By far the most complete analysis of the *dra* system has been in *Rs. rubrum* (Fitzmaurice et al., 1989), although work in *Rb. capsulatus* has demonstrated a substantially similar system (Masepohl et al., 1993). In *Rs. rubrum*, the *dra* genes were identified using degenerate oligonucleotides based on the sequences of DRAG and DRAT. The *draT* and *draG* genes are adjacent to each other and are probably cotranscribed. These genes are immediately adjacent to the *nifHDK* genes, which are transcribed in the opposite direction. The sequences of *draT* and *draG* are unremarkable and possess no obvious similarity to genes in the data banks. Immediately adjacent to *draTG* is another ORF that does possess similarity to ORF-14 in *Azotobacter vinelandii* (Dean and Jacobson, 1993)—ORF-14 has been recently termed *nifO* by Rodriguez-Quinones et al. (1993)—and similarity to the *arsC* of *E. coli* (Rosen et al., 1991), but the significance of these similarities is unclear.

The cloned *dra* region of *Rs. rubrum* has also been moved into other diazotrophs, including the non-phototrophic microaerophile *Azospirillum brasilense*. This organism itself possesses a *dra* system that ADP-ribosylates dinitrogenase reductase in response to fixed nitrogen or anaerobiosis, but not darkness (Fu et al., 1989; Zhang et al., 1992). A *draT*⁻ mutant of *A. brasilense*, carrying the *draTG* genes from *Rs. rubrum*, responds in a fashion similar to the wild-type, indicating proper regulation of the heterologous DRAG and DRAT. Similarly, introduction of *draTG* from either *Rs. rubrum* or *A. brasilense* into *Klebsiella pneumoniae*, which normally lacks this system, results in regulated ADP-ribosylation of dinitrogenase reductase in response to added fixed nitrogen (Fu et al., 1990). These two sets of results strongly suggest that the signal transduction pathway, whether composed of proteins or small molecules, is sufficiently similar in the diverse organisms to effect

apparently proper regulation of DRAG and DRAT.

The *draTG* genes have also been identified in *Rb. capsulatus*, using synthetic oligo probes (Masepohl et al., 1993). In this organism, the *dra* region is not located near the *nif* genes, nor is there a downstream ORF similar to that noted in the above organisms. An insertion in *draT* of *Rb. capsulatus* not only eliminates the reversible ADP-ribosylation of dinitrogenase reductase in response to both darkness and fixed nitrogen, it also apparently eliminates a second regulatory mechanism, which is described further in section IIF below. If this result is confirmed, it indicates that there is another role for DRAT besides ADP-ribosylation of dinitrogenase reductase; a possibility might be the ADP-ribosylation of another protein necessary for nitrogenase activity. DRAT also ADP-ribosylates the alternate dinitrogenase reductase in this organism in response to darkness or ammonia, but does not in response to molybdenum addition.

E. Regulation of DRAG/T Activities

In a regulatory cascade such as the DRAT/DRAG system, it would be possible to achieve control by regulating one or both enzymes. Furthermore, the regulatory enzymes might have either static states (i.e. on or off) or a range of activities. A range of activities can be achieved by partial activation of each enzyme molecule or by controlling a population of enzyme molecules so that some enzyme molecules are active while others are inactive. In the case of DRAT/DRAG, it appears that both enzyme molecules are posttranslationally regulated and that the regulation is on/off.

Demonstration of the reversible modification of dinitrogenase reductase was performed by Kanemoto (1984), who showed that the nitrogenase system could be subjected to repeated cycles of switch-off/switch-on. The modified subunit of dinitrogenase reductase can be separated from the unmodified subunit by electrophoresis on SDS gels, and this allows the analysis of the modification status of the protein. Modification of one subunit of the dimer renders dinitrogenase reductase completely inactive, and it is not possible to modify both subunits of the dimer at one time. The recent crystal structure determination by Georgiadis et al. (1992) shows that the two sites for modification are very close to each other at the surface of the protein and suggests that modification of one subunit blocks the modification

of the other. The acetylene reduction assay allows an estimation of the in vivo nitrogenase activity. A comparison of modification status of dinitrogenase reductase with the whole-cell nitrogenase activities of samples taken during dark/light cycles allowed Kanemoto to conclude that the modification was reversible. Because three cycles of modification/demodification could be observed, it was concluded that sites for modification were being regenerated on the dimeric dinitrogenase reductase protein in vivo.

The conclusion that ADP-ribosylation is responsible for the loss of activity in vivo was confirmed when mutants lacking the system were prepared (see discussion below). Yakunin and Gogotov (1984) proposed that the covalent ADP-ribosylation of dinitrogenase did not affect the ability of the *Rb. capsulatus* enzyme to donate electrons to dinitrogenase if ferredoxin served as the electron donor, and that the loss of activity in vitro was an artifact of the use of dithionite as the electron donor. It is difficult to accept this proposal in light of the overwhelming biochemical and genetic evidence, and Gotto and Yoch (1985a) have directly refuted this hypothesis.

Evidence that DRAG is regulated comes from a pulse-chase experiment in which the turnover of ^{32}P of ADP-ribose bound to dinitrogenase reductase during switch-off conditions was monitored (Kanemoto and Ludden, 1984). *Rs. rubrum* cells were grown under nitrogenase derepressing conditions in the presence of $^{32}\text{PO}_4^{2-}$ and then treated with ammonium to initiate the modification of dinitrogenase reductase. The cell culture was then treated with an excess of $^{31}\text{PO}_4^{2-}$ to chase the label out of ^{32}P -labelled molecules in the cell. The amount of ^{32}P label remaining in ADP-ribose attached to dinitrogenase reductase was monitored and found to have a half-life 3–4 times longer than the half-life of the total cell P, indicating that under the conditions tested, DRAG was not functioning. Under conditions where DRAG is reactivating dinitrogenase reductase, ADP-ribose is removed with a half-life of 4 minutes.

Evidence that DRAT is regulated comes from experiments with *draG* mutants (Liang et al., 1991). Such mutants express *draT* and accumulate DRAT activity. When *draG*⁻ cells are grown under nitrogenase derepressing conditions, the significant majority of dinitrogenase reductase accumulates in the active form until the signal for modification (darkness or ammonium) is given to the culture. Upon signaling, dinitrogenase reductase is irre-

versibly ADP-ribosylated in these cells. The interpretation of this result is that DRAT is regulated in an on/off manner in the cell because dinitrogenase reductase was not modified until the signal to modify was given, thus DRAT was off. Analysis of the dinitrogenase reductase present in the cell indicated that, prior to the negative stimulus, very little of the dinitrogenase reductase was modified, indicating that only trace DRAT activity was present.

DRAT and DRAG have been overexpressed approximately 200-fold in *Rs. rubrum* and the effects of overexpression on the regulation of DRAT and DRAG activities have been studied (Grunwald et al., 1995). In a DRAG overexpresser (DRAT at normal levels) the regulatory system is overcome, and at any time after signaling with ammonium or darkness, only a small percentage of the dinitrogenase reductase is in the modified form. In a DRAT overexpresser (DRAG at normal levels) the regulatory cycle is maintained. Surprisingly, a small amount of DRAG is able to counter the activity of a large excess of DRAT; apparently, the regulation of DRAT is maintained in the presence of a large amount of DRAT, indicating that its regulation is not dependent on stoichiometric amounts of a gene product or small molecule that is present in amounts equivalent to the concentration of DRAT in the wild-type. However, the whole cell nitrogenase activity (acetylene reduction) in a DRAT overexpresser is only 5–10% that of wild-type cells, although the nitrogenase proteins accumulate to at least 50% of the levels observed in wild-type. One explanation for this might be that DRAT binds to dinitrogenase without ADP-ribosylating the protein. At its normal levels, this is not a problem as it ties up less than a percent or two of the total dinitrogenase reductase. However, when DRAT is overexpressed 200-fold, it might tie up a significant amount of the dinitrogenase reductase protein, inhibiting activity. This model has yet to be tested.

Very little is known about proteins that might be involved in the regulation of DRAG and DRAT activities. Mutations downstream of the *dra* region have been isolated and analyzed (Fitzmaurice et al., 1989). ORF mutants show a faster time course of modification in vivo than the wild-type, but show normal kinetics of de-modification of dinitrogenase reductase (switch-on) (Liang et al., 1991). The significance of this relatively small effect on ADP-ribosylation is unclear. In *Rb. capsulatus*, mutants have been isolated with constitutive *nif* expression,

but with apparently normal ADP-ribosylation; *glnB* was one of the affected loci (Hallenbeck, 1992). This result indicates that there is at least some independence between the systems that regulate the transcription of *nif* genes and those that posttranslationally regulate *nif* gene products. Analysis of *ntfBC* mutants of *A. brasilense* suggest that the ADP-ribosylation of dinitrogenase reductase in response to ammonium or anaerobiosis occurs through independent signal transduction pathways (Zhang et al., 1994).

A number of metabolites have been analyzed as potential regulatory agents in the DRAT/DRAG system. Ammonium ion, glutamine, and other nitrogen sources have no observable effect on DRAT or DRAG activity in vitro (Saari et al., 1986; Lowery and Ludden, 1988). The relative in vivo concentrations of ATP, ADP and AMP during switch-off and switch-on have been estimated in several studies (Paul and Ludden, 1984; Nordlund and Hoglund, 1986). In these studies, either darkness, ammonium ion or other effectors leading to switch-off have been employed to perturb the system. In no case has a consistent correlation with an increase in nucleotide concentration been observed. The in vivo glutamine level has been reported to correlate with the onset of switch-off, but other studies have shown that neither glutamine nor any other amino acid level is obligately correlated with switch-off. The pools of pyridine nucleotides have been investigated as well (Nordlund and Hoglund, 1986), and no change in their pools has been tied to changes in the modification status of dinitrogenase reductase. However, Soliman and Nordlund (1992) have provided interesting evidence that exogenously-supplied NAD can stimulate switch-off, and they have shown that label from ^{32}P -NAD supplied to the cells can be incorporated into dinitrogenase reductase.

Because a divalent metal ion such as Mn^{2+} is required for DRAG activity, fluxes in divalent ion pools have been proposed to play a role in regulation of the DRAT/DRAG system. Yoch (1979) first studied Mn^{2+} -starved cells for the ability to regulate nitrogenase activity. His results showed that the cells grew with glutamate as the N source but produced only low levels of nitrogenase activity. These cells were able to switch-off nitrogenase activity. Nordlund and coworkers (Cadez and Nordlund, 1991) have investigated the Ca^{2+} concentration in the medium of *Rs. rubrum* cells during switch-off/switch-on and have observed transients in the concentration of this

ion, suggesting a role for this ion in the regulatory scheme.

Nutritional conditions are important in determining the ability of *Rs. rubrum* to regulate nitrogenase. Munson and Burris (1969) noted that the best activity was obtained in extracts of cells grown under nitrogen starvation. Yoch and Cantu (1980) provided an explanation for this observation when they showed that nitrogen-starved cells were incapable of switch-off. The reason for the inability of nitrogen-starved cells to switch-off is not known, as both DRAT and DRAG are present in these cells and active in extracts (Lowery et al., 1986).

While most experiments on the regulation of nitrogenase have been performed in light-grown cells, *Rs. rubrum* and certain other phototrophs are capable of dark-anaerobic fermentation of pyruvate and nitrogen fixation under these conditions (Uffen and Wolfe, 1970; Madigan et al., 1979; Schultz et al., 1985). Switch-off of nitrogenase occurs in dark pyruvate-grown cells in response to ammonium (Schultz et al., 1985).

While much of the work on regulation of nitrogenase by reversible ADP-ribosylation has been performed in *Rs. rubrum*, the system has also been demonstrated in *Cm. vinosum* (Gotto and Yoch, 1985b), *Rb. capsulatus* (Hallenbeck et al., 1982c; Gotto and Yoch, 1985a; Jouanneau et al., 1989), and *Rhodospseudomonas palustris* (Alef et al., 1981). Evidence against the presence of the system in *Rhodospseudomonas spheroides* has been presented (Jones and Monty, 1979). The system has also been extensively studied in the non-photosynthetic bacteria of the genus *Azospirillum* (Hartmann et al., 1986; Fu et al., 1989; Burris et al., 1991; Zhang et al., 1993).

F. Non-ADPR Regulatory Mechanisms

Although the original observations of Gest and Kamen (1949) can be explained by the action of the reversible ADP-ribosylation system described above, it has become apparent that there are additional complexities in the regulation of nitrogenase activity in phototrophs. The presence of the phenomenon described below not only suggests such a case but serves to remind us that the presence of one regulatory system by no means precludes organisms from elaborating additional, even redundant, mechanisms for regulation.

Two lines of evidence indicate that *Rb. capsulatus* responds to the addition of fixed nitrogen by a

mechanism in addition to the ADP-ribosylation of dinitrogenase reductase (Pierrard et al., 1993). First, following addition of fixed nitrogen to wild-type, acetylene reduction activity falls much faster and to a greater extent than explained by a direct measurement of ADP-ribosylated dinitrogenase reductase. Second, partially active *nifH* mutants, in which the target arginine is replaced by another amino acid, are unable to be ADP-ribosylated but continue to show a rapid loss of nitrogenase activity in response to added fixed nitrogen. In contrast to ADP-ribosylation, this regulatory response does not occur in response to darkness.

The biochemical basis for this effect is unknown, but recent results suggest that it does not occur in a *draT* mutant (Masepohl et al., 1993). This result is consistent with several models: (1) In this organism, DRAT has another substrate in the cell, whose ADP-ribosylation is more rapid than that of dinitrogenase reductase and leads to a loss of nitrogenase activity. Because there is no detectable effect on the electrophoretic mobility of dinitrogenase itself in these strains, a reasonable candidate might be a protein involved in electron transfer to dinitrogenase reductase. Presumably, if it were present at a lower concentration than dinitrogenase reductase (as is the case with flavodoxin in *Klebsiella pneumoniae*), its ADP-ribosylation might be both rapid and complete, relative to that of dinitrogenase reductase. (2) DRAT might physically block activity of dinitrogenase reductase by other mechanisms, though there would appear to be too little DRAT to accomplish this task. The explanation of this surprising result will await further experimentation, but serves as a reminder that the presence of any single regulatory mechanism does not preclude the presence of redundant ones in the same organism. There is currently no evidence for the above response in *Rs. rubrum*.

Acknowledgments

Results from the authors' laboratories reported here have been generously supported by NSF and by the USDA/NRI Competitive Grants Program. The authors thank Gary Nielsen, Doug Lies, Yaoping Zhang, Sandy Grunwald, Stefan Nordlund and Werner Klipp for sharing results of their work before publication. The authors thank Ms. Gail Stirr for her help in editing and preparation of the manuscript.

Summary

Aerobic and anaerobic electron transport chains of facultative phototrophs have been of increasing interest because of their diverse organization of redox carriers and their adaptive regulatory mechanisms of gene expression. During the last decade, studies on the biochemistry of bacterial redox complexes such as NADH-deh and *bc*₁ from *Rhodobacter* species, and Cyt *c*-oxidases of *aa*₃ type from *Rb. sphaeroides* and *Chloroflexus aurantiacus*, have revealed the presence of fewer subunits than corresponding eukaryotic enzymes. This evidence has provided new insights into the biochemical evolution of respiration and also useful indications on structure/function relationships. Recent advances in studying the aerobic and anaerobic respiratory pathways of facultative phototrophs have taken advantage of modern molecular genetics. In particular, the role of soluble cytochrome *c*₂, until recent years considered to be essential for electron transport in the two closely related species *Rb. capsulatus* and *Rb. sphaeroides*, has been better defined. Indeed, it is now clear that two different classes of alternative electron carriers (soluble Cyt iso-*c*₂ and membrane-bound Cyt *c*_y) can operate between the membrane-bound redox complexes instead of, or along with, the Cyt *c*₂. The presence of multiple electron carriers between redox complexes suggests that Cyt *c*_y-like components might be more widely spread among those photosynthetic bacteria where photooxidizable soluble *c*-type hemes are not readily detected, e.g. *Cf. aurantiacus*. The outstanding metabolic versatility of *Rb. capsulatus* made also possible the use of mutants defective in redox carriers of aerobic respiration for the analysis of anaerobic electron transport pathways. Thus, if the role of Cyt *c*₂ in anaerobic light-driven electron flow has partially been reshuffled, Cyt *c*₂ seems to

play a key role in the dark anaerobic pathways leading to NO_2 and N_2O reduction. The use of Cyt *c*-deficient mutants also demonstrated that the ubiquinol/Cyt *c* oxidoreductase is not required for growth with DMSO or TMAO as electron acceptors. These dark anaerobic processes, however, cannot sustain a 'consistent' cell growth in the presence of non fermentable substrates; thus, they must be regarded as advantageous metabolic systems facilitating anaerobic growth in the dark and/or in the light.

I. Introduction

The anoxygenic phototrophic bacteria represent, in terms of morphological, biochemical, and physiological features, a quite heterogeneous group which is unified by the common property of growing by means of an anoxygenic type of photosynthesis. Under natural conditions, however, phototrophic bacteria receive light during only part of the solar day, and even if their growth is restricted to this period, it is likely that they display some alternative metabolic capacity during dark periods. In this respect, several species of purple and green phototrophic bacteria are therefore regarded as 'facultative' in that they can also obtain energy from aerobic and anaerobic dark growth.

This chapter will first address some general remarks on the physiology of facultative phototrophs, and then discuss in detail the biochemical processes that lead to the use of oxygen and other electron acceptors, e.g. nitrate or dimethyl sulfoxide, to convert the oxidation of various substrates to a form immediately available to growth and development.

A. Physiological Aspects: Some General Remarks

Facultative phototrophs are widely distributed in nature, although rarely in high concentrations (Pfennig, 1978; Gest and Favinger, 1983) (see Chapters 1, 4 and 41 by Imhoff, van Gemerden and Mas, and Tabita, respectively, for coverage of taxonomy, physiology, and ecology of anoxygenic phototrophs). The metabolic options available to purple nonsulfur bacteria, e.g. *Rhodobacter*, *Rhodospirillum*, *Rhodopseudomonas*, put them in a position to survive in quite different habitats and many species can use a variety of carbon sources (in

the light or in the dark) such as organic acids or fatty acids (heterotrophy) but also CO_2 as sole carbon source and H_2 as sole electron donor (autotrophy) (Ormerod and Gest, 1962). Most species studied to date are mesophilic, but *Rhodospirillum centenum* has been isolated from a hot spring (Favinger et al., 1989). Typically, sulphide is a growth inhibitor to most species of the Rhodospirillaceae (Hansen and van Gemerden, 1972) unless it is kept at constant and very low levels in continuous cultures (see Chapter 4 by van Gemerden and Mas). In general, purple sulfur bacteria are rather strict anaerobes that can be found just below the oxic-anoxic interface of lakes. However certain members of the Chromatiaceae (*Chromatium*, *Thiocystis*, *Amoebobacter*, *Thiocapsa*) are capable of heterotrophic and/or lithotrophic growth under dark microaerobic conditions (Kämpf and Pfennig, 1980). This growth mode is generally considered a mechanism for temporary survival in transiently oxygenated environments or as a means for maintaining the 'energy-balance' at night (Hashwa and Trüper, 1978).

The green nonsulfur- or green gliding-bacteria, the Chloroflexaceae, are exemplified by the thermophilic genus *Chloroflexus aurantiacus* (Pierson and Castenholz, 1974; Madigan et al., 1974) (see Chapter 3 by Pierson and Castenholz). They usually occur as thick mats in alkaline hot springs, the maximum standing crop occurring at a temperature of 50-55 °C (Bauld and Brock, 1973). *Chloroflexus*, which shares physiological, biochemical, and ultrastructural relationships with both the green and purple bacteria, usually coexists with the cyanobacterium which is the primary producer for photoheterotrophic growth of *Chloroflexus* (Ward et al., 1989). In contrast to green sulfur bacteria, *Chloroflexus aurantiacus* is facultative and indeed grows well as a chemoorganotroph in the dark at full oxygen tension (Pierson, 1985; Zannoni, 1986; Wynn et al., 1987; Zannoni and Fuller, 1988).

In terms of plasma membrane arrangement, a clear distinction exists between purple and green bacteria and, among the same bacterial species, between light- or dark-grown cells (Oelze and Drews, 1972; Oelze and Drews, 1981; Drews, 1985, 1986)

Abbreviations: Cf. – *Chloroflexus*; Cm. – *Chromatium*; DAD – 2,6-Diaminodurene; deh – dehydrogenase; DMSO – Dimethylsulphoxide; HQNO – 2-*n*-heptyl-4-hydroxyquinoline-N-oxide; MQ – Menaquinone; Rb. – *Rhodobacter*; Rp. – *Rhodopseudomonas*; RQ – Rhodoquinone; Rs. – *Rhodospirillum*; TMAO – Trimethylamine-N-oxide; UHDBT – Undecylhydroxydioxobenzothiazole

(see also Chapters 12 and 13 by Drews and Golecki and Oelze and Golecki, respectively). Indeed, under phototrophic growth conditions, all members of the Chromatiaceae and Rhodospirillaceae develop an extensive intracytoplasmic membrane system (ICM) which forms species-specific vesicular, tubular or lamellar structures, often connected to each other and/or to the cytoplasmic membrane (CM) (Oelze and Drews, 1972). These lipoprotein membranes contain all the components involved in electron transport and energy transduction. The formation of the ICM system is strongly inhibited by increasing the light intensity (and/or the oxygen partial pressure) and this facilitates spheroplast disruption by osmotic shock. As will be reported later in this chapter, most of the available literature concerning electron transport and energy transduction in facultative phototrophs is based on results obtained with isolated membrane vesicles. For an extensive coverage of the plasma membrane formation and modulation see the excellent reviews by Drews and Oelze, 1981; Oelze and Drews, 1981; Drews 1985, 1986; Kiley and Kaplan, 1988; and Chapters 12 and 13 by Drews and Golecki and Oelze and Golecki, respectively.

II. Dark Aerobic Electron Transport Chains

A. Redox Complexes and Electron Transport Components

The respiratory systems of facultative phototrophs have greater diversity of electron transfer pathways than mitochondrial respiratory chains, and have exploited unique terminal oxidases, depending on their natural habitats and modes of aerobic growth. In most species there is more than one terminal oxidase, so that the respiratory chain is branched, generally, at the dehydrogenase(s) donor sites. The respiratory electron-transport components include quinones (ubi-, rhodo- and mena-quinones), iron-sulfur proteins, and *a*, *b*, and *c*-type cytochromes (Bartsch, 1978; Baccarini Melandri and Zannoni, 1978; Cramer and Crofts, 1982; Amesz and Knaff, 1988; Anraku, 1988; Jackson, 1988; Prince, 1990; Zannoni and Daldal, 1993). Most of these redox carriers are arranged as membrane-bound, intrinsic complexes. However, some components such as cytochrome *c*₂ are soluble and thought to diffuse along the membrane surface (van Grondelle, 1976,1977) (see however Chapter 34 by Meyer and Donohue). Quinone molecules are always present as

a pool in excess over the other secondary electron transport carriers and in some cases, more than one quinone isoprenolog, e.g. UQ-8 and UQ-10, and species, e.g. UQ and RQ, is likely to be involved in respiration (Ramirez-Ponce et al., 1980; Zannoni and Melandri, 1985). This section describes the present status of information on aerobic respiratory chains of purple and green nonsulfur bacteria, with special emphasis on terminal oxidases. NADH and succinic dehydrogenases are scarcely discussed because of limitation of data, whereas subjects such as **H₂-uptake** hydrogenases and ubiquinol/Cyt *c* oxidoreductases have been extensively reviewed in recent years by others (see also Chapter 14 by Vermeglio et al. and Chapter 35 by Gray and Daldal).

1. H₂-Uptake Hydrogenase

Several purple nonsulfur bacteria are able to grow chemo-lithotrophically in the dark. Under these growth conditions, H₂ serves as the source of energy and reducing power, O₂ as the terminal electron acceptor, and CO₂ as the sole carbon source (Madigan and Gest, 1979; Kelley et al., 1979; Seifert and Pfennig, 1979; Colbeau et al., 1980). In species such as *Rb. capsulatus*, the oxidation of hydrogen is catalyzed by a membrane-bound enzyme (Colbeau and Vignais, 1981) which protrudes on the cytoplasmic side of the membrane (Colbeau et al., 1983; Lissolo et al., 1993); conversely, the hydrogenases of *Thiocapsa roseopersicina* and *Chromatium* are less tightly bound to the membrane (Kovacs et al., 1983; van Heerikhuizen et al., 1981) and, in the case of *T. roseopersicina*, it is oriented towards the periplasmic compartment (Kovacs et al., 1983). The majority of hydrogenases are heterodimeric (subunits *ca.* 34 and 65 kDa) (Adams and Hall, 1979; Colbeau et al., 1983). Nickel is required for the synthesis and activity of the enzyme (Takakuwa and Wall, 1981; Colbeau and Vignais, 1983) and the amount of Fe and labile sulfur seen by spectroscopic techniques is consistent with the presence of a 4Fe-4S cluster (Strekas et al., 1980; Albracht et al., 1983). Among the photosynthetic bacteria, the regulation of hydrogenase synthesis has been studied only in *Rb. capsulatus* (Colbeau and Vignais, 1983); however, the factors involved in the regulation of the enzyme are still poorly understood (see Vignais et al., 1985).

In cells of *Rb. capsulatus*, H₂ is rapidly oxidized either in the light or in the dark (Meyer et al., 1978) with a K_m for H₂ (pH-dependent between 7.5 and 9)

of 0.25 μM (Colbeau and Vignais, 1981). In *Rb. capsulatus*, where the respiratory chain is branched and comprises two terminal oxidases having different sensitivities to CN^- (Marrs and Gest, 1973; La Monica and Marrs, 1976; Zannoni et al., 1974, 1976a,b), the hydrogenase delivers electrons to the ubiquinone pool. Indeed, inhibition of H_2 oxidation by CN^- shows a biphasic pattern (Paul et al., 1979) and mutants of *Rb. capsulatus* defective in either one of the two terminal oxidases or of a functional bc_1 complex are capable of H_2 consumption and chemolithotrophic growth (Madigan and Gest, 1979; Melandri et al., 1982).

In membranes from *Rb. capsulatus*, the oxidation of H_2 is coupled to ATP synthesis and the P/O ratios are generally as high as for NADH oxidation (0.4–0.5) and twice those reported for succinate oxidation (0.2–0.3) (Paul et al., 1979; Melandri et al., 1983). Thus, the pathway from H_2 must involve at least one extra energy transducing site compared to the pathway from succinate; this is consistent with the recent observation that protons resulting from the oxidation of H_2 by methylene blue are released into the periplasmic compartment (scalar protons) in a mutant strain BCX of *Rb. capsulatus* which lacks the *hupC* gene product involved in the transfer of electrons from the hydrogenase to the rest of the chain (Cauvin et al., 1991; Lissolo et al., 1993).

2. NAD(P)H Oxidation and NAD(P)⁺ Reduction

A common feature of both NADH oxidation and NAD^+ reduction in purple bacteria is the inhibition by inhibitors of mitochondrial NADH dehydrogenase (complex I) such as rotenone, amytal, and piericidin A (Keister and Yike, 1967; Gromet-Elhanan, 1969; Klemme, 1969; Baccharini-Melandri et al., 1973; Malkin et al., 1981; Zannoni and Ingledew, 1983a,b). This suggests that the bacterial and the mitochondrial enzymes are related but also that NADH oxidation and NAD^+ reduction are catalyzed by the same enzyme operating in opposite directions. Further evidence for similarities between the two enzymes in bacteria and mitochondria comes from the detection of iron-sulfur centers in bacterial membranes (Dutton and Leigh, 1973; Prince and Ingledew, 1977; Malkin et al., 1981; Zannoni and Ingledew, 1983a,b; Sled' et al., 1993) with EPR spectra and E_m values similar to most of the iron-sulfur centers of mitochondrial complex I (NADH-ubiquinone reductase) (Weiss and Friedrich, 1991; Friedrich et al., 1993).

The present state of knowledge of the NADH-Q oxidoreductases in bacterial respiratory systems is suggestive of two types of NADH-dehydrogenases (Yagi, 1991; Yagi, 1993). One type includes those enzymes (designated NDH-1) that bear an energy-transducing site whereas the enzymes of the second type (designated NDH-2) are not linked to proton translocation. The existence of NDH-1 has been reported in several purple bacteria. These include *Rs. rubrum* (Keister and Yike, 1967; Jones and Vernon, 1969), *Rb. capsulatus* (Klemme, 1969; Baccharini-Melandri et al., 1973; Zannoni and Ingledew, 1983a,b), *Rp. viridis* (Jones and Saunders, 1972) and *Cm. vinosum* (Malkin et al., 1981). Indeed, as the photochemical primary quinone acceptors (Q_A) in these bacteria have $E_{m_{7,0}}$ values that range from 0 to -100 mV (Prince and Dutton, 1978; Knaff, 1978) reduction of NAD^+ ($E_{m_{7,0}}$ of $\text{NADH}/\text{NAD}^+ = -320$ mV) could not occur without additional input of energy. The mechanism of such energy-dependent reversal of the electron flow requires therefore the use of an electric and proton potential difference across the membrane ($\Delta\tilde{\mu}_{\text{H}^+}$) to 'pump' electrons uphill from Q_A to NAD^+ . It is apparent that this type of NAD^+ reduction involves the presence of a membrane-bound NADH-quinone oxidoreductase driving reducing equivalents to NAD^+ . Thus, although the direct detection of a energy coupling linked to NADH-Q oxidoreduction has been reported only in a very few species of purple bacteria, e.g. *Rb. capsulatus* (Baccharini-Melandri et al., 1973), the presence of NDH-1 can be indirectly deduced from the above reported considerations.

In membranes from light-grown cells of *Rb. capsulatus*, 4 ferredoxin-like centers ($g_s = 1.94$, $E_{m_{7,0}}$ of $+120$, -115 , -280 and -370 mV) have been resolved by EPR spectroscopy (Zannoni and Ingledew, 1983b). In contrast, *Rb. capsulatus* M-1, a mutant deficient in both NADH dehydrogenase (Marrs and Gest, 1973) and energy-dependent NAD^+ reduction (Melandri et al., 1983), contain only those centers with $E_{m_{7,0}}$ of $+120$ and -280 mV (Zannoni and Ingledew, 1983a). Thus, the inability of membranes from strain M-1 to perform NADH^- dependent respiration is clearly related to the lack of centers with $E_{m_{7,0}}$ at -370 and -115 mV (Zannoni and Ingledew, 1983a). EPR spectra of *Rb. sphaeroides* chromatophores demonstrated the existence of iron-sulfur clusters with spectral and thermodynamic features close to those of the mitochondrial centers N1a, N1b, N2, N3, N4, and, probably, N5 (Sled' et

al., 1993). An NADH-1 preparation from *Rb. sphaeroides* strain GA cells has been reported recently (Sled' et al., 1993). EPR analysis has revealed that this NADH-1 preparation contains relatively intact clusters N1, N3 and N4, while cluster N2 is considerably altered.

