic background. The finding that a specific DNA sequence variation is more com-

mon among selected short Inuits than among selected tall African tribespeople should not lead one to assume that the DNA sequence variation studied affects stature. It is more likely that the presence of a specific DNA sequence variation is the result of the effects of the separation of the populations for tens of thousands of years. There are apt to be many other sequence changes that also correlate with being part of one of the two populations. Unfortunately, case-control studies are subject to much subtler population-stratification effects. One of the more common errors has been to use laboratory personnel as control subjects in studies of diseases that occur in clinic populations.

Many association studies have been reported in the last decade. The most creditable are extensions of family-based linkage studies in which disease genes are further localized. Frequently, association studies have been conducted to test the hypothesis that a gene plays a role in a disease process. Such hypotheses can be supported but not disproved by association studies. Many reports describing associations between specific DNA sequence variation in the dopamine, subtype 2 ( $D_2$ ), receptor and the occurrence of alcoholism have been published in recent years (Blum et al. 1990). Since the initial observation by Blum and colleagues, studies that replicated or failed to replicate the original observation have been reported. These discrepant results could mean that alternative  $D_2$  receptor alleles affect susceptibility to alcoholism but that such susceptibility may be detectable only in certain populations with specific genetic backgrounds and environmental influences. An alternative explanation is that subtle effects of population stratification are being detected in some of the case-control studies. In a meta-analysis of all available data, it was concluded that we still do not know whether sequence variation in the  $D_2$  receptor affects susceptibility to alcoholism (Gejman et al. 1994; Gelernter et al. 1993).

Two case-control studies have suggested that the DNA sequence variation of the dopamine, subtype 4 ( $D_4$ ), receptor leads specifically to novelty-seeking behavior (Benjamin et al. 1996; Ebstein et al. 1996). But one has to question whether these findings were due to a causal relationship between the specific DNA sequences and novelty-seeking behavior or to biases in the collection of samples from individuals who scored similarly on measures of novelty-seeking behavior.

The fundamental problem with the aforementioned studies focusing on alcoholism (Gejman et al. 1994; Gelernter et al. 1993) and novelty seeking (Benjamin et al. 1996; Ebstein et al. 1996) is the case-control design. It is extremely difficult to identify the appropriate control subject for each individual in a population. Recently, two study designs have been introduced in an attempt to overcome the

problems of the case-control design. The first study design, described by Spielman and Ewens (1996), involves the *transmission disequilibrium test* (TDT). In this approach, samples are obtained from a population of affected individuals and from their parents. A comparison is made between the frequency at which alleles are found in affected individuals and the frequency at which nontransmitted parental alleles are found. The nontransmitted parental alleles serve as the control chromosomes for the affected individuals. The rationale for the TDT is that the nontransmitted alleles come from individuals with same genetic background as that of the subjects. The TDT is just now coming into use, but it is recognized as the tool of choice for future association studies.

Unfortunately, particularly in the case of late-onset diseases, it is not always possible to collect DNA samples for genetic analysis from the parents of affected individuals. This limitation can be overcome by performing a family study (i.e., by collecting samples from large numbers of siblings of affected individuals, to reconstruct the genetic constitution of the parents). But more recently, the practical approach of comparing the frequency at which alleles are found in affected individuals with the frequency at which alleles are found in their unaffected siblings has been suggested (Boehnke and Langefeld 1998; Spielman and Ewens 1998). If the siblings have the same genetic background, the disease-associated allele is likely to be underrepresented in the individuals who do not manifest the trait. The likelihood of seeing an association in a discordant-sib-pair study will diminish if there are large numbers of unaffected siblings who have a specific disease susceptibility sequence but, because of other genetic or environmental factors, do not manifest the trait.

Case-control studies can be used with greater confidence when family-based studies demonstrate linkage. Association studies have the power to localize disease genes with extreme precision. It has been suggested that in the future, when it is possible to screen hundreds of thousands of DNA sequence variations, the TDT will be the method of choice for identifying genes for complex traits (Risch and Merikangas 1996).

## ■ Dementia

Cognitive decline is a prominent feature associated with aging (see Chapter 8). The general population considers failure to remember recent events and misplacing items not only evidence of aging but a possible harbinger of Alzheimer's disease (AD), the most common form of neurodegenerative cognitive impairment. The impor-

tance of cognitive function in the geriatric population is illustrated by the observation that elements of cognitive function can be used to predict life expectancy in normal sexagenarians (Siegler et al. 1982). Although interest in the genetics of normal cognitive function is increasing, most of the effort in human genetics is focused on neurodegenerative diseases that affect cognition. Recent developments in this area have practical import for geriatric neuropsychiatry.

## Alzheimer's Disease

The clinical and pathological features of AD have been described in Chapter 24. From a geneticist's point of view, the salient feature of AD is that few patients with AD have positive family histories. The diagnosis of AD is based on the finding of  $\beta$ -amyloid-containing senile plaques and neurofibrillary tangles composed of hyperphosphorylated tau protein. A key to proving that a particular gene plays a role in the pathogenesis of AD is determining how the gene leads to the key pathological findings.

In the rare cases of familial AD, families have mutations in the  $\beta$ -amyloid precursor protein gene, leading to Mendelianly inherited AD (Chartier Harlin et al. 1991). More common mutations in presenilin 1 (Sherrington et al. 1995) and presenilin 2 (Levy-Lahad et al. 1995) also produce Mendelian, inherited AD, with an early age at onset. Presenilin 1 and 2 have no known function, but these mutations affect the biological processing of the amyloid precursor protein, increasing  $\beta$ -amyloid production in experimental models (Scheuner et al. 1996).

More relevant to the current practice of geriatric neuropsychiatry has been the identification of alternative alleles of apolipoprotein E (*APOE*) as susceptibility loci for AD (Roses 1994). Common variations in the *APOE* gene result in three protein products, referred to as  $\epsilon 2$ ,  $\epsilon 3$ , and  $\epsilon 4$ , with allele frequencies of 0.07, 0.77, and 0.16. The risk for developing AD is substantially higher in individuals who have inherited two  $\epsilon 4$  alleles (2.5% of the population) than in individuals who have two of the more common  $\epsilon 3$  alleles (59% of the population) (Figure 38-3). The average age at onset of AD for individuals with two  $\epsilon 4$  alleles is approximately 15 years less than for individuals with two  $\epsilon 3$  alleles.

The alternative alleles of the *APOE* gene are appropriately referred to as *alleles* rather than *mutations*. The sequence variations that result in the three alternative alleles were fixed into the human genome tens, if not hundreds, of thousands of years ago. These alternative alleles have essentially normal function as determined by the final arbiter of genetics, reproductive fitness. They have become widely

distributed throughout the population, which suggests that there is no obvious disadvantage to having the alleles that would predispose a person to AD.

Results of genetic epidemiological analysis suggest that additional genetic susceptibility factors for AD are yet to be identified. Studying families who have late-onset AD has led to the identification of another susceptibility locus, on chromosome 12 (Pericak-Vance et al. 1997). It is uncertain whether this locus plays a major role in the susceptibility to AD in the general population.

## Frontotemporal Dementia

In behavioral neurology clinics, frontotemporal dementia (FTD) is the next most common cause of heritable dementia (Brun 1993; "Clinical and Neuropathological Criteria for Frontotemporal Dementia" 1994). Because it may be misdiagnosed as AD, the prevalence of FTD in the population is not clear. In behavioral neurology clinic populations, estimates of the percentage of dementia that results in FTD range from 1% to 15%. Most of the variability in the observed frequency in FTD is probably related to referral biases and different levels of detection sensitivity.

The prototypical forms of FTD characteristically are associated with positive family history in 60% of cases

**FIGURE 38-3.** Onset curves estimated by Kaplan-Meier product limit distributions for apolipoprotein E genotypes. The proportion of individuals without Alzheimer's disease is plotted as a function of time for the five most frequent genotypes.

Source. Reprinted from Roses AD: "Apolipoprotein E Affects the Rate of Alzheimer Disease Expression: Beta-Amyloid Burden Is a Secondary Consequence Dependent on APOE Genotype and Duration of Disease." *Journal of Neuropathology and Experimental Neurology* 53:429-437, 1994. Used with permission.

(Gustafson 1993). Many large families have been identified in which FTD is inherited as a Mendelian trait linked to chromosome 17q21-22 (a region containing the *tau* gene). Mutations in the *tau* gene have been identified in several families with FTD and in individuals with a variety of other clinically and pathologically distinct but overlapping conditions with linkage to 17q21-22. Mutations have also been identified in both coding and presumed regulatory sequences. In the vigorous attempts to find *tau* mutations in other families, the focus has primarily been on the coding sequences. These efforts have failed, but more systematic efforts are under way. It is possible that some cases of FTD are due to mutations in other genes. In one family with FTD, the condition was due to the mutation of another gene on chromosome 3 (Brown et al. 1995).

A characteristic feature in all of the families with *tau* mutations has been the presence of aggregates of hyperphosphorylated tau proteins. Some mutations cause neurofibrillary tangles, as seen in AD. Interestingly, very few amyloid plaques are seen in any individuals with *tau* mutations, and *tau* mutations have not been identified in classic AD. This finding suggests that the neurofibrillary tangles seen in AD are induced by biology of the  $\beta$ -amyloid precursor and that the biochemistry of the *tau* gene may be responsible for neuronal death.

## ■ Genetic Testing

When a mutation is identified, it is possible to confirm a diagnosis or make a presymptomatic diagnosis in a relative. As with all genetic diagnostic studies, it is important that testing be performed in the appropriate clinical setting and that genetic counseling occur before and after testing. The clinician should recognize that confirming the diagnosis of a disease by mutation detection can have an effect on family members who may be unwilling participants in the search for knowledge.

DNA from individuals can be sequenced to permit searching for mutations in the amyloid precursor protein, the presenilin genes that are predictors of AD, and the *tau* mutations that cause FTD. These tests are relatively specialized and less widely available than the now routine tests for Huntington's disease. Because mutations in these genes are only rarely responsible for AD and because sequencing is expensive, this type of analysis is usually reserved for subjects with strong family histories. It is uncertain what fraction of FTD cases are due to mutations in *tau*. Because the *tau* gene is large and has complex regulation, it is necessary to screen large segments of DNA sequence for mutations before concluding

that a patient has FTD caused by a non-*tau* mutation.

Although it is commercially available, it is inappropriate to use *APOE* genotyping for predictive testing on the general population or on children of patients with AD (Post et al. 1997). The major reason for this is that the available test does not have a high enough predictive value. Many people who have the  $\epsilon 3/\epsilon 3$  genotype develop AD, and many people who have the  $\epsilon 4/\epsilon 4$  genotype do not develop AD. Further *APOE* genotyping cannot be used to predict the age at onset of disease, and children of patients with AD may be at risk because of mutations in other genes. In the appropriate setting, *APOE* genotyping can aid in confirming AD diagnosis in populations (Mayeux et al. 1998). Typically, 10% of the patients with a clinical diagnosis of probable AD do not have a pathological diagnosis of AD. A higher concordance rate with pathological diagnosis is observed among patients with a clinical diagnosis who also have at least one  $\epsilon 4$  allele. In the near future, *APOE* genotyping may be relevant to clinicians if it can be used to help tailor therapy when multiple therapeutic options are available and their effectiveness is dependent on genotype.

Although medical therapies for most diseases are based on the administration of small molecules, human genetics is spurring the development of alternative strategies. The products of genes identified by human genetic analysis may require delivery to cells in a tissue-specific way. Methods have been developed to insert genes into somatic cells in whole animals. Most approaches rely on the use of modified viruses. The problems of cell targeting, low efficiency, and random DNA insertion are just a few of the obstacles that need to be overcome for this approach to be practical. It is doubtful whether this approach will ever be useful for repairing a mutation that causes a gene to produce a protein with a new toxic function. An approach that has received less attention in the area of genetic disease is the transplantation of tissue to repair an organ (as opposed to organ transplantation). Both fetal neural and autoallogous adrenal tissue have been implanted (Freeman 1997) into the striatum in patients with Parkinson's disease, with mixed results (Kordower et al. 1997; Lieberman et al. 1989) (see Chapter 26). A more practical approach being developed involves transplanting engineered cells grown and selected in vitro.

## ■ Summary

Human genetic analysis has already led to the identification of genes that play roles in the most common causes of cognitive decline in the geriatric population. Additional genes will be implicated in these and other traits of interest

to geriatricians. In some cases, it is now possible to make presymptomatic diagnoses on the basis of DNA analysis. More important, the identification of genes responsible for human disease offers the opportunity for rational development of drugs to treat and prevent disease. Confirmation of the role of the amyloid precursor protein by the finding of mutations in patients with AD has led to a concerted effort to develop drugs that modify the biochemistry of the gene product. Mice that have pathological features of AD have been genetically engineered to overexpress this gene. These mice are being used as reagents to study the interaction of genes and as systems to test treatment strategies.

Genetic analysis will become an integral part of patient care as treatment is tailored to a patient's genetic constitution. All clinical trials designed to discover agents for the prevention and treatment of AD should now include stratification based on *APOE* genotype. Ideally, therapeutic agents that have general efficacy for the treatment of AD will be developed, but this may not be the case if they have been designed to alter the enzymatic action of APOE.

In the future, analysis of *APOE* through study of a patient's DNA sequence and as-yet unidentified genes will become a routine part of medicine and geriatric neuropsychiatry when genotypes are used to tailor therapy. Despite the promise of genetics to predict our fates, we should recognize that our fate is not entirely determined by our genes. Genetics and epidemiology are becoming increasingly linked, such that it may not be possible to identify genes or environmental factors for some complex traits.

# Rehabilitation

Bruce H. Dobkin, M.D.

**G**oals of rehabilitation programs are to lessen physical and cognitive impairments of patients, increase patients' functional independence, decrease the burden of care provided by significant others, reintegrate patients into their families and communities after illness, and improve the quality of life for patients and their families. Rehabilitation is a problem-solving process with a scope so broad that a specialized team of therapists is needed to make efforts successful.

Physical, cognitive, and behavioral interventions could begin at the first sign of any functional decline in geriatric patients. The causes and natural history of neuropsychiatric disablement in geriatric subjects are not well understood (Wade 1996). More often, efforts are implemented at the time of an accident or of diagnosis of an illness. The most common instigators of a functional evaluation are stroke, traumatic brain injury (TBI), Parkinson's disease, memory loss, dementia from Alzheimer's disease or cerebral ischemia, and injuries secondary to loss of balance, gait dysfunction, and falls. Acute strategies are designed to prevent the medical and psychosocial complications that accompany immobility and new physical and cognitive impairments and disabilities. Evaluation and treatment of impairments and disabilities can take place in an inpatient or outpatient setting. The long-term goal of

neuropsychiatric rehabilitation is to lessen disability and handicap.

Assessments, treatments, and outcome measures in rehabilitation are performed by clinicians on at least three levels. *Impairments* include sensorimotor and other neurological, physical, and cognitive deficits, such as a new left hemiparesis and left hemianopsia with hemi-inattention to surroundings. A chronic hip contracture that premorbidly affected walking is a type of impairment that could cause greater disability than one might expect to result from a new stroke. Premorbid impairments in recent memory, word finding, or mood are especially likely to lead to greater-than-expected cognitive dysfunction and disability after a new brain injury. The clinician can use standardized timed tests of physical functioning in elderly patients to obtain a global view of the effects of impairments on important activities. For example, in the Physical Performance Test, a variety of activities are timed, such as walking 50 feet, putting on and removing a jacket, writing a sentence, and climbing a flight of stairs (Reuben and Siu 1990). An obstacle course set up in a hallway was described as a way to assess mobility and balance (Means 1996). Results of tests of postural sway, carried out with or without force plate measures, have been related to the likelihood of falls and disability (Hughes et al. 1996; Wolfson et al. 1992). Significant correlations have been made between speed of walk-

ing and levels of independence in activities of daily living (ADLs) in elderly individuals, with speeds of less than 0.3 m/second associated with dependence in one or more activities on the Barthel Index (Potter et al. 1995).

Disabilities are the functional restrictions induced by impairments, such as not being able to walk across a room without assistance because of hemiparesis. The Barthel Index is often used to grade the level of independence in ADLs but does not include a behavioral or cognitive domain. The Functional Independence Measure is another ordinal scale. It includes several broad measures of cognition (Tables 39–1 and 39–2) (Granger et al. 1986; Ottenbacher et al. 1996).

Handicaps arise from impairments and disabilities. Handicaps include the disadvantages that limit or prevent fulfillment of a usual role, such as no longer being able to visit a friend because left hemiparesis prevents stair climbing. In elderly persons, social isolation may follow development of a physical impairment that limits the ability to walk or drive a car. Handicap can be measured in part by the Frenchay Activities Index (Pedersen et al. 1997).

Health-related quality of life is connected to impairment, disability, and handicap. This measure includes a patient's perception of his or her physical functioning, as well as the mental, psychosocial, and emotional state. Health-related quality of life has been measured using the Sickness Index Profile and the Medical Outcomes Study 36-Item Short-Form Health Survey (SF-36) (Garratt et al.

1993). Many other scales have been used in neuro-rehabilitation and geriatric studies (Dobkin 1996a; Wade 1992).

Disabling neuropsychiatric diseases that are common in the geriatric population cause impairments in sensorimotor skills, cognition, behavior, and emotional control. For example, about half of stroke survivors and persons with chronic multiple sclerosis have cognitive dysfunction, along with about 20% of those with Parkinson's disease (see Chapters 27 and 30). TBI is especially likely to impair attention and executive functions, particularly in older patients after even a mild head injury (see Chapter 28). The combination of physical, cognitive, or behavioral impairments and prescribed and overused centrally acting medications, psychosocial stresses, and other health- and non-health-related issues can lead to profound disability.

**TABLE 39–2. Scoring for the Functional Independence Measure**

---

**Independence** (another person not required for performance of activity; no helper required)

- 7: Complete independence (all of activity's tasks typically performed safely without modification, use of assistive devices, or use of aids and within reasonable amount of time)
- 6: Modified independence (performance of activity involves use of assistive device, more than a reasonable amount of time, and/or safety [risk] considerations)

**Dependence** (another person required for performance of activity, either to supervise or to lend physical assistance, or activity not performed; helper required)

- Modified dependence (patient expends  $\geq 50\%$  of effort)
- 5: Supervision or setup required (patient requires no more help than standby assistance, cueing, or coaxing, without physical contact; or helper sets up needed items or applies orthoses)
  - 4: Minimal contact assistance required (with physical contact, patient requires no more help than touching and expends  $\geq 75\%$  of effort)
  - 3: Moderate assistance required (patient requires no more help than touching and expends  $\geq 50\%$  but  $< 75\%$  of effort)
- Complete dependence (patient expends  $< 50\%$  of effort; maximal or total assistance required, or activity not performed)
- 2: Maximal assistance required (patient expends  $< 50\%$  but  $\geq 25\%$  of effort)
  - 1: Total assistance required (patient expends  $< 25\%$  of effort)
-

Neuropsychiatric rehabilitation involves not only physicians and nurses but also physical, occupational, recreational, and speech-language therapists; social workers; neuropsychologists; orthotists; dieticians; and sometimes engineers. These professionals work as a team to optimize the physical, cognitive, behavioral, psychosocial, and vocational potential of people who are disabled by their impairments. The primary approach of neuropsychiatric rehabilitation is to lessen disability through training and adaptation. Patients should be able to learn and should be motivated and goal directed. Of course, some geriatric patients may not meet these requirements. An aging brain and body may have confounding effects on rehabilitative therapies; physical, cognitive, and behavioral rehabilitation can be a most difficult challenge for the rehabilitation team.

Rehabilitation services are often organized in relation to the disease being managed. The primary distinction is between acute events such as brain and spinal cord trauma and stroke; the more static conditions in which disability might increase with aging and overuse of muscles and joints, such as cerebral palsy and polio; and the variably progressive disorders such as multiple sclerosis and Parkinson's disease. Services should also be driven by the opportunity to optimize home and community activities and return the patient to the community as soon as possible. A return to the home is often as dependent on the services available in the community as on the severity of the disability and the capacity of the family and caregivers to assist the patient.

## ■ Rationale for Gains

Some of the neurobiological mechanisms that might contribute to improvements and, sometimes, increases in impairments and disabilities are outlined in Table 39-3. These mechanisms overlap, and some depend on each other over time. For example, partial recovery of a function because of a partially spared pathway, combined with partial substitution for a function through retraining, may account for gains. Although care must be taken in extrapolating from animal studies of recovery for human interventions (Dobkin 1997), at least a few of these potential mechanisms suggest strategies that can be used by the rehabilitation team to improve outcomes.