Recently, a cluster of 14 genes (designated as *nuo* genes) coding for the subunits of the NADH-Q oxidoreductase of *Rb. capsulatus* has been cloned (Dupuis, 1992). These genes are gathered in a cluster similar to the NQO/*nuo* genes identified in *Paracoccus denitrificans* (Yagi, 1993) and in *E. coli* (Friedrich et al., 1993). The order of these genes is identical in the three species although some open reading frames unrelated to complex I of mitochondria and of *P. denitrificans* have been identified in *Rb. capsulatus* (Dupuis et al., 1993).

Enzymes designated as NDH-1, oxidize not only NADH but also deamino-NADH (Yagi, 1991; Yagi, 1993; Sled' et al., 1993). Conversely, NADPH does not act as a substrate because the NADPH oxidation rate is normally less than 2% of that using NADH. However, the rate of NADPH oxidation by aerobic membranes from *Rb. capsulatus* (MT1131 strain) is approximately 15–20% of that with NADH (D. Zannoni, unpublished).

To our knowledge, there are very few reports on the presence of NDH-2 enzymes in facultative phototrophs (Sled' et al., 1993), although it is clear that dehydrogenases of this type are widely distributed in bacteria (Yagi, 1991, 1993). In general, the membrane oxidation of deamino-NADH is taken as a selective assay for NDH-1 activity in the presence of NDH-2, the latter being insensitive to rotenone, capsaicin or DCCD (Yagi, 1991). To date, very few inhibitors of the NDH-2 type enzymes have been reported, i.e. flavone and platanetin. These compounds, when used at micromolar concentrations, act as both uncoupling agents and inhibitors for the external and internal rotenone-insensitive NAD(P)H dehydrogenases of yeast and plant mitochondria (Cook and Cammack, 1984; de Vries and Grivell, 1988; Rugolo and Zannoni, 1992). Notably, oxidation of NADH by membranes of *Rb. capsulatus* is strongly affected by the NDH-2 type inhibitor, platanetin (D. Zannoni, unpublished). Furthermore, the NADH-Q oxidoreductase activity of semi-aerobically light-grown *Rb. capsulatus* Kb1, is not linked to energy transduction (see also II.4 and III.5) (Zannoni et al., 1978; Melandri et al., 1983b). These results, along with evidence that the K_m^{app} value for

UQ_1 of NADH- UQ_1 reductase activity varies from 8–10 μM to 30–40 μM when cells are shifted from dark-aerobic growth to semiaerobic light-growth, indicate the presence in *Rb. capsulatus* of both NDH-1 and NDH-2 enzymes. However, it must be noticed that the external and the internal rotenone-insensitive NAD(P)H dehydrogenases from plant mitochondria differ from bacterial NDH-2 dehydrogenases (Yagi, 1991, 1993) in several ways: (1) the internal one, and probably also the external, is smaller; (2) they are loosely membrane-bound and are therefore extrinsic proteins; (3) they both oxidize NAD(P)H; (4) Ca^{2+} regulates their activity, at least in situ (Møller et al., 1993).

3. Succinic Dehydrogenase

The enzyme responsible for oxidation of succinate has been characterized in plasma membranes from several species of purple bacteria (Hatefi et al., 1972; Carithers et al., 1977; Prince and Ingledew, 1977; Zannoni and Ingledew, 1983a,b). This enzyme, like mitochondrial succinic dehydrogenase, contain two ferredoxin-type iron-sulfur centers with EPR signals at $g = 1.93$ to 1.94 (reduced form) plus one iron-sulfur center (HiPIP) that is paramagnetic in the oxidized form, having an EPR signal at $g = 2.01$ to 2.02 . This latter center, which is reduced by succinate under steady-state respiration in the presence of TTFA (Zannoni and Ingledew, 1983b), is likely to be analogous to center S-3 of the mitochondrial complex (Ohnishi and Salerno, 1982). The S-3 center has $E_{m,7,0} = +50$ mV in *Cm. vinosum* (Malkin et al., 1981), $+60$ mV in *Cf. aurantiacus* (Zannoni and Ingledew, 1985), $+60$ mV in *Rb. capsulatus* (Zannoni and Ingledew, 1983b), and $E_{m,7,0} = +80$ mV in *Rb. sphaeroides* (Prince and Ingledew, 1977). The other two ferredoxin-type centers have $E_{m,7,0}$ values of $+120$ and -280 mV in *Rb. capsulatus* (Zannoni and Ingledew, 1983b) and $E_{m,7,0} = +90$ mV and -200 mV in *Rb. sphaeroides* (Prince and Ingledew, 1977). Like the mitochondrial S-1 centers, only the more electropositive bacterial centers, i.e. $+120$ and $+90$ mV, are reducible by succinate. These similarities support the close correspondence between mitochondrial and bacterial succinic dehydrogenases.

4. Quinol/Cyt c Oxidoreductases and Quinol Oxidases

All photosynthetic bacteria examined to date have

been shown to contain a multiprotein complex which is functionally and structurally similar to the mitochondrial bc_1 complex (complex III) or ubiquinol/Cyt *c* oxidoreductase. Notably, the possibility of driving cyclic electron flow of photosynthetic bacteria by a single photochemical event, led to the result that most of the data concerning the mechanism and the molecular nature of the bc_1 complex of phototrophs have been obtained by examining phototrophically grown cells. However, considering that kinetic, structural and genetic approaches indicate that the bc_1 complex of aerobically grown cells is the same as the complex in light-grown cells, makes it likely that data available about the 'photosynthetic' bc_1 complex are also valid for the 'aerobic' quinol/Cyt *c* oxidoreductase (Jones and Plewis, 1974; Takamiya et al., 1982; Zannoni, 1982; Wynn et al., 1986; Davidson and Daldal, 1987; Daldal, 1988a; Donohue et al., 1988; Daldal et al., 1989; Lavorel et al., 1989; Venturoli et al., 1990; Zannoni and Moore, 1990). Thus, because of limitation of space, the 'aerobic' bc_1 complex will not be discussed here. For this subject the readers should refer to comprehensive reviews that have appeared in recent years (Dutton, 1986; Hauska, 1986; Amesz and Knaff, 1988; Daldal, 1988a; Jackson, 1988; Prince, 1990; Gennis et al., 1993) and also to Chapters 14 and 35 by Vermeglio et al. and Gray and Daldal, respectively, of this book.

The role of quinone molecules (RQ, UQ and MQ) as physiological electron donors to both the bc_1 complex and the cyanide-resistant oxidase of aerobically dark-grown facultative phototrophs, although largely established (Zannoni and Melandri, 1985), has been examined in some detail only in *Rp. palustris* (King and Drews, 1973) and *Rb. capsulatus* (Zannoni et al., 1976b; Zannoni and Moore, 1990). The recent use of the voltametric technique to detect the level of reduction of the quinone-pool in vivo (Moore et al., 1988; Dry et al., 1989; Moore et al., 1990) allowed the rapid and continuous monitoring of the Q redox state in aerobic membranes of *Rb. capsulatus* (Zannoni and Moore, 1990). The results obtained indicated that in the absence of inhibitors (Fig. 1), the relationship between electron flow and Q redox state approximates linearity over the full range of Q reduction level (from 4–5% to 30%). Conversely, the relationship becomes nonlinear when the cytochrome *c* oxidase dependent flow is blocked by CN^- and/or AA (Fig. 1) and the Q reduction level at which a significant rate of electron flux is seen, is

shifted from 4–5% to 25%. This means that electron flow through the quinol oxidase pathway of *Rb. capsulatus* is strongly limited until the Q-pool reduction level reaches 25%. These results suggested an apparent K_m of QH_2 at the Q_o site of the bc_1 complex of 2.4–3 Q per RC and a K_m at the 'quinol oxidase pathway' site (Q_{ox}) of 15 Q per RC. Notably, in photosynthetic membranes of *Rb. sphaeroides* the apparent K_m of QH_2 at the Q_{ox} -site was calculated to be approximately 3.5 Q per RC (Venturoli et al., 1986). In plant mitochondria, the non-linearity of the relationship between the rate of electron flow catalyzed by the CN^- -resistant pathway and the reduction level of the Q-pool, has been suggested to limit the extent of 'energetically wasteful' respiration (Dry et al., 1989). This proposal is not applicable to *Rb. capsulatus* because observations made with the respiratory mutant R126, lacking a functional bc_1 complex (Robertson et al., 1986), indicate that the quinol oxidase is linked to energy transduction (Zannoni, 1982). In this respect it is noteworthy that light-driven oxygen uptake (noncyclic electron flow) by membranes of *Rb. capsulatus* requires the quinol oxidase pathway (Zannoni et al., 1978; Zannoni et al., 1986). Results of Fig. 2 indicate that a transmembrane ΔpH is formed by membranes of *Rb. capsulatus* R126 as a result of quinol oxidase activity (probably a *bo*-type oxidase, see below). In proteoliposomes containing the Cyt *o* complex of *E. coli*, quinol oxidation is accompanied by H^+ release on the external surface and consumption on the internal surface with a ratio of $1H^+/e^-$ (Matsushita et al., 1984). However, oxidation of reduced TMPD resulted in little change in external pH, suggesting that Cyt *o* in *E. coli* generates a pH gradient from scalar (non-vectorial) proton-consuming and releasing reactions on opposite sides of the membrane (Hamamoto et al., 1985). In contrast, studies in spheroplasts yielded a ratio of $2H^+/e^-$ suggesting an additional vectorial mechanism similar to that observed in the *aa_3*-type cytochrome *c* oxidases (Puustinen et al., 1991; Larsen et al., 1992). Unfortunately, the mechanism of ΔpH formation and the contribution of the quinol oxidase to the overall efficiency of the respiratory chain of *Rb. capsulatus*, is not known. In this respect, Richaud et al. (1986) have demonstrated that restriction of the respiratory flux by light occurs at the NADH dehydrogenase level (NDH-1). This means that under aerobic conditions in the light the quinol oxidase would be

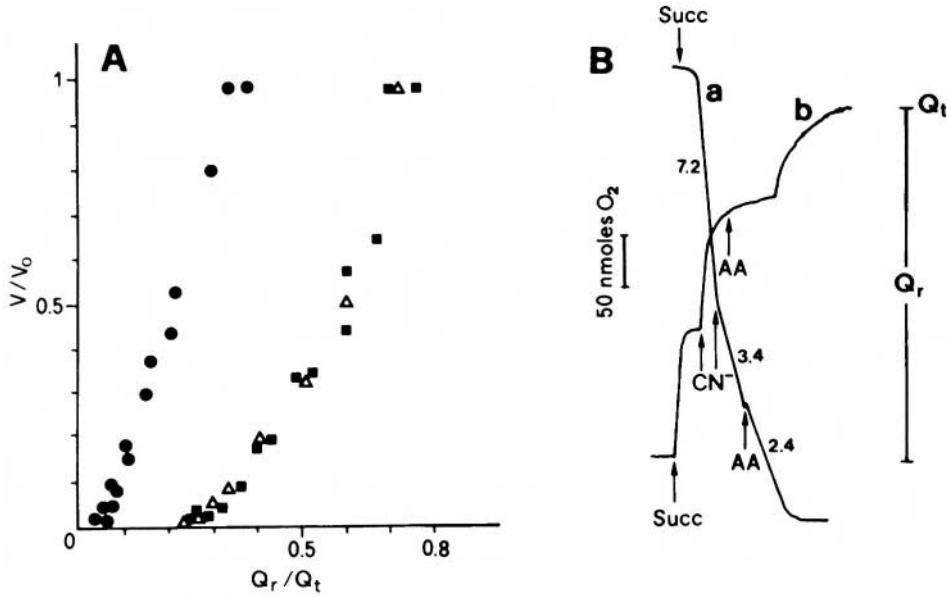

Fig. 1. In panel A, the dependence of respiratory flux on quinone redox state in membranes from *Rb. capsulatus* MT1131 either in the absence (●) or in the presence of 50 μM CN $^-$ (■) and 50 μM CN $^-$ plus 5 μM AA (Δ), is shown. The data are presented as the ratio v/V_0 (where v is the initial rate of respiration in the presence of inhibitor of electron input and V_0 is the uninhibited rate) plotted vs. the proportion of Q in the reduced state (Q_r/Q_t). In panel B, the traces of the simultaneous measurement of O $_2$ consumption and steady-state reduction level of Q as determined by the voltametric technique (see Zannoni and Moore, 1990), are shown. Non standard abbreviations: AA, antimycin A, CN $^-$, potassium cyanide; Succ, succinate. The results are from Zannoni and Moore (1990).

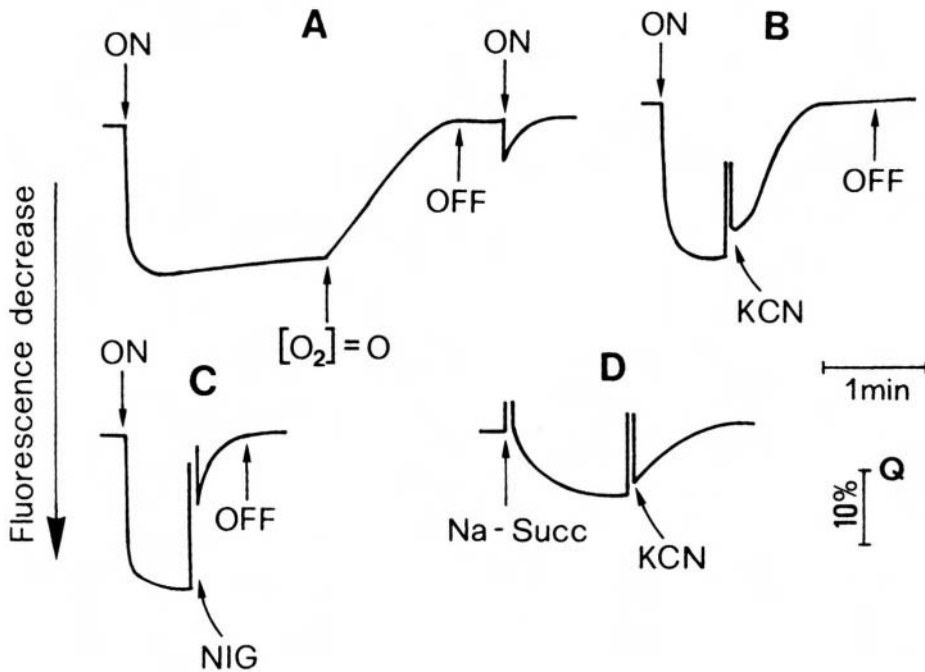

Fig. 2. Formation of an electrochemical potential of protons coupled to O $_2$ consumption through the quinol-oxidase pathway of *Rb. capsulatus* R126 (Q_0 mutant), as monitored by the quenching of the atebriine fluorescence. Traces in A, B and C indicate the atebriine fluorescence quenching induced by light-dependent O $_2$ uptake with ascorbate (2 mM)/TMPD (0.1 mM) as donors (see text for details). In D, the transmembrane ΔpH is induced by succinate oxidation. Additions and abbreviations: Na-Succ, sodium succinate (3 mM); KCN, cyanide (5 mM); Nig, nigericin (2 $\mu\text{g}/\text{ml}$); ON, OFF, light on and off. Adapted from Zannoni (1982).

poorly engaged because of a restriction of electron input (Q/Q_0 lower than 25%, see Fig. 1).

Quinol oxidases have been reported in several aerobically grown photosynthetic bacteria; however, their actual molecular nature is far from clear (Zannoni and Baccarini-Melandri, 1980). In general, the quinol oxidase activity is relatively insensitive to CN^- ($\geq 2-3$ mM) but inhibited by CO; these features have been considered indicative of the presence of cytochromes of the *o*-type in the catalytic activity of the enzyme (Zannoni et al., 1976a,b; Venturoli et al., 1987; Schrattenholz et al., 1989; Varela and Ramirez, 1990). Other inhibitors of the quinol oxidase path way are HQNO, UHDBT and mefloquine, since they act, most likely, at the quinol oxidizing site (Zannoni, 1985; Anraku and Gennis, 1987; Venturoli et al., 1987; Schrattenholz et al., 1989). A cytochrome-*o* complex, claimed to be a quinol oxidase, has been isolated from phototrophically grown *Rhodospirillum rubrum* (Schrattenholz et al., 1989). The complex, composed of 4 subunits (MW of 66, 39, 20 and 11 kDa), contains 2 types of cytochromes (α max at 553 and 561 nm), one of them a cytochrome *o*, and 2 Cu atoms. Recent evidence indicated that heme *o* is a modification of heme *b*, with a hydroxyfarnesyl side-chain addition (Puustinen and Wikstrom, 1991). The heme *b* of the cytochrome *bo* complex of *E. coli* is present as the low-spin six-coordinate Cyt *b*-562 component responsible for the visible absorption of the oxidase and has a split α band at 555 and 563.5 nm (Puustinen et al., 1991; Minghetti et al., 1992). Possibly, the low-spin Cyt *b*-562 corresponds to the *b*-type heme titrated at +250 mV in native membranes of *Rs. rubrum* (Venturoli et al., 1987), *Rb. sphaeroides* (Saunders and Jones, 1975) and *Rb. capsulatus* (Zannoni et al., 1976b; Zannoni et al., 1992). In this respect it might be important to note that most members of the heme-copper oxidase superfamily appear to have in common three core subunits that correspond to the three mitochondrially encoded subunits of the *aa₃*-type oxidase (Hosler et al., 1993). The entire operon of the *bo*-type quinol oxidase of *E. coli* contains five genes corresponding to the five subunits of the purified oxidase (Chepuri et al., 1990). The *bo*-type oxidase does not contain Cu_A which is consistent with the fact that the amino acid residues that are probable ligands of Cu_A in the cytochrome *c* oxidase are not conserved in the sequence of subunit II of the quinol oxidase (van der Oost et al., 1992). Unfortunately there are no data about the possible homology of the quinol oxidizing

sites of the cytochrome *b* subunit of the *bc₁* complex and that of subunit I of the *bo* complex (Hosler et al., 1993; Gennis et al., 1993).

5. Cytochromes of *c* Type and Cyt *c* Oxidases

Membranes isolated from aerobically grown cells of *Rp. viridis*, *Cm. vinosum* and *Cf. aurantiacus* lack a photochemical reaction center (RC) and the multiheme Cyt *c* that operates as immediate donor to the RC in light-grown cells (Wynn et al., 1985, 1987; Kämpf et al., 1987; Zannoni and Venturoli, 1988; Zannoni and Fuller, 1988) (see also Chapters 14 and 35 by Vermeiglio et al. and Gray and Daldal, respectively). Although lacking a tetrahaem Cyt *c*-554, aerobic-membranes from *Cf. aurantiacus* contain several membrane bound *c*-type cytochromes with $Em_{7,0}$ of +270, +130 and 0 mV (Zannoni, 1986; Wynn et al., 1987; Zannoni and Fuller, 1988). Inhibitor studies suggested that both Cyts c_{330} (split α max at 550/553 nm) and c_{270} (α max at 549 nm) are involved in respiratory electron flow through the Cyt *c* oxidase containing pathway whereas Cyt c_0 is not reducible by NADH and succinate (Zannoni and Fuller, 1988). In membranes from cells grown under oxygen saturated conditions no EPR signal characteristic of a reduced Rieske iron sulfur center could be detected (Wynn et al., 1987); conversely, phototrophically grown *Cf. aurantiacus* contains a Rieske-type center with an unusually low $Em_{7,0}$ (+100 mV) (Zannoni and Ingledew, 1985). Although the isolation of the *bc₁* complex of *Cf. aurantiacus* has not yet been reported, thermodynamic considerations (Amesz and Knaff, 1988) suggest that Cyt c_{130} of this organism might be homologous to Cyt c_1 of the *bc₁* complex, whereas Cyt c_{270} might be involved in Cyt *c* oxidase activity (see model scheme in Fig. 3). Perhaps surprisingly, *Cf. aurantiacus* seems to lack soluble *c*-type cytochromes (Bartsch, 1978). This unusual membrane arrangement has been suggested to be characteristic of Gram negative thermophiles (Wood, 1983). However the mesophilic facultative phototrophs, *Rhodofex fermentans* and *Cm. vinosum*, seem to lack soluble *c*-type cytochrome(s) when grown aerobically in the dark (Kämpf et al., 1987; Hochkoeppler et al., 1993). Notably, the soluble high-potential iron-sulfur protein (HiPIP) isolated from *Rhodofex fermentans* has recently been demonstrated to be competent in photosynthetic electron transfer (Hochkoeppler et al., 1995a). Conversely, light-grown *Cf. aurantiacus* contain a

Fig. 3. Models for respiratory electron transport between a non specific dehydrogenase(s) (deH) and the Cyt *c* oxidases from 2 representative members of the 'purple' nonsulfur bacteria (*Rb. sphaeroides*, *Rb. capsulatus*) which contain the periplasmic soluble Cyt *c*₂, and the 'green' nonsulfur bacterium *Cf. aurantiacus* which does not. As discussed in the text, our knowledge of the respiratory systems in *Cf. aurantiacus* is far less complete than those of *Rb. capsulatus* and *Rb. sphaeroides*. The second Cyt *c* oxidase (*cb*-type) of *Rb. sphaeroides* is not shown. Solid lines symbolize components and pathways present in wild type cells, and dashed lines are those that require either a mutation (iso-Cyt *c*₂) or trans-complementation (Cyt *c*_y of *Rb. sphaeroides*) for function. The Cyt *c* oxidases are tentatively arranged as to transmembrane redox complexes containing *aa*₃ and *cb*-type hemes. Dotted lines, interrupted by question marks, suggest hypothetical intermolecular redox exchanges. Abbreviations: *bc*₁, the *bc*₁ complex; UQ, ubiquinone pool; MQ, menaquinone pool; Aur, auracyanin; *c*₂, iso-*c*₂ and *c*_y are the cytochromes *c*₂, iso-*c*₂, and *c*_y. See text for details.

small copper protein (MW = 12.8 kDa), auracyanin, with thermodynamic properties ($E_m = +240$ mV) compatible with a '*c*₂-like' electron transport function (Trost et al., 1988). However, auracyanin behaves as a peripheral membrane protein that can be released by membrane fragments only by salt washing or detergent (LDAO) treatment (Trost et al., 1988). Auracyanin is therefore arranged in a way which appears as intermediate to the two extremes of membrane/bound and periplasmic/soluble *c*-type cytochromes (see below, *c*_y and *c*₂ Cyt) (see Fig. 3).

Considerable evidence has been obtained for the presence of a membrane bound cytochrome oxidase of the *aa*₃-type in chemotrophic cultures of *Cf. aurantiacus* in which the O₂ tension during growth was maintained below the saturation level (termed 'less-aerated cells' in Zannoni and Fuller, 1988; Zannoni, 1986). The two haems ($E_{m_{7,0}}$ of +190 and +330 mV) are present in a 1: 1 ratio and they show spectroscopic properties described for bacterial and mitochondrial oxidases of the *aa*₃-type (Poole, 1983) (see also Table 1). This conclusion is further supported by evidence that a polyclonal antibody raised against the Cyt *aa*₃ of beef-heart mitochondria cross-reacts with a 31 kDa subunit of a Cyt *aa*₃-enriched fraction (solubilization with Triton X-100) from membranes of aerobically dark-grown *Cf. aurantiacus* (R. Bisson and G. Schiavo, personal

communication). Aerobic membranes of *Cf. aurantiacus* can rapidly oxidize ascorbate-TMPD, [$K_{1(CN^{-50\%})} = 8 \mu M$], a redox couple which is thought to interact with cytochromes of the *c*-type. Unfortunately, the actual physiological donor to the oxidase is presently unknown (see however the tentative model in Fig. 3). Membranes isolated from cells of *Cf. aurantiacus* chemotrophically grown under oxygen-saturated conditions are endowed with a Cyt *c* oxidase having properties of a-type bacterial cytochromes, classified as *a*₁ (Wynn et al., 1987). This indicates that oxygen tension strongly affects the terminal oxidase phenotype, this phenomenon being largely present in other bacterial species such as *Escherichia coli* (Haddock and Jones, 1977) and *Rb. sphaeroides* (Sasaki et al., 1970) (see also below).

Aerobically grown cells of *Cm. vinosum* contain, similarly to *Cf. aurantiacus*, three membrane bound *c*-type cytochromes; however, in contrast to *Cf. aurantiacus*, they all have the α band maxima at 551–552 nm and $E_{m_{7,0}}$ values shifted to more positive potentials (+340, +180 and +40 mV) (Wynn et al., 1985). In addition, a soluble *c*-type haem (*c*-550, α band at 550 nm) is present (Knaff et al., 1980). Although the role of the membrane bound cytochromes is presently obscure, it has been speculated that Cyt *c*₁₈₀ might be related to Cyt *c*₁; this suggestion, however, is unlikely because the estimated E_m for

References: 1. Hosler et al., 1992; 2. Gennis et al., 1982; 3. Saunders and Jones, 1974; 4. Sasaki et al., 1970; 5. Hosler et al., 1993; 6. Takamyia and Tanaka, 1983; 7. Zannoni, 1986; 8. Wynn et al., 1987; 9. Gray et al., 1994; 10. King and Drews, 1976.

the Rieske type iron sulfur center of *Cm. vinosum* is approximately +245 mV (Gaul and Knaff, 1983). A possible involvement of Cyt *c*₃₄₀ in the Cyt *c* oxidase activity of *Cm. vinosum* has also been suggested (Wynn et al., 1985). The question of whether the soluble *c*-550 (Em = +240 mV) is involved in oxidative electron transport is still not solved. This soluble and periplasmic *c*-type species (Knaff et al., 1980) (previously referred to as *c*-551 by van Grondelle et al., 1977) has a MW of 15 kDa and is related to the family of *c*-type haems that includes the mitochondrial Cyt *c* and Cyt *c*₂ (Gray et al., 1983). Notably, a similar *c*₂-like cytochrome is also present in *Rp. viridis* and is thought to be the electron donor to the tetraheme subunit of the RC (Shill and Wood, 1984). However, while Cyt *c*-550 is present in aerobically grown *Cm. vinosum* (Wynn et al., 1985), no analogous soluble *c*-type cytochrome could be detected in chemotrophically grown *Rp. viridis* (Kämpf et al., 1987). A soluble *c*-type cytochrome (α max at 552 nm, Em = +287 mV) might be involved in photocyclic electron flow of *Rf. fermentans* but not in respiration of this facultative phototroph (Hochkoeppler et al., 1993).

Membranes isolated from chemotrophically grown *Rp. viridis* contain at least two putative terminal oxidases of the *d*- and *o*-type (Kämpf et al., 1987). How these two oxidases interact with the rest of the respiratory chain is unknown (Kämpf et al., 1987). Equally uncertain is the nature of the cytochrome oxidase system of aerobically grown *Cm. vinosum*, although the lack of heme *a* and *d* suggest that the oxidase(s) is neither a Cyt *aa*₃ type nor a Cyt *d* type (Wynn et al., 1985).

The role of the periplasmic Cyt *c*₂ (13090 MW,

Em_{7,0} = +350 mV) in carrying electrons between the *bc*₁ complex and the Cyt *c* oxidase complex (see below) during respiration, and between the *bc*₁ complex and the oxidized RC during photosynthesis, has long been recognized (Prince et al., 1975; Baccarini-Melandri and Zannoni, 1978; Michels and Haddock, 1980; Zannoni et al., 1980; Hudig et al., 1986; Prince, 1990; Gooley et al., 1990; Caffrey et al., 1992). In recent years, genetic approaches have better defined the role of Cyt *c*₂ in the two closely related species *Rb. capsulatus* and *Rb. sphaeroides*, and revealed that different classes of alternative electron carriers can operate between the membrane-bound redox complexes instead of, or along with, the periplasmic Cyt *c*₂ of these facultative phototrophs (Daldal et al., 1986; Prince et al., 1986; Donohue et al., 1986; Prince and Daldal, 1987) (see Fig. 3). Extensive analyses of *Rb. sphaeroides* and *Rb. capsulatus* Cyt *c*₂⁻ mutants for their ability to grow phototrophically have also revealed that although these purple nonsulfur species are closely related to each other, their Cyt *c*₂⁻-derivatives had different photosynthetic growth phenotypes. Indeed, a *Rb. sphaeroides* Cyt *c*₂⁻ mutant is unable to grow by photosynthesis (Donohue et al., 1986) whereas its *Rb. capsulatus* counterpart is capable of photosynthetic growth (Daldal et al., 1986). Notably, *Rb. sphaeroides* Cyt *c*₂⁻ mutants can give rise to phototrophic competent pseudorevertants (Rott and Donohue, 1990). These pseudorevertants overproduced a new soluble periplasmic Cyt *c*, named iso-Cyt *c*₂, which shows a sequence similarity to Cyt *c*₂ (Fitch et al., 1989) but different biochemical characteristics (α band at 552 nm instead of 550 nm; Em_{7,0} of +300 mV instead of 350 mV; MW of 15 kDa

instead of 13.5 kDa). Genetic analysis revealed that the redox component permitting phototrophic growth of *Rb. capsulatus* Cyt c_2^- mutants is a membrane-associated *c*-type monoheme cytochrome encoded by a gene called *cycY* (Jenney and Daldal, 1993). This membrane bound Cyt *c*, called c_y , has a redox potential of +350 mV (see Zannoni and Daldal, 1993) and it is likely to be homologous to Cyt c_x ($E_m = +354$ mV) detected by spectroscopic methods in chromatophores of a Cyt c_2^- , c_1^- double mutant (MT-GS18) of *Rb. capsulatus* (Jones et al., 1990; Zannoni et al., 1992). Notably, a functional homolog Cyt *c* is not present in *Rb. sphaeroides* but it can be introduced into this species to complement the photosynthetic growth of a mutant lacking Cyt c_2 (Jenney and Daldal, 1993).

Similarly to photosynthesis, respiratory electron transport through the 'branch' involving the bc_1 complex and the cytochrome oxidase of *Rb. capsulatus* does not depend on the presence of soluble periplasmic Cyt c_2 (Daldal, 1988b) (Table 2). Indeed, the respiratory growth of *Rb. capsulatus* mutants (M6G-G4/S4) lacking both Cyt c_2 and a functional quinol oxidase (Qox^-) (Marrs and Gest, 1973; La Monica and Marrs, 1976; Zannoni et al., 1976a,b) is not arrested, and this growth was sensitive to inhibitors of the bc_1 complex and of the Cyt *c* oxidase (Daldal, 1988b). Recently, the kinetic competence of Cyt c_y in respiratory electron flow has been demonstrated (Hochkoeppler et al., 1995b). Thus, Cyt c_y might substitute for Cyt c_2 in both photosynthesis and respiration. Furthermore, Cyt c_y could also be operative in other redox reactions (see III, and see Fig. 4).

The terminal oxidase systems of aerobically dark grown *Rb. capsulatus* and *Rb. sphaeroides* differ markedly. In the latter species aerobic growth leads to the development of a Cyt *c* oxidase similar to the mitochondrial aa_3 complex (Saunders and Jones, 1974; Gennis et al., 1982; Hosler et al., 1993) whereas *Rb. capsulatus* does not synthesize haems of the *a*-type (Zannoni and Baccarini-Melandri, 1980). However, in membranes from cells of *Rb. sphaeroides* grown in the dark with low oxygen concentration or anaerobically in the light, a *cb*-type Cyt *c* oxidase is present (Wale and Jones, 1970; Sasaki et al., 1970; Hosler et al., 1992). This oxidase, which contains at least one *b*- and one *c*-type heme, was reported to be composed of at least 3 subunits (MW of 23,19 and 6 kDa) (Takamyia, 1983; Takamyia and Tanaka, 1983) and to be capable of oxidizing quite efficiently TMPD

Table 2. Respiratory growth rates of various *Rhodobacter capsulatus* wild type and mutant strains

Strain	Phenotype	Doubling time (min)
MT1131	wild type	122
MT-G4/S4	c_2^-	120
M6G	Qox_{260}^-	188
M7G	Cox_{410}^-	208
M6G-G4/S4	c_2^- , Qox_{260}^-	170
M7G-G4/S4	c_2^- , Cox_{410}^-	188
MT-CBC1	bc_1^-	146
MT-GS18	c_2^- , bc_1^-	148

Data from Daldal, 1988b.

in a strain (JS100) from which aa_3 was genetically deleted (Hosler et al., 1992) (see Table 1). The interaction of the two Cyt *c* oxidases of *Rb. sphaeroides* with the rest of the respiratory chain is presently unknown.

The Cyt *c* oxidases of *Rb. capsulatus* and *Rs. rubrum* contain an unusual *b*-type cytochrome that is distinguished from classical cytochrome *o* by its inability to bind CO and by its high $E_{m7.0}$ (Zannoni et al., 1974; Venturoli et al., 1987); this is $+410 \pm 5$ mV in membranes (Zannoni et al., 1974) and +385 mV in a solubilized Cyt *c* oxidase complex from *Rb. capsulatus* (Hudig and Drews (1982a,b). This Cyt *b*-complex shows a DCCD-proton pumping activity of $0.9 H^+/e^-$ when incorporated into proteoliposomes (Hudig and Drews, 1984). A CO-binding cytochrome *c* (MW of 12600, $E_{m7.0}$ of +234 mV) was claimed to function as donor to the high potential *b*-type haem of the oxidase (Hudig and Drews, 1983). This hypothesis, however, was considered in contrast with the current accepted models of redox chains in which Cyt c_2 ($E_{m7.0} = +350$ mV) lies on the pathway to the high potential oxidase (Wood, 1984) (see Fig. 3 and previous discussion on the role of Cyt c_2).

A Cyt *c* oxidase complex has recently been isolated from *Rb. capsulatus* MT-GS18 (c_2^- , c_1^-) (see also Table 2) (Gray et al., 1994). This complex contains 3 subunits (molecular masses of 44,33 and 29 kDa in SDS-PAGE) with haem cofactors of *c*- and *b*-type (2 hemes *c*/2 hemes *b*). The purified complex oxidizes equine Cyt *c* and it is inhibited by CN^- (25 μM). Equilibrium redox titrations could be fitted into at least 3 components with $E_{m7.0}$ of +415 (Cyt *b*, 44 kDa), +320 (Cyt *c*, 29 kDa) and +265 mV (Cyt *c*, 33 kDa) so to suggest a *ccb* type oxidase. By comparing these results with those obtained in a similar preparation from *Rb. capsulatus* M7G-G4/S4 (c_2^- ,

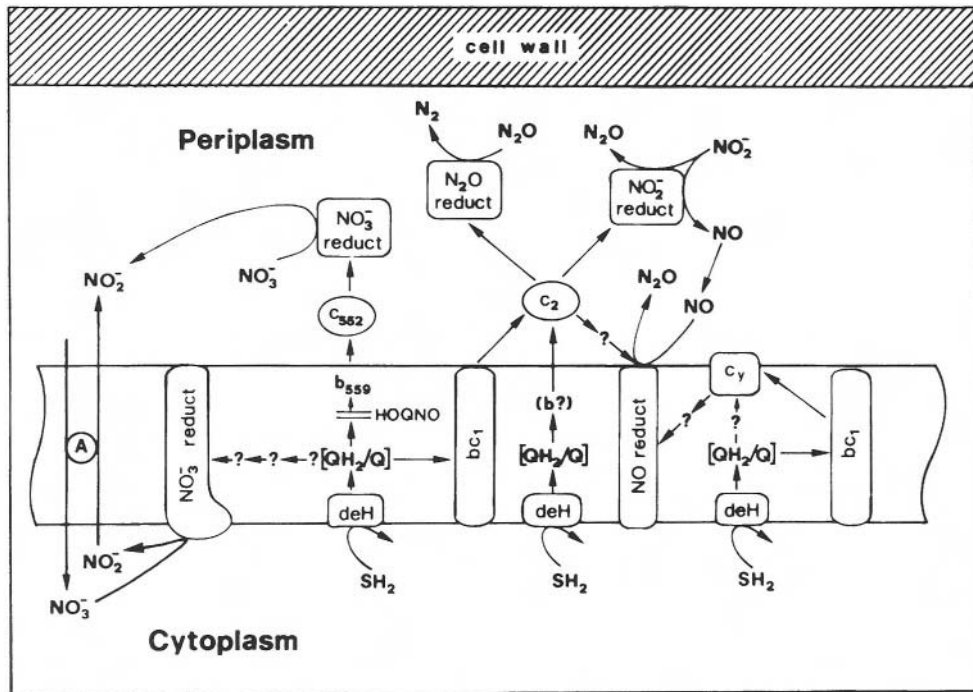

Fig. 4. The postulated organization of the electron transport pathways from ubiquinol to nitrate (NO_3^-), nitrite (NO_2^-), nitric oxide (NO) and nitrous oxide (N_2O) reductases in *Rb. capsulatus*. Two enzymes for NO_3^- reduction are shown, this conclusion based on results with different wild type strains (see text). Two routes for oxidation of ubiquinol and reduction of NO_2^- , NO and N_2O are shown (see text for results in *Rb. capsulatus* MT-CBC1, MT-G4/S4, MT-GS18 and H131 mutants). Whereas a role for Cyt c_2 in N_2O respiration is established (solid arrow) its participation in NO reduction is only by inference, hence the '?' signs (see text). Cyt c_y is suggested to mediate between the NO reductase and either the bc_1 complex or the ubiquinol bc_1 -independent oxidation route. The lack of data about electron transfer from ubiquinol to the membrane bound NO_3^- reductase is symbolized by a dashed line, interrupted by question marks. A nitrate/nitrite antiporter (A) is shown tentatively. Non standard abbreviations: reduct, reductases; b_{559} , Cyt b -559; (b?), undefined Cyt b ; c_y , Cyt c_y ; c_2 , Cyt c_2 ; c_{552} , Cyt c -552; deH, undefined dehydrogenase; bc_1 , Cyt bc_1 complex; SH_2 , undefined electron donor; QH_2/Q , ubiquinol/ubiquinone pool.

Cyt c_{ox}^-) it was confirmed that the M7 mutant, previously characterized by Zannoni et al. (1974) as defective in Cyt b_{415} , lacks not only Cyt b_{415} but also another cytochrome of the c -type, most probably c_{270} (Gray et al., 1994). In this respect, it has recently been reported that mutations in the *fixNOQP* gene cluster of *Bradyrhizobium japonicum*, a symbiotic rhizobium, resulted in defective soybean root-nodule bacteroid development and nitrogen fixation (Presig et al., 1993). The predicted DNA-derived protein sequences suggested that the *fixNOQP* gene products are induced at low oxygen tension and constitute a heme/copper Cyt c oxidase which is composed of several c -type hemes and one heme b (possibly a *ccb* or a *cccb*-type oxidase). Preliminary data indicate that *fixNOQP*-homologous genes are also present in *Rb. capsulatus*; in addition, it has been reported that the *CycM* gene product in *Br. japonicum* is homologous to that of *cycY* (Cyt c_y) in *Rb. capsulatus*

(Bott et al., 1991; Jenney and Daldal, 1993). It is evident how these recent acquisitions might shed a new light over the evolution of nitrogen-fixing organisms and also raise new questions about the structure and function of bacterial oxidases.

III. Dark Anaerobic Electron Transport Chains

A. Generalities

Growth of several facultative phototrophs in an anaerobic environment may proceed by fermentation or by anaerobic respiration (Uffen and Wolfe, 1979; Schultz and Weaver, 1982; McEwan et al., 1982; Richardson et al., 1986). These two modes of growth are not always wholly distinct; fermentation processes produce their own oxidants to balance NADH

production and consumption, and in some cases these can be linked to the redox chain (Madigan and Gest, 1978; Yen and Marrs, 1977). Given an appropriate electron acceptor, the oxidation of fermentation products by the redox chain may also support ATP synthesis. This energy transduction, however, is generally inadequate to sustain a 'significant' bacterial growth so that the electron acceptor must be regarded as an 'accessory oxidant' which allows the dark anaerobic utilization of sugars (see Madigan and Gest, 1978; Yen and Marrs, 1977). Thus, these dark-anaerobic electron transport mechanisms are metabolically different from a true 'anaerobic respiratory process' because the latter implicates a 'consistent' cell growth driven by the oxidation of non fermentable substrates through the respiratory chain (see III.A.4). In summary, although different types of anaerobic electron transport are present in several species of purple non-sulfur bacteria, these respiratory processes are mainly advantageous metabolic systems facilitating anaerobic growth in the dark and in the light (Ferguson et al., 1987). A tentative model summarizing the present state of knowledge of the electron transport pathways from ubiquinol to nitrate, nitrite, nitric oxide and nitrous oxide reductases of *Rb. capsulatus* is depicted in Fig. 4.

1. Reduction of Fumarate

The available structural and functional information about the utilization of fumarate as a terminal oxidant for anaerobic respiration (fumarate reductase) concerns mainly the two anaerobes *Wolinella succinogenes* and *E. coli* (Ingledeew and Poole, 1984; Hamilton, 1988). Although some scattered reports that refer to the presence of membrane-bound fumarate reductase activity in several species of Rhodospirillaceae can be found in the literature, the facultative phototrophs have received little attention with regard to their capability of fumarate reduction (Bose and Gest, 1962; Baccarini-Melandri et al., 1973; Ramirez-Ponce et al., 1980; Beatty and Gest, 1981; Hiraishi, 1988; Hiraishi et al., 1991).

In principle, under strict anaerobic conditions, fumarate can be used as a terminal electron acceptor and thus energy conserved via fumarate respiration; this hypothetical route would involve NADH dehydrogenase, quinone and the membrane bound fumarate reductase (Hamilton, 1988). However, the relatively high redox potential of the fumarate/

succinate couple ($E_{m,0} = +30$ mV) precludes any significant energy conservation during reduction of fumarate by quinol and it also dictates that the donor is menaquinol (MQ, $E_{m,0} = -74$ mV) or rhodoquinol (RQ, $E_{m,0} = -30$ mV) rather than the less strongly reducing ubiquinol ($E_{m,0} = +80$ mV). Fumarate respiration is therefore restricted to MQ-containing species such as for example, *Rs. fulvum*, *Rs. molischianum*, *Rp. viridis*, *Rp. acidophila* and the *Rhodocyclus* group or RQ-containing species such as *Rs. rubrum*, *Rhodomicrobium vannielii* and *Rhodoferax fermentans* (Imhoff, 1984; Zannoni and Melandri, 1985; Hiraishi, 1988; Hiraishi et al., 1991). In this respect, it is interesting to notice that an early study on a RQ-deficient mutant of *Rs. rubrum* demonstrated that RQ was necessary for both photosynthetic growth and NADH-fumarate oxidoreductase activity (Giménez-Gallego et al., 1976; Ramirez-Ponce et al., 1980). This suggests that RQ may be necessary in maintaining the redox balance during phototrophic growth of *Rs. rubrum* through the use of a membrane-bound fumarate reductase. A similar redox system might also be operative during fermentative growth of the purple nonsulfur bacterium *Rhodoferax fermentans* (Hiraishi, 1988). At present, however, the role of fumarate as 'auxiliary' oxidant requires a more accurate verification.

2. Reduction of Nitrate

Studies on the respiration of nitrate (NO_3^- , $E_{m,0}^{\text{NO}_3^-/\text{NO}_2^-} = +420$ mV) by phototrophically grown cells of *Rb. capsulatus* have identified two distinct types of NO_3^- reductase amongst different strains: (1) *Rb. capsulatus* strains AD2 and N22DNAR⁺ contain a periplasmic soluble enzyme (McEwan et al., 1984; McEwan et al., 1987) while (2) *Rb. capsulatus* strain BK5 contains a membrane-bound enzyme which is functionally and structurally related to the enzyme found in *Paracoccus denitrificans* and *E. coli* (Ballard et al., 1990). In cells of *Rb. capsulatus* in which the periplasmic NO_3^- reductase is expressed, reduction of NO_3^- is coupled to generation of a membrane potential ($\Delta\psi$) (McEwan et al., 1984; McEwan et al., 1987). Reduction of NO_3^- cannot, however, support anaerobic dark growth of *Rb. capsulatus* on non-fermentable carbon sources, but it has been speculated that it can facilitate phototrophic growth of this organism in the presence of highly reduced carbon sources such as propionate or butyrate (Richardson et al., 1990). In contrast, several strains of *Rhodopseudomonas*

palustris have been shown to grow anaerobically in the dark in the presence of nitrate (Klemme et al., 1980). Several lines of evidence indicate that the bc_1 complex is not involved in electron transfer to the periplasmic enzyme of *Rb. capsulatus*. The current model is that electrons destined for NO_3^- reduction involve (a) a soluble *c*-type cytochrome (*c*-552, $\text{Em}_{7.0} = +165$ mV), that is released into the periplasm during cell fractionation and which co-fractionates with NO_3^- reductase, and (b) a membrane-bound *b*-type cytochrome (α band at 559 nm). An electron transport pathway that proceeds, $\text{UQH}_2 \rightarrow \text{Cyt } b\text{-559} \rightarrow \text{Cyt } c\text{-552} \rightarrow \text{NO}_3^-$ reductase has therefore been proposed (Richardson et al., 1990). Neither low concentrations of CN^- ($\leq 5 \mu\text{M}$), nor similar amounts of HOQNO (shown to inhibit NO_3^- reduction) prevented the oxidation of the cytochromes by NO_3^- ; this suggests that the site of inhibition is on the reducing side of Cyt *b*-559 and *c*-552 (Richardson et al., 1990). The periplasmic enzyme from *Rb. capsulatus* strain N22DNAR⁺ has been purified as a single polypeptide chain of MW 90,000. It possesses the molybdenum cofactor (McEwan et al. 1987) that is characteristic of NO_3^- reductases in general, but differs from the membrane bound NO_3^- reductases of *E. coli* and *Paracoccus denitrificans* not only in terms of subunit composition (Craske and Ferguson, 1986) and cellular location but also in being relatively insensitive to azide and unable to use chlorate (ClO_3^-) as an alternative substrate (McEwan et al., 1984).

A soluble NO_3^- reductase with an associated *c*-type cytochrome has been isolated by Satoh (1981) from the periplasm of *Rb. sphaeroides* f. sp. *denitrificans* (Sawada and Satoh, 1980). Satoh (1981) suggested that the catalytic activity was due to a 60 kDa polypeptide, a value which is not consistent with that estimated by McEwan et al. (1987) for the analogous enzyme from *Rb. capsulatus*. Another major difference is that the *c*-type haem associated with the enzyme from *Rb. sphaeroides* had a higher $\text{Em}_{7.0}$ value (+251 mV) (Yokota et al., 1984) than that found for Cyt *c*-552 of *Rb. capsulatus*. Notably, in other studies (Michalski and Nicholas, 1985) a polypeptide with an apparent molecular mass of 75 kDa, which was induced by NO_3^- , was identified in soluble fractions. However, a later study by Byrne and Nicholas (1987) concluded that the NO_3^- reductase of *Rb. sphaeroides* f. sp. *denitrificans* was membrane-bound and not periplasmic, an enzyme presumably similar to that identified in *Rb. capsulatus* BK5 (Ballard et al., 1990). In view of the observations

discussed above it seems more likely that *Rb. sphaeroides* f. sp. *denitrificans* can express both the periplasmic and membrane-bound types of respiratory NO_3^- reductase.

3. Nitrite and Nitrous Oxide Reductases

In general, the enzymes responsible for reduction of nitrite (NO_2^-) and nitrous oxide (N_2O) are located in the periplasm of the genera *Rhodobacter* and *Rhodospirillum* (see Hamilton, 1988). There are conflicting results about the nitrite reductase purified from *Rb. sphaeroides* f. sp. *denitrificans*. The enzyme isolated by Sawada et al. (1978) had a mass of 80 kDa, was composed of two subunits (39 kDa), and contained 1 Cu atom per subunit. The pathway of reduction was proposed to proceed from ubiquinol through the bc_1 complex and Cyt c_2 , which is the immediate electron donor for the enzyme (Urata and Satoh, 1984). Michalski and Nicholas (1985) described the purification from the same bacterial species of a protein with two nonidentical subunits of 37.5 and 39.5 kDa, with different isoelectric points. The EPR spectrum was characteristic of types I and II Cu, respectively. Changes in the EPR spectrum observed in the presence of nitrite indicated that the type I Cu is involved in NO_2^- binding and, for topological considerations, the formation of the N-N bond. The type II Cu is thought to act as an electron acceptor.

Rhodobacter capsulatus (strains N22DNAR⁺, MT1131 and AD2) contains a periplasmic nitrous oxide reductase when grown under anaerobic conditions (McEwan et al., 1985a; Richardson et al., 1991). Several lines of evidence which include the use of the Cyt c_2 deficient mutant of *Rb. capsulatus*, MTG4/S4, indicate that in this bacterial species, Cyt c_2 is necessary for electron transport to N_2O (Richardson et al., 1991). It is worth noting that this is the first respiratory pathway in *Rb. capsulatus* for which Cyt c_2 seems to be an essential component (see II.5). A role for the Cyt bc_1 complex in the electron transport pathway to N_2O has also been established (Richardson et al., 1991). However, the presence of N_2O reduction in a mutant of *Rb. capsulatus* (MT-CBC1) deficient in a functional Cyt bc_1 complex (Daldal et al., 1986) (see Table 2) revealed that the bc_1 complex can be substituted by at least one other route of electron flow. This second route involves at least a *b*-type cytochrome as judged by N_2O -oxidized minus reduced spectra of cells of the MT-

CBC1 mutant (Richardson et al., 1989). It should also be noted that in *Rb. sphaeroides* f. sp. *denitrificans* the partial inhibition of the AA-insensitive N_2O -reduction by myxothiazol is interpreted as meaning that in this organism there are also at least two pathways to N_2O (McEwan et al., 1985a).

4. Nitric Oxide Reductase

The evidence that nitric oxide (NO) is an intermediate between nitrite and nitrous oxide in the denitrification process remains to be established (Averill and Tiedje, 1982; Goretski and Hallocher, 1988; Zafiriou et al., 1989). On the other hand, the toxicity of nitric oxide along with its extensive presence in some environments (Rende et al., 1989), suggest that it may be advantageous to possess nitric oxide reductase activity although the extent to which this activity is widespread amongst bacteria in general remains to be seen. There is evidence that many strains of *Rb. capsulatus*, including strain 37b4 which lacks any other reductase activity towards oxy-species of nitrogen (see Richardson et al., 1991), catalyze reduction of NO (Bell et al., 1992). The finding of a discrete NO reductase activity in a denitrifying strain of *Rb. sphaeroides* (Itoh et al., 1989) and the close relationship of *Rb. capsulatus* and *Rb. sphaeroides* suggests that this activity may also be common to many non-denitrifying strains of the latter species. The retention of nitric oxide reductase activity by *Rb. capsulatus* mutants MT-CBC1, MT-GS4/S4, MT-GS18 and H123, deficient in Cyt bc_1 , Cyt c_2 , Cyt [$bc_1 + c_2$] and Cyt c' , respectively (see also Table 2), establishes that neither of these redox carriers is obligatory for electron transport to NO (Bell et al., 1992). On the other hand, the partial inhibition by myxothiazol of NO reduction in both wild type and MT-G4/S4 mutant cells show that the Cyt bc_1 complex is involved in electron transfer to nitric oxide (Bell et al., 1992). This might be either a direct transfer of electrons from the bc_1 complex to the nitric oxide reductase or, which is more likely, an indirect electron transfer mediated by the recently described membrane-bound Cyt c_3 (Zannoni et al., 1992; Jenney and Daldal, 1993) (see II.5). Evidence for including Cyt c_2 on a path to nitric oxide reductase of *Rb. sphaeroides* f. sp. *denitrificans* has been presented (Itoh et al., 1989). It is also noteworthy that antimycin A fails to inhibit completely the reduction of nitric oxide by the latter organism (Shapleigh and Payne, 1985) suggesting that the Cyt bc_1 complex may be

bypassed by electrons destined for the NO reductase as shown for *Rb. capsulatus* (Bell et al., 1992). It has been shown that reduction of NO by DADH₂ does not generate a membrane potential in *Rb. capsulatus*, whereas electron flow from either NADH or succinate does so (Bell et al., 1992); this suggests that NO is reduced at the periplasmic side of the membrane where Cyt c_2 generally operates as electron acceptor from DAD. Thus if nitric oxide reductase is an integral membrane protein in *Rb. capsulatus*, as in *P. stutzeri* (Heiss et al., 1989) and *P. denitrificans* (Carr and Ferguson, 1990), it is likely to presume that protons required for the reduction of NO are taken from the periplasmic side of the plasma membrane.

5. DMSO and TMAO Reductases

Several Rhodospirillaceae can grow anaerobically in darkness in synthetic media containing glucose as sole carbon and energy source with dimethylsulfoxide (DMSO) or trimethylamine-N-oxide (TMAO) as electron acceptors (Yen and Marrs, 1977; Madigan and Gest, 1978; Cox et al., 1980; Madigan et al., 1980). In dark anaerobic batch cultures in fructose plus TMAO medium, reduction of TMAO to trimethylamine (TMA) paralleled growth, and typical fermentation products accumulated, namely, CO_2 and formic, acetic, and lactic acids (Madigan et al., 1980). Notably, pyruvate and TMAO competed for electrons produced in glycolysis; limiting TMAO resulted in far more lactate than was produced when fructose was limited (Madigan et al., 1980). On the other hand, Schultz and Weaver (1982) reported that *Rb. capsulatus* and *Rs. rubrum* both grew on fructose in the absence of an 'accessory oxidant' if the medium contained 0.1% sodium bicarbonate; in addition they found that TMAO and DMSO both supported growth on nonfermentable substrates, including malate, succinate, and acetate, although both rate and extent of growth was very limited. This latter observation led to consideration of the possibility that reduction of DMSO and TMAO might be a further example of an anaerobic respiratory process (McEwan et al., 1983). In this respect McEwan et al. (1983) demonstrated that the addition of TMAO or DMSO to cell suspensions of *Rb. capsulatus*, which had been grown under anaerobic, dark conditions, led to the generation of a rotenone- and uncoupler sensitive membrane potential ($\Delta\psi$) (except strain BK5, see Ballard et al., 1990). This observation could, in principle, be explained solely on the basis of proton

translocation by the NADH-ubiquinone oxidoreductase (complex I), although the relative redox potentials of the electron acceptors ($E_{m_{7,0}}$ (TMAO/TMA) = +130 mV; $E_{m_{7,0}}$ (DMSO/DMS) = +160 mV) might contribute to generate a larger $\Delta\psi$ by a hypothetical ubiquinol-TMAO/DMSO oxidoreductase (see Ferguson 1988). On the other hand, it has also been shown by Yen and Marrs (1977) that a NADH dehydrogenase mutant of *Rb. capsulatus*, M11 strain (see Zannoni and Ingledew, 1983a), grew as well as the wild type strain in anaerobic dark conditions with DMSO so to exclude the requirement of complex I (NDH-1, see II.2) for growth on this oxidant. Moreover, Zannoni and Marrs (1981) demonstrated that membranes of *Rb. capsulatus* R126 and MT113, two mutants lacking of a functional bc_1 complex and of c -type cytochromes, respectively, contained a NDH-2 type dehydrogenase. The results with *Rb. capsulatus* M1, R126 and MT113 mutants suggest therefore that the complete energy transducing redox chain is not required for anaerobic/dark growth of this bacterial species. However, Yen and Marrs (1977) reported that an aminolevulinic acid auxotrophic mutant of *Rb. capsulatus*, which presumably cannot synthesize any cytochromes, was not able to grow under dark/anaerobic conditions with DMSO (supplemented with B_{12}). This suggests that certain cytochromes may be necessary for reduction of DMSO. Taken together these observations can be rationalized in the following way. Reduction of TMAO/DMSO may, in principle, generate a ($\Delta\bar{\mu}_{H^+}$) that is inadequate to sustain a significant growth on a carbon source from which ATP derives solely by respiration. This explanation could account for superior growth of *Rb. capsulatus* on TMAO/DMSO with a sugar than with a non-fermentable carbon source. Clearly these aspects remain to be clarified by further studies.

A single periplasmic enzyme is responsible for reduction of both DMSO and TMAO (McEwan et al., 1985b, 1987; Kelly et al., 1988) which can be conveniently assayed by NMR (King et al., 1987). The enzyme has been purified as a single polypeptide with a MW of 82,000. It behaves as a monomer on gel filtration and EPR studies have shown it to be a pterin-type molybdenum protein (McEwan et al., 1991). A c -type cytochrome (α band at 556 nm; $E_{m_{7,6}}$ = +105 mV; MW = 13,000) co-purifies with the reductase and is oxidised by TMAO or DMSO in the presence of the enzyme (McEwan et al., 1989). In addition to the above redox components a

membrane bound b -type heme ($E_{m_{7,0}}$ = 0 mV; α band at 559 nm) clearly distinct from the b -type hemes of the bc_1 complex is involved in electron transport to DMSO in *Rb. capsulatus* (Zannoni and Marrs, 1981; McEwan et al., 1989). Notably, another c -type cytochrome of apparent molecular mass of 44 kDa has been identified by haem-staining of membrane components of *Rb. capsulatus* after SDS-PAGE (Hudig and Drews, 1986; Zsebo and Hearst, 1984). This 44 kDa-cytochrome is induced during phototrophic growth of *Rb. capsulatus* in the presence of DMSO but not TMAO and has been identified as a cytochrome c peroxidase (Hanlon et al., 1992). Its induction during growth on DMSO but not on TMAO has tentatively been related with the production of toxic dimethylsulfide (DMS) which under certain conditions can be photochemically oxidised to generate free radicals (Brimblecombe and Shooter, 1984; Hanlon et al., 1992).

Acknowledgments

I would like to thank the following colleagues and friends: A. McEwan, S. Ferguson and F. Daldal for supply of published and unpublished material. This work was supported by CNR of Italy (Progetto Finalizzato BTBS).

Summary

Synthesis and accumulation of storage materials occurs in phototrophic sulfur bacteria under virtually all environmental conditions. After summarizing the general characteristics of the different storage products and the maximum contents at which they are found in different organisms, attention is paid to the environmental conditions which affect their accumulation. Although the specific contents are usually high when resources are present in excess, deposition also occurs under conditions of limitation, thus suggesting a strategy which maximizes long term benefit in a fluctuating environment, rather than instantaneous growth. The physiological role of storage products is illustrated through several laboratory experiments, some were fluctuations play a major role, and later on, in a section which describes field situations which actually confirm several of the previous experimental results. The chapter ends with a section which emphasizes the physical effects of the deposition of storage products specially in organisms with a planktonic way of life. Changes in cell size and density derived from the presence of storage structures are discussed, specially in relation to their impact on buoyancy regulation and sinking rates.

I. General Characteristics of the Storage Inclusions of Phototrophic Sulfur Bacteria

The ability to store surplus substrates during unbalanced growth constitutes a widely spread strategy which enables microorganisms to cope with an environment in which fluctuations are the rule rather than the exception. The capacity to accumulate a certain compound during conditions of surplus, clearly becomes a selective advantage when later on this same compound may become limiting.

Phototrophic sulfur bacteria constitute almost a paradigm of this kind of behavior. Depending on the conditions in which they are growing, they can accumulate zero-valence sulfur (S^0), glycogen, poly(3-hydroxyalkanoates) (PHA) and polyphosphate. These compounds are stored intracellularly (and therefore are inclusions) except for sulfur which, in the green sulfur bacteria and in the purple Ectothiorhodospiraceae, is stored extracellularly. However, even in these cases, the fact that extracellular sulfur (at least in the green sulfur bacteria) is not always available to other organisms (Van Gernerden, 1986) makes it a storage compound which behaves, for most purposes, as an intracellular inclusion.

The section which follows will provide some information regarding both the general characteristics of these products, as well as the extent to which they are found in phototrophic sulfur bacteria. Several reviews already exist which deal with different aspects of the metabolism and structure of storage compounds (Dawes and Senior, 1973; Shively, 1974; Merrick, 1978), however, for an in depth description of the macromolecular structure and the metabolism of these compounds the reader is referred to the excellent reviews by Shively et al. (1989) and Dawes (1992).

A. Sulfur

Sulfur globules accumulate during growth on reduced sulfur compounds. They occur extracellularly in green sulfur bacteria as well as in purple sulfur bacteria of the family Ectothiorhodospiraceae, and intracellularly in members of the family Chromatiaceae.