Many lines of animal and human research suggest that partial recovery after a stroke can be due to a functional shift to neighboring neurons. Nudo and colleagues (Nudo and Milliken 1996; Nudo et al. 1996) induced an injury of less than 1 mm to the motor cortex of primates in the neu-

rons that represented movement for the arm. The number of perilesional neurons that represented movements of the digits decreased if the monkey did not practice using its hand to scoop pellets out of a narrow well (Nudo and

**TABLE 39-3. Neurobiological mechanisms for recovery of function**

### Network plasticity

1. Recovery of neuronal excitability
  - Resolution of cellular toxic-metabolic dysfunction
  - Resolution of edema; resorption of blood products
  - Resolution of diaschisis
2. Activity in neurons adjacent to injured ones and in partially spared pathways
3. Alternative behavioral strategies
4. Representational adaptations in neuronal assemblies
  - Expansion of representational maps
  - Recruitment of cells not ordinarily involved in an activity
5. Recruitment of parallel and subcomponent pathways
  - Altered activity of distributed functions of cortical and subcortical neural networks
  - Activation of pattern generators (e.g., for stepping)
  - Recruitment of networks not ordinarily involved in an activity
  - Dependence on task-related stimulation

### Neuronal plasticity

1. Altered efficacy of synaptic activity
  - Activity-dependent unmasking of previously ineffective synapses
  - Learning tied to activity-dependent changes (e.g., long-term potentiation, long-term depression) in synaptic strength in peri-injury and remote regions
  - Increased neuronal responsiveness from denervation hypersensitivity
  - Decrease in number of neurons, as in apoptosis
  - Change in number of a variety of receptors
  - Change in neurotransmitter release and uptake
2. Regeneration and sprouting of axons and dendrites
  - Signaling gene expression for cell viability, growth, and remodeling proteins
  - Modulation by neurotrophic factors
  - Actions of chemoattractants and inhibitors in milieu
3. Remyelination
4. Transsynaptic degeneration
5. Ion channel changes on fibers for impulse conduction
6. Actions of neurotransmitters and neuromodulators

*Source.* Adapted from Dobkin 1996a.

Milliken 1996), but the size of neighboring representations for the digits, wrist, and forearm increased with practice (Nudo et al. 1996). Thus, cortical representational changes are especially likely to occur during training that involves learning and the acquisition of specific skills. The neurons of the ischemic penumbra of an acute cerebral infarction may play an important role in functional gains because this region has a large potential for the learning mechanism of long-term potentiation (Dobkin 1998).

Representational plasticity probably arises when previously silent synapses within thalamocortical and intracortical circuits are unmasked (Donoghue 1997). In some instances, this plasticity is accompanied by sprouting of dendritic arbors over short distances (Jones et al. 1996). Indeed, these findings are further evidence for a key principle of behavioral neuroscience, namely, that experience continuously modifies brain structure, especially at the synapse, beyond the period of neurodevelopment and even in the geriatric population. The rules that govern the plasticity of cortical maps appear to parallel those that drive synaptic plasticity (Buonomano and Merzenich 1998). Neocortical modifications in dendritic length, branching, spine density, synapse size and number, glial size and number, and metabolic activity can be produced not only by a stroke or other brain injury but also by aging, sex hormones, neurotrophins, stress, richer environments, and training in specific tasks (Kolb and Whishaw 1998). Although the specific mechanisms that drive these changes are still not certain, they can be related to increases in afferent drives on interneuronal activity, which in turn increase gene expression and protein synthesis. This cascade causes stronger synaptic interactions within neuronal assemblies that participate in a task and leads to behavioral gains.

Substrates for improvements in motor function include the combination of partially spared pathways, flexible neuronal assemblies that represent movements and sensation, and multiple representational maps for movements in a parallel, distributed system. Large anatomical networks also serve cognitive domains, including those for language, spatial awareness, explicit memory and emotional valence, working memory and executive functions, and face and object recognition (Mesulam 1998). The components of each of these networks are interconnected by the convergence of afferent sensory inputs and the divergence of outputs. Thus, afferent drive from practice should modulate neuronal activity, gene expression, learning, and behavioral change. Positron-emission tomography (PET) and functional magnetic resonance imaging (MRI) studies have begun to reveal changes in the organization of these interactions for particular tasks during normal learning and after a cerebral injury (Dettmers et al.

1997; Frackowiak 1994; Karni et al. 1995; Pizzamiglio et al. 1998).

Are the neurobiological mechanisms that have been associated with gains any less likely to evolve when a neuropsychiatric illness affects an aging brain? Few anatomical studies have compared motor recovery in older patients with that in younger patients. Age-related differences in brain regions associated with cognitive processes have been better researched. Greater age has been correlated with a decrease in the number and length of the primary branches of dendrites, the number of dendritic spines, and the density of synapses (Anderson and Rutledge 1996). Because the synapse is the primary site of activity-dependent plasticity, the finding of a decrease in numbers with increasing age beyond 50 years suggests that neuronal adaptations and learning may be limited after a brain injury.

Cognitive rehabilitation strategies have been developed based on the theory that improvements might be mediated by engaging residual links in a distributed cognitive network with therapy (Mountcastle 1997). This strategy is reflected in the primary approaches to cognitive rehabilitation, which include 1) retraining that stresses mental exercises and general cognitive stimulation; 2) training strategies built on theoretical models of specific neuropsychological and neuropsychiatric impairments; 3) techniques drawn from studies in educational, behavioral, and cognitive psychology; and 4) a psychosocial approach that addresses the cognitive, behavioral, social, and emotional bases and sequelae of any impairment and disability.

A treatment emphasis on behaviorally relevant tasks, with an optimal schedule of practice and feedback, might increase cognitive gains, given that this approach has been found in human and animal studies to enhance upper-extremity and locomotor functions after a brain or spinal cord injury (Dobkin 1996b; Taub and Wolf 1997). This approach may be especially useful for treatment of aphasia, apraxias, and visuospatial, visuoperceptual, attentional, memory, and disruptive behavioral disorders. The optimal duration and intensity of training are uncertain, but more intensive practice seems to enhance subsequent performance (Kwakkel et al. 1997). Unfortunately, most patients receive only a few months of formal inpatient and outpatient retraining, at a modest level of intensity and spread across many tasks.

## ■ Physical Approaches

A recent emphasis of geriatric rehabilitation has been on the prevention of falls. Thirty percent of people over age 65 who live in the community fall each year, and this propor-

tion reaches 50% in people over age 80. Falls are a strong predictor of placement in a skilled nursing facility (Tinetti and Williams 1997). A simple test of standing up, walking, and balance can help predict disability in ADLs (Guralnik et al. 1995). Programs of selective muscle strengthening, stretching, and conditioning exercises can improve strength and safety of mobility in frail elderly individuals (Fiatarone et al. 1994). Indeed, frail nonagenarians who participated in an 8-week program of high-intensity resistance training increased their regional muscle mass, gained in strength by an average of 175%, and improved their walking speed by 48% (Fiatarone et al. 1990). Depression may presage a decline in physical performance as well as follow chronic disability in elderly persons (Penninx et al. 1998). Some studies suggest that aerobic exercise improves sleep quality (King et al. 1997) and neuropsychological testing subscores (Dustman et al. 1984).

Exercise programs that bring geriatric patients together in a social setting might lessen the likelihood of physical decline and depressed mood. For many people, a home-based program preceded by instruction is effective. Rehabilitation interventions might have practical goals, such as improving the elderly patient's ability to cross a street within the time limits of a stoplight, climb a flight of stairs, get in and out of a car, or reduce back or leg joint pain that interferes with mobility. A variety of approaches to physical therapy are used.

### **Exercise and Compensatory Functional Training**

Most therapy programs emphasize education about impairments and disabilities, compensatory techniques for ADLs and mobility, and repetitive passive and active exercises to progress from less complex to more functional movements. In the therapeutic-exercise approach, residual motor skills in affected and unaffected extremities are used to compensate for impairments. The acquisition of self-care and mobility skills may take precedence over the quality of movement, as long as patients are safe. Upper-extremity splints, lower-extremity braces such as ankle-foot orthoses, and assistive devices such as walkers and canes tend to be used early in treatment to promote functional compensation. Therapists also make use of general conditioning exercises and energy conservation techniques.

### **Conditioning and Strengthening**

Light resistance exercises are generally safe and effective in improving strength and sometimes function in patients with upper motor neuron (UMN) diseases or diseases of

the motor unit, including postpolio syndrome, amyotrophic lateral sclerosis, and myasthenia gravis (Agre et al. 1997; Damiano and Abel 1998; Dobkin 1993; Engardt et al. 1995; Milner-Brown and Miller 1988). Resistance exercises can be carried out without an increase in spasticity in patients with UMN diseases and without muscle injury in patients with neuromuscular diseases. Along with specific retraining programs, medications may be useful, including hormones that limit disuse atrophy, such as androgens and human growth factor (Roy et al. 1991), and drugs that act on the neuromuscular junction, such as pyridostigmine; on muscle, such as  $\beta_2$ -adrenergic agonists (Signorile et al. 1995); or on demyelinated axons, such as the aminopyridines (Bever et al. 1996).

Fitness training is valuable and feasible in patients with UMN, extrapyramidal, or motor unit diseases. For example, treadmill walking has been used with success as an aerobic workout in elderly patients with hemiparetic stroke (Macko et al. 1997).

## **Neurophysiological Approaches**

Approaches have been developed that focus on enhancing the movement of paretic limbs affected by UMN disease (Dickstein 1989). These approaches use sensory stimuli and reflexes to facilitate or inhibit tone, as well as single-muscle and whole limb-muscle movements in and out of mass actions called *synergies*. Some therapists try to administer therapy in a sequence reminiscent of the neurodevelopmental evolution from reflexive to more complex movements. Some techniques permit whereas others inhibit spastic, overflow, or synergistic movements. Mobility activities might be performed in a developmental sequence, with the patient rolling onto the side, with arm and leg flexion on the same side; then extending the neck and legs while prone; lying prone while supporting himself or herself on the elbows; doing static and weight-shifting movements while crawling on all four extremities; sitting; standing; and finally walking.

When these approaches have been compared with other therapies in patients with stroke or cerebral palsy, no real differences in outcomes related to gains in ADLs have been found (Ashburn et al. 1993; Giuliani 1995). However, movement, rather than specific ADLs, is taught in these approaches, so perhaps outcome measures have been inappropriate. More important, the studies in neuroplasticity reviewed earlier suggest that therapy structured around learning new sensorimotor relationships in the wake of altered motor control will be more effective than will methods that aim to foster a developmental sequence.

## Motor Learning and Task-Oriented Practice

Another approach involves the use of visual, verbal, and other sensory feedback to achieve task-specific movements, rather than sensory stimuli to facilitate and inhibit movement patterns (Lister 1991). The emphasis is on solving a motor problem rather than on relearning a particular pattern of movement. Studies of motor learning in subjects without brain injuries suggest that practice that is randomly ordered and randomly reinforced produces better posttraining retrieval than do repetitious drills and continuous feedback. Only a few studies have compared these approaches in people with brain injuries, with the same results (Hanlon 1996; Winstein 1999).

## Outcomes

Clinical trials that have focused on elderly patients with particular diseases or risk factors for falls have generally shown a significant functional benefit from physical and occupational therapies during inpatient or outpatient rehabilitation. For example, a meta-analysis of the seven randomized trials of interventions to prevent frailty and falls (Frailty and Injuries: Cooperative Studies of Intervention Techniques [FICSIT]) pointed to the benefit of balance, strengthening, and other exercises in terms of reducing falls. Applegate et al. (1990) found that functional assessment and a team approach to medical care, rehabilitation, and psychosocial support were more effective in producing gains in ADLs than was usual community care. Clinical trials of exercise in patients with multiple sclerosis (Di Fabio et al. 1998) or Parkinson's disease (Comella et al. 1994; Patti et al. 1996) pointed to the beneficial effect of an ongoing strengthening and conditioning program on performance of functional activities. Patients with dementia also show physical benefits from an exercise program (Pomeroy 1993).

Rehabilitation outcomes for other common diseases with neuropsychiatric sequelae, such as stroke, TBI, and spinal cord injury, are affected by advanced age. Rehabilitation team efforts, particularly assessments and functionally oriented services performed in an organized way, appear to improve outcomes in elderly stroke patients more than efforts by less organized medical units involving less organized outpatient services (Hui et al. 1995; Indredavik et al. 1997, 1998; Kaste et al. 1995). Functional gains made during stroke rehabilitation were maintained during 2 years of follow-up in patients under age 70 and in patients 70 years and older, although the older group had a greater risk of death and placement in a nursing home (Borucki et al.

1992). After a traumatic head injury necessitating admission for rehabilitation, age greater than 60 years has been associated with longer confusional states, slower recovery, and worse overall outcome, but inpatient and lengthy outpatient programs appear to improve outcomes (D. I. Katz and Alexander 1994). Although the prognosis for functional gains and 2-year survival is worse and the likelihood of nursing home placement is greater after a spinal cord injury in elderly patients than in patients under age 60 (DeVivo et al. 1990; Penrod et al. 1990), gains in ADLs are common with rehabilitation efforts in elderly individuals. Several randomized clinical trials of older persons with an acute stroke demonstrate that both inpatient and outpatient therapy that is task-specific in its treatment strategy will lessen disabilities (Kwakkel 1999; Walker 1999).

## ■ Cognitive Rehabilitation

Cognitive disturbances are common in patients with recent stroke, TBI, multiple sclerosis, Parkinson's disease, or degenerative brain disease. A prospective study of 227 patients with acute stroke revealed that 35% had measurable cognitive impairments 3 months after onset (Tatemichi et al. 1994) (see Chapter 27). In another study, cognitive decline was observed 3 months after a stroke in 45% of patients ages 55–64 years and in 74% of those ages 75–85 years (Pohjasvaara et al. 1997). Cognitive dysfunction is especially common after TBI (see Chapter 28). Greater severity and longer duration of impairments are associated with lower Glasgow Coma Scale scores on admission for acute care and longer duration of posttraumatic amnesia. Greater severity of cognitive sequelae is strongly associated with age over 60 years (D.I. Katz and Alexander 1994; Levin et al. 1990b). Up to one-half of patients with traumatic spinal cord injury, usually from falls or automobile accidents in geriatric patients, will have cognitive impairments from an associated TBI that may not be obvious early in their care. Of course, any toxic-metabolic or infectious disease will exacerbate cognitive disabilities. A bladder infection or a seizure, for example, often precipitates greater confusion that can last days in a person with dementia or aphasia. Some of the impairments that are often dealt with by the rehabilitation team are listed in Table 39–4. These impairments can also impede gains in mobility, ADLs, and community reintegration.

The amount and rate of recovery of neuropsychological functions vary with the patient's age; the sophistication of the measures used; the type and severity of impairment; the type, severity, and distribution of lesions; and the time since onset. Other more subtle factors, such as the

interactions of pathologies, associated sensorimotor and cognitive impairments, and premorbid intellect and education, can affect the efficacy of a particular therapeutic approach, as well as the natural history of gains. Comparisons between interventions are often confounded by differences in intensity and duration of treatment, lack of specification of the methods of treatment, differences in personal interactions between therapist and patient, and the family's level of success in reinforcing desired behaviors.

## Overview of Therapy

In addition to cognitive strengths and weaknesses, behaviors of everyday life must be assessed in a cognitive rehabilitation program for a geriatric patient. The assessment should reveal functional capabilities, along with barriers to normal functioning at home and in the community. Functional goals are then set by the team of therapists and physicians with the patient and his or her significant others. Goals must be reasonable for the level of impairment and disability of the individual patient at the time of the evaluation. For a therapeutic approach to be effective outside the hospital or clinic, interventions for neuropsychiatric problems need to be provided under conditions similar to those of the patient's normal environment. Trips to a grocery store, a movie theater, or even the hospital cafeteria provide a chance for the patient and therapist to test the patient's balance, walking ability, selective attention, ability to plan, social communication skills, judgment, and compensatory skills. Goals must be set within the constraints of the amount of therapy available, the safest living arrangement for the patient, the patient's financial state, and the availability of community supportive resources. For example, if a patient with an elderly spouse is able to walk, eat, toilet, and dress with supervision by the end of inpatient rehabilitation for a stroke but acts impulsively and becomes confused or delusional at night, a discharge to the home is suitable only if the patient has a caregiver other than the spouse, who cannot be expected to manage the patient.

General approaches to management include training in particular functional adaptive skills, behavioral modification, and remediation of specific cognitive processes. In the *adaptive approach*, therapy is used in an attempt to circumvent the effects of cognitive impairments on targeted daily activities. Repetition, internally generated and externally generated cues, and cognitive assistive devices are used in training. Learning to perform a particular task usually does not mean that learning to perform other tasks not closely related will follow. *Behavioral modification techniques* are most often used in acute and transitional living settings for patients with TBI. Rewards are given for accomplishing a task or for reducing antisocial actions. In the *cognitive remediation approach*, impairments identified by neuropsychological testing are managed individually through addressing some of the components that make up a particular cognitive skill. The emphasis of the techniques is on interventions that cause the patient to use intact cognitive skills to help compensate for more impaired ones. Techniques usually merge as the team experiments with interventions that address the most difficult problems. Outpatients with TBI are the most likely group to require multimodal pro-

grams that stress training in task-specific skills by remediating techniques, awareness about impairments and limitations, and skills needed for independent living and work (Ben-Yishay and Diller 1993).

Aphasia, memory disturbances, and hemi-inattention can cause great disability in older patients. Discussion of these cognitive problems and rehabilitative approaches to them follow.

## Aphasia

**Incidence.** The reported incidence of language disorders in patients with stroke or TBI has varied across studies. In a British health district of 250,000 people, the number of new cases of aphasia in patients with stroke was on average 202 per year (David and Enderby 1990). By 1 month poststroke, 165 of the survivors were potential candidates for speech therapy. In a prospective, community-based Danish study of acute stroke, Pedersen et al. (1995) found that 38% of 881 patients were aphasic on admission, and aphasia was rated as severe on the Scandinavian Stroke Scale in 20% of patients admitted. Nearly one-half of the patients with severe aphasia died shortly after stroke onset, and one-half of the patients with mild aphasia recovered by 1 week. Only 18% of survivors were still aphasic at the time of their acute care and rehabilitation hospital discharge. Patients received speech therapy as needed and were retested at 2-week intervals for 6 months. In 95% of patients with mild aphasia, the highest level of recovery was reached at 2 weeks, whereas best gains were achieved at 6 weeks in those with moderate aphasia and within 10 weeks in those with severe aphasia. Only 8% of patients with severe aphasia fully recovered by 6 months. The best predictor of recovery was a lesser severity of aphasia close to the time of the stroke.

**Treatment.** Twenty percent to 50% of patients with aphasia have some features of the traditional aphasia subtypes (e.g., nonfluent or Broca's aphasia, fluent or Wernicke's aphasia) (Willmes and Poeck 1993). The traditional classification systems with their lists of broadly defined features often do not take sufficiently into account the underlying disturbances of language, so they may not be optimal for directing rehabilitation treatment. The goal of neurolinguistic assessment of aphasia is to specify problems occurring in the units of language, such as simple words, sentences, and discourse. For each unit, the therapist ascertains how the disturbance affects linguistic forms, such as phonemes, syntax, and meaning.

Speech therapists most often attempt to find ways to help patients compensate for defective language function.

These therapists use a wide variety of stimulation-facilitation techniques, including visual and verbal cueing during picture-matching and sentence-completion tasks, along with frequent repetition and positive reinforcement as the patient approaches the desired responses. Initial treatments also involve tasks that relate to self-care, the immediate environment, and emotionally positive experiences. To prevent patient withdrawal and isolation, it is especially important to quickly find a way to obtain reliable verbal or gestural yes-no responses. Behavioral techniques can be used, particularly for patients with TBI, to help patients improve eye contact skills, initiate and stay on a topic, learn to take turns during conversation, adapt to a listener's needs, and use speech to warn, assert, request, acknowledge, or comment.

In addition to the stimulation-facilitation approach to therapy, a variety of more or less well-defined theoretical models for therapy have been proposed. Therapy techniques have been designed for specific aphasia syndromes and neurolinguistic impairments (Helm-Estabrooks and Albert 1991; LaPointe 1990). Examples of a few of the specific approaches for particular problems follow.

The evidence for the efficacy of melodic intonation therapy (MIT) is especially strong ("Assessment" 1994). In MIT, the therapist and the patient melodically intone multisyllabic words and commonly used short phrases while the therapist taps the patient's left hand to mark each syllable. Gradually, the therapist stops intoning and tapping. MIT works best in patients with Broca's aphasia who have sparse or stereotyped nonsense speech and good auditory comprehension.

Patients in whom a single sound, word, or phrase overwhelms any other attempted output can benefit from a program for Voluntary Control of Involuntary Utterances. In this type of program, pauses and other self-monitoring techniques are used to help the patient gain control over perseverative intrusions.

The agrammatism of Broca's aphasia has been treated using the Helm Elicited Language Program for Syntax Stimulation, in which the goal is for the patient to build increasingly more difficult syntactic constructions. The therapist uses a standard series of drawings of common activities and provides a brief verbal description that ends with a question. The question contains a target phrase. The patient tries to use and build on the words of the target phrase in question. As the patient's responses with target words improve, the patient is asked to complete a story about the drawings without having heard the target sentence.

Some patients with minimal or stereotyped output and impaired comprehension have improved with multi-

ple-input phoneme therapy (Stevens 1989). In this 22-step program, the therapist analyzes phonemes produced spontaneously by the patient and then attempts to elicit first a target phoneme, then blends of consonants, then multisyllabic words, and eventually simple sentences. In another approach, some mute or nonfluent aphasic patients can acquire a limited but useful repertoire of gestures using, for example, American Indian sign language.

Comprehension in patients with global or Wernicke's aphasia has been managed using the sentence-level auditory comprehension program, in which patients are trained to discriminate consonant-vowel-consonant words that are the same or that differ by only one phoneme (e.g., *bill*, *pill*, and *fill*). Patients then try to associate word sounds with the written form of the word and later try to identify the target word embedded in a sentence. In patients with global aphasia, visual action therapy (in which patients learn to communicate through pantomime) has decreased limb apraxia and improved auditory comprehension. In another technique, the emphasis is on conveying of ideas in face-to-face interactions, rather than on linguistic accuracy. The aim of this technique is to develop any modality that can be used to transmit a message, including hand and facial gestures and drawing.