The amounts of sulfur stored depend largely on the organisms and especially on the growth conditions (see section II). Table 1 summarizes data on the

maximum specific content of sulfur expressed as a percent of the dry weight in several phototrophic bacteria growing under different conditions. It seems that sulfur storage rarely exceeds 30-35% of the dry weight except in green sulfur bacteria, in which sulfur is formed extracellularly, and in the purple sulfur bacterium *Thiocapsa roseopersicina* in which the content of sulfur reaches values of 54-55%, well above the average. The physiological or ecological meaning of this increased storage remains to be elucidated.

Electron microscopy studies reveal that intracellular sulfur globules are spherical structures with a diameter which occasionally can reach 1 μm (Remsen, 1978), surrounded by a single layer protein membrane (Nicolson and Schmidt, 1971). They are found in the cytoplasm with no further membrane envelopes, although it has been suggested, taking as a basis the observations by Eimhjellen et al. (1967) that sulfur inclusions in *Thiocapsa* could be deposited surrounded by a protein membrane, inside invaginations of the plasma membrane (Shively et al., 1988). Statistical analyses of several samples from a natural population of *Chromatium minus* (Esteve et al., 1990) show rather homogeneous size distributions with average diameters between 317 and 353 nm.

Sulfur globules are evenly distributed in the cytoplasm except in *Chromatium warmingii* in which deposition occurs preferentially at the extremes of the cell (Pfennig and Trüper, 1989). Chemical analysis of the sulfur globules in *Chromatium vinosum* indicate a rather homogeneous composition with 93.5% sulfur, 5.2% protein, 0.55% lipid and 0.047% BChl_a (Schmidt et al., 1971), the last two fractions being attributed by the authors to contamination from chromatophores. Early studies on the protein fraction of the sulfur globule found a single protein. This protein had a molecular weight of 13500 Da in the case of *Chromatium vinosum* (Schmidt et al., 1971) and 18500 Da in the case of *Chromatium buderi* (Remsen, 1978).

More recent studies carried out in *Chromatium vinosum* and *Thiocapsa roseopersicina* indicate the existence of three proteins with molecular weights of 10498, 10651, 8480 and 10619, 10661 and 8759 Da, respectively (D. Brune, personal communication). The protein sequence indicates that the two large proteins from *Chromatium vinosum* are homologous to each other and to the large proteins found in *Thiocapsa*. The small proteins display also a high sequence similarity. Whether these proteins play a

^a Some of the data were originally expressed per weight of protein. In those cases conversion to a % dry weight was carried out assuming that protein accounted for 50% of the structural dry weight.

catalytic role in the deposition and oxidation of elemental sulfur or serve merely a structural function, has not yet been determined. Additional studies on the nature and functional characteristics of these proteins might yield a clue not only to the mechanism of sulfur formation and sulfur oxidation, but also to the actual state of the sulfur contained in the globules.

The molecular structure of the sulfur inclusions has been a matter of speculation for some time. As early as 1887 Winogradsky referred to these structures as 'semi-liquid sulfur'. He based his conclusions mainly on the fact that high temperatures (70 °C) induced the intracellular globules to coalesce into a single large globule. His observations, carried out in colorless sulfur bacteria, were later confirmed in purple sulfur bacteria which displayed a similar phenomenon (Winogradsky, 1945).

Although X-ray diffraction studies of dry preparations of sulfur globules show the presence of crystalline orthorhombic sulfur (Hageage et al., 1970; Trüper and Hathaway, 1967), *in vivo* studies indicate otherwise. After carrying out polarizing microscopy and X-ray diffraction studies on fresh sulfur globules isolated from *Chromatium*, Hageage et al (1970) concluded that sulfur in the inclusions existed in a state resembling that of liquid sulfur and suggested that the globules were symmetrical aggregates of radially arranged arrays of S₈ molecules. Later studies on the effect of sulfur inclusions in cell size and buoyant density provided estimates of the *in vivo* density of these inclusions. The values found were 1.22-1.31 pg · μm⁻³ for the sulfur globules of *Chromatium vinosum* (Guerrero et al., 1984; Mas and Van Gernerden, 1987) and 1.13 for the globules in *Chromatium warmingii* (Guerrero et al., 1984; Mas et al., 1985). These values were much lower than the density of elemental sulfur (1.92-2.07, Weast, 1986) and, thus, it was suggested that the sulfur in sulfur globules was hydrated.

Elemental sulfur is insoluble in water (Weast, 1986), however the presence of long chain sulfanes with hydrophilic termini could provide a certain degree of hydration. Although this hypothesis seems to be correct in the case of extracellularly deposited sulfur in *Thiobacillus* (Steudel, 1989), analyses of the sulfur species present in *Chromatium vinosum* indicate the existence of only S₆, S₇ and S₈ rings (Steudel et al., 1990) and fail to show the presence of any long chain polysulfur compounds. The authors suggest that the sulfur chains responsible for the hydration might be attached to the protein envelope

at the prosthetic groups of the enzymes responsible for the deposition and breakdown of sulfur.

B. Glycogen

Accumulation of storage carbohydrate is observed simultaneously with the production of elemental sulfur during phototrophic growth on sulfide. Despite claims by some authors of specific contents as high as 40% of the dry weight, the specific content of storage carbohydrates in purple sulfur bacteria rarely exceeds 10% (Table 1). In the few cases in which green sulfur bacteria have been analyzed, the contents have been systematically higher (21 and 35% of the dry weight, see Table 1). Analysis of the structure of the storage carbohydrate in *Chromatium vinosum* (Hara et al., 1973) shows a glycogen structure, with chains of α-1,4 linked α-D-glucose with a variable degree of branching provided by α-1,6-glucosyl linkages. It displays a coefficient of sedimentation of 90S and an average chain length of 11, comparable to values of 10-13 found in other bacteria (Dawes, 1992). In *Chlorobium*, glycogen is deposited as rosette-like granules with a diameter of approximately 30 nm. The granules have been found to increase in number but not in size when the specific content of glycogen increases (Sirevåg and Ormerod, 1970).

C. Poly(3-hydroxyalkanoates)

Poly(3-hydroxyalkanoates) (PHA) are accumulated intracellularly by purple sulfur bacteria when growing in the light in the presence of organic acids, or in the dark, as a byproduct of the degradation of intracellularly stored glycogen. So far, PHA have not been detected in green sulfur bacteria.

These molecules are linear polymers with the general structure:

where R has a length between 1 and 10. Polymers constituted by monomers with a homogeneous length of the R side chain are referred to as *homopolymers*. When the monomer composition is heterogeneous, the term *copolymer* is used. Extensive analysis of the amount and composition of PHA deposited intracellularly by phototrophic sulfur bacteria under different growth conditions have been published by

Liebergesell et al. (1991) and are summarized in Table 2. The polymer most commonly found in purple sulfur bacteria was poly(3-hydroxybutyrate) (PHB), a homopolymer of 3-hydroxybutyric acid ($R = 1$). Most purple sulfur bacteria studied seem only able to synthesize PHB, regardless of the organic acid supplied. However, some organisms (*Chromatium vinosum* 1611 (DSM 182), *Chromatium purpuratum* BN5500 and *Lamprocystis roseopersicina* 3112) synthesized a copolymer of β -hydroxybutyrate ($R=1$) and β -hydroxyvalerate ($R = 2$) when incubated in the presence of organic acids with an odd number of carbons. In some organisms the specific content of PHA was as high as 83% of the dry weight, but only when incubating the cells in nitrogen-free medium containing 20 mM acetate. When grown in regular growth medium with a lower concentration of acetate (6.8 mM) the specific content of PHA never surpassed 30% of the dry weight and, in several cases, was close to zero. Analyses carried out on samples from a population of purple sulfur bacteria in Lake Cisó, Spain, indicate a homogeneous composition of the polymer, with virtually 100% hydroxybutyrate (Mas-Castellà, 1991). Similar analyses of samples from the phototrophic layer in microbial mats from the Ebro Delta show the presence of hydroxybutyrate and of important amounts of hydroxyvalerate which in some cases can be the most abundant monomer (Mas-Castellà, 1991).

Although little information is available on the structure of the PHA inclusions of phototrophic sulfur bacteria, a considerable body of data has been gathered on the inclusions present in other organisms. Although early X-ray diffraction studies indicated that native PHB occurred in a crystalline form (Alper et al., 1963), latter studies by different authors suggest that the polymer in the granules is not crystalline, but rather exists in a less compact form, more readily accessible to the enzymes responsible for its degradation. Thus, X-ray diffraction data collected by different authors (Barham, 1990; Kawaguchi and Doi, 1990) agree in that the polymer in the granules must be in an amorphous form which only crystallizes after either heating or removal of the water and lipids present in the granule. This view is supported by C^{13} -NMR analyses of in vivo PHB in several organisms (Barnard and Sanders, 1989; Nicolay et al., 1982). The 'in vivo' density of PHB ($1.155 \text{ pg} \cdot \mu\text{m}^{-3}$) (Mas et al., 1985) is considerably lower than the density of the purified polymer ($1.23\text{-}1.25 \text{ g} \cdot \text{cm}^{-3}$) (Williamson and Wilkinson, 1958; Okamura and Marchessault,

1967). To explain these differences it was postulated that the inclusions were hydrated, with a water content of approximately 40% (Mas et al., 1985).

Electron microscopy studies show that PHA inclusions are spherical structures with a diameter of 240-720 nm in *Bacillus cereus* (Dunlop and Robards, 1973) and 200-700 nm in *Bacillus megaterium* (Ellar et al., 1968), surrounded by a single layer envelope 2-8 nm thick (Merrick, 1978). Similar studies carried out in samples from a natural population of *Chromatium minus* indicate a rather homogeneous size distribution ranging between 252 and 298 nm (Esteve et al., 1990). Chemical analysis of PHB granules (Griebel et al., 1985) shows the presence besides PHB of small amounts of protein (2% w/w) and lipid (0.5% w/w). For a discussion of the use of phototrophic bacteria for production of PHAs and the chemical properties of various PHAs, the reader is referred to Chapter 60 by Fuller.

D. Polyphosphate

Polyphosphates are linear polymers of orthophosphate with variable chain-length ($3\text{-}10^3$) which can be found as a variety of different fractions, forming intracellular granules (Kulaev, 1979), soluble in the cytoplasm (Ferguson et al., 1979), in the periplasmic space (Ostrovsky et al., 1980) or even associated to PHB and Ca^{++} , delimiting transport channels in the cytoplasmic membrane (Reusch and Sadoff, 1988). Each of these fractions probably fulfills a rather specific role (Halvorson, 1990; Kulaev, 1990). Little is known about accumulation of polyphosphates by phototrophic sulfur bacteria. Their presence has been detected in *Chlorobium limicola* (Hughes et al., 1963, Cole and Hughes, 1965), as well as in *Chromatium minutissimum* where it reached around 2% of the dry weight (Zaitseva et al., 1965). Experiments carried out with *Chromatium vinosum* (Mas and Van Gemerden, 1992) growing at a constant dilution rate in a chemostat and experiencing different degrees of phosphate limitation, revealed that the cells adjusted to the limitation with an almost threefold decrease in their phosphorus content (from 0.85 to 0.30 $\mu\text{mol P} \cdot \text{mg}^{-1}$ protein). Whether the surplus P was present as poly-P or as other P containing molecules was not determined; however, the value found provides an estimate of the maximum amount of P accumulated in the cell when growing in a medium containing excess P.

Table 2. Poly(3-hydroxyalkanoate) (PHA) content of various purple sulfur bacteria expressed as a percentage of the dry weight. Data from Liebergessell et al. 1991.

II. Environmental Conditions Leading to the Accumulation of Storage Compounds

In aerobic heterotrophic bacteria, reserve material and energy storage often is regarded as being synonymous. However in phototrophic bacteria one has to differentiate between energy storage compounds, conservation of carbon skeletons, and conservation of reducing power. Being able to survive under anoxic conditions with the energy liberated in the degradation of glycogen makes this an energy storage compound, in contrast to poly(3-hydroxybutyrate) (PHB) and other poly(3-hydroxyalkanoates) (PHA), which cannot be degraded under anoxic dark conditions. However, in the light, these compounds supply extremely valuable precursors for the synthesis of essential cell components. The so-called 'elemental sulfur' or 'zero-valent sulfur' (S^0), deposited intracellularly by members of the family Chromatiaceae, provides neither carbon nor energy under anoxic conditions, but still is a powerful electron donor when sulfide becomes depleted.

In general, storage compounds are synthesized when substrates are present in excess. The nature of the storage compound very much depends on the nature of the substrate. Sulfide (and other reduced forms of sulfur) in combination with carbon dioxide, as well as organic compounds such as malate can be converted into glycogen, whereas the presence of e.g. acetate tends to result in the intracellular storage of PHB (Stanier et al., 1959).

Purple sulfur bacteria growing in batch culture on sulfide/ CO_2 accumulate glycogen as long as sulfide is present. In the early stages of growth the reducing equivalents required for the conversion of carbon dioxide into structural cell material and glycogen are obtained mainly from the oxidation of sulfide to sulfur, and to a far lesser extent from the oxidation of S^0 to sulfate, although large differences between different strains can be observed. In *Chromatium vinosum* DSM 185, growth continues at μ_{max} after sulfide depletion, at the expense of stored S^0 and glycogen (Van Gernerden and Beeftink, 1978, see Fig. 1). In the stationary phase of growth the concentration of glycogen is zero. The above data clearly show that the rate-limiting step in the Calvin cycle exceeds the specific rate of growth, enabling the deposition of storage compounds. A temporary intracellular accumulation of glycogen also was observed in *Thiocapsa roseopersicina* during growth

Fig. 1. Electron donor oxidation and product formation during batch growth of *Chromatium vinosum* strain DSM 185. Redrawn from Van Gernerden and Beeftink, 1978.

on sulfide (Visscher et al., 1990), thiosulfate (De Wit and Van Gernerden, 1987), polysulfide (S_3^{2-}) (Visscher et al, 1990), and dimethyl sulfide (Visscher and Van Gernerden, 1991).

When growth of *Chromatium vinosum* was inhibited by the addition of growth inhibitors, enhanced rates of glycogen formation were observed whereas substrate oxidation rates remained constant (Van Gernerden and Beeftink, 1978). Glycogen synthesis, together with the intracellular storage of S^0 thus enables continued growth after external substrates have been exhausted. High rates of carbon dioxide incorporation and sulfide oxidation also have been reported to occur in short-term experiments with *Chromatium okenii* (Trüper, 1964a,b; Trüper and Schlegel, 1964), *Chromatium weissii* and *Chromatium vinosum* (Van Gernerden, 1974). In view of the relatively low specific growth rates of purple sulfur bacteria (see Van Gernerden, 1984), these observations suggest that glycogen was synthesized.

Sulfide-limited cultures of *Chromatium vinosum* synthesize glycogen at all dilution rates imposed, the

rate roughly being proportional to the dilution rate except for dilution rates close to μ_{\max} . At dilution rates $< 85\%$ of μ_{\max} about 5% of the reducing power obtained by sulfide and sulfur oxidation is channeled into the synthesis of glycogen. At higher specific growth rates this value may increase to 14% (Beefink and Van Gernerden, 1979).

Immediately after removal of nutrient limitation (addition of sulfide directly to the culture over and above that supplied with the metering pump) increased rates of glycogen synthesis were observed. After the addition of chloramphenicol cultures showed similar high rates as observed in batch cultures, irrespective of the dilution rate imposed. Apparently, the maximum specific rate of synthesis in this organism is unaffected by the specific growth rate.

Although sulfur and glycogen are stored during sulfide limited growth of *Chromatium vinosum*, their content is highly increased when the organisms are either light or phosphate limited. A conceptual model of how these factors interact to support growth has been sketched in Fig. 2. According to this model, the metabolic rates of the different processes required for growth must be high enough to support growth at a given rate. A low supply of N or P will reduce the specific growth rate; however all the requirements for photosynthesis are present and the organism keeps synthesizing organic carbon which is then routed towards synthesis of glycogen. In the event of a reduced energy supply such as during light limitation, organic carbon will be formed at a lower rate. However, since even under these conditions glycogen is synthesized, glycogen synthesis obviously competes with growth processes for the products of photosynthesis.

Some data illustrating this point have been plotted in Fig. 3 as the amount of reducing power stored per mg protein, as either glycogen or sulfur. The results correspond to *Chromatium vinosum* growing at a constant specific growth rate (0.07 h^{-1}) but subject to three different types of limitation. The lowest contents are found when the organisms are sulfide limited. Phosphate limitation results in much higher contents of both sulfur and glycogen which share, in roughly equal proportions, the reducing power stored. Under light limitation, the content of sulfur is as high as during P limitation, however, the amount of glycogen is lower, as could be expected in a situation of insufficient energy supply.

Fig. 2. Interaction of the main resources required for autotrophic growth in phototrophic sulfur bacteria. The metabolic rates of the different processes must be high enough to support growth at a given rate. A low supply of N or P will reduce the specific growth rate; however, all the requirements for photosynthesis are present and the organism accumulates glycogen. During light limitation, organic carbon will be formed at a lower rate. However, even under this condition glycogen is synthesized and thus competes with growth for the products of photosynthesis. Sulfur will be accumulated whenever sulfide is present.

III. Physiological Role of Storage Compounds

A. Experimental Studies Under Fluctuating Conditions

Oxygen exerts an inhibitory effect on the synthesis of photopigments by anoxygenic phototrophic bacteria. Incubation of *Thiocapsa roseopersicina* under oxic conditions for a prolonged period of time results in completely colorless cells which grow chemotrophically. Consequently, the yield per reducing equivalent is severely reduced to about one third of that obtained during phototrophic growth (De Wit and Van Gernerden, 1987) and is comparable to that found in genuine chemolithotrophs such as *Thiobacillus* sp. (Kelly, 1982). Once exposed to the presence of oxygen, the time course of the concentration of BChl *a* in a continuous culture of *Thiocapsa roseopersicina* followed the theoretical wash-out curve, suggesting that this photopigment was not actively degraded. When present, BChl *a* remained functional. It was observed that the protein yield during incubations in 24-h oxic/anoxic regimen, in which the oxic period was 4 to 21 h, was virtually identical to that observed during continuously anoxic conditions despite the fact that the photopigment content was decreasing in proportion to the length of the oxic period. Incubation at a 3h anoxic/21h oxic regime resulted in a BChl *a* content equal to about

Fig. 3. Storage of reducing power as either glycogen or sulfur in sulfide, light, or phosphate limited steady state cultures of *Chromatium vinosum* strain DSM 185 growing at $D = 0.07 \text{ h}^{-1}$. (Drawn using data from Van Gernerden et al., 1990)

20% of that observed during continuously anoxic conditions. Apparently, under the latter conditions these organisms have a large surplus of photopigments (De Wit and Van Gernerden, 1990a). At even shorter anoxic periods, however, insufficient photopigments are synthesized to allow full phototrophic growth and the organism shifts to a combined photochemotrophic metabolism, as could be judged from the yield (Schaub and Van Gernerden, 1994).

The role of glycogen to sustain phototrophic growth becomes apparent when *Thiocapsa* is incubated in a regimen in which light conditions were combined with the presence of oxygen, and dark conditions with anoxia. After being incubated at such a regimen for a prolonged period of time, a repeating pattern of phenomena emerged. As expected, during the oxic-light periods no synthesis of BChla took place, in contrast to anoxic-dark periods. Concomitantly, glycogen, accumulated during the preceding oxic-light period using the BChl still present, was degraded in the dark (Fig. 4). It was calculated on the basis of known synthetic pathways of bacteriochlorophyll and spirilloxanthin, the major carotenoid of *Thiocapsa*, that, depending on the regimen employed, degradation of 20-50% of the stored glycogen could account for the observed synthesis of photopigments in the dark (De Wit and Van Gernerden, 1990a). As was judged from the growth yield, the organisms were growing phototrophically and did not use their

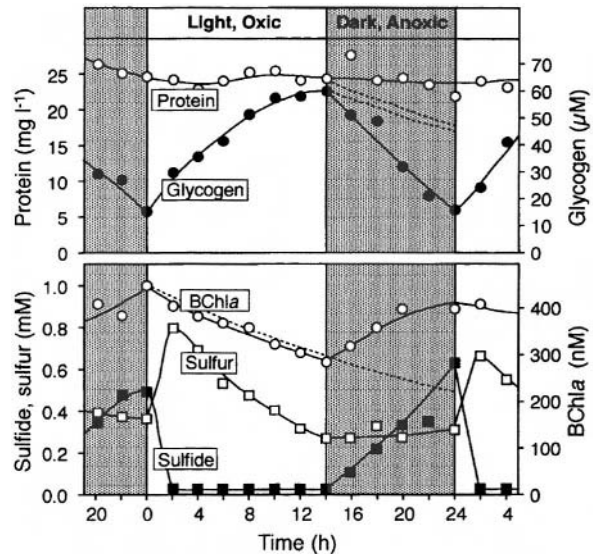

Fig. 4. Time course of the concentration of BChla, protein, glycogen and S⁰ in a continuous culture of *Thiocapsa roseopersicina* strain M1 after cultivation for five volume changes under a 14h oxic-light/10 h anoxic-dark regimen. The theoretical washout curves expected if synthesis did not occur are shown as dashed lines. (Redrawn from DeWit and Van Gernerden, 1990b.)

chemotrophic potential. These data show the functional role of glycogen during incubation under circumstances mimicking environmental conditions.

B. Dark Metabolism and Survival

Anoxygenic phototrophic bacteria, for which light is the ultimate source of energy, would be deprived of energy for maintenance purposes in the dark unless materials such as glycogen were stored in the light. It thus appears ecologically relevant that at least some glycogen is stored by cells facing sulfide limitation (see Section II).

From an energy point of view, the most efficient way to use glycogen in the dark would be to convert each glycosyl moiety to two carbon dioxide and two acetyl-CoA, followed by a conversion of the latter to acetate via acetyl phosphate. Taking into account that the initial phosphorylation does not require the participation of ATP but instead is carried out with P_i, five ATP could be produced from each glycosyl moiety. From a carbon-preserving point of view, however, this metabolic route is not very efficient, since all carbon, initially fixed at great expense through the Calvin cycle, would be excreted. The possibility of re-assimilation of acetate in the subsequent light period depends on the activities of

other organisms, a fact often overlooked by scientists studying pure cultures. It appears that another way to degrade glycogen is feasible in purple sulfur bacteria. This metabolic route involves the condensation of two acetyl-CoA to form one aceto-acetyl-CoA, which, after reduction to 3-hydroxybutyryl-CoA, can be polymerized to form poly-3-hydroxybutyrate (PHB). Following this route would result in less energy to become available upon glycogen degradation (three ATP for each glycosyl moiety instead of five), however, four out of six carbon atoms present in glycogen would be preserved in PHB. In both pathways NADH is formed. In the first pathway eight [H] are produced in the breakdown of one glycosyl moiety, and in the second pathway six. With no energy input required, S° could serve as an acceptor for these electrons, resulting in the formation of sulfide (mid-point potentials: $NAD^+/NADH = -320$ mV, $S^{\circ}/H_2S = -280$ mV).

Utilization of S° in the dark accompanied by the production of sulfide has been observed both in cultures of the large celled species *Chromatium okenii* (Trüper and Schlegel, 1964), and in cultures of the small-sized *Chromatium vinosum* (Van Gernerden, 1968b) in which PHB accumulated in agreement with the following stoichiometry:

Hendley (1955) observed that acetate was formed in the endogenous metabolism of 'Thiorhodaceae' (Chromatiaceae). However, the organisms, grown in media containing hydrogen as the electron donor, did not contain intracellular S° , thus making the formation of sulfide inconceivable. Data on the production of hydrogen, energetically a less favorable option, were not reported. De Wit (1989) observed in *Thiocapsa roseopersicina* cultures which were repeatedly replenished with sulfide in order to reach high glycogen concentration, that dark incubation did not result in PHB accumulation. Instead, acetate was excreted in addition to sulfide. The molar ratio of glycosyl moieties to acetate and sulfide was 1 to 2.4 to 3.7. These phenomena, so far not observed in pure cultures of other anoxygenic phototrophs, suggest the following stoichiometry:

Liebergesell et al. (1991) showed that some members of the Chromatiaceae do not (or hardly) form PHB under growing conditions although they have the metabolic capacity to do so (see Table 2). Therefore, although it is tempting to consider the two different ways of glycogen degradation described above as 'strategies', data from more organisms growing under various conditions are required before a firm statement can be made in this respect.

C. The Role of S° as Electron Storage in Purple and Green Sulfur Bacteria

As shown above, the S° in Chromatiaceae can be regarded a genuine storage compound. In fact, S° is a powerful electron donor: during its oxidation to SO_4^{2-} six electrons are released, compared to two electrons liberated during the oxidation of H_2S to S° . Due to the intracellular deposition, no other individual than the organism itself will be able to profit from the temporary accumulation of S° . This can be demonstrated using sulfide-limited chemostats by stepwise increasing the sulfide concentration in the reservoir ($S_{R-sulfide}$). According to the theory of continuous cultivation, the concentration of external substrates at any given value of the dilution rate D depends on the kinetic characteristics of the organism cultivated and is not influenced by the concentration of the limiting substrate in the reservoir solution. Accordingly, in sulfide limited continuous cultures of *Chromatium vinosum*, the steady state sulfide concentration is identical at increasing values of $S_{R-sulfide}$, however, the S° concentration is proportional to the magnitude of $S_{R-sulfide}$ as is biomass. As a consequence, the ratio of S° to protein was constant.

In Chlorobiaceae S° is deposited outside the cells. Nevertheless, the S° concentration in cultures of *Chlorobium limicola* also appeared to be affected by the magnitude of $S_{R-sulfide}$, indicating that the S° produced by one individual is not available to other individuals. This is further illustrated by the fact that in chemostat cultures of *Chlorobium*, as in cultures of *Chromatium*, the ratio of S° to protein was constant. The mechanistic explanation of this phenomenon in

Chlorobium could be that the S° is retained by the formation of extracellular capsules or pili, as described for other strains (Cohen-Bazire, 1963; K Schmidt, pers. comm.). Consequently, S° in *Chlorobium*, despite being deposited outside the cells, has to be regarded a storage product (Van Gernerden, 1986). Data on other anoxygenic phototrophs are lacking at the moment, and it would be particularly interesting to know how *Ectothiorhodospira* species would react.

IV. Storage Compounds in Natural Populations of Phototrophic Sulfur Bacteria

Storage inclusions also have been quantified in natural populations of phototrophic sulfur bacteria. In such cases, their distribution in space follows rather closely the distribution of bacterial biomass. This point is illustrated rather clearly in Fig. 5 (redrawn after Guerrero et al., 1985a), which depicts the variations with depth of bacterial abundance, sulfur, glycogen and PHB in a summer day in Lake Cisó (Spain), when the water column was stratified. The community of phototrophic sulfur bacteria consisted of green sulfur bacteria and two purple sulfur bacteria, a medium sized *Chromatium* and a smaller aggregate forming organism later identified as *Amoebobacter* (Pedrós-Alió and Guerrero, 1993). Green sulfur

bacteria constituted only a small fraction of the community (Fig. 5A) and therefore, it can be assumed that the storage compounds measured resided mainly with the purple sulfur bacteria, which represented more than 90 % of the total biovolume. Although glycogen, sulfur and PHB obviously are more abundant at the peak of bacterial biomass, their distribution says little about the physiological state of the organisms. To gain some insight on this point, the data from Fig. 5 have been used as a basis to calculate the specific contents of each of the inclusions at each depth. The results have been plotted in Fig. 6 together with the vertical profile of light penetration at that moment. Light was almost extinguished at 2 m and phototrophic sulfur bacteria below that depth were facing virtual darkness. The specific contents of sulfur, glycogen and PHB changed with depth, in agreement with what could be expected from such a situation. Cells in the upper part of the bacterial plate where light irradiance is high, are loaded with glycogen and sulfur, and contain little PHB. As they enter the twilight zone and begin to sink, they start using up their intracellular stores of glycogen and sulfur, simultaneously depositing PHB as an end product of their dark metabolism. However, in most cases this is a one way trip and, unless given the chance to return to the surface layers (such as during holomictic overturn), the organisms eventually die. This loss of viability with depth has been documented by Van Gernerden et al. (1985).

Fig. 5. Vertical distribution of bacteriochlorophylls (A), biovolume of Chromatiaceae (B), glycogen and sulfur (C) and PHB (D) in Lake Cisó (6 July, 1982, at zenith). Redrawn from Guerrero et al., 1985.

Fig. 6. Vertical distribution of irradiance (expressed as a % of the surface irradiance) (A), and specific contents of glycogen (B), sulfur (C) and PHB (D) in Lake Cisó (6 July, 1982, at zenith). Calculated and redrawn from data in Guerrero et al., 1985.

The specific content of sulfur and PHB also has been quantified in ultrathin sections corresponding to samples from Lake Cisó (Esteve et al., 1990). The results of this study indicate that the specific content of PHB increases with depth, and that this increase is not due to an increase in the size of the PHB inclusions, but rather to an increase in their number. The specific content of sulfur, however, does not change with depth, an observation which clearly disagrees with the data shown in Fig. 6. Similar differences between variations in the specific content of sulfur and variations in cell size (Mas and Van Gernerden, 1987) led the authors to postulate that utilization of intracellular sulfur might proceed without a concomitant reduction in the structure of the sulfur globule which would then remain as an empty shell until further degradation of the structure occurred. Clarification of this point requires, no doubt, further studies.

Besides their involvement in the rather hopeless task of maintaining viability during sinking to the sediment, storage inclusions carry out a remarkable role during day/night fluctuations. This has been shown in studies conducted both in Lake Cisó (Guerrero et al., 1985a, Van Gernerden et al., 1985) and in Lago di Cadagno Switzerland, Del Don et al., 1991; Bachofen et al., 1991).

Both in Lake Cisó (Fig. 7) and in Lago di Cadagno the concentration of sulfide at the depth of maximum

biomass increased during the night, a phenomenon attributed to the dark metabolism of the organism. Concomitantly, glycogen concentrations were reported to decrease during the night. In Lake Cisó sulfide production and glycogen depletion were accompanied by an increase in the concentrations of PHB (Van Gernerden et al., 1985). In Lago di Cadagno, acetate, instead of PHB, was produced in the dark (Del Don et al., 1991). Thus, the phenomena observed in Lake Cisó appear to follow the stoichiometry given in equation 1, whereas those in Lago di Cadagno rather point to a stoichiometry similar to that described by equation 2 (see above). Attention is focused to the fact that the dominant organisms in these lakes belong to different species. Detailed field data, in combination with experimental studies on isolated strains are required to evaluate the possibility of different strategies.

V. Physical Consequences of the Accumulation of Storage Compounds

Storage inclusions accumulate in amounts which can constitute a large fraction of the dry weight of the organism. This accumulation has an inevitable effect on some physical properties of the organisms such as their size and specific density.

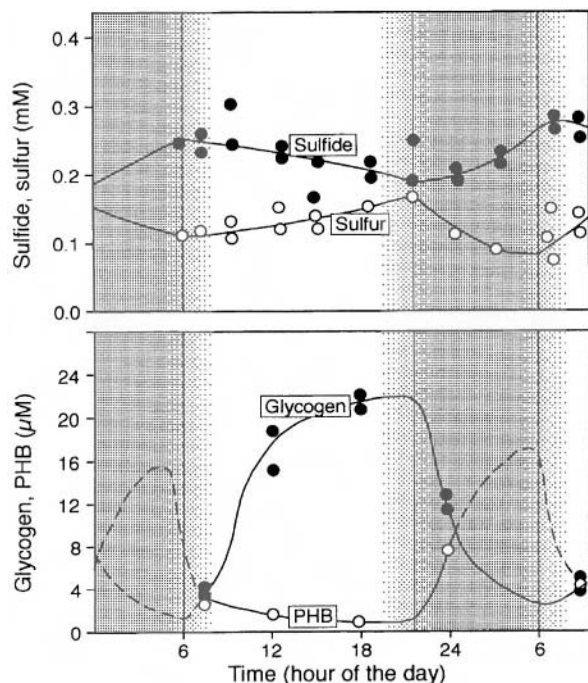

Fig. 7. Diel fluctuations in the concentrations of sulfide, sulfur, glycogen and PHB at a depth of 2 m in Lake Cisó on 6-7 July, 1982. Redrawn from Van Gernerden et al., 1985.

A. Cell Size

Electron micrographs (Fig. 8) usually show a large part of the intracellular volume occupied by storage inclusions. Electron microscopy studies carried out by Esteve et al. (1990) in natural samples indicated that sulfur occupied as an average 7% of the total cell volume, while PHA granules filled between 0.6 and 12.2% of the intracellular space. Experiments carried out in the laboratory (Mas and Van Gernerden, 1987) under conditions which favored the accumulation of sulfur showed that cells of *Chromatium vinosum* in which the content of sulfur was 25% of the dry weight, had 25% of their total cell volume occupied by sulfur inclusions. In order to accommodate structures of this size, the volume of the cell must increase. Variations in cell size related to the accumulation or depletion of intracellular sulfur have been repeatedly reported in the literature (Van Gernerden, 1968a, Guerrero et al., 1984; Mas and Van Gernerden, 1987; Montesinos, 1987). However, the fact that cell size can also change as a function of the specific growth rate of the organism (Schaechter et al., 1958; Shehata and Marr, 1971) often has hampered the discrimination between the effect of

Fig. 8. Ultrathin section of a cell of *Chromatium minus* collected from the bottom of the plate at lake Cisó. The cell contains a large amount of PHB (white inclusion bodies) and a smaller amount of sulfur (dark-gray inclusions). Electron micrograph provided by I. Esteve.

both factors. Experiments carried out with *Chromatium vinosum* undergoing a shift from a low to a high dilution rate in a chemostat ($0.029 \rightarrow 0.086 \text{ h}^{-1}$, app. $25 \rightarrow 75\%$ of μ_{max}) showed an increase in cell size from 3.23 to $5.45 \mu\text{m}^3$ (Fig. 9). The contribution of sulfur inclusions to this increase was $1.35 \mu\text{m}^3$, while $0.87 \mu\text{m}^3$ were considered a consequence of the increased specific growth rate (Mas and Van Gernerden, 1987). These observations indicate that when changes in the content of sulfur inclusions occur along with variations in the specific growth rate, the content of sulfur is still the main determinant of the variations in volume observed.

B. Cell Density

Storage inclusions are compact structures with a specific density higher than that of the surrounding cytoplasm. Therefore, their deposition inside the cell usually results in an increase in the density of the organism. This phenomenon, which has been well documented for storage carbohydrates in *Escherichia coli* (Mas et al., 1989) and for poly(3-hydroxybutyrate) in *Alcaligenes eutrophus* (Pedrós-Alió et al., 1985), is also observed in phototrophic sulfur bacteria especially in relation to the accumulation of sulfur which seems to be the main factor in density differences (Table 3). Studies carried out in *Chromatium warmingii* and *Chromatium vinosum*, show increases of $0.037 \text{ pg} \cdot \mu\text{m}^{-3}$ and 0.050 to 0.064 , respectively, when undergoing sulfur accumulation. Similar studies carried out in *Chlorobium limicola* which deposits sulfur extracellularly indicate a similar effect, with an increase of $0.029 \text{ pg} \cdot \mu\text{m}^{-3}$. This suggests that sulfur globules of green sulfur bacteria,

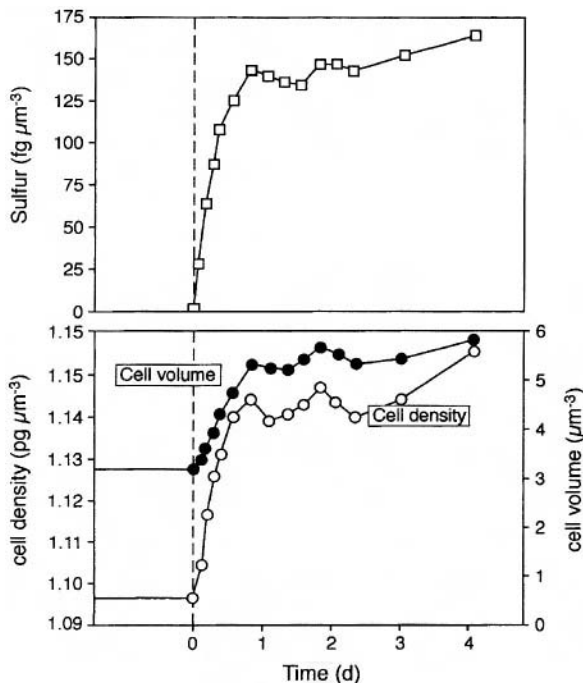

Fig. 9. Variation in the specific content of sulfur (upper panel) and cell volume and buoyant density (lower panel) in a sulfide-limited continuous culture of *Chromatium vinosum* strain DSM 185 during a shift-up from a low (0.029 h^{-1}) to a high dilution rate (0.086 h^{-1}). Redrawn from Mas and Van Gernerden, 1987.

although accumulated extracellularly, somehow might remain attached to the cell, thus supporting the idea (Van Gernerden, 1986) that sulfur in *Chlorobium* should also be considered a storage polymer. Carbohydrates, which are usually present in amounts much lower than sulfur (see Table 1), have a marginal impact on density which only becomes relevant in organisms such as *Pelodictyon phaeochlathratiforme* in which storage carbohydrates can account for as much as 35% of the dry weight (Overmann et al., 1991). In this case, the observed increase in density ($0.037 \text{ pg} \cdot \mu\text{m}^{-3}$) is comparable to the changes due to the presence of sulfur in other organisms. Variations in density as a function of the amount of inclusions are described by a hyperbolic function which asymptotically approaches a maximum value, set by the actual density of the inclusion being accumulated (Mas et al., 1985).

Experimental determinations of this 'in vivo' density for the sulfur inclusions in *Chromatium vinosum* and *Chromatium warmingii* provide different values for each organism (1.22–1.23 and 1.132, respectively) suggesting that the structure of the

sulfur globule is different in each organism (Guerrero et al., 1984; Mas et al., 1985). Although no similar data on storage carbohydrates and PHA are available for phototrophic sulfur bacteria, studies performed in *Escherichia coli* (Mas et al., 1985; Mas et al., 1989) and in *Alcaligenes eutrophus* (Pedrós-Alió et al., 1985; Mas et al., 1985) indicate that the in vivo density of the storage carbohydrate in *Escherichia coli* is somewhere between $1.21\text{--}1.29 \text{ pg} \cdot \mu\text{m}^{-3}$, while PHB from *Alcaligenes eutrophus* has an in vivo density of $1.15 \text{ pg} \cdot \mu\text{m}^{-3}$. The values mentioned above constitute the highest densities the organisms could reach if virtually all the intracellular space were filled with inclusion bodies. However, this is hardly ever the case, and accumulation usually stops well before reaching these densities. Occasional claims of unusually high cell densities are often the consequence of the utilization of high osmolarity media such as sucrose for the construction of gradients used in density determination. While these media might prove suitable for the separation of fractions with different densities, they are completely inadequate to carry out analytical determinations because loss of water from the cell due to osmotic stress results in artificially high densities. An extensive discussion of this topic can be found in Guerrero et al. (1985b).

C. Impact on Sedimentation Rates

Many phototrophic sulfur bacteria develop in planktonic environments where the increase in size and density derived from the presence of storage inclusions potentially could increase their sinking speed and, thus, favor their removal from the water column (see Chapter 4 by Van Gernerden and Mas).

However, field studies carried out in Lake Cisó failed to find a correlation between the actual densities of the organisms in the lake and the rate at which they were sinking (Pedrós-Alió et al., 1989). Despite the fact that theoretical sinking speeds, calculated according to Stoke's law ($1.6\text{--}18.4 \text{ cm} \cdot \text{d}^{-1}$) were comparable to sinking speeds actually measured in the laboratory by other authors ($19.2 \text{ cm} \cdot \text{d}^{-1}$ Matsuyama, 1991), the rates measured were well below the minimum predicted. Cell motility, water turbulence and probably, the presence of loosely attached slime layers might have had an effect on sedimentation not predicted by Stokes law, and thus, have lead to the observed discrepancies.

Although their direct effect on sinking rates seems

Table 3. Variation in the specific density of several phototrophic sulfur bacteria, related to changes in the content of different storage compounds

irrelevant, inclusions might play an important role in the modulation of buoyancy in organisms containing gas vesicles. This function has been well documented in cyanobacteria (Kromkamp and Mur, 1984; Thomas and Walsby, 1985; Utkilen et al., 1985). In some of these organisms, accumulation or degradation of carbohydrate, which actually acts as a ballast, enables the organism to switch from positive to negative buoyancy and, thus, regulate its vertical position within the water column. Studies carried out in *Pelodictyon phaeoclathratiforme* (Overmann et al., 1991) suggest that carbohydrates might play a similar role; however, density of this organism is also determined by the presence of extracellular slime layers and by a certain amount of protein ballast.

VI. Concluding Remarks

Accumulation of storage compounds constitutes one of the most remarkable adaptive features of phototrophic sulfur bacteria. The capacity to synthesize them enables the organism to take advantage of resource pulses in a limiting environment or, on the contrary, to survive short periods of starvation in a otherwise rich environment. The

difference between both situations might be subtle but it certainly calls for different abilities. In the first case, the organism must possess low maintenance requirements, an efficient harvesting system which surpasses the potential for growth, together with a large storage capacity. In the second case, what is needed is the possibility to store a certain amount of substrate even when growth is limited by that substrate, in order to survive periods of complete deprivation later on. Phototrophic sulfur bacteria seem well suited to face both situations. When facing a pulse of substrates, they are able to take up and store considerable amounts of energy, carbon and reducing power. When growing in a fluctuating environment, they manage to store enough resources to be able to overcome the fluctuations.

Very often, physiological studies concentrate on how the organisms can adapt to a certain set of environmental conditions, under the assumption that these conditions will hold steady. However, in nature, this is seldom the case. Thus, physiologists should consider the artificial constraints imposed by a constant laboratory environment and try to understand the metabolic strategy of the organism living in a continuously changing environment.

Summary

The nonsulfur purple bacteria exhibit remarkable versatility in aromatic compound transformations. In recent years it has become evident that these bacteria use a much wider range of lignin-derived monomers for photosynthetic and aerobic growth than was previously suspected. While aerobic attack on the benzene ring appears to follow patterns common to aerobic pseudomonads, the anaerobic pathway is radically different, and the reductive attack on the ring, first suggested for *Rhodospseudomonas palustris* growing on benzoate, has now become firmly established. Coenzyme A thioesters are involved in removal of sidechains from complex aromatic acids prior to attack on the ring itself, and also at all stages of degradation of the nucleus up to and including ring opening. Probable intermediates in the ring reduction reactions have been identified both in vivo and in vitro, but characterization of the enzymes and cofactors involved has yet to be achieved. Two aromatic acid CoA ligases have been purified and the corresponding genes cloned and sequenced. A regulatory gene involved in expression of the ligase needed for 4-hydroxybenzoate activation has also been identified and belongs to the cyclic AMP receptor protein family of transcriptional activators. Disruption of this gene has specific effects on aromatic acid metabolism. There is increasing evidence that the aromatic acid degradation

process is similar in phototrophs and in denitrifying bacteria, but very little is known of the pathways followed in sulfate- or iron-reducing bacteria that utilize aromatic compounds. At present, methods for assessing which type of microorganism plays the major role in degrading natural or unnatural aromatic nucleus-containing compounds in natural environments are not adequate for determining how important the role of nonsulfur photosynthetic bacteria may be on a global scale.

I. Introduction

The photosynthetic bacteria have remarkable physiological flexibility, particularly in terms of energy source, which can originate from light, respiration using a number of electron acceptors in addition to oxygen, and even fermentation (Biebl and Pfennig, 1981). By comparison, the range of carbon sources used has appeared to be modest, with a general preference for fatty or dicarboxylic acids over the sugars favored by many conventional chemoorganotrophs. In the interests of obtaining rapid growth and large cell yields for experimental purposes, or of developing elective culture procedures, the range of organic molecules that can support growth of these bacteria has probably been greatly underestimated, however. This is well exemplified by the range of aromatic compounds that can be used as carbon source to support growth of nonsulfur purple bacteria if one is patient enough to observe cultures over long periods. It may be the case that substrates that can at best support only slow growth still serve as significant carbon sources in natural environments, particularly where there are relatively few organisms which compete for their use. This chapter will be concerned primarily with the physiological, biochemical and regulatory aspects of aromatic compound utilization by photosynthetic bacteria that have come into focus since this subject was reviewed in the Clayton and Sistrom volume on these microorganisms (Dutton and Evans, 1978).

II. Physiology

When Sher and Proctor (1960) first investigated the use of benzoate as a carbon source, most of the strains of *Rhodospseudomonas palustris*, as well as of *Rhodobacter sphaeroides*, *Rhodospseudomonas gelatinosa* (now *Rubrivivax gelatinosus*) and some of *Rhodospirillum rubrum* in the van Niel culture

collection at Pacific Grove were found to grow well anaerobically in light with benzoate as substrate. Since then, a number of studies suggest that the range of photosynthetic bacteria that use aromatic compounds as carbon sources is more restricted, and the general experience has been that the ability is well-developed primarily in strains of *Rp. palustris* (e.g. Biebl and Pfennig, 1981; Harwood and Gibson, 1988; Madigan and Gest, 1988; Khanna et al. 1992). However, *Rhodospirillum fulvum* (Pfennig et al., 1965), *Rhodocyclus purpureus* (Pfennig, 1978) and strains of *Rubrivivax gelatinosus* (Rahalkar et al., 1991), *Rp. acidophila* (Yamanaka et al., 1983) as well as *Rhodomicrobium vannielii* (Wright and Madigan, 1991) have also been shown to grow at the expense of aromatic compounds.

If the range of species that can utilize aromatic compounds has decreased over the last years, the opposite is true for the range of compounds containing benzene nuclei that can be attacked by purple bacteria growing either photosynthetically or as aerobic chemoorganotrophs (Harwood and Gibson, 1988). The original work commonly explored growth only on benzoate or 4-hydroxybenzoate, but a more systematic investigation of potential substrates has since shown that hydroxylated and methoxylated aromatic acids and aldehydes are commonly used growth substrates, as are aromatic acids with extended side chains. Although most of these compounds support growth both in the presence and absence of oxygen, metabolism of some is restricted to aerobic or anaerobic phototrophic conditions. For example, benzoate, as had been recognized earlier, does not serve as an aerobic growth substrate for any strain of photosynthetic bacterium studied to date, although 4-hydroxybenzoate is commonly used under these conditions. Both benzoate and 4-hydroxybenzoate support rates of anaerobic, photosynthetic growth that are about half those obtained with more conventional carbon sources such as malate or succinate. Typical generation times for *Rp. palustris* growing on these aromatic acids are 12–14 h. ω -Phenylalkane carboxylates, with side chain lengths

from three to eight carbons, are excellent substrates for *Rp. palustris* (Harwood and Gibson, 1988; Elder et al., 1992a; Madigan and Gest, 1988), as are several unsubstituted or 4-hydroxylated lignin-related monomers, such as *trans*-cinnamate and 4-hydroxycinnamate (4-coumarate).

It is clear from published work that there is a considerable amount of strain variation in the range of aromatic substrates utilized photosynthetically. The ability to degrade lignin-related compounds with 3-methoxyl or 3-hydroxyl substitutions is a strain-dependent trait in *Rp. palustris*, and these substrates typically support growth rates that are much lower than attained with benzoate (Harwood and Gibson, 1988). A recent report includes phenol among substrates supporting photosynthetic growth of a strain of *Rp. palustris* isolated from effluent of a petrochemical waste water treatment plant (Khanna et al., 1992). With the exception of this last report, a preexisting carboxyl group, or one readily derived from an alcohol or aldehyde substituent, appear to be essential for utilization. As a final example, a strain of *Rp. palustris* that is able to incorporate ^{14}C from isotopically labeled 3-chlorobenzoate when growing in mixtures of benzoate and the chlorinated analog, has been described (Kamal and Wyndham, 1990), although chlorobenzoates are generally toxic to this microorganism. A more versatile isolate has recently been described (van der Woude et al., 1994) which, unlike Kamal and Wyndham's (1990), is able to grow on 3-chlorobenzoate alone. When cultured with mixed chlorobenzoates, this strain also continues to metabolize 2-, 4- or 3,5- chlorobenzoates after exhaustion of the favored substrate 3-chlorobenzoate. Both of these studies suggest that chlorobenzoate-metabolizing enzymes are not normally expressed and that benzoate or 3-chlorobenzoate may be needed as cosubstrates to permit induction of these enzymes.

III. Biochemistry

A. Major Metabolic Themes of Aromatic Acid Degradation

The presence of an aryl group at the distal end of a long-chain fatty acid should offer little hindrance to a conventional oxidative attack on the molecule, although such a bulky group only a few carbons' removed from the carboxyl group probably demands

some degree of enzyme specialization. The benzene ring itself is stabilized by about 125 kJ per mol of resonance energy, however, and this presents a formidable barrier to attack by any organism. Radically different biochemical strategies have evolved to meet this challenge under aerobic and anaerobic conditions. Although there are indeed differences in the details of the metabolic pathways used by different microorganisms, these represent relatively minor variations on broad general themes.

Aerobically, ring resonance is distorted by introducing hydroxyl groups, followed by dioxygenase-catalyzed ring cleavage either between or adjacent to vicinal hydroxyls. These reactions require participation of molecular oxygen and are thus restricted to aerobic conditions. Only one study of the pathway used for aerobic degradation of 4-hydroxybenzoate by *Rp. palustris* has been carried out (Hegeman, 1967), and we are not aware of detailed studies of the aerobic metabolism of aromatic compounds by other species of photosynthetic bacteria.

Anaerobically, the rings of only one, or perhaps two, aromatic acids are attacked. More complex molecules are first converted to the central intermediates benzoate or 4-hydroxybenzoate or their coenzyme A thioesters. The CoA modification serves several functions. It can facilitate uptake of substrate into the cell, since rapid conversion to a non-diffusible CoA derivative by a cytoplasmic enzyme with high affinity for its aromatic substrate will maintain a downhill concentration gradient between the cell and its environment. A high internal concentration of the substrate for the next reaction can be built up, which would assist in pushing an energetically unfavorable reaction. In fact, we have estimated the steady state intracellular benzoyl CoA concentration in cells of *Rp. palustris* growing on benzoate to be about $200\mu\text{M}$. The increased size of the thioester also allows more interactions between these substrates and their enzymes. The ring itself is attacked reductively, and the reduced product subjected to a series of reactions leading to formation of a cyclic β -keto thioester, which is then cleaved to yield a 7-carbon dicarboxylic derivative. This molecule is readily converted to reactants in central metabolic pathways. These themes are illustrated in Fig. 1. Anaerobic transformations carried out by *Rp. palustris* are discussed in greater detail in the sections that follow.

Fig. 1. Outline of major metabolic steps used by *Rp. palustris* for degrading aromatic acids aerobically and anaerobically.

B. Removal of Ring Substituents by Phototrophic Cells

Aromatic compounds with extended acyl side chains often support growth rates of *Rp. palustris* that are higher than those seen with simple aromatic acids, either aerobically or anaerobically (Harwood and Gibson, 1988; Elder et al., 1992a; Rahalkar et al., 1993). The pattern of molar growth yields in photosynthetic cultures growing on compounds with side chains of varying length strongly suggests that these are attacked by β -oxidation mechanisms (Elder et al., 1992a), since cell mass formed increases with side chain length, and ring degradation occurs only when successive removal of 2-carbon units yields

benzoate or 4-hydroxybenzoate. In the strains used for these studies, phenylacetate is not attacked, and accumulates in cultures grown with aromatic substrates carrying even-numbered carbon side chains. By analogy with long-chain fatty acid β -oxidation, coenzyme A modification would be expected as the initial step, and two ligases have been detected in extracts of cinnamate-grown cells, one relatively specific for cinnamate among the substrates tested, and one also able to thioesterify compounds such as ferulate and caffeate that have additional ring substituents (Elder et al., 1992b). Expected intermediates in degradation of some of these compounds have been detected in culture supernatants. Benzoate was found transiently during growth

on *trans*-cinnamate (Elder et al., 1992a) and both cinnamate and benzoate were detected when phenylvalerate was utilized (Rahalkar et al., 1993). Taken together, these findings suggest not only that the sidechain is degraded by stepwise removal of 2-carbon units, but that a complex interaction between thioesterification and hydrolysis reactions is occurring during this process (Elder and Kelly, 1994). It is also conceivable that the relatively plentiful energy supply (i.e. light) that may be enjoyed by photosynthetic bacteria permits a simple hydrolysis rather than the thiolitic cleavage typical of the β -oxidation sequence found in other aerobic and anaerobic microorganisms. Other than the initial thioesterification, these reactions have not yet been characterized in any detail. Side chain degradation evidently precedes modification of any other ring substituents, since protocatechuate was detected during growth on caffeate, and vanillate during growth on ferulate (Harwood and Gibson, 1988). The low cell yield of some strains on ferulate suggests that growth may be solely at the expense of the side chain and that, as in the case of long-chain substituents with even numbers of carbons, the aromatic nucleus itself is not always used (Harwood and Gibson, 1988; Elder et al., 1992b; Rahalkar et al., 1993). The reactions undergone by aromatic ring substituents are summarized in Fig. 2.

Although the suggested β -oxidation reactions fit well with all observations, some *Rp. palustris* strains appear also to be able to carry out an anaerobic removal of a single carbon unit, since benzoylformate and mandelate were used by our strains (Harwood and Gibson, 1988), and an unusual characteristic of the strain studied by Rahalkar et al. (1993) was photosynthetic growth on phenylacetate.

By analogy with other anaerobic systems, reductive dechlorination of 3-chlorobenzoate may be predicted to occur before reduction of the aromatic nucleus, but this has not actually been shown to be the case.

C. Anaerobic Attack on the Aromatic Ring

A novel reductive attack on benzoate during photosynthetic growth was first proposed by Dutton and Evans (1969), based on the results of classical isotope dilution experiments. Concentrated suspensions of *Rp. palustris* were incubated with radioactively labeled benzoate in the presence of several possible partially or fully reduced intermediates, which were subsequently reisolated and their specific radioactivity established. The results of these

experiments suggested a pathway involving reductive ring saturation, followed by a series of reactions analogous to a β -oxidation, prior to opening the ring to yield pimelate (Figs 1 and 3). Support for this suggested pathway came from a series of mutants isolated by Guyer and Hegeman (1969) that had restricted abilities to utilize some of the proposed intermediates as growth substrates. Some years elapsed before it was fully recognized that the actual substrates involved in the benzoate degradation sequence were coenzyme A thioesters rather than the free acids (Whittle et al., 1976; Hutber and Ribbons, 1983; Harwood and Gibson, 1986; Evans and Fuchs, 1988).

Detection of excreted metabolites has played a key role in establishing routes of aerobic aromatic metabolism, as well as in supporting β -oxidation as a mechanism for degrading phenylalkanoates under anaerobic conditions in *Rp. palustris*. However, this approach has not been useful, at least to date, for detecting and analyzing intermediates of benzoate degradation. One reason for this may be that coenzyme A thioesters cannot pass through the cell membrane, and that very little intracellular hydrolysis to yield diffusible products occurs. In addition, small quantities of hydrolyzed intermediates that may have escaped from cells would be difficult to detect, even under ideal conditions, because of the low extinction coefficients of metabolites that have lost aromaticity. Several possible intermediates are also autoxidizable, and may merge with the growth substrate during preparations for analysis.

Although much remains uncertain about the pathway proposed, several recent findings have contributed some clarification to the reductive phase of the reaction scheme. Intracellularly, small quantities of two unconjugated cyclohexadiene derivatives—cyclohexa-2,5-diene-1-carboxylate and cyclohexa-1,4-diene-1-carboxylate—were detected in the putative CoA thioester pools of *Rp. palustris* growing exponentially on benzoate as carbon source (Gibson and Gibson, 1992), suggesting an initial two electron reduction analogous to the chemical reduction of the benzene nucleus in the Birch reaction (Birch and Smith, 1958). More recently, Fuchs and his colleagues have succeeded in demonstrating reduction of benzoyl CoA with cell extracts of a denitrifying pseudomonad (Koch and Fuchs, 1992), and detected the conjugated isomer cyclohexa-1,5-diene-1-carboxyl-CoA directly using NMR methods (Koch et al., 1993). They also found the same product

Fig. 2. Pathways for the degradation of substituents of aromatic acids by *Rp. palustris*. Many of the routes shown have been inferred from work with cell cultures and not all enzymatic activities have been demonstrated. Although it is presumed that the degradation of many aromatic acids is initiated by addition of CoA, this has not been indicated in this figure in every case.

Fig. 3. A current view of the pathway proposed for anaerobic benzoate degradation in *R. palustris*. † – metabolites from experiments of Dutton and Evans with whole cells (1969); * – detected in soluble contents of cells growing exponentially on benzoate (Gibson and Gibson, 1992); † – detected as products in cell-free reactions (Koch et al., 1993).

in experiments with *Rp. palustris* extracts. These additions to the pathway as proposed initially are shown in Fig. 3. The differences between the metabolites detected in extracts and in whole cells are not yet explained, but kinetic effects may significantly alter the distribution of intermediates in vivo and in vitro. The physiological electron donor in the initial ring reduction is not known.

It seems probable that reductive saturation of the benzene ring involves a single pathway, and that 4-hydroxybenzoate, as well as other aromatic acids with side chains in addition to a 4-hydroxyl group, such as 4-hydroxycinnamate, undergo reductive dehydroxylation before ring reduction. Free benzoate has been detected in the culture medium of some strains of *Rp. palustris* during growth on 4-hydroxybenzoate (Evans and Fuchs, 1988; unpublished observations from our laboratories), and benzoyl CoA as well as 4-hydroxybenzoyl CoA have been seen among early products in the small molecule pools of cells that had taken up ^{14}C -4-hydroxybenzoate for one to two minutes (Perrotta and Gibson, unpublished). An oxygen-sensitive dehydroxylating enzyme which carries out the reduced benzyl viologen-dependent reduction of 4-hydroxybenzoyl CoA to benzoyl CoA has been purified and characterized by Brackmann and Fuchs (1993) from extracts of a denitrifying bacterium grown anaerobically on 4-hydroxybenzoate. These workers also detected this activity in extracts of *Rp. palustris*.

The alicyclic intermediates detected in the experiments of Dutton and Evans suggested that ring reduction proceeded at least to the state of a cyclohexene carboxyl derivative. The subsequent steps that they postulated resembled those involved in β -oxidation of fatty acids, including a hydration, a dehydrogenation and a cleavage (Fig. 3), and it seems probable that the early intracellular and in vitro benzoyl CoA reduction products that have been detected (Gibson and Gibson, 1992; Koch et al., 1993) are converted to a cyclohex-1-enecarboxyl CoA. Enzyme activities catalyzing the sequential hydration and dehydrogenation of cyclohex-1-enecarboxyl CoA (Fig. 3) were demonstrated in cell extracts (Whittle et al., 1976; Hutber and Ribbons, 1983), and recent reinvestigation of these reactions has indicated that these activities are increased at least three-fold by growth on benzoate (Perrotta and Harwood, 1994). An apparent 2-ketocyclohexanecarboxyl CoA cleavage that does not require coenzyme A has also been detected, suggesting that

cleavage of the ring is hydrolytic rather than thiolitic (Perrotta and Harwood, 1994).

A significantly different benzoyl CoA degradation pathway, yielding 3-hydroxypimelyl CoA on ring opening, was recently suggested for the denitrifying pseudomonads, and also for *Rp. palustris* (Koch et al., 1993; Fig. 3), although all the postulated intermediates were not detected in their experiments. Until the enzymes involved have been characterized it is not possible to distinguish clearly between products in the mainstream of carbon flow and those resulting from side reactions.

A pathway for β -oxidation of pimelyl CoA to 3-hydroxypimelyl CoA followed by cleavage to yield acetyl CoA and glutaryl CoA was suggested by Blakley (1978) based on studies of cyclohexanecarboxylate utilization by a strain of *Alcaligenes*. His further proposal that glutaryl CoA is oxidatively decarboxylated to crotonyl CoA is supported by the recent demonstration of these reactions in extracts of benzoate-grown *Rp. palustris*, *Rhodomicrobium vannielii* and *Rhodocyclus purpureus*, as well as denitrifying pseudomonads (Härtel et al., 1993). Glutaryl CoA dehydrogenases which catalyze both the oxidation and decarboxylation reactions leading to formation of crotonyl CoA have been purified from two denitrifying strains (Härtel et al., 1993).