Acquired dyslexia evolves into one of several varieties that permit specific treatment approaches. In one subject who had phonological dyslexia and read only common whole words, training to go from spelling to sounding out words that were read was associated with a change in brain activation on functional MRI from the left angular gyrus to the left lingual gyrus (Small et al. 1998). Computer software has been designed to aid patients with specific language impairments. For example, the computer provided voiced and printed words along with concept images and storyboards, and improved expressive communication (Steele et al. 1992). Performance of visual-matching and reading comprehension tasks on the computer improved performance of several language tasks not involving a computer (R.C. Katz and Wertz 1997).

Aphasia therapy always includes family training so that those closest to the patient can provide the stimulation and structured environment needed for maximal communication. Frustration and depression in the patient can be managed with behavioral techniques and antidepressant medication (see Chapter 13).

Aging, as well as Alzheimer's and Parkinson's diseases, is often accompanied by impairment in word finding, especially in the finding of proper names. Some of the interventions just described may help, but rehearsal of a person's name before an anticipated meeting or, on making a new acquaintance, repeating the person's name a few times to

oneself and linking it to some related image seems to work best. In some instances, a person with high-frequency sensorineural hearing loss who begins wearing hearing aids may realize that he or she may not have clearly heard names of others introduced in the past, which interfered with recall.

**Outcome.** The wide range of cognitive and linguistic and nonlinguistic communication strengths and weaknesses of people with aphasia has made trials of interventions difficult to perform and the results difficult to interpret. Robey (1998) performed a meta-analysis of 55 trials that met reasonable criteria for inclusion in this analysis of studies of outcomes of speech therapy in patients with aphasia after a stroke. Differences between treated and untreated patients were significant at all stages of recovery. Better outcomes were obtained when therapy was started in the acute stage. Treatments in excess of 2 hours per week produced greater gains than did lesser amounts of therapy. Patients with severe aphasia made large gains when treated by a speech-language pathologist. A language stimulation-facilitation technique was tested in enough cases for the analysis to show its greater-than-average effect. There were not enough studies to permit comparison of effects of treatments across different types of aphasia. Family members, under the direction of a therapist, have been shown to be able to help patients progress.

## Memory Disturbances

Memory disturbances can have a profoundly negative influence on compensation and new learning in patients undergoing neurorehabilitation.

**Incidence.** The incidence of and risk factors for memory loss and dementia caused by one or more strokes have become increasingly appreciated (Desmond et al. 1996; Gorelick 1997; Henon et al. 1997; Kokmen et al. 1996; Moroney et al. 1996; Pohjasvaara et al. 1997; Tatemichi et al. 1992) (also see Chapter 23). The incidence of dementia in population- and community-based studies ranges from nine times greater in the first year after a stroke and two times greater each subsequent year, compared with the expected incidence of dementia in an age-controlled group; to an incidence of about 20% at 3 months after a stroke; to an incidence of 30% among all stroke survivors in a population survey. The frequency of dementia increases with increasing age and varies with the definition used to designate dementia. Even mild aphasia may affect verbal memory and can interfere with verbal learning during rehabilitation (Ween et al. 1996).

Memory impairments after TBI have been related to

the time from injury to assessment as well as to the nature of the memory task and the severity of the injury. A group of 102 patients with TBI, ages 10–60 years, who were hospitalized after any period of unconsciousness or after posttraumatic amnesia of more than 1 hour or with evidence of cerebral trauma were examined at 1 and 12 months postinjury (Dikmen et al. 1987). At 1 month, these patients scored significantly lower on the Wechsler Memory Scale and the Selective Reminding Test than did an age-matched control group. Those who could not follow a command for the longest duration of time beyond 24 hours postinjury scored lower on more subtests of the Wechsler Memory Scale, compared with control subjects. Tests of orientation and short-term memory were not as sensitive to memory deficits as tests that required storage of new information for later use. At 1 year, patients performed better than they had 1 month after onset.

**Treatment.** Most rehabilitative techniques to improve attention, encoding of new information, recognition, and retrieval have been developed for people with TBI. However, the techniques are applicable to most geriatric patients with neuropsychiatric disturbances. Memory interventions include methods to improve learning ability and assist compensation through the use of memory aids. Rehabilitation of some people with memory impairment may require a different approach than usual. For example, block practice with mass repetition of a drill improves performance during the acquisition of a task or new information in people with normal memory. However, long-term retention is less compared with when random schedules of practice are used. With contextual interference, in which repetition is spaced out or several tasks are intermingled during practice, performance may be worse in the short term. Retention, however, and even generalization of performance under different conditions will be greater (Schmidt 1988). Frequency of feedback on performance must also be addressed during training. In normal subjects, constant feedback may improve immediate performance, but an intermittent schedule may improve long-term retention. Much less is known about the optimal way to enhance learning in a patient with an aged brain and with a focal or diffuse brain injury or degenerative disease. Severely amnesic subjects learn poorly with trial-and-error training. More frequent feedback that prevented errors was shown to improve retention (Wilson et al. 1994). On the other hand, a study of people with hemiparesis from a chronic stroke revealed that sensorimotor damage to the brain affects the control and execution of motor skills but not the ability to learn those skills (Winstein 1999).

Because there are differences in how implicit and ex-

PLICIT memories are retained, a variety of approaches to retraining can be used. In priming, amnesic patients are exposed to verbal and especially nonverbal information, and then the patients are aided, through cues and prompts, in recalling that information. Priming does not require semantic processing for encoding. Priming is rather specific to the particular properties of the input and relies on perceptual representations stored by modality-specific memory subsystems, such as those that process word forms and visual objects. Tests of recognition memory are especially sensitive means of detecting residual memory in patients with severe amnesia. This implicit memory can even support the rapid acquisition of novel verbal and nonverbal material. The implicit memory system is independent of the hippocampal and diencephalic structures that are affected in amnesia (Musen and Squire 1992). Priming seems particularly useful during rehabilitation to enhance procedural memory for the acquisition of motor skills.

In cognitive remediation of amnesic disorders, patients are trained in the use of the subcomponent processes that underlie declarative and nondeclarative memory. Therapists can then take a restorative or compensatory approach to affect particular memory skills for functionally important activities. For example, Sohlberg and Mateer (1989) suggested addressing—in order—attentional impairments that could interfere with memory training, through use of strategies to improve focused, sustained, selective, alternating, and then divided attention. Impairments in encoding and recall of information are then addressed by employing associative and external cues meant to prompt an action, with increasingly longer intervals being used.

Many patients with moderate to severe TBI underestimate their memory and emotional impairments, even as they acknowledge physical and other cognitive problems. They may deny having the impairment and withdraw or become angry when attempts at rehabilitation are made. The rehabilitation team must provide the counseling and insight required to overcome this problem. Patients with minor TBI often complain about difficulty in sustained and alternating attention. They struggle to keep information and tasks in mind when forced to deal with more than one item at a time, and they quickly become fatigued when working on a modestly demanding task. The same sort of attentional and executive dysfunction may arise during aging and with neurodegenerative diseases. The most practical rehabilitative interventions for memory, attentional, and executive dysfunction include the patient's limiting subjects to one task at a time, blocking out telephone calls and other interruptions, and writing down the order in which things need to be done.

In patients with moderate to severe TBI, even repeti-

tive drills can have little impact on general recall or on memory outside the training session. Patients can be helped with external aids such as a calendar and appointment diary and internal strategies such as rehearsal and visual imagery. Some memory devices are listed in Table 39–5. Electronic pagers that carry messages (Wilson et al. 1997) or electronic calendars with alarms are especially useful for reminding people to perform daily tasks.

Computers, which might one day serve as neural prostheses, have been tried out extensively in cognitive remediation and skills training. Although software programs abound for working on reaction times, aspects of attention, language, problem solving, and other cognitive tasks, the efficacy of this approach has not been clearly demonstrated. Some amnesic patients have been able to be trained in tasks such as data entry, database management,

and word processing because of preserved cognitive abilities, including the ability to respond to partial cues and acquire procedural information (Glisky 1992). This knowledge often will not be carried over when even modest changes are made in the tasks. Through reliance on procedural memory, verbal and visual mnemonic strategies have been used to teach subjects a computer graphics program (Prevey et al. 1991). Cooking and vocational tasks were taught using an interactive software program that cued each subtask in order to build up to the desired task (Kirsch et al. 1992).

Studies involving single subjects and small groups have suggested that some medications may benefit patients with impairments in attention and memory. TBI may lead to damage in a particular neurotransmitter system, such as cholinergic neurons (Schmidt and Grady 1995). Presynaptic cholinergic neurotransmitter concentrations were abnormal in a human postmortem study of TBI (Dewar and Graham 1996). Thus, cognitive rehabilitation trials of cholinergic-enhancing drugs such as donepezil and citicoline (Spiers et al. 1996) seem warranted. Neurotrophic factors have been shown in animal models of trauma to protect cholinergic septal neurons from apoptosis and to improve cognition (Sinson et al. 1997). Replacement therapies for other neurotransmitters, such as dopaminergic (Dobkin and Hanlon 1992; McDowell et al. 1998) and noradrenergic agents (Mattay et al. 1996), have a few human studies to commend them (Plenger et al. 1996; Powell et al. 1996). For example, bromocriptine improved performances on prefrontal tests, such as tests involving carrying out dual tasks, in patients with TBI who had impaired capacities in working memory (McDowell et al. 1998). The ampakines, a new class of drugs that enhance AMPA receptor-mediated currents, show some promise in improving encoding aspects of memory in people with normal memory and may be tried in those who need cognitive rehabilitation (Ingvar et al. 1997).

**Outcome.** Memory-related processes tend to improve in the first 3 months after a stroke, but the rehabilitation team must be on the watch for any need of compensatory aids or other strategies for patients with memory deficits. After a mild TBI, memory usually recovers by 3 months. The rate and degree of improvement noted varies with the test used to measure severity, the time from injury to testing, and the comparison group (Dikmen et al. 1986). One year after severe closed head injury, patients whose case data were entered in the Traumatic Coma Data Bank had greater impairments in verbal and visual memory, as well as other neurobehaviors such as naming items shown and copying constructions with blocks, compared with healthy

individuals (Levin et al. 1990a). Selective rather than global cognitive impairments were likely at 1 year. Memory was disproportionately impaired compared with overall intellectual functioning in 15% of the moderately injured and 30% of the severely injured patients. Subjects in these studies did undergo rehabilitation, but no specific program was provided to all patients.

## Hemi-Inattention

Hemiattentional disorders can arise from injury within any node in the cortical-limbic-reticular network that directs attention and integrates the localization and identification of a stimulus, as well its importance to the person (Watson et al. 1994). Unilateral neglect arises from injuries to the posterior parietal cortex, the prefrontal cortex that encompasses the frontal eye fields, and the cingulate gyrus; these regions include representations for sensation, for motor activities such as visual scanning and limb exploration, and for motivational relevance, respectively. Subcortical areas such as the thalamus, striatum, and superior colliculus coordinate the distribution of attention. Atrophy of frontal white matter and the diencephalon contributes to persistent anosognosia (Starkstein et al. 1992). The anterior and posterior extensions of a lesion could also produce impairments in attentional and intentional processes that contribute to neglect (D'Esposito et al. 1993).

**Incidence.** In a community-based study involving 281 patients who had had a first acute stroke 3 weeks earlier and who had left or right cerebral lesions, visual neglect was de-

tected in 10% by having subjects copy a Greek Cross and complete the Raven's Colored Progressive Matrices (Sunderland et al. 1987). Only about one-half had hemianopsia or visual extinction. The neglect was modestly associated with poorer ADL scores and slower recovery. Severe neglect was rare beyond 6 months. In another study (Stone et al. 1992), visual neglect, documented by a battery of seven tests by 3 days after a stroke, was greater in right than in left hemisphere cases. In this study and others, however, right-sided inattention was detected in 15%–40% of nonaphasic patients with acute left cerebral infarcts.

**Treatment.** The initial choice of intervention depends on the proposed mechanism of unilateral neglect or hemispatial inattention to which the team ascribes (Halligan and Marshall 1994). For example, the patient can be treated for an underaroused injured hemisphere that has difficulty processing sensory inputs. A powerful bias of the intact hemisphere for attention to contralateral space could necessitate finding a way to lessen the imbalance. Some patients have difficulty disengaging from sensory inputs. Other strategies might have to be developed if the mental representation of contralesional space has been degraded or if a unilateral impairment in the activation of motor programs delays or prevents the intention to move to the contralesional side. If the initial theory-based intervention is not successful, others should be tried. Some of the ways that clinicians have tried to manage hemi-inattention are listed in Table 39–6. These approaches have not produced robust or consistent results.

**TABLE 39–6. Interventions for hemi-inattention**

Intervention	Study
Multisensory visual and sensory cues, then fading cues	Ben-Yishay and Diller 1993
Verbal elaboration of visual analysis	Hanlon and Dobkin 1992
Visual imagery	Smania et al. 1997
Environmental adaptations	Loverro and Reding 1988
Video feedback	Tham and Tegner 1997
Monocular and binocular patches and prisms	Butter and Kirsch 1992; Dobkin 1996a; Rossi et al. 1990; Serfaty et al. 1995
Warning sound at time of left visual event	Robertson et al. 1999
Left limb movement in left hemisphere	Robertson and North 1992
Head and trunk midline adjustments	Karnath et al. 1991; Mennemeier et al. 1994; Simon et al. 1995; Taylor et al. 1994; Wiart et al. 1997
Vestibular stimulation	Rode et al. 1992; Rubens 1985; Vallar et al. 1990
Reduction of hemianoptic defects	Kerkhoff et al. 1994
Pharmacotherapy	Fleet et al. 1987
Computer training	Gray et al. 1992; Robertson et al. 1990

**Outcome.** In most patients, hemiattentional disorders improve or resolve without specific interventions. Persistence of spatial hemineglect can increase disability. Of 150 consecutive patients with moderate disability after a new stroke, 32% had visual neglect (Kalra et al. 1997). The neglect was modestly associated with poorer ADL scores and slower recovery, though severe neglect was rare beyond 6 months. In another study, only 14 of 84 patients with initial neglect had Barthel Index scores indicating moderate or severe dependence in ADLs in follow-up (Stone et al. 1993). Using data from the National Institute of Neurological Disorders and Stroke (NINDS) Stroke Data Bank, Marshall et al. (1994) examined the effect of hemineglect on the ADL scores at 7–10 days and 1 year after onset of a first stroke. Patients who had anosognosia, visual neglect, tactile extinction, motor impersistence, or auditory neglect had the lowest Barthel Index scores at 1 year, even after adjustment for initial ADL scores and for poststroke rehabilitation.

Recovery from neglect has been reported to be most rapid within the first 2 weeks, regardless of the side of the stroke, and to plateau at 3 months, when most patients have little visual neglect. Severe visual neglect and anosognosia in the first week tend to predict some level of persistent impairment at 6 months. Many patients have more subtle and lingering impairments that are detected only with more sensitive measures. For example, a group of patients with right hemisphere stroke showed a strong, consistent rightward attentional bias soon after stroke onset, as well as an inability to reorient their attention leftward (Mattingley et al. 1994). Twelve months after onset, the attentional bias continued, but they could fully reorient to left hemispace when performing line bisection and cancellation pencil-and-paper tasks.

## ■ Behavioral Disorders

Neurobehavioral and affective disorders can be a primary focus of rehabilitation efforts after stroke and TBI and can confound reintegration of a patient into the home or community.

### Personality Disorders

Alterations in personality have been reported in up to 75% of patients from 1 to 15 years after TBI and tend not to improve beyond 2 years after onset (Van Zomeran and Saan 1990). In one study (Brooke et al. 1992a), agitated motor and verbal behaviors—which are difficult to define and treat (Fugate et al. 1997)—were found in 11% of patients

with TBI during inpatient rehabilitation, and restlessness was present in 35% of patients. Agitation is an emotional state that may include generalized or more focused fear and anxiety, uncertainty, repetitive behaviors, restlessness, and explosiveness. Agitated patients are not always aggressive. Aggression is common in patients after serious TBI and can be verbal or physical against self, objects, or other people (see Chapter 22). As cognition improves, agitation decreases, but directed and nondirected aggressive, impulsive behavior may evolve. Persistent aggression and emotional dyscontrol suggest premorbid mood and behavioral disorders (Fugate et al. 1997).

Interventions include a medical assessment to determine whether exacerbating problems such as pain and drug-induced confusion exist, behavioral modification with positive and consistently applied reinforcements, a structured milieu, individual and group psychotherapy, and pharmacotherapy. Hypoarousal sometimes improves with administration of stimulants such as methylphenidate and amphetamine or treatment with dopamine agonists. Aggressive or agitated behavior is sometimes decreased by blocking dopaminergic and noradrenergic receptors with haloperidol or risperidone, each of which has a rapid action. Buspirone can be useful for treating aggressive or agitated behavior but may take a week or more to reach a therapeutic level.  $\beta$ -Blockers can also decrease irritability. In a randomized trial of propranolol with a dose escalation to 420 mg/day, there was a reduction in intensity of agitation, but not frequency of episodes, compared with placebo in patients with TBI (Brooke et al. 1992b). Hypomanic behavior may respond to lithium therapy. Anticonvulsants such as carbamazepine sometimes prevent outbursts related to episodic dyscontrol.

## Affective Disorders

Depression is very common after stroke (see Chapter 27). In the community-based Framingham Study, depression was diagnosed in 47% of 6-month survivors of stroke and in 25% of age- and sex-matched controls (Wolf et al. 1990). In a population-based cohort of Swedish stroke patients whose mean age was 73 years, the prevalence of major depression was 25% at the time of hospital discharge, 30% at 3 months poststroke, 16% at 1 year, 19% at 2 years, and 29% at 3 years poststroke (Astrom et al. 1993). In this and many other studies, a left anterior infarct, dysphasia, and living alone contributed to depression at time of discharge. At 3 months, greater dependence in ADLs and relative social isolation were associated with depression. Also contributory were few social contacts at 1 and 2 years.

Anxiety is another stroke-related affective disorder

(see Chapters 15 and 27). A generalized anxiety disorder was present in 28% of patients with recent stroke and was associated with greater social isolation and greater dependence in ADLs (Astrom 1996). Apathy was found in about one-quarter of patients within 10 days of a stroke. It was associated with greater cognitive impairment, poorer ADL scores, and some major, but not minor, depression (Starkstein et al. 1993).

Depression is diagnosed in 25%–60% of patients with TBI (see Chapter 28) (Gualtieri and Cox 1991). Late-onset depression has been associated with premorbid psychiatric history and lower psychosocial function (Jorge et al. 1993).

Clinicians should manage mood disorders aggressively, especially when progress in rehabilitation falls short of expectations. Patients with depression may respond to any class of antidepressant medications and require the same care in dosing that is usually taken with any elderly person (Lebowitz et al. 1997). The same medications can help alleviate pseudobulbar emotional incontinence with its involuntary weeping, grimacing, and laughing. Patients must be closely monitored for adverse reactions to the antidepressants, including sedation; insomnia; anticholinergic effects on the bowel, the bladder, and salivation; orthostatic hypotension; cardiac arrhythmias; anxiety; extrapyramidal symptoms; and serotonin syndrome (see Chapter 34).

Treatment of depression after stroke can be quite effective. In natural history studies, 60% of patients who were depressed at less than 3 months after stroke onset were recovered at 1-year follow-up (Astrom et al. 1993). About 20% of patients were found to have a persisting generalized anxiety disorder 3 years after a stroke (Astrom 1996).

## ■ Conclusions

A rehabilitation team with experience in the management of physical, behavioral, and cognitive impairments and disabilities can lessen the handicaps and social isolation experienced by some aging patients, especially those with acute or chronic neuropsychiatric disease. Programs of physical exercise and problem solving that promote more independent ADLs and community activities can also lead to a better quality of life.

# Ethical Issues

Peter J. Whitehouse, M.D., Ph.D.

A variety of ethical issues confront geriatric neuropsychiatrists and other health care professionals caring for elderly persons with illnesses that may affect decision-making abilities. Dealing with conflicts of human values and with different views of what it means to be a healthy human being is an important part of the care. Yet it is this art, which is not well understood or well taught, that differentiates the physician from the technologist. Practicing this art in geriatric neuropsychiatry raises special issues of relevance to healer, patient, and society.

The practice of geriatric neuropsychiatry is challenging from an ethical point of view for several specific reasons. First, much of ethics, particularly in the Western world, is based on engaging a rational autonomous self (Engelhardt 1996; Whitehouse and Deal 1995). Neuropsychiatric diseases threaten the rationality and autonomy of our patients. Second, the later stages of life are associated with specific concerns about quality of life and, eventually,

quality of death (Whitehouse and Rabins 1992).

Moral and ethical issues will become more prevalent in the future practice of geriatric neuropsychiatry. One reason stems from the fact that there will be a greater number of older individuals, not only in the Western world but also in countries that are currently less industrialized (see Chapter 2). Thus, the ethical problems surrounding the care of older patients with neurological and psychiatric disease will increase. A second reason that moral and ethical issues will become more prevalent is that the revolution in molecular medicine, particularly genetics, will continue to lead to new technologies, with attendant moral issues (see Chapter 38). Third, revolutions in health care system economics, which are occurring, in part, in response to the graying of our population, will themselves generate new value conflicts for physicians and other providers.

The history of ethics extends back centuries—certainly most notably, in Western traditions, to the Greek philosophers. It is beyond the scope of this chapter to

---

review the world's literature on how human beings have explored their differences concerning fundamental issues about life. However, it is critical—particularly as our clinical practices include patients from more and more ethnic groups—that we respect the vastly different cultural beliefs concerning self, family, community, society, and spirit. At the same time, we need to recognize the universal issues relevant to human beings with neuropsychiatric diseases.

The field of bioethics itself is new; the word *bioethics* was not coined until 1970 (Brody 1992; Chambers 1998; Fox 1990; Potter 1971, 1988; Reich 1995). A consideration of this modern time may be most helpful to the geriatric neuropsychiatrist to understand the current methods of biomedical ethicists. But we must not forget, as physicians and scientists frequently do, that these considerations occur in rich historical and cultural contexts.

Bioethicists are becoming more unified and the field is becoming more professionalized, as illustrated by the merging of several organizations to form the new American Society for Bioethics and Humanities. The field will continue to evolve as members of this organization and others consider the rules for specialization in clinical bioethics consultation and the content of new doctoral programs in bioethics. Defining the knowledge base of this inherently interdisciplinary field is challenging. Tensions exist between those who approach ethics through philosophy and those who approach it through practical clinical issues. There is much discussion within the field about the future of bioethics, the emergence of bioethics as a professional field, and the contribution of bioethics to society (Carter 1998; Pellegrino 1993). Issues associated with geriatrics and neuropsychiatry will play important roles in this evolution of bioethics.

In this chapter, I first discuss the concept of bioethics and consider its methods, particularly in relationship to ethics consultations. I then review issues that arise in the clinical practice of geriatric neuropsychiatry and issues that arise in research. Finally, I discuss issues that will likely be more prominent in geriatric neuropsychiatry and in biomedical ethics in years to come. One theme in this chapter will be constant: an understanding of ethical issues requires a knowledge of the science and practice of medicine, plus a view of the broader social context combined with a passion for human beings as individuals and humanity as a whole.

Some of the ethical problems that I discuss in this chapter are general ones faced by all health care providers. More attention is paid in this chapter to those issues specific to the practice of geriatric neuropsychiatry. It is, of course, the patient populations (and, to a certain extent, the types of research) that define the ethical problems that need to be considered. I consider that the practice of geriatric

neuropsychiatry is focused on three broad groups of patients: those patients with mental retardation, those with newly acquired cognitive impairments such as dementia, and those with mental illness. Each of these groups brings special issues to the table for ethical deliberation. Patients with mental retardation have never had entirely normal intellects and may never have been able to understand fully or even appreciate that there are ethical issues involved in their participation in research or their receiving of clinical care. Patients with an acquired dementia may have had the opportunity to write advance directives or at least to converse with others about their health care. Patients with mental illness, such as schizophrenia or depression, often have fluctuating decision-making ability. Combinations of mental retardation, dementia, mental illness, and other conditions such as delirium can occur in individual patients. In the case of all three groups of patients, the caregivers—either substitute decision makers by legal definition or close family members with intimate knowledge of the patient and his or her values—play important roles in the resolving of ethical dilemmas.

## ■ Methods in Ethics

As mentioned earlier, an ethical issue involves conflict of human values or differences of opinion about what constitutes good or poor quality of life. An ethicist assists others, be they professionals or patients, in exploring and resolving such conflicts. What are the methods by which an ethicist would accomplish this aim?

The dominant mode of ethical practice for those exposed to contemporary bioethics is based on understanding and application of three principles: autonomy, beneficence, and justice (Beauchamp and Childress 1989). Each ethical situation is analyzed in terms of these three ideas. *Autonomy* refers to the preservation of the right of the individual to make decisions about his or her life course. *Beneficence* relates to the responsibilities of human beings to each other, particularly the principle of nonmaleficence (i.e., doing no harm to others). Finally, *justice* involves extending the scope of ethical analysis to include society, with questions asked about the fairness of health care decisions in terms of their impact not only on the patient and the patient's immediate family but on society at large.

In geriatric neuropsychiatry, these principles can be applied in various ways. In clinical practice and research, we wish to respect the rights of individuals to make their own choices as much as possible. However, in the case of an individual who is decisionally impaired, we need to consider how to provide health care that reflects the values of

the patient as expressed through a substitute decision maker or that reflects consideration of the best interests of the patient. In research, the principal issue is how to balance potential risk and benefit to the individual and to society. As the number of elderly individuals with neuropsychiatric conditions increases, the issues of distributive justice (e.g., in discussions of health care rationing) will become more important. The question of how much health care should be provided to individuals with severe dementia, for example, might be considered with the concept of distributive justice in mind.

Although ethical analysis based on these three principles has been helpful, there are other ways of approaching ethical issues. Another important approach is *discourse* or *communicative ethics* (Post et al. 1994). In contrast to principle-based ethics—in which the focus is generally on abstract principles and in which the ethicist may assume a philosopher role rather than a more clinical role—discourse ethics takes its cue from the practical, real-world struggle that individuals face in the care of someone with a neuropsychiatric condition. The focus here is on the quality of communication between the parties involved in the ethical dispute. Ethics consultation frequently involves considerable effort to clarify the positions of the different parties involved in a dispute and to facilitate more effective communication among these parties.

Two other methods in ethics that are relevant to physicians are *casuistry* and *narrative ethics* (Jonsen and Toulmin 1988; Nussbaum 1992). In both these forms of ethical deliberation, the focus is on the life stories of the individuals and groups dealing with value issues. The importance of how a story is told is made clear with these approaches. Much of medicine involves a stylized presentation of people's life histories. What is selected and what is ignored are critical in the definition and resolution of ethical problems. In both casuistry and narrative ethics, the true richness of an individual life is stressed. The value conflicts involved in a particular life situation are exceedingly complex. Any ethics consultation should be undertaken with humility and respect for this complexity.

There is a dynamic tension between ethics and law (see Chapter 41). Practitioners, and especially ethicists, must be aware of the laws of the various jurisdictions in which they practice. Ethical issues are broader in scope and may not be addressed by specific laws. However, it is often difficult to do what is perceived to be right if it is different from what is legal. Every health care organization has a set of ethical guidelines concerning certain common clinical dilemmas such as “Do not resuscitate” orders, medical futility, and physician impairment. Professional organizations frequently develop ethical guidelines for their members as well.

## ■ Clinical Ethics

### Diagnostic Disclosure

In geriatric neuropsychiatry, labeling an individual as a patient has ethical implications. Labeling an individual as having a disease, such as schizophrenia, can profoundly affect the behavior of other individuals toward this person. What information should be provided to the patient and his or her family concerning the diagnosis and prognosis is often not clear. This is particularly true in the case of a condition such as Alzheimer's disease, with its grave prognosis. Most physicians, at least in this country, support the principle of autonomy and believe individuals should be informed of their diagnosis, but how much information should be provided is often less clear. The clinician should attempt to understand the patient and his or her family's prior understanding of the disease and share new information on the basis of this understanding. The clinician must also remember that what one tells people (or thinks one tells) is often different from what is heard.

### Selection of Therapeutic Agents

Geriatric neuropsychiatrists are able to suggest a variety of interventions to patients with neurological and mental disease. Many of these interventions are nonpharmacological, namely individual and group psychosocial therapies (see Chapter 36). In many cases, the efficacy of these interventions is not well understood. Selection of therapy is often based on training biases or personal experiences as much as on scientific findings.

The selection of medication is a similarly complex process, in which trade-offs between different benefits and side effects are made. Particularly in neuropsychiatry, with the strong influence of pharmaceutical companies, physicians must attempt to ensure that the decision to use particular medications is based on the best scientific evidence.

Physician involvement in the business of medicine also raises ethical issues. Geriatric neuropsychiatrists who have a financial interest in health care may have a conflict of interest. Use of equipment or admission of a patient to a particular facility should not be determined by the financial reward to the physician involved in the care of that patient. Establishing appropriate guidelines for pharmaceutical company involvement in the continuing education of physicians is a difficult task. Conflicts or confluences of interest are part of life and are issues of growing importance in clinical and research practice (Kodish et al. 1996).

## Managed Care

The business of medicine is rapidly changing. Physicians have experienced a significant loss of control over the individual care for their patients as care pathways, limited drug formularies, and other mechanisms have been introduced that limit physician choice in diagnosis and treatment. The most startling change in the health care system in the United States (similar forces are at work in all industrialized countries) has been the introduction of managed care. In a fee-for-service environment, the ethical dilemma facing physicians is that the more tests and interventions a patient undergoes, the more the patient's physician's income is likely to increase. Thus, incentives exist for ordering more tests and procedures rather than conserving diagnostic and therapeutic resources. In managed care, in which a certain dollar amount is provided to the health organization for a specified set of health care benefits, the incentives are reversed. It may be to the financial advantage of the physician, or at least the health care organization with which he or she is affiliated, if fewer tests and interventions are performed and fewer hospitalizations occur. The ethics of managed care is a growing part of biomedical ethics (Berenson 1998) and is evolving as some of the original excesses of managed care (e.g., the gag rule to prevent physicians from fully discussing treatment options with patients) are being eliminated. The balance of power among the forces at work—consumers, professionals, governments, and the private sector—will continue to shift, to reflect, it is to be hoped, wise social policies.

Driving health care reform in Western Europe, North America, and Japan is the fact that health care costs are becoming an increasing burden on the economy. The growing number of older individuals, combined with lower birth rates, creates dependency ratios with fewer workers in the economy supporting more retirees. As the introduction of expensive technology continues, the dilemma becomes that of providing care in face of escalating costs. Some form of health care rationing already occurs, as in the state of Oregon, and such rationing will likely become more common. Ideally, rationing should be based not only on the cost of the intervention but also on the intervention's efficacy. Even efficacy (i.e., data adequate for regulatory approval) is not enough, as effectiveness (i.e., contribution to a meaningful population impact) is becoming a central issue. Much of the practice of medicine is *not* based on results of well-controlled, randomized, double-blind trials. Medicine is becoming more outcome-research based and evidence based. However, randomized trials of all interventions that geriatric neuropsychiatrists wish to consider offering their patients cannot be performed as they would

be too expensive. Outcome research will be helpful, but improving society's processes for long-term decision making will be more critical. Thus, scientific and political processes for weighing evidence and making decisions about what interventions are effective and congruent with social values will continue to be exceedingly complex (Bulger et al. 1995).

Moreover, even when we have decided whether an intervention is valued appropriately in terms of cost, questions remain: Who shall pay? Who shall be eligible for these services? In the United States, we have been ambivalent about whether a basic minimal package of health care should be available to all, regardless of income, and if such a package were made available, what mental health care should be included.

These decision-making issues about allocation of resources indicate that, in the future, the organizational aspects of health care may be as much a concern in bioethics as bedside dilemmas. In general, ethicists—especially physician and other clinical ethicists—are used to focusing on value conflicts in individual cases. In the future, value conflicts within and among organizations may well become more important in the theories and practice of bioethics. The use and distribution of power among the major players in health care will be topics of particular interest (Brody 1992).

## End-of-Life Care

A particularly important subject of ethical discussion for geriatric health care providers is end-of-life care. Too often in American medicine, there has been a preoccupation with the goal of preventing death from illness (i.e., quantity rather than quality of life). Physicians have considered themselves failures when their patients died. However, people do die, and older people are at more risk for death. The fact that the hospice movement has grown is a good sign. Some people believe that hospice care is appropriate for those with conditions besides cancer, conditions including severe Alzheimer's disease (Post and Whitehouse 1998b; Whitehouse et al. 1996).

Major changes have also occurred in our country in attitudes toward physician-assisted suicide and euthanasia. Geriatric neuropsychiatrists may become involved in deciding whether specific treatments (or, for example, provision of food and fluids in the case of patients with severe dementia) should be considered at the end of life. As a rule, all of the current laws and regulations that relate to the issue of euthanasia or assisted suicide require a patient to be competent to participate in the procedure. In the future, we will have to ask whether advance directives concerning eutha-

nesia in later stages of severe neuropsychiatric disease are appropriate means for expressing values of patients. The Royal Dutch Medical Society is preparing a report on this topic as it relates to patients with dementia or other neuropsychiatric conditions. The concept of human dignity figures large in this analysis of physician involvement and social sanctions of assisted death in patients with dementia. Ethical exploration of the concept of dignity in health care will be essential in the future (Moody 1998).

### Advance Directives

The use of advance directives has been encouraged, for good reason, by a variety of patient and professional groups (see Chapter 41). It makes sense for individuals to express in writing their wishes concerning care in circumstances in which they may not be able to make their own decisions. The rules regarding how advance directives should be used, particularly in circumstances in which cognitive impairment is involved, vary from state to state. The advance directive can take the form of a *living will*, a document that lists conditions or events that may occur in the future and the patient's desired responses to those situations. Another form of advance directive is a *durable power of attorney*, by which a patient appoints an individual who would make decisions if the patient became incompetent. In my view, advance planning should incorporate both features. In the event that the patient becomes incompetent, the clinician can weigh the evidence from written documents concerning the patient's wishes and the wishes of the identified substitute decision maker. The surrogate decision maker can make the decision on the basis of how he or she believes the patient would have made the decision under the circumstances—a true substituted judgment. Another decision standard is *best interest*, which reflects the surrogate decision maker's views concerning what is judged optimal for the patient at the time of decision making. Both forms of reasoning are appropriate but should be made explicit because substitute decision makers may not entirely follow the wishes of the impaired individual.

Geriatric neuropsychiatrists will have to ensure that advance directives play an appropriate role in their provision of health care. Currently, only a relatively small number of individuals execute advance directives.

### Competency Assessment

Geriatric neuropsychiatrists may be called on to attest to the competency of patients (Appelbaum and Grisso 1995). The declaration of competency is made by a judge. Ideally, if the advance directives are used to identify surrogate deci-

sion makers, legal proceedings can be minimized. However, a durable power of attorney must be executed when the patient is competent to designate such decision maker. If the patient is already incompetent, the courts may need to appoint a guardian.

A variety of approaches have been suggested for making a recommendation to the courts about a patient's competency (see Chapter 41). Formal neuropsychological tests can be administered, as can mental status tests with a focus on judgment or problem-solving abilities. The clinician can discuss with the patient circumstances that are similar to the decision facing that individual and can evaluate the patient's ability to make judgments about these practical, real-world problems.

Levels of competency are definable. At the lowest level, the patient recognizes that there is a decision to be made. Competency at higher levels (defined legally in a hierarchical fashion) includes an understanding of the contexts and possible ramifications of decisions beyond the immediate situation.

Also during the assessment for competency, the clinician should assess who would be an appropriate surrogate decision maker, should one need to be appointed by the court. In situations in which the courts are involved, there are frequently conflicts among family members. Assessment of the family structure and process is as important as assessment of the individual patient.

## ■ Ethical Issues in Research

### Conflict of Interest

A variety of conflicts of interest can occur in research (Levine 1998). When a professional is both a clinician and a researcher, a conflict of interest exists. A clinician must consider currently available therapies for his or her patient first and participation by the patient in research second. Being involved in research gives the professional the incentive to recruit the individual into the protocol. This conflict of interest should be made explicit to potential subjects and the research team. If the conflict is of sufficient magnitude, an independent individual should be assigned the role of obtaining informed consent. Clinicians and researchers alike must recognize that patients and families often find these conceptual differences between the roles of patient and subject difficult to understand.

Financial conflicts of interest may also exist. Increasingly, scientists and clinicians have financial stakes in the performance of products being evaluated in research. These stakes are frequently bigger for basic biological sci-

entists, who may, for example, start biotechnology companies after making basic research discoveries. Clinicians may, for example, consult for or obtain grants from pharmaceutical companies whose products they are testing. Most authors agree that there are different levels of conflict of interest, the levels depending on the nature of the relationship and the amount of potential financial gain. Serving as a one-time speaker for a company is considerably different from being a major stockholder in that same company. Research institutions of various kinds are required by granting agencies such as the National Institutes of Health to have formal policies on this topic.

The procedure most widely used to address the problem of conflict of interest is disclosure. For example, a clinician reporting the results of a study would identify support from the pharmaceutical industry or elsewhere. Disclosure is now required to the appropriate administrative structure within the organization conducting research. The extent of the disclosure (i.e., to whom and in what detail) can vary, however, which is a problem. Writing down one's conflicts of interest on a piece of paper that is subsequently filed and viewed by only a small group of people would hardly meet a requirement for public disclosure.

A fine line will continue to exist between appropriate and inappropriate conflict of interest. If we are to facilitate academic, industry, and governmental collaboration, sharing of resources and expertise is required. Thus, at least a confluence of interest is necessary and desirable for advancement of science and treatment methods. On the other hand, a few absolute proscriptions should probably exist. For example, individuals who have major financial stakes that depend on the profitability of particular products should probably not be involved in testing them.

## Research Design

Although not always seen as an ethical issue, the quality of science proposed in a research project is of ethical concern (Kass et al. 1996; Levine 1988). A requirement of research design is that the experimental hypotheses actually be addressed by the study in an appropriate fashion. In other words, the study should actually produce answers to (or at least provide credible evidence relating to) important questions.

Certain specific aspects of the research design may also be ethically problematic. I will use as examples two issues in the field of Alzheimer's disease, with consequences on practice (see also Chapter 24).

One issue concerns the use of placebos. Donepezil, the second drug approved for use as a symptomatic cognitive enhancer in patients with Alzheimer's disease, is viewed by

some as the pharmacological standard. Tacrine, the first approved agent, had many side effects, and clinical and market interest in tacrine did not match the interest in donepezil. Given the efficacy of the standard drug (donepezil), should equivalence studies (or studies with similar designs) comparing other drugs with the standard drug be performed instead of placebo-controlled studies? This issue is complex and requires the defining of the clinical standard of practice, as well as a consideration of the scientific, and ultimately social, consequences of using designs that do not incorporate placebos (Karlavish and Whitehouse 1998).

Who should decide whether placebo use is appropriate in trials involving patients with schizophrenia or dementia is another facet of the issue of placebo use. Most ethical formulations have focused on the role of clinicians and professionals in such social judgments. For example, the concept of clinical equipoise asserts that there ought to be a condition of uncertainty about the state of knowledge in the minds of practitioners. Thus, a randomized controlled trial becomes essential for obtaining knowledge needed to advance practice (Karlavish and Whitehouse 1998). Community equipoise is an extension of clinical equipoise to involve more than just clinical. I believe that assessment of the state of the field and decisions concerning research designs such as placebo-controlled trials should incorporate the voices and values of patients and families as well as professionals.

For example, representatives from the Alzheimer's Association in Cleveland (Post and Whitehouse 1995), the Alzheimer's Society of Canada (Cohen et al. 1999), and Alzheimer's Disease International (Brodaty et al. 1999) considered topics such as therapeutic goals, the role of spirituality, and informed consent in research. A variety of approaches can be used to obtain grassroots input. Professional input should be combined with lay input to develop new ways of analyzing issues. Eventually, approaches involving computer networks may improve community discourse.

A second ethical issue that arises in therapeutic trials involving patients with Alzheimer's disease has to do with drug therapies that are presented as more than symptomatic treatments of cognition, that is, as treatments that actually slow progression of disease. Studies have suggested that treatment with estrogens, vitamin E, or anti-inflammatory agents may slow the deterioration (Sano et al. 1997; Whitehouse 1998). Vitamin E is increasingly used in clinical practice today with that therapeutic goal in mind. Consensus has not been achieved, however, regarding how one would design a study so that, after completion of the study, a regulatory claim could be made that treatment with the

study drug results not only in prolonged symptomatic improvement but also in alteration of the disease course (Whitehouse et al. 1998). One design involves withdrawal of a medication that has been demonstrated to be more effective in improving the patients' symptoms than placebo. The protocol to demonstrate a modifying effect on disease course thus involves withdrawing the medication and observing what happens to the patients once the medication is withdrawn. If the drug's effects are purely symptomatic, one would expect the conditions of the patients taking the drug to deteriorate to the same level as those of the patients who had been taking the placebo for the entire study. If treatment with the drug has a prolonged or sustained benefit, then the patients' conditions might deteriorate but would never fall to the level of those of the patients taking the placebo. Thus, the ethical issue in this design is that one must give a medicine, demonstrate that it is effective, and then withdraw it to try to differentiate a symptomatic from a sustained effect. Ultimately, a principal issue in research ethics is the balance between opportunity and risk for the individual and the benefits and dangers to society of certain research policies and procedures.

### **Informed Consent**

Clinical research is dependent on the obtaining of voluntary consent from informed patients. Federal guidelines exist for research involving prisoners and children. However, attempts to develop such regulations for those with mental illness, mental retardation, or cognitive impairment have failed because of the political tensions between the clinician-scientists and the patient groups. Scientists have been concerned that regulations would impede scientific progress, whereas the patient groups have been concerned that subjects would not have adequate protection. A variety of national and international groups are now examining the issue of informed consent in those who are cognitively impaired. I and my colleagues have worked with Alzheimer's Disease International and the World Health Organization to develop guidelines to educate ethics review committees globally (Brodsky et al. 1999). In ethical deliberations, the approval and monitoring of protocols should be close to the patient, family, and community (e.g., local ethics review committees) but should be guided by broader global, societal, and cultural input. Most important in the United States are the efforts of the National Bioethics Advisory Committee. The focus of these efforts is on genetics (e.g., cloning) and participation in research (e.g., informed consent and mental illness).