D. Enzymology

Most of the detailed work on enzymes involved in aromatic acid metabolism has centered on the coenzyme A ligases. Two ligases, one apparently specific to 4-hydroxybenzoate degradation and the other involved in benzoate utilization have been purified and characterized from *Rp. palustris* (Geissler et al., 1988; Gibson et al., 1994). As noted above, two enzymes that activate cinnamate have also been resolved (Elder et al., 1992b). These are clearly distinct from the benzoate and 4-hydroxybenzoate enzymes studied in our laboratories, which do not react with cinnamate. Some characteristics of the aromatic CoA ligases so far known are summarized in Table 1. The benzoate and 4-hydroxybenzoate CoA ligases have quite narrow, but overlapping, substrate specificities. They differ considerably from each other in terms of molecular and kinetic characteristics, and antisera prepared against each of the purified enzymes do not cross-react. The high in vitro affinity of benzoate CoA ligase for its aromatic substrate parallels the high affinity of whole cell

uptake for this substrate, and we have suggested that the enzyme plays a role in substrate acquisition from the environment as well as in its subsequent metabolism (Harwood and Gibson, 1986). A curious and as yet unexplained finding is that purified 4-hydroxybenzoate CoA ligase has a much lower affinity for 4-hydroxybenzoate than do intact cells (Merkel et al., 1989; Gibson et al., 1994). *Rp. palustris* presumably has additional CoA ligases, since the enzymes characterized so far do not use alicyclic acids as substrates. One such enzyme has recently been partially purified and characterized (Kuever et al., unpublished) and activates a range of both alicyclic and aromatic acid substrates. This enzyme is expressed during growth on alicyclic substrates such as cyclohexane carboxylate, or cyclohex-1-ene-1-carboxylate, as well as aromatic acids, but not on succinate, and is immunologically distinct from the two ligases already purified in our laboratory.

Other portions of the proposed benzoate degradation reaction sequence have so far been studied only in crude extracts. The initial reductive step(s) are clearly extremely sensitive to oxygen inactivation, and so differ both from the ligase reactions and those

converting cyclohex-1-ene-carboxyl CoA to pimelyl CoA in this characteristic (Hutber and Ribbons, 1983; Perrotta and Harwood, 1994).

III. Regulation and Genetics

A. Expression of Aromatic Acid CoA Ligases

Antisera prepared against the two purified CoA ligases from *Rp. palustris* have been used to follow expression of these enzymes by Western immunoblotting. This approach avoids potential complications caused by an unexplained partial inhibition of activities in crude extracts (Geissler et al., 1988; Gibson et al., 1994). Benzoate CoA ligase is induced by growth on several metabolizable aromatic acids, including benzoate (Table 1), as well as by growth on succinate in the presence of non-metabolizable aromatic acids—for example, 3-chlorobenzoate, 2-aminobenzoate and 4-methylbenzoate—with various ring substituents. Cyclohexadiene- and cyclohexenecarboxylates also elicit expression. Antigen was not detected in extracts of cyclohexane carboxylate grown cells, nor following

growth on succinate (Kim and Harwood, 1991). The diversity of aromatic compounds that can serve as inducers may reflect the role of benzoate as a critical central metabolite in aromatic compound degradation. The 4-hydroxybenzoate CoA ligase, in contrast, is fully induced only by growth on 4-hydroxybenzoate or 4-hydroxycinnamate. Of the two cinnamate CoA ligases resolved by Elder et al. (1992b), activity measurements indicated that one was constitutively expressed, even when malate was the growth substrate, but the second was found only after growth on aromatic acids bearing side chains (Table 1).

B. Genetic Approaches

As far as we are aware, genetic analyses of aromatic acid degradation systems have only been attempted in *Rp. palustris* (Guyer and Hegeman, 1969; Elder et al., 1993), and the intensive efforts to apply such approaches in our laboratories have only recently begun to yield useful information (Dispensa et al., 1992; Gibson et al., 1994). So far, only a few stable mutants have been isolated that are unable to grow on aromatic compounds. Some possible explanations for this are that *Rp. palustris* has very effective repair mechanisms, and that a measure of redundancy is built into the pathways through somewhat relaxed substrate specificities of the enzymes involved or even alternative routes of carbon flow.

1. Benzoate and 4-Hydroxybenzoate CoA Ligase Genes

We have used immunoscreening to identify and isolate *Rp. palustris* clones encoding the benzoate and 4-hydroxybenzoate CoA ligase genes (*badA* and *hbaA*) (Gibson et al., 1994; Eglund and Harwood, 1994). Both genes are chromosomally encoded and both have been sequenced and found to share 50% predicted amino acid identity. In addition, they are each about 20% identical at the amino acid level to a number of coenzyme A ligases that are not involved in anaerobic aromatic compound metabolism. These include acetate CoA ligases from bacteria and fungi (Connerton et al., 1990; Eggen et al., 1991), aromatic CoA ligases required for the aerobic degradation of 3-chlorobenzoate (Babbitt et al., 1992) and 2-aminobenzoate (Altenschmidt and Fuchs, 1992), and coumarate CoA ligases involved in phenylpropanoid biosynthesis in plants (Lozoya et al., 1988).

Studies with purified enzymes and with extracts

of cells grown under different conditions suggest that some aromatic acids can be activated by more than one CoA ligase, and this seems to be the case for benzoate. A *badA* mutant that we constructed by gene replacement techniques (Eglund et al., unpublished) had extremely low levels of ligase activity when mutant cell extracts were assayed with 10 μ M benzoate, a concentration that gives maximal ligase activity in wild-type cell extracts. Despite this, the *badA* mutant had a normal growth rate on benzoate under laboratory culture conditions (3 mM benzoate). Further experiments showed that when *badA* cell extracts were assayed at high benzoate concentrations (1mM), benzoate CoA ligase activities were about the same as those seen in wild type cells. Thus *Rp. palustris* must have another enzyme with benzoate-CoA ligase activity, in addition to the *badA* product, that can function when benzoate is present at relatively high concentrations.

In contrast to the situation with benzoate, 4-hydroxybenzoate appears to be activated by a single CoA ligase. An *hbaA* mutant that was constructed lacked detectable 4-hydroxybenzoate-CoA ligase activity and was also incapable of anaerobic growth on 4-hydroxybenzoate (Gibson et al., 1994).

There are open reading frames (ORFs) adjacent to each of the ligase genes, and preliminary evidence suggests that at least one of these ORFs may be cotranscribed with the benzoate CoA ligase gene. This provides some hope that the genes for anaerobic degradation of aromatic acids may be organized into operons, a situation which would greatly simplify further genetic analysis.

2. *aadR*, a Regulatory Gene Involved in Anaerobic Aromatic Degradation

Intensive study of the few stable *Rp. palustris* mutants that we have isolated following random screening for defective growth on benzoate or 4-hydroxybenzoate has led to the identification of a gene termed *aadR*, for anaerobic aromatic degradation regulator (Dispensa et al., 1992). *AadR* mutants are unable to grow photosynthetically on 4-hydroxybenzoate and grow only very slowly on benzoate. Aerobic growth on 4-hydroxybenzoate remains unimpaired, as does anaerobic growth on succinate and other organic acids. *AadR* is required for expression of 4-hydroxybenzoate CoA ligase, and also for 4-hydroxybenzoate-induced expression of benzoate CoA ligase, as evidenced in Western blots.

Additional, as yet uncharacterized, functions needed for optimal growth on benzoate also appear to be controlled, at least in part, by *aadR*, since all these mutants grow much more slowly than the parent on this carbon source.

The deduced amino acid sequence of the *aadR* gene product indicates that it is a member of the cyclic AMP receptor protein (Crp) family of transcriptional regulators. In addition to Crp, this family includes Fnr, a regulator of genes required for anaerobic respiration in *Escherichia coli* (Fischer, 1994). Although *aadR* mutants do not have an *fnr*-like phenotype, the AadR protein contains several of the conserved cysteine residues that have been proposed to play a role in redox potential sensing by Fnr. The greatest similarity between AadR and other members of the Crp family is to the FixK proteins of nitrogen-fixing bacteria (Batut et al., 1989; Fischer, 1994), but dinitrogen-dependent growth of *Rp. palustris* is not affected by the *aadR* mutation. The very distinctive phenotype of the *Rp. palustris aadR* mutants indicates that AadR protein functions specifically as a transcriptional regulator of genes required for anaerobic aromatic acid degradation.

V. Ecology

Nonsulfur purple photosynthetic bacteria are universally distributed and it is relatively easy to isolate species and strains that will grow on aromatic compounds anaerobically in light. As already noted, the range of compounds used by such isolates includes many that may arise during anaerobic lignin degradation as well as a number of potentially toxic human products that are of environmental concern. Where this has been investigated, the affinity of whole cells for aromatic substrates is very high indeed, with apparent K_m values below micromolar levels (Harwood and Gibson, 1986; Merkel et al., 1989), and virtually complete assimilation of carbon from aromatic substrates into photosynthetic bacterial biomass has been noted repeatedly (for example, Wright and Madigan, 1991). Anaerobic utilization and mineralization of many compounds containing benzene nuclei is also carried out by some denitrifying pseudomonads, by sulfate and iron reducers and also by methanogenic consortia (see Evans and Fuchs, 1988; Fuchs et al., 1994), and one may speculate as to which physiological type plays an overall dominant role in natural environments. Significant factors that

will affect which type or types will function effectively in any natural system will include their versatility in carbon source utilization and their ability to both tolerate and exploit rapidly changing environmental conditions such as oxygen levels. Substrate affinity must be another significant factor. Various metabolic characteristics of *Rp. palustris* discussed in this chapter suggest that it and its relatives may be competitive under some conditions. However, massive growth of nonsulfur purple bacteria are uncommon in natural systems, and there are as yet no good methods for determining which aspects of genetic potential are expressed in nature. Although infrared light used by photosynthetic bacteria penetrates solid substrata better than visible wavelengths, the depth to which this energy source will be available is still quite limited. Taken together, these factors suggest that anoxygenic phototrophs are likely to be only minor, although occasionally significant, participants in the anaerobic turnover of aromatic compounds in most natural systems.

VI. Comparative Aspects

Since a reductive pathway for anaerobic degradation of aromatic compounds was first proposed, evidence has accumulated for similar pathways in a number of bacteria that can use such substrates in the absence of molecular oxygen. Particularly impressive progress has come from the studies of Fuch's group with two denitrifying bacteria. It is worth pointing out, however, that very little is known about how aromatic compounds are degraded by microorganisms such as sulfate or iron reducers, in which an adequate metabolic energy supply is far less easily obtained than in phototrophs. It remains possible that as the activities of more microorganisms are explored in increasing detail, distinctly different routes for the anaerobic degradation of aromatic nuclei will be revealed, much as has occurred in the study of aerobic pathways.

Acknowledgments

The work from our laboratories was supported in part by a grant (DE-FG02-86ER13495) from the Department of Energy, Division of Energy Biosciences to JG, and by grants from the U. S. Army Research office (DAAL03-92-G-0104 and DAAL03-

92-G-0313) with co-funding by the Department of Energy, Division of Energy Biosciences, to CSH.

Summary

Remarkably little is known about the motility, behavior and transport systems of phototrophic bacteria, perhaps because in the past there has been a general assumption that these were basic bacterial functions that would turn out to be the same as those characterized in enteric bacteria. However, we hope that the following brief review will show that in all three areas the purple non-sulfur bacteria have proved to be different from the enteric bacteria in many important ways and may well provide a better model system for species under growth limiting conditions. The work described is limited, reflecting the dearth of data in these fields and is concentrated mainly on the *Rhodobacter* species. As the latter have provided us with many unexpected surprises, what would we find if the green bacteria were studied in detail?

Many species of anoxygenic phototrophs are motile, using a variety of patterns of flagellation e.g. peritrichous, polar tufts, single flagella. However, *Rb. sphaeroides* was the first species to be found which could only rotate its flagellum in one direction, stopping rotation with a full Δp to change direction. This has implications for the mechanism of proton transport through flagella in general, and the cloning of the motor genes will be particularly important in helping characterize the energetics of motor function. In addition to a unidirectional motor, and perhaps in some way connected, chemotaxis to the dominant chemoattractants has been found to require transport and metabolism. *Rb. sphaeroides* also does have chemoreceptors suggesting two chemosensory pathways operating in parallel. It seems probable that *Rhodobacter* provides a model for one end of the sensory spectrum, linking its responses to its current growth requirement, whereas the enteric bacteria provide the other end of the spectrum, primarily using dedicated receptors. Other photosynthetic species may lie somewhere between, using dedicated and metabolism based sensing equally. The type of sensing may reflect the increased importance of the flexible electron transport mechanisms in these species compared to enteric species. Similar motility and chemosensing systems have recently been identified in a number of rhizosphere bacteria, suggesting a more widespread distribution.

The *Rhodobacter* species also show prolonged chemokinesis in response to some chemoattractants. Chemokinesis depends on transport but not metabolism; however, as little is known about transport, the mechanism involved is unclear. Investigation into different transport mechanisms in the purple non-sulfur bacteria suggests a new class of periplasmic binding protein dependent transporter, highlighting the importance of pH_i in controlling transport.

It is hoped that this chapter will highlight the value of investigating what may be considered common bacterial phenomena in the phototrophic species, as it does not produce 'me too' data, but reveals the true diversity of bacterial systems and the adaptation of physiology to fit their growth environment.

I. Introduction

Why study standard physiological phenomena in species of anoxygenic photosynthetic bacteria when there is so much information from the enteric species? The limited studies undertaken so far using the purple non-sulfur bacteria have already revealed that bacteria use a far more diverse range of mechanisms than previously thought to transport solutes and to swim and sense their environment. But, in addition,

there are technical advantages to working with the *Rhodobacter* species not available to those working with enterics. One advantage is related to the techniques that are available to study the bioenergetics of phototrophic bacteria, which are of use in determining the relationship between e.g. solute uptake and its driving force and the electrochemical proton gradient and flagellar rotation i.e. the mechanism of energy coupling in these systems. For example, the ability to use non-invasive methods

such as carotenoid electrochromism to measure membrane potential (Jackson, 1988) has proved of great value, since the extremely fast response time of the absorbance changes can be used to measure membrane ionic currents and their dependence on membrane potential. Although the transmembrane distribution of lipophilic cations has also been used to determine membrane potential, there is continuing controversy over which method (ion distribution or electrochromism) is the more reliable (Crielaard et al., 1988). In addition, light is an almost 'instantaneous' and controllable energy source which has obvious advantages when investigating the energetics of these processes. The bioenergetic advantages are now enhanced by the advanced genetic systems available for *Rb. capsulatus* and *Rb. sphaeroides*, which, although not yet quite on a par with the enteric bacteria, has made possible the cloning and analysis of genes involved in transport, flagella synthesis and rotation, and chemotaxis.

II. Motility and Behavior

A. Historical Perspective

Motility is widespread amongst photosynthetic bacteria and, in the vast majority of cases, the motor organelle is the flagellum. Early microscopic studies of motility by Ehrenberg and Engelmann in the 19th century (Ehrenberg, 1838; Engelmann, 1881), concentrated on the photosynthetic bacteria. Ehrenberg was able to observe polar bundles of 'wave-shaped' flagella on cells of what was probably a *Chromatium* species, and he presumed that these might be required for motion. Engelmann cultured photosynthetic bacteria from the river Rhine and studied their randomly stopping and starting motility. He also noted that the bacteria could accumulate in spots of light, the first indication of phototaxis (see taxis section later in this chapter). Later work in the 1960s by Cohen-Bazire and London (1967) revealed the microscopic structure of isolated flagella from *Rhodospirillum rubrum*. They showed the flagellum,

complete with the basal-body, consisting of a series of proteinaceous rings embedded in the cell wall and membranes (a typical electron micrograph of an *Rs. rubrum* flagellum is shown in Fig. 2). From this early structural work, theories for the rotational mechanism of flagellar action were developed. More recently, molecular genetic analysis in enteric and photosynthetic bacteria has been used to probe the structure and function of these bacterial 'propellers'.

B. Motility

Most species of the purple non-sulfur bacteria (on which this review will necessarily concentrate because of the dearth of data from other species) are flagellate, as are many Chromatiaceae, and fresh environmental isolates are nearly always highly motile. Most patterns of flagellation seen on non-photosynthetic species have been identified on one or more photosynthetic species (Fig. 1). *Chromatium* swims with a single tuft of flagella whereas *Rs. rubrum* has bipolar bundles (lophotrichous) (Clayton, 1957; Pfennig, 1968) *Rhodobacter* and *Rhodopseudomonas* species are uniflagellate with a medial or sub-polar flagellum (Armitage and Macnab, 1987; Tauschel, 1987). Peritrichous or lateral flagella, as found in the much studied enteric and bacillus species, have been identified on *Rhodomicrobium vannielii* and the swarming phase of *Rhodospirillum centenum*. *Rhodospirillum centenum* swims in liquid medium by means of a single, possibly sheathed, polar flagellum but when grown on solid media a large number of lateral flagella are induced. These lateral flagella appear to allow the colonies of *Rs. centenum* to swarm towards and away from the light (see later). The induction of lateral flagella appears to be the result of surface contact not viscosity as, unlike *Vibrio parahaemolyticus* or *Serratia marcescens*, lateral flagella are not induced by increasing viscosity (Ragatz et al., 1995).

1. Flagellar structure

The structure of the flagella of enteric bacteria has

Abbreviations: Che – chemotaxis proteins; CM – cytoplasmic membrane; *Cm.* – *Chromatium*; Dct – dicarboxylate transport system; DMSO – dimethyl sulphoxide; *Ec.* – *Ectothiorhodospira*; FPr – fructose protein; HPK – histidine protein kinase; HPr – histidine protein; ICM – intracytoplasmic membrane; Kdp – high-affinity potassium transport system; MCP – methyl accepting chemotaxis protein; Mod – molybdenum transport system; Mot – motor proteins; MSX – methionine sulfoxamine; ORF – open reading frame; PBP – periplasmic binding protein; PCPPTS – chemotaxis protein; PEP – phosphoenolpyruvate; pH_i – intracellular pH; Pro – proline transport system; PTS – phosphotransferase sugar transport system; *Rb.* – *Rhodobacter*; *Rs.* – *Rhodospirillum*; *Rp.* – *Rhodopseudomonas*; ΔNa^+ – sodium motive force; Δp – electrochemical proton gradient; $\Delta \psi$ – membrane potential

Fig. 1. Different patterns of motility (a) peritrichously flagellate species swimming with a rotating bundle, periodically the flagella switch from CCW to CW rotation, the bundle is forced apart and the cell 'tumbles', smooth swimming resumes in a new direction; (b) polarly flagellate species changing direction by briefly 'backing-up' as a result of a transient change from CCW to CW flagellar rotation; (c) direction changing as a result of stopping flagellar rotation, the loss of torque causes the flagellum to 'relax' and Brownian motion reorients the cell for future smooth swimming; (d) lophotrichously flagellate species, swimming equally well in either direction and coordinating flagellar switching.

been characterised in great detail (Iino, 1985; Macnab, 1992) and it seems likely that the overall structure and organization is similar in all bacterial species. However, the purple non-sulfur bacteria have provided a few surprises and the differences from enteric models are helping to characterise motor function in general. More recently, some other (non-photosynthetic) species have been characterized in which motility is more closely allied to that found in *Rhodobacter* than to that found in enteric bacteria.

A stylized drawing of a flagellum is shown in Fig. 2. The flagellar filament is a semi-rigid helix, 15 nm in diameter and 3–10 μm in length, made up of approximately 20,000 flagellin subunits polymerized in an 11-start-helix to form a hollow protein cylinder. Flagellins (usually about 50–60 kDa) do not show great sequence conservation between species, except at the N and C terminal regions that seem to be involved in subunit interaction; indeed an antiserum against *Rb. sphaeroides* flagellin reacts very poorly with flagellins from other photosynthetic species. The functional flagellar filament forms a helix of specific wavelength and handedness; the structure results from the two alternative interactions between

the flagellin subunits, one resulting in a shorter protofilament and one a longer. The arrangement of the subunits into the 11 protofilaments that make up the flagellum means that there are 12 polymorphic forms of the flagellum. In many species the handedness and wavelength alter as the number of protofilaments forced into the short conformation changes when the direction of flagellar rotation changes. This results in a change in swimming direction as the flagellar bundle is forced apart and the cell 'tumbles' (Fig. 1). *Rb. sphaeroides* shows a dramatic change in flagellar shape during swimming. Motor rotation causes a normal functional helix, but periodically the motor stops rotating and the flagellum relaxes to a short-wavelength large-amplitude coil, during which time Brownian motion reorients the cell before rotation starts again.

The flagellar filament is connected to the rotor by a hook, so called because in most species it is hook shaped. The hook has a similar subunit arrangement to the filament and is thought to act both as a universal joint, allowing peritrichous flagella to come together as a rotating bundle and as a mechanism for transferring torque changes from the motor to the

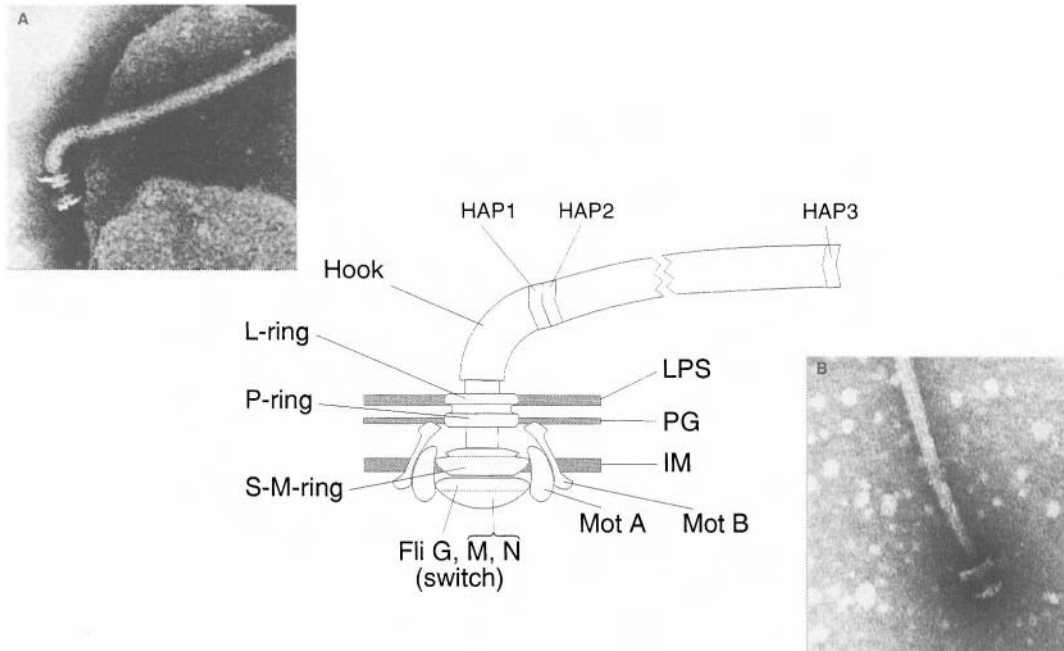

Fig. 2. Diagrammatic representation of the flagellar motor with negative stained electron micrographs of the isolated motor from (A) *Rs. rubrum* and (B) *Rb. sphaeroides*. HAP = hook associated proteins, LPS = lipopolysaccharide, PG = peptidoglycan, IM = inner membrane, MotA/B = motor proteins. (A) reproduced from Cohen-Bazire and London (1967) with permission.

filament. At the boundary between the hook and filament are hook-accessory proteins (HAPs) which may help polymerization and torque transfer.

The hook connects to the rod, and this in turn is connected to a series of membrane and wall-bound rings. The M-S ring (see Fig. 2) located in the cytoplasmic membrane and the membrane-associated proteins FliG, M, and N (switch-complex), at the cytoplasmic face of the M-S ring, are thought to be where rotation is both generated and the direction of rotation controlled (see section on taxis). The other rings probably act as 'washers' to allow passage of the rotating rod through the outer layers of the cell. Complexes of two proteins, Mot A and B are arranged around the M-S ring and these seem to be the force-generating units, acting as the proton channels and the stators of the motor.

2. Flagellar Rotation

a. Energy Source

The energy for flagellar rotation comes from the electrochemical proton gradient (Δp) across the cytoplasmic membrane; ATP is not required for flagellar rotation although it may be needed for tactic

responses. Experiments on *Rp. palustris* by Tauschel (Tauschel, 1987) suggested that there was ATPase activity on the cytoplasmic side of the flagellar basal-body. The identification of ATPase activity in the flagellar assembly protein, FliI, makes it probable that the activity is involved in flagellin export rather than rotation (Dreyfus et al., 1993). FliI has now been independently identified in *Rb. sphaeroides* by two groups (G. Dreyfus, I.P. Goodfellow, C. E. Pollitt and R. E. Sockett, unpublished).

It is assumed that the protons which cause the rotation of the flagellum come from the bulk phase in the periplasm, but the presence of localized electron transport chains dedicated to the flagellum has not been tested experimentally. However, as *Rb. sphaeroides* is motile under both aerobic and photosynthetic conditions (in the latter case the predominant electron transport components are located in the ICM whereas the flagellar motor presumably remains associated with the CM), it seems probable that bulk phase protons drive rotation.

Studies with free swimming *Rb. sphaeroides* show that, as with other species, the threshold for motility is very low, below -15 mV, with a linear increase in speed as the Δp rises until the speed saturates at about -50 mV (Harrison et al., 1994). The range is

somewhat lower for *Rb. sphaeroides* than *E. coli*, which may reflect either the difference between single and peritrichous flagella or a true difference in motor behavior. The maximum swimming speed varies from species to species, with peritrichously flagellated bacteria swimming at about $15 \mu\text{m s}^{-1}$ and mono-flagellate species such as *Rb. sphaeroides* swimming at speeds of up to $100 \mu\text{m s}^{-1}$; representing a flagellar rotation rate of over 100 Hz. Calculations suggest that it takes between 200 and 1000 protons per rotation, which means that motility may take up to 1% Δp for bacteria growing in minimal media (Meister et al., 1987; Brown et al., 1993). *Rb. sphaeroides* swims efficiently (using Δp not a ΔNa^+) between pH6 and pH9, reflecting the low threshold for motility; the velocity starts to fall as the pH is increased above 9 but does not stop until close to 10 (Packer et al., 1994). Interestingly, although the speed of flagellar rotation saturates at about -50 mV and remains constant as the Δp is increased to saturation, it is possible to make *Rb. sphaeroides* swim faster by stimulation with a range of chemokinetic compounds (see later), suggesting that the efficiency can be increased.

The mechanism by which the electrochemical proton gradient is transduced into rotational work is unknown, as reflected by the large number of theoretical papers on the subject (see Blair, 1990). The MotA protein in *E. coli* has been identified as the probable site of proton transport, possibly with MotB as the stator and the energy transduction occurring in either the M-S-ring or the switch complex. Recently two *Rb. sphaeroides* flagellar motor genes have been identified (Sockett et al., 1990; Sockett and Armitage, 1991); and sequenced (Shah et al., 1995; Shah and Sockett, 1995). The protein encoded by one of these genes has been found by *phoA* fusion analysis to be located in the cytoplasmic membrane with a C terminal periplasmic domain. This *Rb. sphaeroides* motor gene shows limited homology to MotB of enteric bacteria. MotB homology is strongest in the single membrane spanning domain which may form part of the proton channel, along with MotA. The periplasmic domain of *Rb. sphaeroides* MotB differs from others in that it does not contain obvious peptidoglycan binding motifs. The product of the second *Rb. sphaeroides* gene has 21% identity to MotA from enteric bacteria; it has a predicted secondary structure consisting of four membrane-spanning helices, and a central, charged, cytoplasmic domain. Although the level of identity is not high,

several amino acids identified in enteric bacteria as being absolutely required for rotation (Blair and Berg, 1990), are conserved in the *Rb. sphaeroides* genes. The molecular comparison of *Rb. sphaeroides* and *E. coli* flagellar motor proteins will be of particular interest for identifying the residues important for proton transport and for helping identify the differences between a switching and a unidirectional motor.

b. Swimming Patterns

Rotation of flagella in most bacterial species, including *Rs. rubrum* and *Chromatium* spp., is bidirectional, with frequent switching from clockwise to counterclockwise. *Rs. rubrum* swims in a series of runs and reversals, the cells back-up as the rotational direction of the flagellar bundle changes (Clayton, 1957; Mitchell et al., 1991). The periodic switch in the direction of rotation from CCW to CW is what changes the swimming direction of a cell and is the response modulated during taxis to bias the usual 3 dimensional swimming pattern towards an attractant. The control of switching has been, as will be seen later, the subject of a great deal of research in enteric bacteria and in these species (and probably many others) direction changing is brought about by the binding of a small 12 kDa protein, CheY, to the switch complex when phosphorylated (phosphorylation being controlled by either environmental stimuli or modulated internally) (Barak and Eisenbach, 1992a). However a 12 kDa protein can only diffuse a limited distance (Ishihara et al., 1983) and is unlikely to be the cause of the coordinated switching of the flagellar bundles of *Rs. rubrum*, where reversal in rotation direction occurs simultaneously at each end, even in cells $60 \mu\text{m}$ long. It is possible that an electrical signal may coordinate flagellar reversal in these species, but as yet there is no definitive evidence for this (Lee and Fitzsimmons, 1976).

Although the coordination between the polar flagellar bundles may be electrical, the control of flagellar switching during chemotaxis may still involve CheY, as proteins showing homology to the enteric chemosensory proteins controlling CheY have been identified in *Rs. rubrum* (Sockett et al., 1987; Morgan et al., 1993). How the two systems interact has not been investigated, but the recent identification of the clustering of the chemosensory proteins in *E. coli* (Maddock and Shapiro, 1993) suggests the possibility that these proteins are clustered around

the tufts of flagella, allowing a rapid chemosensory response. No studies have yet been carried out on switch proteins in photosynthetic bacteria, but in enteric bacteria the FliN, M and G proteins are implicated in generating flagellar reversals (Jones and Aizawa, 1991). It may well be that similar proteins are present in *Rs. rubrum*, responding to chemosensory signals, but there may be additional proteins responding to electrical signaling.

The *Rb. sphaeroides* flagellum rotates unidirectionally, intermittently stopping, then restarting rotation, the bacterium moving off in a new direction (Armitage and Macnab, 1987). The flagellar stopping frequency is increased if the bacteria swim down a gradient of a positive tactic effector (see later). Until recently it was thought that rotation was always clockwise in these bacteria, but recently a naturally occurring variant has been found in wild-type populations which shows exclusively counter-clockwise rotation (H. Packer and J. P. Armitage, 1993). The CCW rotating flagellum has a different handedness and wavelength compared to the CW flagellum, and is more efficient at moving the cell through viscous environments, but whether this is of physiological relevance is not known. The rotational stopping frequency and swimming speed of cells from the same population varies quite dramatically. It is not known whether stopping and speed changes represent the action of a 'clutch' i.e. decoupling the energy supply from the flagellum; or the action of a 'brake' i.e. blocking rotation of the flagellum with the energy supply left 'plugged in'.