The issue of informed consent is complex because a variety of different regulatory bodies—from national groups

such as the Office for Protection and Research and the Federal Drug Administration to state law and local ethical review committees (institutional review boards)—are involved in the area of informed consent. The basic standard of practice is to assess whether a patient is competent to decide on his or her own about participation and, if the patient does not appear to be competent, to inquire of an appropriate family member or other representative whether approval for participation should be granted. In practice, often two signatures are collected and the precise legal standing of the substitute decision maker is not always identified. Efforts to clarify the roles of proxy decision makers are ongoing.

Questions relating to the issue of informed consent include the following: How should competence to make research decisions be established? How should a surrogate decision maker be identified? What are the absolutes (e.g., patients with cognitive incapacity should not participate in risks research that has no possible therapeutic benefit) that can help the surrogate decision maker decide what kinds of research should or should not be permitted? Finally, what kinds of monitoring should be performed to ensure that informed consent is obtained correctly and adequate informed consent is obtained (and the actual study is conducted well)?

### **Future Ethical Issues**

As discussed earlier, ethical issues in geriatric neuropsychiatry are evolving rapidly, for several reasons. First, the science surrounding geriatric neuropsychiatry is exciting and is likely to lead to findings that have important therapeutic and diagnostic implications. Second, the population with geriatric neuropsychiatric conditions is growing. Third, the field of biomedical ethics itself is evolving, and topics that relate directly to geriatric neuropsychiatry, from genetic testing to health care rationing, are being addressed. In this section, I review some of the important issues that are likely to become more prominent in the near future.

It is likely that different genes that either cause or increase susceptibility to a variety of neuropsychiatric conditions will be identified (Gershon et al. 1998) (see Chapter 38). This is particularly the case in neurodegenerative diseases, such as Alzheimer's disease and Huntington's disease (Post and Whitehouse 1998a). In the case of autosomal dominant forms of these diseases, presymptomatic genetic testing is already theoretically feasible in families with specific identified mutations. Guidelines have been created for such testing, which provide family members at risk with

information about the presence or absence of the specific mutation. However, although many potential patients initially express interest in this type of testing, relatively little presymptomatic testing has been done, at least for Alzheimer's disease.

Another area of genetics that will be problematic is the identification of further susceptibility loci. For example, one locus in Alzheimer's disease on chromosome 19, the apolipoprotein E (*APOE*) gene, modifies the risk of individuals having Alzheimer's disease (see Chapter 24). Being *APOE4*-positive makes a diagnosis of Alzheimer's disease more likely if cognitive impairment is present. Testing for the autosomal dominant mutations and susceptibility loci is available commercially. Strong statements have been made in support of their current use (often by those who have a financial stake in this use). Yet susceptibility testing is fraught with scientific as well as ethical difficulties. A principal problem relates to the extent to which research samples are representative of patients most likely to be seen by clinicians. For example, there is evidence to suggest that the increased risk associated with being *APOE4*-positive varies with gender and ethnic background. If the ethnic background of the clinician's patient is different from those of research samples, the clinician may find it impossible to assign a specific risk in association with an *APOE4*-positive state. Confidentiality is also an issue. For example, should insurance companies have access to genetic information that might allow them to prevent an individual from obtaining health care insurance or at least to charge higher premiums?

Related to the use of genetic testing in living patients is the use of genetic material from tissue specimens obtained from persons while still alive or at autopsy. There are a number of questions regarding this issue: Should researchers who obtain genetic material be able to use this material for research in areas that are different from the areas specified by the patient? How long should tissues be stored? What rights should patients have to profits from the commercialization of any technology developed in association with the use of the patients' tissue? Genetic issues in geriatric neuropsychiatry will continue to yield questions relating to individuals' rights and social justice.

Another trend is the consideration of broad cultural issues when ethical issues in neuropsychiatric disease are considered. Already, multisite, multinational studies are often conducted in which protocol approval needs to be obtained from ethics review boards representing many different nationalities and cultures. Even within the United States, with its diverse populations, different cultural attitudes toward research and therapeutic goals are evident. The attitudes of African Americans are still affected by the

Tuskegee "experiments." In this long-running study, black men with untreated syphilis were observed even after penicillin (an effective agent against syphilis) was discovered. The revelations of the National Radiation Research Review Committee suggest the problems of obtaining adequate informed consent and monitoring studies are still with us (Faden 1996). In the study described, adults and children with or without mental impairment were exposed to radiation in various forms without being told the risks or even that they were being exposed to radioactive substances.

Moreover, because of a variety of factors, principally the financial health of individual nations, the standard of practice may vary in different countries. Here are a few examples: There is considerable controversy concerning AIDS research in African nations that do not have access to the modern medications that are available in the United States. Given that the standard of care is different in Africa, is it acceptable that studies be done in Africa that would be considered unethical in the United States? In the case of Alzheimer's disease, treatment with donepezil may become such a standard of practice in the United States that conducting placebo-controlled studies may be viewed as unethical. Could an American scientist then conduct placebo-controlled research in a country where this use of donepezil had not been approved or where it had been approved but the drug was not affordable for a large segment of the population? A critical issue in this area of international ethics is the relative benefit to various parties, especially the developing country that is the site of the research.

Finally, it is likely that the discipline of bioethics will continue to evolve in ways that will affect geriatric neuropsychiatry practice. Modern medical bioethics evolved from considerations of the impact of medical technologies. For example, the Kennedy Institute, which was founded in 1970, used the word *bioethics* in its title and was principally organized to address ethical issues associated with the care of patients with mental retardation and the use of reproductive technologies. However, the original formulation of bioethics by Van Rensselaer Potter involved a much broader vision of the relationship between science and philosophy and between biology and values. Potter's vision was that bioethics would be a bridge to the future. His bioethics was rooted in land and environmental ethics (McKim 1997). Potter and I developed the idea of creating a bridge between medical and ecological ethics. The survival of human beings and other species, along with environmental stewardship, ought to be the principal focus of a deep bioethics (Potter and Whitehouse 1998; Whitehouse 1998). The word *deep* in *deep bioethics* is borrowed from the phrase *deep ecology*, which is used to describe the approach

in which we are to look beyond the numerous individual environmental crises and develop a vision of our individual and species' relationships to nature. Scientific and certain religious beliefs have been interpreted as granting permission to dominate natural processes. Like Potter, deep ecologists ask us to develop individual creeds to guide our own behavior as citizens and professionals. As a species, we should view ourselves as stewards rather than controllers of nature.

In the future, greater concerns will be raised regarding the deterioration of our environment, partly occurring as a result of scientific "progress." The growth of the world's population continues to be a concern. A special part of this growth is the increase in the proportion of elderly individuals. Thus, the ethically appropriate and wise use of our scientific knowledge and technology will be critically important. However, thoughtless application, purely for short-term economic progress and without regard for long-term consequences, will be the death of civilization and perhaps our species.

The next millennium will bring revolution in the biological and informational sciences. Geriatric neuropsychiatry will remain an exciting field but will remain a really important one only if we balance our passions for scientific progress and professional security with sincere and genuine humility regarding our role in the community of human beings and other living creatures.

# Competency and Related Forensic Issues

J. Edward Spar, M.D.

Neuropsychiatric illness in elderly patients commonly leads to abnormalities in mood, memory and other cognitive functions, and the ability to perform activities of daily living. When these deficits become grossly evident, concerns about the mental capacity or competency of the affected individual tend to arise. Health care providers may question the patient's ability to give informed consent for medical treatment or to make end-of-life decisions regarding resuscitation and life support. Attorneys may become concerned about future challenges to the provisions of wills, gifts, and trusts, and concerned friends or relatives may recommend that durable powers of attorney be executed or may contemplate guardianship or conservatorship. If the impaired patient has a driving-related mishap (e.g., gets lost or has an accident), his or her competency to drive may be challenged, and the right to drive may be lost.

In this chapter, I first consider the broad legal construct of *mental capacity* or *competency* (the two terms, as well as the term *competence*, are used interchangeably here) and then discuss the specific social contexts in which the geriatric neuropsychiatrist is likely to perform a contemporaneous or retrospective evaluation of competency. Several re-

lated forensic issues (e.g., limitations on the requirement for informed consent, elder abuse, and undue influence) are addressed in this discussion.

CAVEAT: For purposes of illustration and discussion, I refer in this chapter to *California law*. Because statutory and governing case laws differ considerably from state to state, the reader is strongly urged to check the law applicable to his or her jurisdiction.

## ■ What Is Competency?

In the literature on competency, the term *competency* is generally used in reference to decision making and communicating capacity. The President's Commission for the Study of Ethical Problems in Medicine and Biobehavioral Research (President's Commission 1982) defined *competency* as "the ability to make autonomous decisions; to reason and deliberate and to understand and communicate information; and the possession of goals and values" (p. 57). Hoge et al. (1997) defined *decisional competence* as "the capacity to: understand information relevant to the issue at hand; think rationally about alternative courses of action; appreciate

one's situation as a person confronted with a specific decision; and express a choice among alternatives" (pp. 146–147).

The presence of terms such as *ability* and *capacity* in statutory definitions of competency has an important practical implication. The court in *Estate of Jenks* made the distinction (as it applies in the testamentary context) thus: "It is the generally recognized rule that testamentary capacity requires only that the testator have *capacity* to know and understand the nature and extent of his bounty, as distinguished from the requirement that he have *actual knowledge* thereof" (*Estate of Jenks* 1971, emphasis added).

It is a presumption in common law that every adult is competent for all legal purposes until proven otherwise, and a formal, legally binding determination of incompetency can be made only by a court. Still, the vast majority of competency determinations are informal and are made by physicians, attorneys, police officers, and other professional and nonprofessional workers in the course of everyday practice. Physicians and other health care professionals make competency judgments when they seek informed consent for risky or invasive medical procedures, lawyers informally assess their clients' competency before taking on estate planning assignments or when designing a criminal defense, and police officers make implicit judgments of competency when deciding whether certain detained individuals should be taken to the police station for booking or to the local emergency room for psychiatric evaluation.

The consequences of a formal determination of incompetency are generally twofold. On the one hand, as an instance of the state acting in *parens patriae* (as a "benevolent parent"), the judgment confers certain protections: appointment of a conservator or guardian protects the individual from the consequences of his or her own poor financial decisions, or inability to secure food, clothing, shelter, or medical care; and a judgment of lack of contractual capacity may excuse an individual from the performance required of an otherwise valid contract. On the other hand, the individual found to be incompetent also pays a price for this protection, namely the loss of certain rights of self-determination, such as the rights to accept or refuse treatment, to enter a plea or to stand trial, to enter into contracts, and to make a will. Some formal judgments of incompetence derive more from the police power of the state and are legitimized by society's concern for the potential victims of the incompetent individual. A finding of incompetence in this context is likely to involve involuntary hospitalization or medical treatment. By contrast, informal judgments of incompetency generally lead to the withholding of certain professional services, at least until further steps are taken.

Formal competency determinations are made in both criminal and civil contexts. Although geriatric neuropsychiatrists are relatively unlikely to become involved in the criminal justice system, this chapter would be incomplete without at least a brief consideration of criminal competency. A more detailed and comprehensive discussion of civil competency follows this section on criminal competency.

## ■ Competency in Criminal Law

Mr. J, an 83-year-old retired attorney, had early vascular dementia when the Securities and Exchange Commission initiated an investigation of insider trading. By the time the commission had compiled enough evidence to prosecute him, Mr. J's cognitive function had deteriorated dramatically. He was disoriented to year, month, season, and date; did not know his address or telephone number; and had moderate to severe impairment of new learning, recent recall, and remote memory. He was unable to name any presidents including the current one, even when given clues, and could not recall the names of any of his past employers or the ages of his children, the names of their spouses, or whether they had children. A neuropsychiatrist consulted by the court opined that Mr. J lacked the capacity to stand trial or to plead guilty.

In the criminal context, the two major types of competency have traditionally been *competency to plead guilty* and *competency to stand trial*. In *Dusky v. United States* (1960), the Supreme Court stated that a defendant is competent to stand trial if "[the defendant] has sufficient present ability to consult with his lawyer with a reasonable degree of rational understanding—and . . . a rational as well as factual understanding of the proceedings against him." According to this definition, both decisional competency *and* actual understanding are required. In the case cited above, the neuropsychiatrist opined that Mr. J did not meet either of these criteria. Given that defense attorneys question their clients' ability to meet the Supreme Court's standard in 8%–15% of felony cases, it has been estimated that 25,000 competency evaluations of criminal defendants occur per year (Hoge et al. 1997), making this by far the most common formal determination of competency. In 1993, the Supreme Court held that competency to plead guilty and competency to stand trial are in fact the same (*Godinez v. Moran* 1993). Issues related to this "composite" competency, which has been termed *adjudicative competence* by Hoge et al. (1997), have led to the creation of a substantial literature on the topic (review of which is beyond the scope of this chapter, as are the related issues of diminished

capacity and the insanity defense), aimed at the problem of specifying criteria, screening for, and ultimately determining adjudicative competence in criminal defendants. Hoge and colleagues (1997) provided a review of this topic.

## ■ Competency in Civil Law

The types of civil competency most likely to concern geriatric neuropsychiatrists are competency 1) to give informed consent for medical care, 2) to execute an advance directive, 3) to give informed consent for enrollment in a study, 4) to enter into (and be held accountable for) a contract (contractual capacity), 5) to execute a will (testamentary capacity) or trust, 6) to provide self-care (provide oneself with food, clothing, shelter, and medical care), and 7) to manage one's finances.

### Competency to Give Informed Consent for Medical Care

The capacity to give informed consent for medical care is probably the most studied of all the varieties of civil competency. Four components of decisional competency in the medical setting were distinguished by Appelbaum and Grisso (1988) and have been accepted by most authors: the ability to communicate a choice, to understand relevant information, to appreciate the situation and its consequences, and to manipulate information rationally. Though seemingly straightforward, this definition raises several questions. First, it is not always clear what “rationally manipulating information” means; it has been often noted that the treating physician is most likely to conclude that the manipulation is not rational if the outcome of the manipulation (i.e., the patient's decision to accept or reject the proposed intervention) does not agree with what the physician believes makes the most sense. On this point Appelbaum and Grisso (1988) stated: “Rational manipulation involves the ability to reach conclusions that are logically consistent with the starting premises. This requires both weighing the risks and benefits of a single option and the usually more complex process of weighing multiple options simultaneously . . .” (p. 1636). The notion of appreciation may also be obscure to many clinicians. Schaffner (1991) defined *appreciation* as “not only factual understanding and rational manipulation of the information, but an additional facility for applying general information to particular circumstances and for comprehending the crucial nature of certain data” (p. 255), and Appelbaum and Roth (1982) stated that “‘appreciation’ is taken to be an affective, as well as a cognitive, recognition of the nature of the situation” (p. 955).

A thornier problem in the application of the four components of decisional competency is the question of operationalization, that is, what observable criteria would satisfy the definitions of the relevant terms. That is, with the meaning of the terms having been clarified, how does the clinician determine whether understanding and appreciation are present or rational manipulation of information is actually taking place? A potentially important step toward resolution of this problem was taken by Grisso and colleagues (1997), who developed the MacArthur Competence Assessment Tool-Technique, a semistructured interview procedure that guides clinicians and patients through a process of disclosure of information related to informed consent, and an assessment of patients' capacities to make decisions based on the information. Information specific to the patient's situation is used, and only 15–20 minutes are required for the procedure. Preliminary data obtained using this instrument in patients with schizophrenia and schizoaffective disorder suggest that it has acceptable reliability, validity, and clinical feasibility. However, the authors recognized that the elements of decisional competence assessed by this instrument “are not the only factors in ultimate clinical or legal judgments of competence” and anticipated that the main use for the tool would be in “the midrange of ambiguous cases of competence . . . especially when clinicians have reason to believe that their judgments might later be questioned—for example, in legal proceedings about a patient's capacity to decide or about the reasonableness of a clinician's decision to accept a patient's decision or to turn instead to a surrogate” (Grisso et al. 1997, p. 1419)

Capacity is only one of three equally important components of informed consent for medical care. The President's Commission (1982) concluded that the patient must be provided with appropriate information regarding the recommended medical intervention (the categories of information required by California law are listed in Table 41–1) and that the consent must be given voluntarily—that is, it cannot be a result of coercion or threats (discussed in a later section).

Even when a proposed medical intervention is associated with enough risk to warrant seeking informed consent from the patient, there are limits to the kind and amount of information that the clinician must provide, and there are circumstances in which the intervention may proceed without informed consent. In nonemergent situations, courts have ruled that physicians have the responsibility to exercise “therapeutic privilege”—that is, to approach the process of obtaining informed consent in a clinically sensitive and appropriate manner. *Natanson v. Kline* (1960) established that a clinician should provide the information

**TABLE 41-1. Requirements of informed consent: what patients must be told about a proposed treatment**

The nature and seriousness of the illness, disorder, or defect that the person has
The nature of the medical treatment that is being recommended by the person's health care providers
The probable degree and duration of any benefits and risks of any medical intervention that is being recommended by the person's health care providers, and the consequences of lack of treatment
The nature, risks, and benefits of any reasonable alternatives

Source. Data from California Probate Code § 813.

that the hypothetical “reasonable medical practitioner” would provide to his or her patient. But in *Canterbury v. Spence* (1972) the court turned this reasoning around, concluding that the person receiving the information (the hypothetical “reasonable person”) should determine what information is provided. In both of these landmark cases, the notion of reasonability was used in setting lower and upper limits on the information imparted; that is, too much information was considered possibly to be as unreasonable as too little information. In *Natanson v. Kline*, the court noted that full disclosure “could so alarm the patient that it would, in fact, constitute bad medical practice,” and in *Canterbury v. Spence* the court recognized that, for some patients, disclosing certain information could “foreclose a rational decision, or complicate or hinder the treatment, or perhaps even pose psychological damage to the patient.” In a 1985 Massachusetts case (*Precourt v. Frederick*), the court was even more explicit, stating: “A physician is not required to inform a patient of remote risks” and “There must be a reasonable accommodation between the patient's right to know, and fairness to physicians and society's interest that medicine be practiced . . . without unrealistic and unnecessary burdens on practitioners.”

Informed consent is generally not required in an emergent situation, in which significant harm would come to a patient (or to others, in the case of a violent patient) if the intervention were delayed so that informed consent could be obtained. Under these circumstances, the principle of implied consent applies—that is, the physician may perform the intervention to which a reasonable, self-interested patient would consent, given the opportunity. Similarly, if the patient is unconscious or otherwise incompetent to participate in the consent process, and no substitute decision maker (e.g., guardian or conservator, attorney-in-fact for health care, or, in some jurisdictions, next of kin) or advance directive is available, the physician may ad-

minister appropriate treatment until the patient is able to consent. In California, *emergency medical care* is defined as “those medical services required for the immediate diagnosis and treatment of medical conditions which, if not immediately diagnosed and treated, could lead to serious physical or mental disability or death” (California Health and Safety Code § 1799.110b; see also California Probate Code § 3210). However, the definition of *emergency* may differ in other jurisdictions, and the reader is advised to check applicable local law.

### Competency to Execute an Advance Directive

Mrs. R, an 88-year-old woman with advanced Alzheimer's disease, was admitted to a long-term care facility. As was routine at the facility, on the day of admission Mrs. R was asked to execute a durable power of attorney for health care, appointing her daughter as her attorney-in-fact. She complied, and later that day Mrs. R's daughter was approached for consent to administer neuroleptic medications to her mother. Is anything wrong with this picture?

Advance directives are legal instruments intended to ensure that appropriate decisions regarding medical care are made when a patient becomes incompetent to give informed consent. The Patient Self-Determination Act (Omnibus Budget Reconciliation Act of 1990), which became federal law on December 1, 1991, mandates that hospitals, nursing homes, and other health care organizations provide information to patients concerning availability and use of these instruments.

There are generally two types of advance directives: *proxy directives*, such as the durable power of attorney for health care (DPAHC) or health care proxy, and *instruction directives*, such as the living will. DPAHC allows an individual (the *principal*) to authorize another person, usually a family member or spouse (the *attorney-in-fact*), to give or withhold consent for medical care for the principal if the principal becomes incompetent: “A durable Power of attorney is a power of attorney by which a principal designates another his attorney in fact and the writing contains the words, ‘This power of attorney shall not be affected by disability of the principal,’ or ‘This power of attorney shall become effective upon the disability or incapacity of the principal’ or similar words showing the intent of the principal that the authority conferred shall be exercisable notwithstanding the principal's subsequent disability or incapacity” (Uniform Durable Power of Attorney Act). Some states have enacted similar laws creating the health care proxy.

A living will, a document that is created by an individual when he or she is of sound mind, specifies the limits of care to be given by health care providers if the individual “become[s] unable to participate in decisions regarding . . . medical care.” One widely circulated version (the source of the previous quotation and available from the Society for the Right to Die, 250 West 57th St., New York, NY 10107) directs the attending physician “to withhold or withdraw treatment that merely prolongs . . . dying” if the individual develops “an incurable or irreversible mental or physical condition with no reasonable expectation of recovery.” It also has a section in which the individual can specify particular treatments that he or she does not want, as well as particular preferences regarding treatment and the end of his or her life (e.g., the preference to die at home).

There are clear advantages and disadvantages to both types of directives. A proxy has much more flexibility than an “instructive” has, and a proxy can respond to circumstances that may not have been anticipated by the principal. On the other hand, a proxy can also betray the trust of the principal by making decisions that the principal would not have endorsed. In some states, a living will and DPAHC or health care proxy can be combined, resulting in an instrument that requires the attorney-in-fact or proxy to follow the provisions of the living will and authorizes the exercise of his or her judgment in circumstances not covered by the will.