Studying the *Rb. sphaeroides* flagellum gives a unique opportunity to look at the activity of a single copy enzyme under different conditions and at different stages of the cell cycle. Heterogeneity in the motility of *Rb. sphaeroides* may merely reflect variation in flagellar activity which is present in all enzymes in cells, but which is averaged out by the presence of multiple copies of the enzyme.

3. Flagellar Genetics and Biosynthesis

The biosynthesis of flagella has been extensively studied in enteric bacteria by several workers (Koch et al., 1982; Iino, 1985; Macnab, 1992), and it has been established that flagellar components are synthesised and assembled in a defined order. The rings and rod are synthesised and assembled first followed by the hook, HAPs and filament. The motor and switch components are added last, after the

passive structural elements of the flagellum have been assembled. The axial components of the flagellum such as the hook and filament are exported from the cell to their final position in the flagellum by a *sec*- independent pathway. Axial proteins do not have signal sequences, and it is thought that their export is mediated by a specific protein complex which includes the FliI, FlhA and FliP proteins. Recently a 5.5 kb *EcoRI* restriction fragment with homology to *fliI* (the flagellar specific, ATP-binding export protein) from *Salmonella typhimurium* was isolated from *Rb. sphaeroides* (G. Dreyfus unpublished). Transposon insertions in this clone resulted in nonmotile mutants with no flagellar filament, with one of these mutants accumulating cytoplasmic flagellin monomers (C. E. Pollitt and R.E. Sockett unpublished), suggesting that a similar flagellar export pathway exists in *Rhodobacter* to that present in enteric bacteria.

In *Rb. sphaeroides*, transposon mutations in at least 20 different genes result in a filament-minus phenotype. This indicates that flagellar assembly in this bacterium must proceed by a similar hierarchical pathway and it is probable that even more flagellar genes exist, as over 30 genes are involved in flagellar biosynthesis in enteric species. Genes encoding the flagellar filament and the proteins responsible for its export cluster to one 15 kb region not closely linked to the flagellar motor genes. All the flagellar genes cloned to date, map to one 244 kb *AseI* fragment on the physical map of the *Rb. sphaeroides* genome (Suwanto and Kaplan, 1989) adjacent to the genes encoding the photosynthetic apparatus.

C. Behavioral Responses

Bacteria don't just swim randomly, they use environmental signals to control their direction changing frequency and bias their overall movement to either maintain themselves in, or move towards, an optimum environment for growth. There is good evidence that if a bacterial species swims, motility provides a survival advantage for that species in their particular environment. In fact, in rich or well mixed environments bacteria often lose motility as it no longer provides a survival advantage. Because it takes up to 5% of a bacterial genome to make a functional flagellum, the energy involved in its synthesis and operation, particularly under growth-limiting conditions, would favor the rapid loss of the phenotype if it did not provide an advantage.

All motile bacteria can sense and respond to a wide range of physical and chemical stimuli, but the flexible metabolism of the purple non-sulfur bacteria means that not only can they probably sense more than most other species, but the response shown to a particular stimulus will depend on the current growth conditions. Amongst stimuli sensed are light, oxygen and other terminal electron acceptors, organic acids, sugars and inorganic ions. The signals coming from the different receptor systems must be integrated to balance the different responses, ensuring, for example, that a photosynthetically growing cell does not follow a light or electron donor gradient into an oxygenated environment.

1. Chemotaxis

All motile species investigated swim towards some chemicals but the sensing mechanisms vary from species to species. Most bacteria are too small to sense a chemical (or any other) gradient across their body length; they must therefore temporally sense their environment, comparing the concentration of a present stimulus with that a period of time earlier.

Changes in the concentration of specific chemicals are sensed through a range of different mechanisms, all finally integrating to control the flagellar motor. Three chemotactic systems have been identified (i) the dedicated receptor system (MCPs), (ii) the transport dependent sugar chemotaxis system based on PTS transport and (iii) a metabolism based chemosensing system linked to the current growth limitations of the cells. It is probable that all three systems interact and the relative importance of different chemosensing pathways varies between species, possibly related to their growth environment (see later).

a. Methylation-Dependent Chemotaxis

This is probably the best characterised chemosensing system in biology, with the most data coming (of course) from enteric bacteria (Bourett et al., 1991; Armitage, 1992). Dedicated membrane-spanning chemosensory proteins (methyl-accepting chemotaxis proteins, MCPs) bind a limited number of chemoeffectors, and the conformational change caused by the effector binding transduces the information to a cytoplasmic messenger. The chemoeffector needs only to bind to the MCP for a sensory signal to occur, neither transport nor

metabolism are required. There are several hundred copies (in *E. coli*) of 4 different MCPs, each responding to about 2 different effectors. The different MCPs have conserved cytoplasmic regions, responsible for signaling, and variable periplasmic regions, responsible for binding the chemoeffector. Antibodies have been raised against the Trg receptor in *E. coli* (this is the receptor responsible for sensing ribose and galactose) and these not only cross react with other MCPs from *E. coli* but also from a wide range of other unrelated species. These studies have revealed MCPs in *Rs. rubrum* and *Cm. vinosum* but not in *Rb. sphaeroides* (Sockett et al., 1987; Morgan et al., 1993). The cross-reaction with *Rs. rubrum*, however, was very weak compared to the cross-reaction shown to some more distantly related species, such as *Halobacterium halobium* (now *H. salinarium*). This implies that either the MCPs in *Rs. rubrum* are very different from those in other species, or there are fewer of them, perhaps clustered around the flagellar tufts.

Figure 3 shows the sensory pathway from the MCPs to the flagellar motor. A change in MCP conformation caused by a change in chemoeffector binding on the periplasmic side is transmitted to two proteins associated with the cytoplasmic side of the receptor, CheW and CheA. CheA is a histidine protein kinase, related to the HPKs involved in controlling transcriptional regulators in the two-component sensing systems. If there is an increase in repellent binding to a receptor, CheA autophosphorylates, but instead of phosphorylating a transcriptional regulator (as seen in the other two-component systems) it phosphorylates two intracellular non-DNA binding proteins (Bourett et al., 1991). CheY, a small diffusible protein (12 kD), is phosphorylated within milliseconds, and when phosphorylated binds to the switch on the flagellar motor causing it to rotate in the opposite direction and the bacterium to change swimming direction. The rate of dephosphorylation is controlled by CheZ which appears to be present at a constant concentration and activity; therefore the more CheY phosphorylated by CheA the more frequent the direction changing.

Being able to sense a gradient depends on the ability to adapt (Schnitzer et al., 1990). If a cell continued to respond after being stimulated it would not be able to sense a change in that or any other signal, nor would it be able to 'sense' the direction of any gradient. The second protein phosphorylated by CheA is a specific methyl esterase, CheB, involved

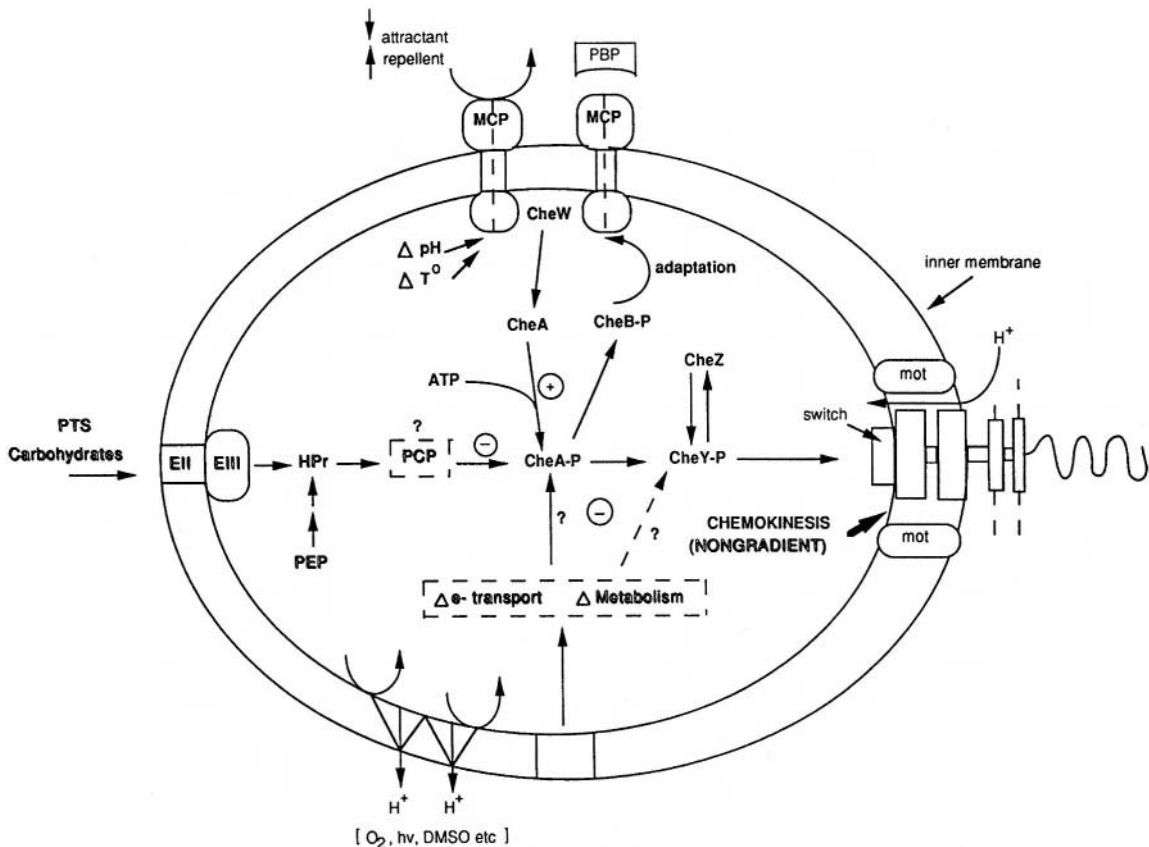

Fig. 3. Possible pathway for the integration of sensory pathways in bacteria. A reduction in chemoeffector binding to an MCP results in an increase in CheA-P and thus CheY-P and an increase in flagellar switching, whereas an increase in transport through the PTS causes a reduction in CheA-P and thus a reduction in switching. CheA-P also controls the activity of the adaptation pathway by controlling the activity of the methyl esterase, CheB. The site of interaction of the electron transport-dependent signal and the metabolism dependent pathway have not been identified. Chemokinesis appears to effect motor activity directly. MCP = methyl accepting chemotaxis protein, Che proteins = sensory pathway, PCP = PTS-chemotaxis protein, PBP = periplasmic binding protein, HPr = histidine protein.

in adaptation to new but stable environments. There are four specific glutamate residues on the cytoplasmic side of the MCP which can be methylated by a specific methyl transferase (CheR). As the methyl transferase is present at constant activity but the activity of the methyl esterase is changed by phosphorylation, an increase in CheA-P causes an increase in CheB-P, and hence its activity. If the level of CheB-P increases, methyl groups are removed from the MCP to match the change in binding and reset the signaling state of the MCP. The adaptation cycle can take several minutes and the difference in time between sensory signaling and adaptation and the extent of methylation provides the 'memory' in the system.

In enteric bacteria and many other species living in nutrient rich environments, this system appears to

be the primary chemical sensing system. It has also been implicated in thermosensing and pH sensing; possibly by directly changing the conformation of the cytoplasmic component of the MCP. However, in many other species, primarily those living in nutrient limited environments, this may be only one of several different sensing pathways, and by no means the dominant pathway.

b. Methylation-Independent Chemotaxis

Sugars. Sugars that are transported via a binding-protein-dependent system may be sensed through MCPs e.g. the galactose-charged galactose-binding protein binds not only to the transport protein but also to the MCP, Trg. However there are other sugars that do not use the MCP system but need to be

transported through the PTS system for a sensory signal to occur (Postma et al., 1993). Detailed experiments on enteric bacteria have shown that it is the rate of turnover of phosphates on EI protein of the phosphotransferase pathway that causes the chemotactic signal, but how this signals to the flagellar motor is not understood. EI appears to control the activity of CheA, but the mechanism is currently unclear. Adaptation, that essential of chemotaxis, is proposed to involve the resetting of the metabolic pathway involved in controlling phosphorylation.

The role of PTS-dependent chemosensing in photosynthetic bacteria is unresolved. In enteric bacteria fructose transport through the fructose PTS does not cause chemotaxis. This appears to be because the rate of phosphorylation of FPr in the fructose-PTS, although sufficient to allow transport, does not cause a chemotactic signal unless greatly over-expressed. In *Rb. sphaeroides* the only PTS system is for fructose, and it is related to the FPr dependent fructose system; other sugars use other, as yet not well characterised, systems (see section III)(Saier et al., 1971). Fructose, glucose, mannose, and sorbitol all cause good chemoattractant responses in *Rb. sphaeroides*, suggesting that the chemotactic signal is independent of either the MCP or PTS pathways (Y. Jezore and J. P. Armitage, unpublished).

Metabolism-Dependent Chemotaxis. All the chemoattractants identified for *Rb. sphaeroides* are metabolites, including the weak organic acids (which are repellents for enteric bacteria), sugars and amino acids (Armitage et al., 1990). Most attractants are effective in the mM concentration range. Despite extensive searching by our group and by others, membrane bound MCPs have not been identified in *Rb. sphaeroides* by either methylation/demethylation reactions or by antibody hybridization (Sockett et al., 1987; Morgan et al., 1993). Methionine auxotrophs also behave normally; methionine starvation in enteric bacteria results in an inability to adapt and therefore loss of taxis. Except for fructose, the chemoattractant sugars are not transported through a PTS pathway, and even that pathway is the one not involved in chemosensing in enteric bacteria.

However, *Rb. sphaeroides* does show true chemotaxis, the removal of an attractant such as pyruvate results in a transient change in swimming behavior, showing that the cells respond and then adapt. Unlike the responses seen in enteric cells, the major response

identified in individual cells of *Rb. sphaeroides* is an increase in stopping frequency when moving down a gradient; the bacterial equivalent of a pessimist! *E. coli* responds to an increase in attractant but *Rb. sphaeroides* ignores an increase, at least of the dominant attractants, and responds only to a step down, whether it is a chemoattractant, electron acceptor or light. Modeling shows that even a pessimistic system results in accumulation in regions of high attractant. In addition, the number of responsive cells of *Rb. sphaeroides* in a population depends on the growth limitation of the population—more cells in a starved population show a response compared to a well fed population. The population must also have been induced for growth on a particular chemoeffector for a chemotactic response to occur (Poole et al., 1990b); this is very different from the MCP-dependent sensing in enteric bacteria where sensing is completely separate from metabolism. Transport and, at least limited, metabolism are required for a chemotactic response in *Rb. sphaeroides* to some compounds. For example, the alanine analogue, 2-aminoisobutyrate, although transported through the alanine transport system, does not cause a tactic response (Poole et al., 1993). The inhibition of glutamine synthetase by MSX inhibits ammonia taxis without inhibiting transport (Poole and Armitage, 1989). Similarly the transportable succinate analogue, malonate, does not cause chemotaxis, although as will be seen later, malonate does cause chemokinesis. Data on the Dct transport system suggest that *Rb. capsulatus* also requires transport and metabolism for chemotactic responses to dicarboxylates, as no Dct mutants have been identified which have lost the chemotactic response to dicarboxylates without the additional loss of transport (D. J. Kelly, unpublished). Mutants in the newly identified periplasmic binding protein-dependent glutamate transport system of *Rb. sphaeroides* (Jacobs et al., 1995) have also been shown to lose their chemotactic response to glutamate. Interestingly, complementation of the transport defect by the expression of the unrelated H⁺-dependent glutamate transporter from *E. coli* in *Rb. sphaeroides* also led to the restoration of chemotaxis towards glutamate (W. Konigs, personal communication). This suggests that the mechanism of transport is not important in signal transduction and supports the idea that metabolism is required for chemotaxis in *Rb. sphaeroides*. All of these data are incompatible

with a transport-independent, dedicated, membrane spanning sensory protein such as the MCP being the major sensory pathway.

How does chemotactic signaling occur in *Rhodobacter* species and how does it relate to that identified in enteric bacteria? If different chemo-attractants are present at one time, unrelated compounds are found to compete. For example, either succinate or fructose can inhibit chemotaxis towards alanine (Poole et al., 1993). However, competition only occurs if the specific metabolic pathway of the successful competing compound has been induced. All these data imply that the bacteria may be sensing a change in concentration of a common metabolic intermediate, but what is this intermediate and to what does it signal? Arsenate has been shown to inhibit chemotaxis, suggesting that phosphorylation is required for a response. Calcium, acetyl adenylate, acetyl phosphate and fumarate have all been implicated in motor switching in other species, but their mechanism of interaction with the Che pathway and their role in vivo are unknown (Wolfe et al., 1988; Barak and Eisenbach, 1992b; Lukat et al., 1992; Tisa and Adler, 1992).

Homologues of the *che* genes of *E. coli* have recently been identified in *Rb. sphaeroides*. The gene arrangement in a *che/mcp* cluster is unlike that identified in enteric species, but related to that recently identified in other related species, *Rhizobium melioli* (Greck et al., 1995) and *Caulobacter crescentus* (M. R. K. Alley and L. Shapiro, personal communication). Antibody raised against *C. crescentus* MCPa has identified at least two 65 kD MCP homologues (Ward et al., 1995b). Sequencing has identified two putative *mcp* genes in the chemotaxis cluster. Why were these not identified using the *E. coli* antibody? It seems probable that the *Rb. sphaeroides* MCPs are present in low numbers, they have a sequence which in the protein has been shown to localize the *C. crescentus* MCPs to the cell pole suggesting that in *Rb. sphaeroides* they are also localized, although whether this is at the pole or close to the flagellar motor remains to be determined. This, combined with the limited similarity to the *E. coli* MCP and the dominant metabolism based chemotaxis system, probably explains why it was not identified earlier. In addition, the MCP has only one membrane spanning region, the majority of the protein being cytoplasmic, possibly related to the cytoplasmic MCP identified in *Myxococcus xanthus* (McBride et al., 1992). This is

compatible with a cytoplasmic sensory signal.

Perhaps the most significant finding, however, is that of two *cheY* homologues, in addition to *cheA*, *cheW*, *cheR* and probably *cheB* (Ward et al., 1995a). No chemotaxis mutants have ever been identified by transposon mutagenesis in *Rb. sphaeroides*. It is now apparent that the loss of one *cheY* is compensated for to some extent by the second, as they are on separate operons (loss of *cheY* in *E. coli* results in smooth swimming and an obvious phenotype). Why should there be two CheY proteins? This is the protein which when phosphorylated binds to the motor switch. It could be related to the unidirectional motor, but on the other hand it may imply two different phosphorylation paths; a 'classical' pathway from MCPs to CheA and CheY2 with the phosphorylation of the second CheY controlled by a phospho-donor linked to metabolism. This remains to be resolved by detailed molecular biology and protein chemistry.

All the behavioral chemotaxis experiments on *Rb. sphaeroides* suggest that chemotaxis is directly linked to their current growth requirements. The MCP based system in enteric bacteria, with dedicated sensing proteins, means that these bacteria must respond to a change in effector whether required for growth or not, for example *E. coli* will swim towards maltose in a background of galactose. An intracellular sensing system sensing a change in an intermediary metabolite would result in a chemotactic response only if there was an increase in metabolic rate, transiently altering the concentration of that intermediate. This may be an advantage for organisms living in growth limited environments. The MCP and metabolism based systems may operate side by side, the MCPs sensing a limited range of essential chemoattractants and an intracellular system sensing a change in metabolic rate. Rather than the MCP-based system being dominant, as it appears (at least in the laboratory) for enteric bacteria, it may just be one of several systems feeding sensory information into the motor.

c. Electron-Transport Dependent Chemotaxis

For photosynthetic bacteria growing under both heterotrophic and photoheterotrophic conditions, the rate of electron transport is obviously crucial. It would therefore be expected that they would respond to changes in the concentration of electron donors and electron acceptors. The study of the mechanisms

involved in these responses has been complicated by two factors: (i) any change in the rate of electron transport causes at least a transient change in the electrochemical proton gradient (Δp), which is the driving force for flagellar rotation and therefore any change in flagellar behavior may be a direct effect on the flagellum rather than a sensory response, and (ii) the complexity and flexibility of the electron transport chain in most photosynthetic bacteria.

Rb. sphaeroides shows good positive aerotaxis when grown aerobically, but negative aerotaxis when grown anaerobically in the light. This type of response was first seen by Engelmann back in the 1880s when he saw photosynthetic bacteria accumulate around air bubbles in dim light but move away from the air bubbles in bright light. Recent advances in motion analysis have made possible characterization of the aerotactic response by following the behavior of single cells in an oxygen gradient. A response equivalent to the chemotactic response has been identified, with an increase in stopping (and therefore direction) changing frequency of aerobically grown cells as the oxygen concentration falls (P. Hamblin, H. L. Packer, J. P. Armitage, unpublished).

Rb. sphaeroides grown anaerobically in the dark with DMSO as an electron acceptor shows chemotaxis towards DMSO when incubated anaerobically in the dark, but if incubated in either the light or aerobically in the dark, DMSO taxis is lost, paralleling the loss of electron transport to the DMSO reductase. DMSO reductase mutants also show no response to a gradient of DMSO. Therefore, no DMSO 'receptor' exists other than the reductase, and electron transport to the reductase is essential for a sensory response (D. Gauden, J. P. Armitage, unpublished). This supports data from *E. coli* on chemotaxis towards nitrate (Shioi and Taylor, 1984). What these data do not identify is whether the signal is a change in Δp caused by the change in electron transport or a change in the electron transport rate itself, altering either a redox sensitive protein or a component of the electron transport chain. Selective inhibition of different branches of the electron transport chain had suggested that a change in Δp was required for a sensory signal (Armitage et al., 1985). However, recent experiments exploiting the different kinetics of DMSO and TMAO binding to the DMSO reductase enzyme suggest that the rate of electron transport, presumably altering the redox state of an intermediate, is important (D. E. Gauden and J. P. Armitage, unpublished). This is supported by the unexpected

finding that *Rb. sphaeroides* responded to the removal of an uncoupler by a 'step-down' stop response, equivalent to moving down a gradient; no response was seen to the addition of FCCP. The addition of FCCP would result in a decrease in Δp but an increase in the rate of electron transport, whereas its removal would produce the reverse changes. As *Rb. sphaeroides* only responds to a decrease in stimulus, the stop response on FCCP removal is probably the result of the decrease in electron transport.

These data suggest that the primary tactic signal is either the change in Δp or the change in electron transport. What is the subsequent intracellular signal and does it interact with the Che pathway? Aerotaxis in *E. coli* occurs in the absence of MCPs, but there is some evidence that at least CheY may be required in *E. coli*. Early suggestions that the Arc pathway may be involved in aerotactic signaling in *E. coli* have proved unfounded, as mutants in this pathway respond normally toward oxygen (B. L. Taylor, I. B. Zhulin, unpublished). Glagolev has suggested a 'protometer' sensing mechanism which responds to changes in Δp ; this could be part of the motor itself or it may be part of the sensory pathway (Glagolev, 1984). However, as yet there are no data that can separate a Δp from a redox sensor.

2. Phototaxis

Photosynthetic bacteria accumulate in the light, the preferred wavelengths matching the photosynthetic absorption spectrum for most photosynthetic species. However, whether this can be considered a 'true' tactic response is still controversial, with some workers maintaining that, by comparison with eukaryotic microorganisms, bacteria cover too short a distance in a given time to be able to sense a gradient and simply accumulate as a result of 'trapping', changing direction as they swim over a light/dark boundary. However, new data suggest that this may be too simplistic a view. There are two crucial questions about the photoresponses in eubacteria: (i) could a simple step-down response without adaptation work for all bacterial species, and (ii) is accumulation in a light spot all that occurs or can bacteria sense a light gradient.

Important new data on the photobehavior of *Rs. centenum* support the view that bacteria can sense and respond to light gradients. Using the converging light test for phototaxis originally devised by Buder in 1917, Ragatz et al. (1995) have shown that

swarming colonies of *Rs. centenum* show a true phototactic response. These authors have redefined the light responses, describing the simple response to a change in light intensity when, for example, a cell moves over a light-dark boundary, as 'scotophobia.' Using a converging beam of light they showed that *Rs. centenum* moved towards the light source, even though the intensity was decreasing, a phototactic response rather than a scotophobic response where the intensity would have been sensed.

It has been recognized for some time that the halobacteria have specific photosensory proteins that generate positive and negative phototactic responses (Oesterhelt and Marwan, 1990). Recently a similar protein, the yellow protein, has been identified in the halophilic eubacterium *Ectothiorhodospira halophila* (Sprenger et al., 1993) and swarming colonies of *Rs. centenum* move away from light at 585 nm and towards light at 800–880 nm (Ragatz et al., 1994, 1995). In addition, calculations suggest that although the random swimming pattern shown by cells may not expose them to a significant light gradient in open water, in very turbid water or mud, a significant light gradient can be formed and a 'memory' of over 30 s would allow this gradient to be sensed.

In general nonsulfur purple bacteria have not been shown to have a true 'negative' phototactic response. However, the photoactive yellow protein has recently been identified in *Rb. sphaeroides* (K. Hellingserf and W. Hoff, unpublished). In general, however, they respond to a reduction in light intensity or a shift in light quality to a less photoactive wavelength. In the 1950s Clayton did a series of seminal experiments examining the motile behavior of cells of *Rs. rubrum* to changes in light intensity (Clayton, 1953a; Clayton, 1953b; Clayton, 1953c). He carried out a range of step-down experiments, showing that *Rs. rubrum* could respond to a change in light intensity of as little as 2% over a 100 fold range of background intensities. The strength of the response depended on both the duration of the stimulus and its strength, with two sub-threshold stimuli being additive if given more than 250 ms and less than 3 s apart. These led to the idea that a perturbation in photosynthesis led to a signal (then ATP was suggested) causing the bacteria to reverse direction.

More recent work has confirmed that active photosynthetic electron transport is required (c.f. aerotaxis) for accumulation. Inhibition of electron transport in either *Rs. rubrum* or *Rb. sphaeroides* led to the loss of phototaxis (Harayama and Iino, 1977),

and reaction center mutants fail to show phototaxis even though fully pigmented (Armitage and Evans, 1981). Therefore, there is not a specific sensory pigment involved, as in *Halobacterium salinarium*, but instead the direct or indirect sensing of a change in electron transport is occurring. Does the change in rate of electron transport simply make the flagella reverse rotation, and if so what is the signal and how does it relate to other electron transport dependent taxes?

The majority of photosynthetic species do have tufts of flagella and do change direction by reversal. A fall in photosynthetic electron transport when swimming over a light-dark boundary linked to flagellar reversal could result in trapping. However, *Rb. sphaeroides* does not reverse direction when given a step-down in light intensity, but increases its stopping frequency. If the response was a simple 'stop', then the cells would become trapped in the dark rather than the light. If, however, there was memory in the system and the cells stop and start for a period of time, a new direction may take them into higher light intensities. This 'memory' suggests a taxis system similar to chemotaxis. The early experiments of Clayton did show that *Rs. rubrum* reversed for up to 30 s after the light intensity was reduced, and reversals were suppressed if the light intensity was increased. *Rb. sphaeroides* shows an increase in stopping frequency for up to 2 min after a reduction in light intensity. This is consistent with the behavior of cells in gradients of oxygen or other electron acceptors (see aerotaxis).

One major physiological role of phototactic responses may be in interacting with other electron transport dependent systems. If *Rb. sphaeroides* is incubated in subsaturating light and given a light gradient, it only swims into the increased light if the medium is anaerobic; oxygenated buffer causes a repellent response. Measurement of the $\Delta\psi$ using the electrochromic response of the carotenoids showed that the addition of a pulse of oxygen to *Rb. sphaeroides* in the light resulted in a transient fall in the size of the $\Delta\psi$, presumably as electron transport was directed towards the alternative cytochrome oxidase (Armitage et al., 1985). This change in electron flow probably causes a stop signal, resulting in the bacteria not following a light gradient into an aerobic environment. Whether it is the change in electron flow through a key signaling component of the electron transport chain or the change in $\Delta\psi$ that causes the signal, has not yet been identified.

Rs. centenum shows both a positive phototactic response, with the maximum response in the region of infrared light harvesting and bacteriochlorophyll absorbance (875–800 nm) and a negative phototactic response in regions of visible light (450–590 nm), regions where carotenoids and bacteriochlorophyll also absorb (Ragatz et al., 1995). These data suggest a more complex system of light sensing and signalling, as light absorbance in both these regions would be expected to change the $\Delta\Psi$. *Rs. centenum*, and possibly other species, may have a sensing mechanism which can estimate the ratios of particular wavelengths and use this to maintain their optimum position in, for example, stratified mats.

The behavioral responses to light, oxygen and DMSO all seem to rely on electron transport. As the components of the electron transport chain are shared, it seems unlikely that it is the electron donors or acceptors that are sensed directly, rather it is the flux in electron transport that is sensed, with bacteria moving towards environments where electron transport rates are increased and away from regions where they decrease. The response will depend on the necessary metabolites to sustain or increase the rate. Therefore, unlike chemotaxis (particularly MCP-dependent chemotaxis), there would be no receptor for each effector, but a sensor responding to the changes in electron transport, be that Δp or redox change. If this is the case for most species, phototaxis is no different from any other sensory signal sensed through the electron transport chain.

3. Kinesis

The addition of certain chemoattractants cause *Rb. sphaeroides* to increase its swimming speed by up to 25%. This increase in swimming speed is caused by the flagella rotating faster, but occurs in the absence of increased metabolism and without any measurable increase in the driving force for flagellar rotation, the Δp , or any change in the rate of electron transport (Poole et al., 1990a and 1991; Brown et al., 1993). Chemokinesis (probably more accurately called orthokinesis), as a sustained increase in the rate of flagellar rotation, has only been seen in bacterial species which do not depend primarily on MCPs for chemotaxis, and it is possible that the adaptation cycle in MCP-dependent chemotaxis inhibits any but transient kinetic effects. Chemokinesis in *Rb. sphaeroides* is only seen to a limited range of chemoattractants, mainly organic acids and inorganic

ions such as K^+ and Rb^+ , but not to other chemoattractants e.g. sugars and most amino acids. Unlike chemotaxis, chemokinesis also occurs in response to some non-metabolizable but transportable analogues such as malonate. Evidence suggests that chemokinesis depends on specific transport pathways; benzoate did not cause chemokinesis although it did get into cells, and aspartate but not glutamate caused chemokinesis (Packer and Armitage, 1994). Understanding the role of specific transport pathways in inducing an increase in swimming speed will have to wait until there is more understanding of transport in nonsulfur purple bacteria, however it may be worth noting that (a) all chemokinetic compounds also caused some cell swelling and with the same time course, and (b) data suggest that the transport pathways involved may involve changes in pH.