Obviously, advance directives are intended to be executed when the principal *is* competent to give or withhold consent for medical care, and one might think that the standard for competency to execute an advance directive would be the same as the standard for competency to consent to medical care. Yet California law states: “A natural person having the *capacity to contract* may execute a power of attorney” (California Probate Code § 4120, emphasis added). However, different standards for competency to execute an advance directive may obtain in other states. Therefore, depending on the prevailing definitions of *capacity* to give informed consent to medical treatment and capacity to execute an advance directive, the long-term care facility’s handling of Mrs. R (in the previous case example) could be appropriate—that is, she could simultaneously have the capacity to execute a DPAHC and not have the capacity to consent to treatment with a neuroleptic. In a similar vein, the powers of the attorney-in-fact differ from state to state. California law prohibits the attorney-in-fact from consenting to placement in a mental health treatment facility, convulsive treatment, psychosurgery, sterilization, or abortion (California Probate Code § 4722) and also prohibits the attorney-in-fact from consenting to health care

or consenting to the withholding or withdrawal of health care “necessary to keep the principal alive, if the principal objects to the health care or to the withholding or withdrawal of the health care. In such a case, the case is governed by the law that would apply if there were no durable power of attorney for health care” (California Probate Code § 4724). This section appears to reflect the will of the California legislature that individuals retain the authority to make end-of-life decisions, even if they are incompetent to make other medical decisions.

Much has been written about the question of which rules should govern the decisions of substitute decision makers such as attorneys-in-fact. The prevailing view is known as the doctrine of “substituted judgment,” according to which the substitute decision maker should act, as much as possible, in accordance with the wishes, values, and goals of the principal. The alternative, “best interests,” approach calls upon the substitute decision maker to perform an “objective assessment of the burdens and benefits for this patient” as the basis for his or her decision (Fellows 1998, p. 924). The court in a New Jersey case (*In re Conroy* 1985) spelled out a three-step protocol for analyzing the patient’s wishes. First, consider any statements or other directives made by the patient. If these are not conclusive, then attempt to deduce the patient’s wishes from his or her more generally held values, religious beliefs, and so on. Finally, if these steps leave the issue in doubt, revert to what a person in the patient’s situation might reasonably choose.

### **Competency to Consent to Enrollment in a Research Study**

The considerations just discussed regarding competency to consent to medical care generally apply to competency to consent to enrollment in a study. Before an investigator can claim to have secured informed consent, the subject must have been supplied with appropriate information, *voluntary* consent must have been obtained, and the subject must have been considered competent. In 1982, the President’s Commission clearly spelled out the disclosures required under ordinary circumstances (Table 41–2), and in 1996, the Food and Drug Administration published an “exception to informed consent” rule intended to govern research conducted in medically emergent circumstances (Federal Register 1996). To date, however, no comparable guidelines have been articulated for the conduct of research using cognitively impaired (marginally competent or frankly incompetent) subjects in nonemergent situations, although the National Bioethics Advisory Commission (created by President Clinton in 1995) is in the process of drafting a report on this issue (Marwick 1998). Such

**TABLE 41-2. Disclosures required for research subjects**

Information about how the subject can have pertinent questions answered
A statement about voluntary participation, indicating that refusal to participate involves no penalties or loss of benefits

---

guidelines are likely to have important implications for research involving patients with dementia.

Several authors have addressed the problems associated with the use of proxy decision makers for incompetent research subjects. Kapp (1994) identified three “axes” of concern. The first axis is the question of who should act as a proxy decision maker for the impaired research subject, how that person should be selected, and what procedural safeguards should exist to prevent exploitation of the subject by the proxy. In order of decreasing formality, the approaches he discussed included 1) appointment (by a court) of a regular guardian with explicit authority to consent to the principal’s participation in research; 2) appointment (by a court) of a guardian *ad litem* (a person appointed to act on behalf of a principal for a specific task) with explicit authority to consent to the principal’s participation in a particular research project; 3) execution (when the principal is clearly competent) of a durable power of attorney for research participation, in jurisdictions where such an instrument is available; 4) reliance on the informed consent of family members, in states that have statutes authorizing family members to act as proxies for health care decisions in the absence of an advance directive; and 5) reliance on the informal informed consent of family members, in states that do not have statutes authorizing family members to act as proxies for health care decisions in the absence of an advance directive. Of these, Kapp clearly endorsed the third approach, considering the fourth a backup procedure and the first an approach of last resort. The second axis of concern is the proxy’s role and the criteria to be used to make decisions regarding research participation. Kapp agreed with most authorities that the proxy should first protect the subject from harm, but Kapp stated that as long as the wishes of the subject on this point were clear, substituted judgment could permit the proxy to accept whatever de-

gree of risk the subject would have accepted, had he or she been competent. The third axis of concern is the type of research and the kind and quantity of risk to the subject—both considerations, in Kapp’s view, being proper foci of the attention of proxy decision makers.

Bonnie (1997) expanded on Kapp’s third-axis concerns, recommending that institutional review boards follow the “operative standard of informed consent used in everyday clinical and research practice[, which] varies according to the degree of risk” (p. 110). Bonnie suggested that proxy decision makers be used to provide concurrent authorization for research participation by impaired subjects who are capable only of assenting and, in some cases, even for participation by those fully capable of informed consent (a kind of reverse second opinion). For example, an 85-year-old, mildly cognitively impaired patient agrees to participate in a clinical trial of a cognitive-enhancing medication. The investigator believes that the patient is capable of giving informed consent for study participation and obtains that consent but also obtains written informed consent from the attorney-in-fact for health care. The latter consent serves as a confirmation of the investigator’s judgment that the patient’s consent is a true expression of the patient’s goals and values.). Bonnie also stated that statutory authorization of family members to act as proxies for *health care* decisions in the absence of an advance directive “can reasonably be construed to cover research with potential therapeutic benefit that is properly linked with clinical care, and the statutes can be amended to clarify their application to research settings” (Bonnie 1997, p. 110).

### Competency to Enter Into a Contract or Make a Gift

Mr. M, an 86-year-old developer who owned a chain of long-term care facilities, was dying of lung cancer. Shortly before his death, his 51-year-old wife of 10 years convinced him to transfer all of his assets to her in exchange for a very modest monthly stipend. The execution of the transfer took place in Mr. M’s hospital room and was attended by several attorneys, who had the foresight to have the proceedings videotaped. After Mr. M died, his daughter challenged the transfer on the basis of the claim that he lacked contractual capacity. A neuropsychiatrist reviewed his medical records, which clearly documented moderately severe delirium on the date of the videotape session, and also reviewed the videotape, which equally clearly demonstrated Mr. M’s distractibility, inattention, recent memory impairment, and obvious lack of understanding of the meaning and consequences of the transfer.

Whereas the traditional view of contract versus property law distinguishes between the “future orientation” of con-

tracts and the “present orientation” of a gift, competency to enter into a contract and competency to give a gift during one’s lifetime (*inter vivos*) are treated as essentially the same in contemporary legal literature (Meiklejohn 1988–1989). Geriatric neuropsychiatrists are likely to become involved in legal action related to contractual competency in two situations: 1) when an individual who has entered into a contract or made a gift (the *grantor*) attempts to escape responsibility for the future performance demanded by the contract or to retrieve assets already transferred per the terms of the contract or gift, on the basis of the claim that he or she lacked contractual competency at the time; and 2) when the establishment of a conservatorship of estate (discussed shortly) is under contemplation by a court because a proposed conservatee is thought to be unable, on the basis of mental incapacity, to manage his or her finances or resist fraud or undue influence. Although courts have the authority to grant exceptions in specific cases, the establishment of a conservatorship generally creates an irrebuttable presumption that the conservatee lacks contractual and donative (but not testamentary) capacity.

Definitions of *contractual capacity* vary widely by jurisdiction. The Restatement (Second) of Contracts (1979) provides as follows: “A person incurs only voidable contractual duties by entering into a transaction if by reason of mental illness or defect (a) he is unable to understand in a reasonable manner the nature and consequences of the transaction, or (b) he is unable to act in a reasonable manner in relation to the transaction and the other party has reason to know of his condition.” But until 1996, California law stated: “A person entirely without understanding has no power to make a contract of any kind” (California Civil Code § 38) and “A conveyance or other contract made by a person of unsound mind, but not entirely without understanding, made before his incapacity has been judicially determined, is subject to rescission” (California Civil Code § 39a). In part because of the vagueness of this standard, a new section (California Civil Code § 39b) was added to the California code (as part of the Due Process in Competence Determinations Act) in 1996. This section is intended to anchor contractual capacity to the statutory definition of persons who qualify for a conservatorship of estate. It states: “A rebuttable presumption affecting the burden of proof that a person is of unsound mind shall exist if the person is substantially unable to manage his or her own financial resources or resist fraud or undue influence.” This statute provides a partial remedy for situations in which an individual, typically elderly and cognitively impaired, who qualifies for but has not (yet) been provided a conservator of estate has entered into an unwise contract (e.g., for unneeded home improvements) because of impaired judgment.

If it can be proven that a conservatorship *could* have been established, the usual assumption that every adult is competent for all legal purposes is reversed, and the other party to the contract must prove that the elderly individual possessed contractual capacity (Hankin 1995).

Mr. K, a 92-year-old man with early Alzheimer’s disease, had been a shrewd and successful businessman in his youth. Within the past 2 years, he had invested a large amount of money in an extremely unwise business venture of a distant friend and had loaned large sums of money to several acquaintances without securing collateral and, in one case, with no documentation at all. His oldest son petitioned the probate court to appoint a conservator of estate. After appointing an attorney for Mr. K and obtaining a psychiatric evaluation, the court complied, over Mr. K’s objection. The conservator immediately initiated legal proceedings under California Civil Code § 39b to rescind the prior investments and recover some of the assets that had been loaned away.

When a claim of contractual or donative incompetency is adjudicated, courts tend to give substantial weight to facts besides the degree of mental impairment of the grantor, such as the substantive fairness (i.e., the terms of the contract or gift, as opposed to the procedural fairness) of the transaction in question. In other words, the fact that the grantor agreed to an obviously bad deal may be regarded as evidence supporting the claim that the grantor was incompetent.

### Competency to Make a Will

Mr. R, an 84-year-old retired tractor repairman, owned a small house in the countryside, where he had lived alone for almost 50 years. His cousin Lem was his only living relative. Mr. R had moved to a board-and-care facility at the onset of cognitive decline, and after several years he decided to write a will leaving his house to Lem. The attorney called in by the board-and-care facility at Mr. R’s request recognized that Mr. R was obviously cognitively impaired and arranged to have Mr. R evaluated by a geriatric neuropsychiatrist. Mr. R was found to be severely impaired in all cognitive spheres, with a Mini-Mental State Exam score of 10 and comparably low scores on several supplementary standardized instruments. But when asked about his will, Mr. R said, “When I die, I’m leaving the house to my cousin Lem. It’s all I got, and Lem is my only family. I want it that way in my will. That’s all.” During an hour-long interview, Mr. R added little to that remark but said nothing suggestive of delusional thought.

Most states define *testamentary capacity* as the capacity to “understand the nature of the testamentary act, understand

and recollect the nature and situation of his or her property, and remember and understand his or her relations to his or her living descendants, spouse, and parents, and those whose interests are affected by the will.” Some states require only one or two of these criteria to be met, and many states also require that “the testator [be] also free of . . . delusions or hallucinations [that] result in the person’s devising his or her property in a way which, except for the existence of the delusions or hallucinations, he or she would not have done” (California Probate Code § 6100.5). In general, if lack of testamentary capacity is proven, the entire will or codicil (modification to an existing will) is invalid. Testamentary capacity is generally recognized as “only a modest level of competence (‘the weakest class of sound minds’)” (*Estate of Rosen* 1982), and legal presumptions relating to this competency have traditionally also helped to set the bar fairly low. Accordingly, despite advanced dementia, Mr. R clearly met these criteria for testamentary capacity.

Besides the general presumption that the testator was competent at the time the will was executed, it has also been stated that “when one has a mental disorder in which there are lucid periods, it is presumed that his will has been made during a time of lucidity” (*Estate of Goetz* 1967). The trend of more recent cases, though, has been toward increasing recognition that—at least in the case of progressive illnesses, such as Alzheimer’s disease and vascular dementia—once testamentary capacity has been lost, it is unlikely to return, even for brief periods.

Despite the fact that testamentary capacity is a low standard, wills are vulnerable to challenge if an aggrieved party can produce any evidence of mental impairment in the testator, and a medical record containing the mere diagnosis of a neuropsychiatric illness is almost always enough, all things else being equal, to encourage contestants to proceed. Although it is common knowledge among neuropsychiatrists that a diagnosis alone does not imply any particular level of intellectual function or automatically determine the presence or absence of any type of competency, many judges, attorneys, and juries are not in possession of this insight and may need to be educated through expert testimony.

In many will contests, the allegation that the testator lacked testamentary capacity at the time the will was executed is accompanied by the allegation that the will, or parts of it, is the product of undue influence. Because testamentary capacity is such a low standard, and because prospective evaluation of the testator is rarely performed (and if it is, it is almost always at the request of a competent testator or by his or her anticipated beneficiaries), it is usually very difficult to prove that a testator did not possess testa-

mentary capacity at the precise moment that the contested will was signed (executed). Accordingly, an allegation of undue influence often proves to be the stronger case for the contestant. Any part of a will that is proven to be a result of undue influence is overturned, but the remainder remains valid if the will without the influenced provisions still makes sense and the testator otherwise had testamentary capacity. Undue influence is discussed later in this chapter.

### **Competency to Execute a Trust**

Trusts are increasingly popular instruments with which to determine the disposition of one’s assets after death, and to that extent a trust serves the same function as a will and the relatively low standard for testamentary capacity should apply. But even if it did, the testamentary standard of understanding the nature of the testamentary act would almost always require more intact intellectual function than that required for a will because trusts are generally more complicated than wills, with more, and more detailed, provisions. Moreover, whereas a will is simply a piece of paper with a set of instructions, a trust is a more abstract entity that requires relatively intact higher intellectual functions to grasp. Some courts have differentiated the standards of competency for trusts and wills on the basis of the fact that establishing a trust entails a step in addition to merely signing a set of instructions: the creator of the trust must also transfer his or her property to the trust. This act would seem to require contractual or donative capacity, which is widely but not universally regarded as a higher level of competency than mere testamentary capacity. (For example, in *Citizen’s National Bank v. Pearson* [1978], the court stated: “Greater mental capacity is required to make a deed than is required to execute a will.”) Another path to the same conclusion is the argument that because the trustee is endowed with the authority to enter into contracts involving the trust assets, the creator of the trust should possess contractual capacity. The question regarding which standard applies to trusts may admit of different answers, depending on the specific details of the trust and the state in which it is created. An approach under development in California is to require contractual capacity for the creation of a trust and testamentary capacity for execution of amendments to a trust that affect only the after-death disposition of the trust estate.

### **Undue Influence: The Question of Voluntariness**

As mentioned earlier, the question of undue influence is commonly raised in conjunction with a claim of lack of tes-

tamentary capacity and in connection with contested trusts, contracts, and gifts. Susceptibility to undue influence is also one of the criteria for establishment of a conservatorship of estate in California and some other states, and the underlying question of voluntariness is also relevant to the issue of informed consent for medical care. Yet, undue influence is a complex and poorly defined legal concept at best. In the legal literature, the question of undue influence tends to be reduced to the “will substitution test”—that is, was the testator’s mind so controlled by another person that his or her will is actually the will of another person? Depending on the situation, this “will substitution” may require an element of “coercion, compulsion, or restraint,” as in the testamentary context, or merely consist “1) [i]n the use, by one in whom a confidence is reposed by another, or who holds a real or apparent authority over him, of such confidence or authority for the purpose of obtaining an unfair advantage over him; 2) [i]n taking an unfair advantage of another’s weakness of mind; or, 3) [i]n taking a grossly oppressive and unfair advantage of another’s necessities or distress” (California Civil Code § 1575) with regard to *contracts*. Courts generally approach the issue of undue influence from two closely related legal perspectives, each of which can be thought of as a legal “theory” of undue influence. Although the assumption that undue influence is wielded by a stronger party to the detriment of a weaker party is common to both, the presumption model and the susceptibility model differ in their relative weighting of the evidence (Wrosch 1992). In the presumption model, the evidence focused on is the relationship between the donor and the receiver of the gift or bequest. In some jurisdictions, the mere existence of a confidential and trusting relationship, such as that between an elderly patient with neuropsychiatric illness and his or her primary caregiver, may be enough to shift the burden of proof to the recipient, who then must prove that undue influence did not occur. The presumption of undue influence is strengthened if the donor is mentally weak; a diagnosis of mental illness or retardation is generally adequate to support this claim, and in some cases even recognition that the donor is passive or manipulable will suffice. The presumption of undue influence is also strengthened if the recipient is a clerical, church, or spiritual adviser who fails to ascertain that a donor has received competent and independent advice, or if the recipient actively procures the gift or bequest, or if the recipient unduly benefits from the gift or bequest.

A somewhat weaker set of factors are widely regarded as indicia (that is, they serve to strengthen a claim of undue influence but do not, by themselves, establish a presumption) of undue influence in a testamentary context. These include “unnatural provisions in the will, provisions in the

will that are inconsistent with prior or subsequent expressions of the testator’s intentions, and a relationship between the testator and the beneficiary that created an opportunity to control the testamentary act” (Spar and Garb 1992).

In the susceptibility model, the focus is more on the relative mental weakness of the donor or testator. But even if it is shown by clear and convincing evidence that the donor or testator was susceptible to undue influence (for example, by expert neuropsychiatric testimony that the donor or testator was mentally impaired), it would still be necessary to show that some kind of improper influence was exerted by the recipient and that the influence sufficed to replace the will of the donor or testator with that of the recipient.

In both the presumption and susceptibility models, a diagnosis of neuropsychiatric illness in the allegedly influenced party will generally support a claim of undue influence, but such a diagnosis is rarely more than just one consideration of many. Singer (1992) identified six additional factors that “are prominent in undue influence situations. They are the production of isolation, the creation of the ‘siege mentality,’ the fostering of dependence, the creation of powerlessness, the use of fear and deception, and keeping the victim unaware of the manipulative program put into place to influence and control the person and to obtain the signing of documents which benefit the manipulators at the cost of the signer” (p. 8). These factors notwithstanding, it is important to remember that influence, even that which is clearly coercive, is not undue if it does not change the preexisting disposition of the testator. That is, if the bequest or gift would have been made anyway, absent the influence, then no undue influence has occurred. Obviously, knowledge of the testator’s long-term wishes and intentions is critical to the establishment of this defense.

Geriatric neuropsychiatrists are likely to become involved in undue-influence evaluations in the clinical context when an individual is believed by friends or family to be vulnerable to exploitation and a conservatorship or guardianship of estate is under consideration. A typical situation involves an elderly divorced or widowed person with vascular or Alzheimer’s dementia who has fallen under the sway of a much younger individual who has gradually taken over many caregiving functions and, in some cases, has even become romantically involved with the elderly person. Particularly if there is no close family, or if preexisting family dynamics are distant or conflictful, it may be an easy matter for the younger person to create several of the circumstances listed by Singer (1992). Naive family members may exacerbate the situation by opposing the relationship or by

suggesting that mental impairment is present, both of which responses may facilitate the creation of the siege mentality. Inappropriate gifts, excessive payments for services rendered, new trusts and wills, and even late-life marriages are typical results of this situation, especially if there are substantial assets. This scenario presents a major dilemma for lawmakers, adult protective service workers, and the courts. Establishment of a conservatorship may protect whatever assets are left by the time the court has acted, but it is not a particularly effective remedy for already lost assets. Laws against fiduciary abuse may serve the function of intimidating some victimizers, but even this approach is often too little, too late. At the same time, social and legal preventive and remedial maneuvers must also take into consideration the fact that older individuals, even those with neuropsychiatric illness, can make authentic, reasoned changes in their long-held values, and some May-December romances are real.

### **Competency to Care for Oneself and Manage One's Finances**

Laws exist in all 50 states and the District of Columbia providing for the appointment by a court of a guardian or conservator for persons found incompetent to care for themselves or manage their finances. In California, the term *conservator* is used for both the individual appointed to make personal decisions (*conservator of person*) and the individual appointed to make financial decisions (*conservator of estate*), but in most states the former is called a "guardian." (California reserves the term *guardian* for minors.) Criteria for appointment of a conservator of person or estate (both roles may be assumed by the same person) are as follows: a conservator of person "may be appointed for a person who is unable to provide properly for his or her personal needs for physical health, food, clothing, or shelter" (California Probate Code § 1801[a]), and a conservator of estate "may be appointed for a person who is substantially unable to manage his or her own financial resources or resist fraud or undue influence" (California Probate Code § 1801[b]). These criteria clearly refer to complex social behavior rather than to the cognitive (i.e., decisional) impairments that presumably underlie the functional deficits. In some states, a more cognitively oriented definition is used, following the Uniform Probate Code (§ 5-103), which defines an incapacitated individual as someone who is "impaired by reason of mental illness, mental deficiency, physical illness or disability, advanced age, chronic use of drugs, chronic intoxication, or other cause (except minority) to the extent that he lacks sufficient understanding or capacity to make

or communicate responsible decisions concerning his person."

In general, the powers of the conservator of person and the conservator of estate are quite broad: the conservator of person has the power to make decisions regarding place of residence and administration of medical care, and the conservator of estate has the power to manage property, assets, and income (this includes the power to enter into contractual arrangements on behalf of the principal). In California, the conservator of person can consent to medical care, but not over the objection of the conservatee, unless the court has granted general or specific medical power—that is, the power to consent to all medical care (general power) or to consent to a specific treatment (specific power) even over the objection of the conservatee. The establishment of a conservator of estate automatically renders the conservatee incompetent to contract or to transfer property but does not establish lack of testamentary capacity.

Conservatorship and guardianship are clearly radical solutions to the competency problems occasioned by neuropsychiatric and other illnesses. The process of appointment of a guardian or conservator is often demeaning and embarrassing to the conservatee, and disagreement over the need for conservatorship and the motivations of those who support or resist it may lead to long-lasting intra-familial conflict and resentment. The appointment is also expensive and time-consuming. In response to these shortcomings, most states have provision for limited conservatorship and guardianship, wherein only some of the powers just discussed are granted to the conservator, while the rest remain with the conservatee, as determined by the court on a case-by-case basis. But even this approach is costly and demeaning to the patient and, despite court oversight, sometimes conducive to fiduciary and even physical abuse by guardians. And the process of adjudication of conservatorship and guardianship itself has been criticized. "Guardianship petitions often recite minimal facts in support of the claim of incompetence; often, in fact, they simply restate the circular and conclusory language of the statutory definitions of incompetency. . . . Far too often, [courts] are satisfied with only a perfunctory assessment of the alleged incompetent's mental capacity. . . . Typically, evidence is limited to a brief letter from a physician stating that the patient is incompetent. A complete psychiatric evaluation and formal mental status exam are rarely included" (Rosoff and Gottlieb 1987, pp. 15–16). Clearly, alternatives to conservatorship and guardianship are highly desirable, and fortunately there are several. Wilber and Reynolds (1995) reviewed these alternatives, which are displayed and partly explained in Table 41–3.

**TABLE 41-3.** Characteristics of financial and health-related services available to older persons

Service	Capacity		Appropriateness to address risk to the older person			Complexity
	Required for execution	Survives incapacity	Personal risk: high, medium, low	Financial risk: high, medium, low	Oversight or recourse	Ability to address complex financial or medical issues
Power of attorney	Yes	No	Low	Medium	By family; legal action	Medium
Bill-paying service	Yes	Not usually	Low	Medium	Agency audit; legal action	Low
Joint accounts/joint tenancy	Yes	Yes	Low	Low	Virtually none; legal action	Low
Durable power of attorney	Yes	Yes	Low	High	By family; legal action	Medium
Durable power of attorney for health care	Yes	Yes	Medium	Low	By family; legal action	Medium
Representative payee	No	Yes	Medium	Medium	Virtually; none by fed govt agency	Low
Personal trusts	Yes	Yes, if drawn properly	Medium	High	Internal audit; banking commissioner, legal action	High
Limited guardianship	No	Yes	High	High	Court; legal action	High
Plenary guardianship	No	Yes	High	High	Court; legal action	High

## ■ Elder Abuse

One of the consequences of diminished competency in elderly individuals, and one of the indications for establishment of guardianship and conservatorship, is vulnerability to various forms of abuse. This issue was placed on the national agenda beginning with a report entitled "Elder Abuse: The Hidden Problem" (U.S. House Select Committee on Aging 1980). Estimates of the prevalence of abuse in the 1980s indicated that 10% of Americans over age 65 were victims of some type of abuse (Clark 1984), with 4% subjected to moderate or severe abuse (U.S. House Subcommittee on Health and Long-Term Care of the Select Committee on Aging 1985). More recent studies from England (Ogg and Bennett 1992) and Canada (Podkies 1992) have supported those estimates. From the beginning, the medical profession assumed a major role in the identification and prevention of this problem. In its Resolution 112, the American Medical Association (AMA) urged the development of diagnostic and treatment guidelines and the proposal of model legislation, and an AMA re-

port in 1992 stated that physicians "are in an ideal position to recognize, manage, and prevent elder mistreatment" (American Medical Association 1992). The legislative program has been quite successful, and there are now elder abuse statutes in every state; all statutes except those in Colorado, New York, and Wisconsin include mandatory reporting laws. Definitions of elder abuse tend to vary from state to state, although most states recognize some combination of physical abuse, neglect, and financial exploitation (known as *fiduciary abuse* in California when perpetrated by caregivers or others), but definitions within those categories also vary greatly, depending on the statutory distinctions between physical and psychological harm, harmful effects and harmful intentions, and acts of omission versus acts of commission (Brewer and Jones 1989).

The success of the medical profession's recognition-and-management agenda has been less impressive. Rosenblatt et al. (1996) looked at elder abuse reports in Michigan between 1989 and 1993 and found that physicians contributed only 2% of the 17,238 reported cases of elder abuse. The study's authors cited inconsistent definitions of abuse, denial (by the patient and by the physician),

fear of the consequences of reporting abuse, and ageism and lack of knowledge (on the part of physicians) as reasons for this low rate. They also suggested that physicians may be hesitant to report for fear of making the problem worse, may wish to maintain relationships with the patients and families and avoid court involvement, and may have little faith that state intervention will result in a better outcome. In states in which statutory protection is not provided, physicians may also fail to report suspected abuse for fear of legal liability. The American College of Emergency Physicians (1998) published a policy statement opposing mandatory reporting of abuse to the criminal justice system if the patient is competent, and calling for immunity from liability (in states with mandatory reporting requirements) for persons who do report abuse. They also called for standardized definitions of elder abuse, written protocols on recognition and treatment of elder abuse, and further research in the area.

Lachs et al. (1997) followed 2,812 community-dwelling older adults (median age, 75 years) in Connecticut for 9 years and identified cases of reported and verified elder mistreatment (including abuse, neglect, exploitation, and abandonment) through a state social service agency. They found poverty, nonwhite race, functional disability, and worsening cognitive impairment to be risk factors for reported elder mistreatment and suggested that reporting bias may have led to overestimation of the effects of race and poverty. The total number of cases of corroborated mistreatment was only 47 (30 cases of neglect, 9 of abuse, and 8 of exploitation), resulting in a sampling adjusted 9-year prevalence of 1.6%. Adult children were the most common perpetrators of abuse (45%), followed by spouses (26%), grandchildren, and paid caregivers. A significantly higher prevalence of elder abuse was reported by Comijs and colleagues, who studied a population-based sample of 1797 older people living independently in Amsterdam, The Netherlands. They found a 1.2% 1-year prevalence of physical aggression, 1.4% for financial mistreatment, and 0.2% for neglect. And there is evidence that elder abuse has significant effects on mortality. Lachs and colleagues (1998) followed the community-dwelling cohort described above for an additional 4 years and found that subjects seen for elder mistreatment during the follow-up period had lower rates of survival (95) than the noninvestigated cohort members (40%) ( $P < .001$ ). After statistically correcting for demographic characteristics, chronic diseases, functional status, social networks, cognitive status, and depressive symptomatology, the risk of death remained higher for those subjected to elder treatment (odds ratio, 3.1; 95% confidence interval, 1.4–6.7) when compared with other members of the cohort.

## ■ Competency to Drive

The proportion of the American population that drives is rapidly aging, and it is estimated that by the year 2024, one in four drivers in the United States will be over age 65. Declining competency among these drivers is well documented: among older drivers, as a group, the frequency of crashes per mile is approximately twice that among younger drivers, and older drivers incur more fatalities per mile driven than any other age group except males under age 25 (Owsley 1997). Fife et al. (1984) found that vehicle crashes are the second major reason (falls were first) for injury-related emergency room visits among older adults, and Reuben et al. (1988) reported that crashes are the leading cause of injury-related deaths among seniors. Multiple age-related factors are likely to contribute to this phenomenon, including declining visual and auditory acuity, effects of physical and neuropsychiatric illnesses and their treatments, and declining decisional competence due to slowing of cognitive processes and reaction time and deficits in attention, concentration, and visuospatial functions (see Chapter 8).

Although available data are not adequate to determine the precise contribution of each of these factors, some generalizations are possible. McCloskey et al. (1994) found that several ophthalmological problems that affect vision and would seem likely to increase crash risk in fact did not. These included retinal disorders, macular degeneration, myopia and presbyopia, and monocular vision. Glaucoma, however, was associated with an (increased) relative risk (odds ratio) of 1.5. In another study, Foley et al. (1995) found that having cataracts severe enough to preclude reading a newspaper or recognizing a friend across the street was associated with an odds ratio of only 0.9 (the difference was not statistically significant). Similarly, hearing impairment did not increase crash risk, but when a hearing aid was worn while driving, the risk of crashing was increased by an odds ratio of 1.9 (McCloskey et al. 1994).

Koepsell et al. (1994) looked at other medical conditions common among elderly persons, including stroke; coronary disease including heart attack, angina, and coronary disease requiring surgery; chronic obstructive pulmonary disease; cancer; asthma; osteoarthritis and rheumatoid arthritis; and diabetes and found that only coronary disease (odds ratio, 1.4) and diabetes (odds ratio, 2.6) were associated with increased crash risk. Certain medications are also important contributors to crash risk. In a study involving older drivers in Tennessee, Ray et al. (1992) found that current use of benzodiazepines was statistically significantly associated with a relative risk of injurious crashes of 1.5, whereas current use of cyclic antidepressants was asso-

ciated with a twofold increased risk. Foley et al. (1995) reported that neither the use of opioids nor the use of antihistamines was associated with increased crash risk, but use of nonsteroidal anti-inflammatory agents was found to carry a relative risk of 1.9.

Foley and colleagues (1995) also studied the contribution of physical limitation, reduced ability to perform activities of daily living, various chronic symptoms such as back pain, and depressive symptoms and cognitive deficits to the risk of injurious crash in an undiagnosed population (the geographically defined Established Populations for Epidemiological Study of the Elderly cohort, comprising rural residents of Iowa over age 65). Back pain within the past 12 months and scoring in the highest quintile of depressive symptoms were both associated with an odds ratio of 1.5, whereas scoring poorly on a delayed-recall test (recalling fewer than three words) was associated with an odds ratio of 1.4.

As is suggested by the latter finding, dementia is a well-established risk factor for crashes among elderly patients. Fitten et al. (1995) conducted a prospective study comparing elderly subjects with mild Alzheimer's disease and mild vascular dementia with an age-matched, cognitively intact, healthy control group; an age-matched control group with diabetes; and a young, healthy control group. Subjects completed a standardized driving test, conducted on a course designed to reproduce low-level traffic conditions similar to a suburban drive. Both groups of subjects with dementia performed significantly more poorly on the driving test than any of the control groups. Moreover, subjects with dementia committed more serious driving errors, particularly in the more complex parts of the course. Scores on the Mini-Mental State Exam and on the Sternberg test (another test of short-term memory), along with measures of visual tracking, were the best predictors of driving scores. The healthy elderly control subjects performed as well as the healthy younger control subjects.

In an attempt to characterize more precisely the types of driving errors made by patients with dementia, Dobbs (1997) studied 115 cognitively impaired seniors (average age, 72 years), all of whom were still driving. Each subject drove a road course involving 37 maneuvers and a route requiring approximately 40 minutes of driving time. A driving evaluator in the car (who had control of an auxiliary brake pedal) recorded each driving error. Subjects were also given a battery of cognitive and motor tests considered to be predictive of driving performance. Control groups of cognitively intact elderly individuals (average age, 69 years) and cognitively intact young subjects (average age, 36 years) were studied as well.

Three types of driving errors were observed. The most

serious errors were characterized as errors that "could have resulted in a crash had the driving instructor not taken control of the vehicle or the traffic adjusted" (Dobbs 1997, p. 10). These errors were made almost exclusively by subjects with dementia, and three of the four control subjects who made errors of this type were subsequently found, by cognitive testing, to have dementia or be otherwise cognitively impaired. Another, less serious, type of error (e.g., poor positioning on turns or observational errors) was made by drivers in each group but more frequently by the subjects with dementia, and the third type of error, the sort typically made by experienced drivers (e.g., rolling stops), was not committed more often by members of any one study group. Interestingly, Mini-Mental State Exam scores did not identify *individuals* who performed poorly on the driving test, and 25% of the subjects with dementia demonstrated driving competence within the range of that of the control subjects. The latter finding is consistent with previous reports indicating that early-stage Alzheimer's disease is not associated with increased crash risk (Drachman and Swearer 1993).

Dobbs (1997) concluded that diminished driving competence among individuals with dementia is most likely to be picked up by a test protocol (course and scoring procedure) that focuses on very serious errors, but the author also acknowledged that subjecting every cognitively impaired driver to an extensive and detailed road test would be prohibitively costly. Moreover, Dobbs observed that road testing of more impaired drivers is too dangerous to undertake without specially trained evaluators and specially equipped vehicles.

Two alternative approaches for determining competency to drive have been explored and reported in the literature: cognitive assessment and driving simulation. The first involves attempts to determine the specific type and magnitude of sensory and cognitive impairments that lead to serious driving errors, and to develop practical test procedures that could be applied to large numbers of individuals. Several groups have conducted such investigations (Ball et al. 1993; Parasuraman and Nestor 1991), and deficits in attentional processes have emerged as the best predictors of incompetent driving. Most specifically, measuring *useful field of view* (UFOV), the area of the visual field in which information can be rapidly extracted without eye and head movements, appears to be valuable in this context. Three functions contribute to the ability to extract information in this way: the ability to quickly process what is seen, the ability to divide attention, and the ability to distinguish target from background. Impairments in each of these functions can result in diminished UFOV (Ball 1997). Because many neuropsychiatric illnesses common among elderly individuals can lead to deficits in these func-

tions, driving competency evaluations based on UFOV promise to be applicable across the spectrum of diagnoses, not just Alzheimer's or vascular dementia. Early results indicate that subjects with cognitive impairment and intact UFOV do not crash at a higher rate than mentally intact subjects with comparable UFOV. Ball and colleagues (1993) used greater-than-40% reduction in UFOV to distinguish high-risk from low-risk drivers, regardless of diagnosis, and were able to identify a group of high-risk drivers that were 6 times as likely to crash as age-matched low-risk drivers. Further research is expected to clarify the role of UFOV testing in the determination of competency to drive.

Other mediating factors besides UFOV may also be important in patients with Alzheimer's disease. Rizzo and colleagues (1998) examined the perception of movement and shape in 41 subjects with mild to moderate Alzheimer's disease (mean age 72.3 years) compared with 22 subjects without dementia (mean age 71.7 years), and found that the demented subjects had significantly higher thresholds for perceiving shapes defined by motion cues that did nondemented control subjects. They concluded that this deficit could negatively affect the ability to navigate and to recognize objects in relative motion.

The second approach to the assessment of driving competency involves the use of driving simulators, and some preliminary findings suggest that such simulators, designed in light of information regarding crash risk (e.g., the usefulness of measures of UFOV), may represent a practical approach to screening for incompetent drivers. To date, though, prospective studies that would allow meaningful calculation of the diagnostic confidence (i.e., the positive and negative predictive values) of such measures have yet to be published (Bylsma 1997). Lundberg et al. (1997) also suggested that in individuals with dementia, the driving simulator may measure the ability to perform a novel task (i.e., driving a simulator) more than real-life driving ability per se.

Despite the preliminary nature of the research discussed here, the problems posed by drivers with dementia have generated a significant amount of attention in scientific and policy-making circles, and several states have passed legislation requiring physicians to report individuals with dementia or other conditions involving cognitive impairment to the health department. In 1994, the Swedish National Road Administration invited representatives from several research groups in North America and Europe to meet and prepare a consensus statement on dementia and driving based on available scientific data. That group concluded the following: "1) . . . Individuals with moderate and severe dementia should not drive; 2) There is not, at present, sufficient knowledge about the way in

which different cognitive impairments influence driving ability. Much research is needed before general conclusions can be drawn concerning if and when persons with mild dementia should stop driving; 3) In the meantime, these cases should be carefully evaluated in an individualized manner" (Johansson and Lundberg 1997, p. 67). The group did not specify criteria for distinguishing moderate from severe dementia, but the article including the conference findings implied that a score of 2–3 on the Washington Clinical Dementia Rating Scale would suffice.

This emerging consensus notwithstanding, the clinician who encounters an elderly patient with cognitive or other impairment that increases the likelihood of driving difficulties, including crashes, may find himself or herself in a position involving conflicts of both obligation and interest. Loss of what many people perceive as the right to drive is experienced by some older patients as an intolerable deprivation of autonomy and freedom (even if the deprivation is of more symbolic than practical significance), and the clinician is clearly obligated to protect his or her patient from the practical inconvenience and psychological pain related to this loss, whenever it is reasonable to do so. At the same time, the clinician has an obligation to try to protect the patient from the possible untoward consequences of his or her impairment, and the clinician also has an obligation to society to protect it from the dangers posed by the significantly impaired driver. The physician's interest may be jeopardized by the legal consequences of failure to report the diagnosis of dementia, but his or her interest may also be jeopardized by reporting such a diagnosis, if the angry patient fires or sues the physician. And none of these conflicts is necessarily resolved by the development of better, more scientifically based criteria to determine high risk, for even when such criteria become available, some patients will not agree with them or will believe that theirs is the exceptional case and will mistrust and be resentful of the physician for offering sincere advice and/or for following a legal mandate. This appears to be one aspect of clinical geriatric practice that is not likely to be ameliorated by scientific or technological progress.

### ■ **Loss of Competence and Cognitive Impairment: Which Cognitive Functions Are Critical?**

Although it is clear that cognitive functions decline with advancing age even in the healthy individual, the rate of this decline and the order in which specific functions are lost vary greatly from person to person, and only broad generalizations are supported by the published data (see Chapter

8). These data suggest that normal aging is typically accompanied by mild generalized slowing of cognitive processes; mild declines in complex attention, executive functions, verbal fluency, and immediate, working, and implicit memory; and moderate declines in recent memory (Spar and La Rue 1997). Wolinsky and colleagues (Wolinsky and Johnson 1991, 1992a, 1992b; Wolinsky et al. 1992a, 1992b), using items from the Activities of Daily Living Scale and the Instrumental Activities of Daily Living Scale, identified three distinct dimensions of everyday function. These dimensions, termed *basic ADLs* (basic activities of daily living) (bathing, dressing, and toileting), *household ADLs* (meal preparation, housework, and shopping), and *advanced ADLs* (e.g., completing a medical history form, ordering merchandise from a catalog, computing taxi rates, or determining the amount due on a telephone bill), were later verified by Fitzgerald et al. (1993), who also showed that ratings for advanced ADLs (but not for the more basic categories) were predictive of scores on the Short Portable Mental Status Questionnaire. It follows that in elderly adults without dementia, the ability to perform these more cognitively complex advanced ADLs is likely to deteriorate before the ability to perform the basic and household ADLs, but data are lacking to link deterioration in these functions with impairments in specific cognitive functions.

Similarly, the specific cognitive changes associated with loss of competency in pathological states such as Alzheimer's disease are only beginning to be understood. Marson et al. (1995) studied 29 patients with probable Alzheimer's disease and 15 cognitively intact elderly control subjects. Using stepwise multiple regression analysis, they found that measures of word fluency best predicted the capacity to "provide rational reasons" for a treatment choice in both groups, although the associations were not strong ( $R^2$ : control subjects, .33; patients with Alzheimer's disease, .36). The study also produced a two-variable non-parametric discriminant function that achieved a classification rate for the entire sample of 93%, and the authors concluded that "measures of semantic word fluency/executive function . . . and of simple attention represent cognitive functions that are integrally related to the competency status of both normal control subjects and patients with [Alzheimer's disease] under a rational reasons standard" (Marson et al. 1995, p. 958).

## ■ Expert Consultation and Testimony on Competency

In addition to the inevitable competency determinations that arise in their clinical practices, such as those related to

driving, geriatric neuropsychiatrists are also particularly qualified to provide expert forensic consultation and testimony regarding questions of competency and susceptibility to undue influence. Accordingly, neuropsychiatrists need to be familiar with local statutes and case laws defining the various forms of competency. The neuropsychiatric expert may be asked to perform a contemporaneous evaluation of an individual's competency or susceptibility to undue influence or state an opinion on the competency and susceptibility to undue influence of an individual who has since died. Guidelines for such evaluations in the testamentary context have been published previously (Spar and Garb 1992) and are applicable to each of the forms of decisional competency discussed in this chapter but will not be reviewed here. However, I suggest two revisions to those guidelines.

First, it is recommended that the medical expert avoid testifying on the issue of undue influence per se because it is a legal conclusion beyond the expertise of the physician who is not also an attorney. Rather, medical expert testimony should be restricted to the question of the presence and severity of mental impairment and how the patient's *vulnerability* to influence, persuasion, manipulation, being taken advantage of, and so on is affected by that impairment. If circumstances permit, testimony on whether particular decisions made by the impaired individual are the direct result of such manipulation and persuasion may also be justified and may be permitted.

The second revision is based on Rule 703 of the Federal Rules of Evidence, which states: "The facts or data in the particular case upon which an expert bases an opinion or inference may be those perceived by or made known to the expert at or before the hearing. If of a type reasonably relied upon by experts in the particular field in forming opinions or inferences upon the subject, the facts or data need not be admissible in evidence." When the neuropsychiatrist's expert opinion is based on retrospective evaluation, direct examination should elicit testimony that clinical assessment and diagnosis of neuropsychiatric illness in the elderly is commonly reliant on information provided by sources (such as spouses, relatives, caregivers, and medical records) other than direct examination of the patient, especially if the patient is severely cognitively impaired, uncooperative, mute, or catatonic. This explanation may be important testimony if the court is inclined to believe, as some clearly are, that retrospective evaluation is not part of reasonable clinical practice and therefore not "protected" by Rule 703 and of highly questionable probative value. Anticipating and correcting this misperception can be of great value in preserving the proper weight of expert testimony.

However it is performed, the expert role is substantially different from the role of clinician, and somewhat different ethical principles obtain. The clinician's obligation to act in the best interests of the patient is replaced by the consultant's mandate to provide an honest and objective opinion and, in the testimonial context, to express that opinion in a convincing manner. Because the two obligations can easily conflict, it is usually not recommended for one individual to assume both roles for the same patient.

## ■ Implications for Clinicians

As the population ages and the public becomes increasingly aware of conditions such as Alzheimer's disease, circumstances calling for formal assessment of competency and susceptibility to undue influence are likely to arise more frequently, and neuropsychiatrists who perform these evaluations need to be familiar with applicable statutory and case law. Moreover, because the need for competency assessment is not always anticipated by patients or their attorneys, neuropsychiatrists can also provide a potentially valuable service by performing routine clinical evaluations that include enough content (e.g., comments on how the observed impairments are likely to affect competency and susceptibility to undue influence) to support future retrospective assessments of their patients' competency and susceptibility to influence.

Similarly, even if their patient contact is largely consultative in nature, neuropsychiatrists may find themselves in a position to recognize and report signs of elder abuse, to identify individuals whose deteriorating mental functions warrant consideration of guardianship or conservatorship (or less restrictive forms of assistance), and to diagnose and report conditions that may adversely affect driving safety. Accordingly, they should stay abreast of local laws and regulations that delimit the clinician's responsibilities in these areas as well.

## ■ Summary and Recommendations

There are many legal definitions of mental competency, depending on the specific task and the jurisdiction. And, as Marlowe (1994) observed, "legal concepts often do not have immediately discernible scientific counterparts . . . [and] it is therefore necessary for clinicians operationally to define or translate legal concepts into observable, definable, and measurable scientific terms" (p. 12). In a study de-

signed in part to assess how successfully this translation has been effected by psychiatric expert witnesses, colleagues and I (Spar et al. 1995) submitted the following open-ended statement to 300 probate judges around the United States: "Psychiatric expert testimony on matters of mental capacity and susceptibility to undue influence would be most useful to the court if physicians would . . ." (p. 396). The only recurring response (provided by 14 of the 73 who completed the statement) was, in essence, "use lay terms and avoid technical language." A large majority of 119 respondents to other, more structured, survey questions also agreed that psychiatric testimony on impaired mental capacity and susceptibility to undue influence should focus on the specific mental function deficits that underlie the observed impairment (Spar et al. 1995), and a slightly smaller majority agreed that experts should use standardized tests in their evaluations.

Supported by these results, the two senior authors, assisted by a coalition of attorneys and other experts, drafted and helped pass a California law called the Due Process in Competence Determinations Act (DPCDA), which went into effect January 1, 1996. Under the DPCDA (Table 41-4), judges are authorized to require experts testifying on impaired competency to specify at least one mental function deficit that accounts for the alleged incompetency and to explain how that deficit is connected to that impairment. (For example: "Mr. P demonstrated profound deficits in remote memory, as evidenced by an inability to name any presidents, identify the countries that fought in the Gulf War, or recall the names of all of his children or that he had four grandchildren. Because of this deficit, he lacked the capacity to remember and understand his relations to his living descendants and therefore failed to meet one of the criteria for testamentary capacity.") The statute includes a list of mental functions that we believed would be familiar to mental health professionals in many disciplines and comprehensible to attorneys, judges, and jurors and that describes functions that lend themselves to measurement or, at a minimum, description in numbered terms used by widely available assessment instruments. Glass (1997), concluding a review of proposed approaches to competency determination published during the past two decades, stated: "There is still no agreement on either the exact criteria or the methods of assessing mental competency" (p. 32). Although the DPCDA is not offered as a solution to this problem, it is hoped that by facilitating the process of direct and cross-examination, demystifying the process of psychiatric evaluation, and encouraging measurement, more consistent and therefore more just outcomes of formal competency determinations will follow.

**TABLE 41-4. Due Process in Competence Determinations Act**

810. The Legislature finds and declares the following:

(a) A person who has a mental or physical disorder may still be capable of contracting, conveying, marrying, making medical decisions, executing wills or trusts, and performing other actions.

(b) A judicial determination that a person suffers from one or more mental deficits so substantial that, under the circumstances, the person should be deemed to lack the legal capacity to perform a specific act, should be based on evidence of a deficit in one or more of the person's mental functions rather than on a diagnosis of a person's mental or physical disorder.

811. (a) A determination that a person is of unsound mind or lacks the capacity to make a decision or do a certain act, including, but not limited to, the incapacity to contract, to make a conveyance, to marry, to make medical decisions, to vote, or to execute wills or trusts, shall be supported by evidence of a deficit in at least one of the following mental functions, subject to subdivision (b):

- (1) Alertness and attention, including, but not limited to, the following:
  - (A) Level of arousal or consciousness.
  - (B) Orientation to time, place, person, and situation.
  - (C) Ability to attend and concentrate.
- (2) Information processing, including, but not limited to, the following:
  - (A) Short- and long-term memory, including immediate recall.
  - (B) Ability to understand or communicate with others, either verbally or otherwise.
  - (C) Recognition of familiar objects and familiar persons.

(D) Ability to understand and appreciate quantities.

(E) Ability to reason using abstract concepts.

(F) Ability to plan, organize, and carry out actions in one's own rational self-interest.

(G) Ability to reason logically.

(3) Thought processes. Deficits in these functions may be demonstrated by the presence of the following:

(A) Severely disorganized thinking.

(B) Hallucinations.

(C) Delusions.

(D) Uncontrollable, repetitive, or intrusive thoughts.

(4) Ability to modulate mood and affect. Deficits in this ability may be demonstrated by the presence of a pervasive and persistent or recurrent state of euphoria, anger, anxiety, fear, panic, depression, hopelessness or despair, helplessness, apathy or indifference, which is inappropriate in degree to the individual's circumstances.

(b) A deficit in the mental functions listed above may be considered only if the deficit, by itself or in combination with one or more other mental function deficits, significantly impairs the person's ability to understand and appreciate the consequences of his or her actions with regard to the type of act or decision in question.

(c) In determining whether a person suffers from a deficit in mental function so substantial that the person lacks the capacity to do a certain act, the court may take into consideration the frequency, severity, and duration of periods of impairment.

(d) The mere diagnosis of a mental or physical disorder shall not be sufficient in and of itself to support a determination that a person is of unsound mind or lacks the capacity to do a certain act.

# Index

Page numbers printed in **boldface** type refer to tables or figures.

- Abbreviated Injury Scale (AIS), 623
- Abscess, of brain, 686  
cerebrospinal fluid profile in, **677**  
dementia due to, 500
- Abuse, of elders, 955–956
- Accidents, as cause of death, **21**
- Acetaminophen, metabolism of, **757**
- Acetazolamide, neuropsychiatric disorders induced by, 726
- Acetophenazine, dosage of, **800**
- Acetylcholine (ACh)  
age-related changes in, **41**, 57–58  
aggression and, 480  
behavioral alterations associated with disturbances of, **100**  
origins and destinations of, **99**
- Action-intentional neglect, 731
- Activities of daily living (ADLs)  
assessment of, 112–113, 139  
depression and, following stroke, 605, **606**  
limitation of, epidemiology of, 26, **26**  
neglect and, 929
- Acyclovir, neuropsychiatric disorders induced by, 725
- Adapin (doxepin)  
dosage of, **783**  
for pain, 424, 783  
side effects of, **580**
- Adaptive approach, for cognitive rehabilitation, 923
- Adderall, 790
- Addictions  
definition of, **368**  
limbic system and, **91**, 92
- Adjudicative competence, 946–947
- Admission evaluation, for nursing homes, 898
- Adolescent history, 111–112
- Adrenal gland, age-related changes in, **63**
- Adrenal medullary transplantation, for Parkinson's disease, 567
- $\alpha$ -Adrenergic blockage, with antipsychotic drugs, **802**
- $\beta$ -Adrenergic blockers. *See also specific drugs*  
for anxiety disorders, 358  
for dementia, 810  
depression induced by, 709  
drug interactions of, 721–722  
during electroconvulsive therapy, 847  
for essential tremor, 533  
metabolism of, **757**  
sleep disorders induced by, 712
- Adrenergic system, in normal aging and common diseases, **701**, 702
- Adrenocorticotrophic hormone (ACTH), neuropsychiatric disorders induced by, 726
- Adrenoleukodystrophy (ALD), 679–680
- $\alpha$ -Adrenoreceptors, pain and, 420
- Adriamycin, metabolism of, **757**
- Adulthood, history of, 112
- Advance directives  
competency to execute, 948–949  
ethical issues concerning, 939
- Adventitia, arterial, 49
- Affect  
assessment of, 117  
in Parkinson's disease, with dementia, 573
- Affective disorders. *See* Bipolar disorder; Depression; major depression; Mania; Mood disorders
- Affective symptoms, psychotic, 332
- African American elderly persons, proportion of population, 18, **19**
- Age  
alcohol use and abuse and, 371–372  
delirium and, 446  
neuropsychiatric effects of traumatic brain injury and, 635, **635**, 636–637, **637**
- Age-appropriate normative data, 144
- Age-associated memory impairment (AAMI), 165–175  
age-inappropriate forgetfulness and, 169–170  
alternative approaches to, 169  
biological bases of, 173  
definitions related to, 167  
diagnostic criteria for, 167–168  
original, applicability of, 170–172  
as diagnostic entity, 172  
future research strategies for, 173–174  
historical background of, 165–167  
memory tests and  
clinical use of, 174–175  
differential sensitivity of, 172  
utility of construct, 168–169
- Age-consistent memory impairment (ACMI), 167
- Aggression, 477–485  
in dementia, treatment of, 806–811  
depression associated with, 472  
epidemiology of, 478–479  
etiology of, 480–481  
evaluation of, 481–482, **482**  
management of, 482–485, **486**  
in mentally retarded elderly persons, 471–472  
in nursing homes, 899–900  
psychopathology related to, 479  
in seizure disorders, 661
- Aging  
alcohol neurotoxicity and, 375–376  
of brain. *See* Anatomic brain  
imaging, aging effects on brain structure and; Brain, aging of  
demography of, 7  
disease distinguished from, 57  
DNA changes due to, 907  
epidemiology of, 17–28  
chronic conditions and, 24–25, **25**  
comorbidity and, 25  
functional limitations and, 25–26, **26**

- Tramadol, metabolism of, 757
- Transcortical aphasia  
 motor, 733–734  
 sensory, **136**, 734, **734**
- Transcortical sensory aphasia, **136**
- Transcranial magnetic stimulation (TMS), 279, 851  
 repetitive, for depression, 791
- Transinstitutionalization, 893
- Transmission disequilibrium test (TDT), 911
- Transmitter systems  
 age-related changes in, 57–58, 60–62  
 aggression and, 480  
 behavior and, 98, **99**, **100**
- Tranlycypromine (Parnate), dosage of, 788, **788**
- Traumatic brain injury (TBI), 621–646  
 alcohol and, 627  
 Alzheimer's disease and, 643–645  
 $\beta$ -amyloid deposition and, 644  
 apolipoprotein E-4 allele and, 644–645  
 dementia pugilistica and, 643  
 epidemiological studies of, 643–644  
 dementia differentiated from, 635–636, **636**  
 epidemiology of, 626, **627**  
 history of, 111  
 mechanism of, 626, **627**  
 neuropsychiatric consequences of, 631–643  
 animal studies of, 634  
 dementia, 503  
 diagnosis of, 638–639  
 human studies of, 634–637  
 management of, 639–643  
 mania, 614  
 of mild traumatic brain injury, 631–632  
 of severe traumatic brain injury, 632–634  
 treatment of, 640–641, **641**  
 normal aging differentiated from, 634–635  
 outcome following, 625–626, 627–630  
 indices of, 629  
 measurement of, 625  
 mortality and, 629–630, **630**, **631**  
 neurological sequelae and, 628–629, **629**  
 predictors of, 625–626  
 pathophysiology of, 623–625  
 of primary brain injury, 623–624  
 of secondary brain injury, 624–625  
 prior, 627  
 severity of, 622–623, **623**  
 terminology related to, 622–623  
 types of, 622
- Traumatic injuries, dystonia following, 547
- Trazodone (Desyrel)  
 for dementia, **505**, **506**, 809–810  
 for depression, following stroke, 608  
 dosage of, **783**  
 for insomnia, 805  
 neuropsychiatric disorders induced by, 724  
 for pain, 425  
 side effects of, 477
- Tremor, **532**, 532–534  
 cerebellar, 534  
 drug-induced, **711**  
 cerebellar outflow, 534  
 drug-induced, 534  
 dystonic, 544  
 essential, 533  
 familial, 533  
 kinetic (intention), 532, **532**, 534  
 midbrain (“rubral”), 534  
 orthostatic, 534  
 parkinsonian, neuroleptic-induced, 534  
 physiological, drug-induced, **711**  
 postural, 532, **532**  
 primary writing tremor, 533–534  
 rest, 532, **532**  
 senile, 533
- Triacetyloleandomycin, metabolism of, **757**
- Triamcinolone, neuropsychiatric disorders induced by, 726
- Triamterene + hydrochlorothiazide (Dyazide), anticholinergic drug level in, **448**
- Triazolam  
 dosage of, **805**  
 metabolism of, **755**, 796
- Tricyclic antidepressants (TCAs). *See* Heterocyclic antidepressants (HCAs), tricyclic; *specific drugs*
- Trifluoperazine  
 for dementia, **506**  
 dosage of, **800**
- Triflupromazine, dosage of, **800**
- Trigeminal neuralgia, treatment of, 424, 425
- Trihexyphenidyl  
 neuropsychiatric disorders induced by, 723  
 for Parkinson's disease, 565
- Trimethoprim, neuropsychiatric disorders induced by, 726
- Trimipramine (Surmontil)  
 dosage of, **783**  
 metabolism of, **755**
- Tropic factors, aging and, 62
- Trusts  
 competency to execute, 952  
 personal, **955**
- Tryptophan, neuropsychiatric disorders induced by, 728
- Tumors. *See* Cancer; Neoplastic disease
- Turner's syndrome, 34
- Undue influence, competency and, 952–954
- Unilateral neglect, 135
- Urinary incontinence, in hydrocephalic dementia, 497, 498
- Urological side effects, with antidepressants, **785**
- Useful field of view (UFOV), competency to drive and, 957–958
- Usual aging, 145
- Validity, ecological, of neuropsychological tests, 159
- Valproate  
 neuropsychiatric disorders induced by, 723  
 for seizure disorders, 662
- Valproic acid (Depakene), 325, **325**, **662**  
 for bipolar disorder, 794  
 interactions of, 795  
 neuropsychiatric side effects of, 325  
 for pain, 425–426  
 psychiatric effects of, 663  
 for self-injurious behaviors, in mentally retarded elderly persons, 471  
 side effects of, 795
- Vascular chorea, 539–540
- Vascular dementia (VaD), 116, 136, 492–496, **494**  
 clinical features of, 493  
 diagnostic criteria for, **494**

- differential diagnosis of, 157, 297, **297**, 299–300, **300**  
epidemiology of, 493  
evaluation of, 496, **497**, **498**  
hypoperfusion of watershed areas, 495, **495**  
multi-infarct, 492, 493  
    multi-infarct disease differentiated from, 341–342  
neuropsychological profile in, **156**  
small-vessel disease, 495, **495**  
strategic single-infarct, 493, 495, **495**  
subtypes of, 493, **495**, 495–496  
treatment of, 496
- Vascular depression, 316
- Vascular system, age-related changes in, 46, 49–50, **49–55**, 52
- Vasculitides, 687–690
- Vasoactive intestinal peptide, 102
- Vasodilators, for cognitive decline, 814–815
- Vegetative functions, survey of, 112
- Venlafaxine (Effexor)  
    for anxiety, 358, 799  
    for dementia, 811  
    for depression, 783  
    major, 322, **323**  
    dosage of, **783**  
    metabolism of, **755**  
    neurotransmitter effects of, **579**  
    for pain, 425  
    side effects of, **580**
- Ventral striatum, 97
- Ventricular ectopy, during  
    electroconvulsive therapy, 847
- Ventricular enlargement, traumatic  
    brain injury and, 624
- Ventricular size  
    aging and, **186**, 186–188, **187**  
    neuropsychological correlates of, 194–195  
    in late-life—onset psychosis, **335**, 336
- Ventricular-to-brain ratio (VBR), in  
    late-life—onset psychosis, **335**, 335–336
- Verapamil  
    for bipolar disorder, 794  
    interactions of, 795  
    metabolism of, **758**  
    for pain, 426  
    side effects of, 795
- Veratrum, neuropsychiatric disorders  
    induced by, 728
- Verbal descriptor scale (VDS), 416
- Verbal fluency  
    assessment of, 129  
    for assessment of response control, 132
- Vigabatrin (Sabril), **662**  
    for pain, 426  
    psychiatric effects of, 663
- Vinblastine, metabolism of, **757**
- Vincristine, neuropsychiatric disorders  
    induced by, 726
- Violence. *See also* Aggression  
    history of, 111
- Viral infections, 682–685. *See also specific infections*
- Vision  
    assessment of, 119  
    competency to drive and, 957–958
- Visual agnosia, 134
- Visual analogue scale (VAS), 416
- Visual cortex, primary, 84
- Visual fields, assessment of, 119
- Visual Form Discrimination Test, 153
- Visual impairment, **65**, 65–66  
    epidemiology of, 25, **25**
- Visual object agnosia, 87, 738–739, **739**
- Visual-spatial-motor deficits, alcohol  
    abuse and, 376–377
- Visual systems  
    dorsal, 738, **738**  
    ventral, 738–739, **739**
- Visuoconstructive processes, assessment  
    of, tests for, 153–154
- Visuoperceptual function, deficits of, **737**, 737–739  
    in Parkinson's disease, 568
- Visuospatial function  
    assessment of, 129, **130**, **131**  
    tests for, 153–154  
    deficits of, in Alzheimer's disease, 513  
    hemispheric dominance for, 89  
    in Parkinson's disease, with  
        dementia, 573
- Vitamin B12 deficiency, 67  
    dementia due to, 502–503
- Vitamin E  
    for Alzheimer's disease, 11  
    for cognitive decline, 816
- Vivactil (protriptyline)  
    dosage of, **783**  
    for pain, 425
- Vocal tics, 551–552
- Volume of distribution, 780
- Voluntariness, competency and,  
    952–954
- Wandering, by nursing home residents,  
    899
- Warfarin  
    anticholinergic drug level in, **448**  
    metabolism of, **758**
- WCST, 153
- Wechsler Abbreviated Scale of  
    Intelligence, 151
- Wechsler Adult Intelligence Scale III  
    (WAIS-III), 145, 151, 153, 166  
    ventricular size and, 195
- Wechsler Adult Intelligence Scale—  
    Revised (WAIS-R), 151, 153, 166
- Wechsler Memory Scale (WMS), 172,  
    174  
    corpus callosum and, 195  
    ventricular size and, 195
- Wechsler Memory Scale III (WMS-III),  
    145, 150, 151, 166, 174
- Wechsler Memory Scale—Revised  
    (WMS-R), 145, 150, 151, 166, 172
- Wegener's granulomatosis, 689
- Wellbutrin. *See* Bupropion (Wellbutrin)
- Werner's syndrome, 34
- Wernicke's aphasia, 115, 128, 734, **734**  
    treatment of, 925
- Wernicke's area, 84
- White matter, of brain  
    abnormalities of, in late-life—onset  
        psychosis, **335**, **336**, 336–337  
    age-related changes in, 44–45  
    age-related reduction of, 191  
    connections of, 85–87, **87**, **88**
- White matter disease, neuroimaging in,  
    514
- Widowhood, sleep and, 404
- Wills, competency to make, 951–952
- “Will substitution test,” 953
- Wilson's disease, **97**
- Withdrawal  
    from alcohol, 377  
    cognitive deficits following,  
        377–378  
    from benzodiazepines, 383–384, 798,  
        **798**  
    factors affecting severity of  
        symptoms of, 384  
    presentation in elderly persons,  
        384  
    types and frequency of symptoms  
        in, 383–384, **384**  
    from opioids, 424

- Women. *See also* Sex  
ability to be independent, 28
- Word list test, for assessment of  
memory, 128
- Working memory, in Alzheimer's  
disease, 513
- Writer's cramp, 546
- Writing ability, assessment of, 129
- Writing tremor, primary, 533–534
- Xanthomatosis, cerebrotendinous, 680
- Xenon-133 technique, 240
- X-ray CT, 183–184
- Yohimbine, neuropsychiatric disorders  
induced by, 728
- Zacopride, for cognitive decline,  
816
- Zarontin (ethosuximide), **662**  
metabolism of, 758  
neuropsychiatric disorders induced  
by, 723  
psychiatric effects of, 663
- Zidovudine (AZT), neuropsychiatric  
disorders induced by, 728
- Ziprasidone, 800
- Zofran (ondansetron hydrochloride),  
for late-life—onset psychosis,  
340
- Zoloft. *See* Sertraline (Zoloft)
- Zolpidem  
delirium and cognitive impairment  
induced by, 708  
dosage of, **805**  
for insomnia, 805
- Zonisamide, for pain, 426
- Zotepine, for psychoses, drug-induced,  
586
- Zyprexa. *See* Olanzapine (Zyprexa)