Whatever the cause, chemokinesis would cause a cell population to spread, not to accumulate; unlike chemotaxis, there was no obvious adaptation to chemokinesis. As long as a detectable concentration of effector was present, the cells swam at an increased speed. Could this have a role in vivo? Computer modelling suggests that although chemokinesis would cause a population to spread, it would not stop a tactic response from occurring when a gradient was encountered, and it may even enhance the response (Poole et al., 1991).

Nonsulfur purple bacteria therefore show tactic responses to a wide range of environmental effectors. The limited data so far suggest that some sensory pathways are similar to those identified in enteric bacteria, e.g. electron transport dependent taxis and MCP-dependent chemotaxis, but that chemotaxis is also metabolism dependent, using a *che* pathway which appears to be a modification of that found in enteric bacteria, probably modified to suit the variable growth conditions of these species.

III. Solute Transport

A. Introduction

Although many anoxygenic photosynthetic bacteria are capable of actively transporting a large variety of solutes from the environment, as with motility and taxis, detailed studies on the structure and mechanism of the transport systems responsible have mainly been performed on *Rhodobacter* species. Hopefully, this will be a temporary state of affairs, as the

bioenergetic advantages involved in using photosynthetic bacteria as model systems to study transport mechanisms, in addition to the intrinsic importance of understanding transport processes in these organisms in their own right, become appreciated.

A number of the prominent and in some cases unique physiological properties which phototrophic bacteria possess are linked to the functioning of efficient solute transport systems, although this is often overlooked. For example, the biosynthesis of bacteriochlorophyll requires magnesium which has to be accumulated from the environment. Similarly, the high cytochrome content of many phototrophs requires iron transport for the biosynthesis of the heme moiety. Nitrogenase synthesis requires transport of both iron and molybdenum and nickel transport is necessary for incorporation into the hydrogenases that allow many phototrophs to grow autotrophically. Transport systems for the organic electron donors and carbon sources used during photoheterotrophic growth are essential and also seem intimately involved in eliciting chemotaxis. Here, information concerning the mechanism and structure of some of the better studied solute transport systems in phototrophs (primarily the purple bacteria) will be reviewed.

B. Inorganic Ions

1. Potassium

Potassium is now recognized to have multiple roles in bacteria, the most important of which include the regulation of pHi (Booth, 1985), osmotic regulation (Epstein, 1986) and the controlled dissipation of the proton-motive force under certain conditions (Mulder et al., 1988). Potassium transport in purple bacteria was first studied by Jasper (1978), who concluded from experiments with $^{42}\text{K}^+$ that a single K^+ transporter existed in *Rb. capsulatus*, with an apparent K_m value of 0.2 mM. This system also transported Rb^+ with lower affinity. More recent studies have revealed several important physiological roles for potassium transport in anoxygenic phototrophs. In potassium, as opposed to sodium phosphate buffer, the membrane potential in energized *Rb. sphaeroides* cells was decreased and the ΔpH increased (Abee et al., 1988), consistent with the operation of an electrogenic K^+ uptake system. Using carotenoid electrochromism to monitor membrane potential, Golby et al., (1990a) found that the addition of K^+ or Rb^+ (but not Na^+) to washed cells of *Rb. capsulatus* resulted in an increase

in the ionic current across the cytoplasmic membrane and to a decrease in membrane potential upon illumination, which was attributed to the electrophoretic uptake of these ions. The response was half-maximal at about 0.4 mM K^+ or 2.0 mM Rb^+ , values of the same order as the K_m values determined by Jasper (1978) and indicative of a low affinity uptake system, possibly similar to the TrkA system of enteric bacteria. This system appears to be a uniporter (Golby et al., 1990b) and is constitutive. It plays a key role in the regulation of the pHi, which is significantly increased at all external pH values in the presence of K^+ (Abee et al., 1988). Because of the excellent time resolution of the electrochromic response, it was possible to determine that the increase in the K^+ dependent ionic current was not instantaneous with the increase in membrane potential at the onset of illumination (Golby et al., 1990a), providing evidence for a $\Delta\psi$ -mediated activation of the transporter ($t_{1/2} = 120$ ms). This phenomenon is undoubtedly found in many types of bacterial membrane transporter but is particularly amenable to study in phototrophs which have electrochromically responsive carotenoids.

Recently, it has been found that *Rhodobacter* cells can induce the synthesis of a Kdp-like high-affinity K^+ uptake system when grown in media of low K^+ concentration (Abee et al., 1992 a,b). A vanadate sensitive, K^+ stimulated ATPase activity was purified from cytoplasmic membranes of *Rb. sphaeroides* and was found to be composed of three subunits of 70, 43.5 and 23.5 kDa, corresponding to the KdpB, A and C subunits of the *E. coli* complex, respectively. However, only the KdpB-like protein (the catalytic subunit) was immunologically cross-reactive. This type of high-affinity K^+ ATPase appears to be widely distributed in nonsulfur purple bacteria (Abee et al., 1992b) and is likely to be the major mechanism whereby potassium is obtained from low external concentrations.

It has long been known that a significant membrane potential is maintained in *Rhodobacter* cells incubated under strictly anaerobic conditions in the dark (Cotton et al., 1981). Several explanations have been advanced to explain the origin of this dark potential, but the key observation that KCl significantly decreased the potential in *Rb. sphaeroides* (Abee et al., 1988) led to the suggestion that it is a result of the electrogenic efflux of K^+ . In experiments with *Rb. capsulatus*, where the dark anaerobic membrane potential was measured by carotenoid electrochromism (Golby et al., 1990a), it was shown that the decrease in $\Delta\psi$ was

proportional to the logarithm of the external K^+ concentration, indicating a Nernstian relationship between $\Delta\psi$ and the internal and external K^+ concentration. Other electrogenic processes may also make a smaller contribution to the anaerobic dark $\Delta\psi$ in *Rb. capsulatus* (Golby et al., 1990a). However, in *Rhodospirillum rubrum*, the dark potential could be largely abolished by DCCD, suggesting its dependence on ATP hydrolysis rather than K^+ efflux (Fenoll et al., 1985).

2. Ammonium

Although widely used as a source of nitrogen, uptake of the ammonium ion in anoxygenic phototrophs has not been studied extensively. This is at least partly due to technical difficulties in measuring the flux of NH_4^+ directly. Instead, the analogue methylammonium has traditionally been used but this is known to be converted by glutamine synthetase to γ -glutamyl-methylamide in *Rb. capsulatus* (Yoch et al., 1983). Those direct measurements which have been performed indicate the presence of more than one NH_4^+ uptake system in many species; in *Rb. capsulatus*, NH_4^+ uptake was characterised by two K_m values of $1.7 \mu M$ and $11.1 \mu M$ (Sharak Genthner and Wall, 1985). In these studies, a tight coupling was observed between transport and assimilation of NH_4^+ , as mutants deficient in glutamine synthetase did not take up ammonium ions. Evidence for an ammonium transporter in *Rs. rubrum* has also been obtained (Alef and Kleiner, 1982). More recently, it has become clear that potassium and ammonium ions can be transported by the same carrier in many bacteria and that this can have important physiological consequences. In *Rb. capsulatus*, several pieces of evidence indicate that the low-affinity K^+ transporter, described above, is also capable of transporting NH_4^+ (Golby et al., 1990a,b). In contrast to the high-affinity uptake systems characterised by Sharak Genthner and Wall (1985), ammonium transport via the K^+ uptake system is not inhibited by low concentrations of methylamine and the concentration dependence of the NH_4^+ dependent ionic current indicates an approximate K_m value of 3 mM (Golby et al., 1990a). The physiological significance of these observations is that, as a consequence of electrophoretic ammonium uptake, $\Delta\psi$ is decreased and ΔpH increased; this may be followed by the passive efflux of NH_3 from the cell in response to the increased

ΔpH , thus leading to a partial dissipation of the Δp . This may be one example of an 'energy-spilling' reaction which could operate in photosynthetic bacteria in particular circumstances. Indeed, evidence for such reactions has been obtained with *Rb. capsulatus* cells grown anaerobically under illuminated conditions in which the energy supply exceeds the demands of anabolism (Taylor and Jackson, 1987).

3. Divalent Cations

Separate transport systems for the energy-dependent uptake of magnesium and manganese have been described in both chemoheterotrophically grown and photoheterotrophically grown cells of *Rb. capsulatus* (Jasper and Silver, 1978). The characteristics of these systems are distinct, with respective K_m values for magnesium and manganese of $55 \mu M$ and $0.5 \mu M$. The maximum rate of transport for magnesium was up to a hundred-fold higher than that of manganese. Several divalent cations were competitive inhibitors of magnesium transport; Fe^{2+} , Mn^{2+} ($K_i = 250 \mu M$) and Co^{2+} ($K_i = 270 \mu M$). Calcium did not inhibit transport, and it was also demonstrated that *Rb. capsulatus* cells did not normally accumulate Ca^{2+} , but that an energy dependent efflux system may be present for this ion. Accumulated magnesium was not tightly bound to cellular components and under de-energized conditions was exported from the cells. The details of the efflux process have not been elucidated and there is little additional information on magnesium transport in any other anoxygenic phototroph. In contrast, much more is known about magnesium transport in enteric bacteria (Gibson et al., 1991). With the current high level of interest in bacteriochlorophyll biosynthesis and its control, it would be relevant to know more about the molecular properties of the magnesium transport systems in phototrophic bacteria.

Nickel is a component of the hydrogenase and urease of *Rb. capsulatus* and its uptake was studied by Takakuwa (1987). There appeared to be a sharp pH optimum for uptake (at pH 7.0) and the optimum temperature was $28 \text{ }^\circ\text{C}$. The concentration dependence obeyed Michaelis-Menten kinetics with a measured K_m value of $5.5 \mu M$. This indicates the operation of a high-affinity uptake system for this ion. A number of other divalent cations inhibited the uptake of nickel, particularly magnesium and cobalt, which gave K_i values of less than $100 \mu M$. It is

therefore possible that a common transport system exists for nickel, magnesium and cobalt in *Rhodobacter*, but ultimate confirmation of this will require identification and mutagenesis of the genes involved.

4. Iron

Despite the enormous interest in electron transport processes and cytochrome complexes in phototrophic bacteria, there is a surprising lack of information concerning the mechanisms by which iron is acquired and managed by these organisms. Two studies have directly addressed the question of iron transport (Moody and Dailey, 1984; Moody and Dailey, 1985), both using *Rb. sphaeroides* as the model system. It was found that growth in an iron-deficient medium under either aerobic or anaerobic conditions did not result in the production of soluble phenolate or hydroxamate siderophores. No evidence was obtained for any siderophore remaining associated with the cells. In addition, iron-limited cells were unable to remove iron from ferric transferrin unless supplemented with 2,3-dihydroxybenzoic acid (Moody and Dailey, 1984). However, radiolabelled iron was taken up when supplied as ferric chloride, ferric citrate or ferric parabactin (a siderophore from *Paracoccus denitrificans*). In the case of ferric citrate, the citrate itself was not taken up by the cells. There were no significant differences in the protein profiles of cells grown under low or high iron conditions, and no evidence for the induction of specific outer membrane proteins in response to iron starvation (Moody and Dailey, 1985). Membrane vesicles prepared from aerobically grown cells were able to transport iron in the presence of NADH as electron donor. Uptake was sensitive to triphenylmethylphosphonium, possibly suggesting a $\Delta\Psi$ driven process, although a very high concentration of inhibitor (5 mM) was used. Inhibition of ferrochelatase by N-methylprotoporphyrin did not result in a decrease in iron uptake, indicating that heme synthesis and iron transport are not tightly coupled (Moody and Dailey, 1985). Radiolabelled gallium (an iron analogue which is trivalent and cannot be reduced) was not taken up by intact cells, although excess Ga^{3+} did inhibit the uptake of ferric iron. These results suggested a model for transport in which ferric iron is recognized by a transport protein, reduced to the ferrous state and then transported into the cell. No details are available concerning the molecular nature of the transport system(s) involved.

5. Molybdenum

Molybdenum is of particular importance in photosynthetic bacteria, not only because of the widespread ability of these organisms to fix nitrogen using the molybdenum containing nitrogenase, but also because some of the terminal oxidoreductases involved in anaerobic electron transport contain the molybdenum cofactor molybdopterin (Ferguson et al., 1987). Although transport is clearly essential for molybdenum incorporation into the cytoplasmic nitrogenase, the question of how this metal is incorporated into the periplasmic oxidoreductases is unresolved. Recently, the genes encoding a high-affinity transport system for molybdate from *Rb. capsulatus* have been cloned and sequenced (Wang et al., 1993). Four genes, *modABCD*, form an operon located in the *nif* region B of the *Rb. capsulatus* chromosome, downstream of the *nifB(II)* gene. These four *mod* genes encode a periplasmic binding-protein dependent transporter. ModA is a hydrophilic protein containing a typical signal sequence and was proposed to be a periplasmic molybdate-binding protein, although this has not yet been tested experimentally. ModB is a hydrophobic, presumably integral membrane, component homologous to ChI of *E. coli*, and ModC is a member of the ATP-binding-protein superfamily homologous with ChID of *E. coli*. The function of the *modD* gene product is unknown. Insertion mutations in *modA*, *modB* or *modC* resulted in a 500-fold increase in the concentration of molybdenum required to repress the alternative nitrogenase, indicating that although the *mod* genes are involved in high-affinity molybdenum uptake, an additional transport system of lower affinity must also be present in *Rb. capsulatus*. Two additional open-reading frames (*mopA* and *mopB*) upstream of the *mod* operon which encode highly homologous proteins were also identified by Wang et al., (1993). They share significant sequence similarity with low molecular weight molybdenum-pterin-binding proteins from *Clostridium pasteurianum* but their role in molybdenum metabolism is at present unclear.

C. Sugars

Many photosynthetic bacteria do not grow particularly well on sugars, probably because they are sensitive to the acidification that can result from sugar metabolism (Willison, 1993), particularly under oxygen-limiting

conditions. In general terms, very little information is available on the mechanisms of sugar transport, with the exception of fructose uptake. In several members of the purple non-sulfur bacteria, including *Rhodospirillum* and *Rhodobacter*, fructose uptake is catalysed by an inducible fructose specific PTS system (Saier et al., 1971). This system has turned out to be of general interest, as it is much simpler in structure than many other types of PTS. The system consists of just two proteins, a membrane bound component with molecular weight of 55,000 kDa (FruA) and a 110,000 kDa soluble protein (FruB) which is probably dimeric (Saier et al., 1971; Lolkema et al., 1985). Daniels et al. (1988) isolated Tn5 insertion mutants of *Rb. capsulatus* defective in growth on fructose. The mutants were totally lacking in fructose fermentation, fructose uptake, phosphoenolpyruvate-dependent fructose phosphorylation activity and fructose-1-phosphate dependent fructose transphosphorylation. An operon containing three genes, *fruBKA*, with the *fruK* gene encoding fructose-1-phosphate kinase was identified (Wu et al., 1990). The sequence analysis of the *fruB* gene has revealed that it encodes an unusual and complex protein which contains three distinct domains that are normally located in separate proteins in other PTS systems; a fructose specific enzyme III-like N-terminal domain (B), an FPr(HPr)-like domain (H) and a C-terminal enzyme I-like domain (I) which has striking sequence similarity to maize pyruvate : phosphate dikinase. These three functional units are joined by two flexible linker regions, rich in ala, gly and pro residues. Sequence comparisons with other known PTS proteins allowed the identification of three conserved histidine residues in each domain that are predicted to be the sites of phosphorylation. Thus the data indicate that FruB(HI) is a multi-phosphoryl transfer protein. The *fruA* gene encodes the fructose permease (enzyme II) of the system (Wu and Saier, 1990) and is very similar to the fructose enzyme II of *E. coli*. However, although it had been originally proposed that a histidyl residue was the phosphorylation site in the *E. coli* enzyme II, this residue is not conserved in the *Rb. capsulatus* FruA protein. Instead, a conserved cysteine residue present in both proteins and subsequently identified in other types of enzyme II is now thought to be the actual phosphorylation site. Thus, studies on the *Rb. capsulatus* fructose-PTS have led to important conclusions regarding the mechanism of group translocation in general.

D. Organic Acids

Organic acids have long been known to be very effective growth substrates for purple non-sulfur bacteria and can be used as both carbon and energy source under chemoheterotrophic conditions or as carbon source and electron donor under photoheterotrophic conditions. In the latter case, if the organic acid is relatively reduced, an electron sink such as carbon dioxide or an auxiliary oxidant such as dimethylsulphoxide is required to maintain redox balance (Ferguson et al., 1987). Traditionally, the C4-dicarboxylates malate and succinate have been used routinely for the growth of purple phototrophs but pyruvate and lactate are also excellent substrates. Both D- and L-malate can be used by *Rhodobacter* strains (Stahl and Sojka, 1973).

The transport of C4-dicarboxylates was first studied by Gibson (1975) who showed that *Rb. sphaeroides* possessed an inducible transport system for malate, succinate and fumarate. Subsequently, C4-dicarboxylate transport has been studied in most detail in *Rb. capsulatus*. The major route for the transport of malate, succinate and fumarate is a high-affinity binding-protein-dependent system (Dct) which is essential for growth on these substrates under aerobic/dark conditions (Hamblin et al., 1990; Shaw and Kelly, 1991). The binding protein has been purified (Shaw et al., 1991) and its ligand binding kinetics analyzed in detail (Walmsley et al., 1992 a,b). It is able to bind L-malate, succinate and fumarate with high affinity and D-malate with somewhat lower affinity, but does not bind other organic acids significantly. The Dct system is regulated in activity by the intracellular pH value (Shaw and Kelly, 1991). Interestingly, *dct* mutants are still able to grow slowly on C4-dicarboxylates photoheterotrophically, due to the presence of additional low-affinity systems which are not present aerobically (Hamblin et al., 1990; M. C. Behrendt and D. J. Kelly, unpublished). The *dct* locus has been cloned and sequenced (Shaw et al., 1991; Hamblin et al., 1993 M. J. Hamblin and D. J. Kelly, unpublished) and this has revealed that it is not a conventional periplasmic transport system. Five *dct* genes have been identified, two of which (*dctS* and *dctR*) encode a translationally coupled two-component sensor-regulator pair which regulate expression of the structural genes. DctS and DctR share the greatest sequence similarity with the FixLJ system in *Rhizobium* (Hamblin et al., 1993). Three structural genes are present; *dctP*, which encodes a

periplasmic C4-dicarboxylate binding protein, *dctQ*, encoding a small integral membrane protein, and *dctM*, which encodes a large integral membrane protein. These form an operon divergently transcribed from *dctSR*.

Insertion mutations in any of the *dct* genes leads to the abolition of chemotaxis to C4-dicarboxylates, supporting other work indicating that transport itself or an intracellular signal is necessary for chemotaxis and that the sensor-regulator pair is not directly involved. The *dct* locus has been physically mapped at high resolution on the *Rb. capsulatus* chromosome (Fonstein and Haselkorn, 1993). Significantly, there is no gene at the *dct* locus encoding the type of conserved ATP-binding protein characteristic of conventional periplasmic permeases. Moreover, operons encoding homologues of DctP, Q and M are present in *E. coli* (Sofia et al., 1994) and *Bordetella pertussis* (Willems et al., 1992) but again, there is no ATP-binding protein in these systems. There is also bioenergetic evidence to indicate that dicarboxylate transport through the Dct system is driven by the membrane potential rather than by ATP hydrolysis (Forward et al., 1993). It has been proposed that this system is a representative of a novel class of symporter which possesses a periplasmic binding-protein. It is not known how widespread this type of transporter is, but as most other purple non-sulfur bacteria are capable of efficient growth on C4-dicarboxylates (with the interesting exception of *Rs. centenum*; Stadtwald-Demchick et al., 1990), it is presumably common in this group at least. There is a report that the purple sulfur bacterium *Ectothiorhodospira shaposnikovii* contains a sodium-ion driven dicarboxylate symporter (Karzanov and Ivanovsky, 1980) but this system has not been investigated further.

The transport of other organic acids has not been studied at the molecular level in phototrophic bacteria. Gibson (1975) obtained evidence for more than one system for pyruvate transport in *Rb. sphaeroides*, and both high-affinity and low-affinity systems exist for this substrate in *Rb. capsulatus* (H. V. Modak and D. J. Kelly, unpubl).

E. Amino Acids

The uptake of certain amino acids has been studied extensively in purple non-sulfur bacteria in an effort to understand the way in which bacterial solute transport processes in general are regulated by the proton-motive force. In *Rb. sphaeroides*, the

relationship between alanine transport and the magnitude and composition of the proton-motive force was determined in a number of investigations (Elferink et al., 1984, 1987). It was found that under conditions where the rate of electron transport was low, but where a significant membrane potential existed, e.g. under anaerobic dark incubation conditions, alanine transport did not occur. Conversely, high rates of electron transfer correlated with high alanine uptake rates. This formed part of the evidence which led to the proposal that there are direct interactions between components of the electron transport chain and solute transport systems (Elferink et al., 1984, 1987). However, in these studies, it was assumed that the alanine uptake system in *Rb. sphaeroides* was a typical secondary transporter. This appeared consistent with the fact that alanine uptake could be measured in membrane vesicles and could be energized by either respiratory or photosynthetic electron transport (Hellingwerf et al., 1975). However, it was later shown that in fact the alanine transporter is an osmotic-shock sensitive, binding-protein dependent system which is strongly regulated in activity by the intracellular pH value (Abee et al., 1989). This system is vanadate sensitive and is likely to be a typical ATP-driven periplasmic permease. Thus, at least some of the earlier results can be explained by the significant regulatory effect exerted by internal pH on the transporter, without the need to invoke direct interactions with the electron transport chain. The ability to detect alanine uptake in membrane vesicles is more puzzling, but may be due to residual binding-protein and ATP remaining associated with the vesicles. In addition, the presence of an additional alanine transporter cannot be ruled out.

The binding-protein dependent glutamate transport system in *Rb. sphaeroides* has recently been characterised (M. Jacobs and W. N. Konings, unpublished) and the glutamate binding-protein purified. This binding-protein has a high affinity for both glutamate and glutamine but does not bind aspartate or arginine. However, the latter amino acids do inhibit glutamate transport. This suggests that there may be two binding-proteins present which interact with the same membrane complex. Transport systems for several other amino acids (leucine, proline, glutamine and histidine) have been detected in intact cells of *Rb. sphaeroides* (Abee, 1989) and these were all found to be sensitive to inhibition by vanadate, suggesting the involvement of a phos-

phorylated intermediate in the uptake process. Vanadate sensitivity appears to be a characteristic of ATP-driven, binding-protein dependent systems and it is striking that, so far, only binding-protein dependent amino-acid transport systems have been found in *Rhodobacter*.

F. Nucleotides

Nucleotide transport in eukaryotic cells is well-known, but most free-living bacteria appear to be unable to transport nucleotides across the cytoplasmic membrane, although these molecules can pass through the outer membrane (Nikaido and Varra, 1985). Until recently, evidence for nucleotide transport systems in bacteria had come only from intracellular and/or parasitic species. However, it has been reported (Hochman et al., 1978, 1981) that cytoplasmic membrane vesicles isolated from *Rb. capsulatus* have the ability to transport adenine nucleotides. In this study, transport activity was not detectable in intact cells, suggesting that the outer membrane in this organism is impermeable to these molecules, i.e. the reverse of the situation normally encountered. From both direct and indirect measurements of adenine nucleotide transport, it seemed possible that an ADP-ATP exchanger was present, but it proved insensitive to inhibitors of the mitochondrial ADP-ATP exchanger (Carmeli and Lifshitz, 1989). These results are interesting but caution needs to be exercised in interpreting them, since there are difficulties in analyzing nucleotide transport; adenine nucleotide pools in cells or vesicles turn over rapidly and it is difficult to separate transport from metabolism. Nevertheless, it was suggested that this transporter could function to transfer ATP to the periplasm for various energy requiring reactions (as yet ill-defined). If confirmed, the properties and role of this system would prove of general interest.

G. Other Solutes

Some work has been performed on the transport systems involved in the responses of photosynthetic bacteria to osmotic stress (Abee et al., 1990). In *Rb. sphaeroides*, an increase in ionic strength resulting from the addition of sodium chloride to the growth medium results in a decrease in growth rate. This effect could be overcome by the addition of betaine (N,N,N-trimethylglycine), which was effective under either aerobic or anaerobic growth conditions.

Choline was also identified as an efficient osmoprotectant but only under aerobic conditions; it was found that choline was converted to betaine by an oxygen-dependent system. Betaine and choline transport were examined. In cells grown and assayed either in the absence of added NaCl or in 0.3M NaCl, similar affinities for betaine were determined (K_1 values of 15.1 μM and 18.2 μM respectively), but the V_{max} was increased from 3.2 to 9.2 $\text{nmol min}^{-1} \text{mg protein}^{-1}$. In each case, only one transport system could be distinguished kinetically. This system also transported proline, with lower affinity, and proline was also found to be mildly osmoprotective. Choline was transported by a separate system with similar kinetic properties in cells from high or low osmolarity growth media (K_1 2.4–3.0 μM and V_{max} 5.4–4.2 $\text{nmol min}^{-1} \text{mg protein}^{-1}$). The addition of either choline or betaine to growth media did not result in the induction of alternative transport systems. It would be interesting to know whether either of the transport systems identified are binding-protein dependent or not and how similar they are to the well studied ProU and ProP systems in enteric bacteria.

IV. Future Perspective

In recent years, investigations of transport and motility processes in purple anoxygenic phototrophs have led to important insights into bacterial solute transport, flagellar activity and tactic behavioral responses in general. In particular, the central importance of pHi as a regulator of the activity of transport systems has become evident. The relationship between potassium transport, pHi and the activity of other transport systems in phototrophs is now appreciated. The properties of periplasmic binding-protein-dependent transport systems are of particular interest in phototrophic bacteria, as the unusual nature of the *Rhodobacter* Dct system suggests that not all such transporters are members of the ABC-superfamily, but instead may represent a new class of secondary transporter. The unidirectional motor of *Rb. sphaeroides* has been identified, with its implications for flagellar rotation in general, as has a metabolism-based chemotaxis system which may well operate alongside the MCP-based system, using two independent CheY response regulators, in a wide range of species.

Photosynthetic bacteria grow under a wide range of conditions, inducing metabolic pathways in

response to changing conditions. They have therefore evolved a range of systems for sensing, moving towards and transporting different metabolites, dependent on their current environment and requirements. This flexibility combined with the bioenergetic and genetic advantages of these species makes them ideal for studying the diverse transport and sensing systems that are emerging as investigation moves beyond the enteric bacteria. These systems, which are producing so many surprises, also need to be understood if we are to understand the physiology of the photosynthetic bacteria as a whole.

Acknowledgments

The authors would like to thank C. Bauer, G. Dreyfus, W. Konings, R. Schmitt, L. Shapiro and B. L. Taylor for unpublished data. The work of the authors described here was supported by the SERC (J.P.A., D.J.K. and R.E.S.) and the Wellcome Trust (J.P.A.)

Summary

Genetic manipulation has become widely used in the study of purple photosynthetic bacteria. Some species have been extensively characterized genetically and thus are readily amenable to new applications of these techniques, while in other species genetic work is being developed and may require some adaptation of existing protocols. Genetic studies in purple bacteria include both classical genetic mapping that yields information about the genomic distribution of the genetic loci under study and molecular genetic techniques that employ recombinant DNA techniques and center on analysis at a nucleotide level. As a result of these studies, a large number of genes have been characterized, most prominently those whose products are involved in photosynthesis and nitrogen fixation, but also including a variety of other processes. Techniques that have been used to identify genes range from complementation of mutant strains to hybridization probes based on homologous genes or the amino acid sequences of proteins. The functional properties of genes have been studied by the generation of random mutations by chemical or transposon mutagenesis and by site-directed insertions, deletions and alterations of nucleotide sequences. The transcription and translation of genes have been investigated through gene fusions and in vitro and heterologous expression systems. The combination of classical genetics with the advances in molecular biological techniques provides an array of tools for dissecting the underlying basis for metabolic processes in these bacteria.

I. Introduction

The goal of this chapter is to summarize genetic techniques that have been applied to purple photosynthetic bacteria, including basic manipulations such as the transfer of DNA, as well as genetic mapping, cloning, sequencing, mutagenesis and analyses of gene expression. Adaptations of microbial genetic and molecular biological methods developed in other bacteria have generally been used for purple bacteria, although the unique physiology of these bacteria has also been exploited. These applications serve as a source for the types of options available when approaching the genetic study of any particular aspect of these bacteria, and provide a foundation for further analyses of genes already defined. The majority of genetic work has been performed in the two closely related species of purple nonsulfur bacteria, *Rhodobacter capsulatus* and *Rhodobacter sphaeroides*. Other purple nonsulfur bacteria for which some genetic information is available include *Rhodobacter blasticus*, *Rhodobacter marinus*, *Rhodopseudomonas acidophila*, *Rhodopseudomonas palustris*, *Rhodopseudomonas viridis*, *Rhodo-*

spirillum centenum, *Rhodospirillum rubrum*, *Roseobacter denitrificans* and *Rubrivivax gelatinosus*. In addition, the purple sulfur bacterium, *Chromatium vinosum*, has been the focus of a number of genetic studies.

A. Gene Transfer

1. Conjugation

Conjugation is the most commonly used method of transferring DNA into purple bacteria. Transfer can take place both between *Escherichia coli* and the purple bacteria and among various purple species. Matings are performed by mixing the donor and recipient cells and plating on a solid surface, such as an aged agar plate or a membrane filter, incubating for several hours to overnight, and then replica plating, replating or overlaying with a selection medium (reviewed in Donohue and Kaplan, 1991; Table 1). Selection for the recipient over the donor strain is usually accomplished by antibiotic resistance markers in the recipient or auxotrophic markers in the donor. Mutants with enhanced recipient activity that is thought to be due to inactivation of the restriction system have been isolated from *Rb. capsulatus* (Taylor et al., 1983) and *Rb. sphaeroides* (Sistrom et al., 1984).

Both the chromosome and plasmids can be

Abbreviations: ALA-5-aminolevulinic acid; *Cm.* - *Chromatium*; *E. coli* - *Escherichia coli*; GTA - gene transfer agent; kb - kilobase pair; PCR - polymerase chain reaction; PHB - poly(3-hydroxybutyrate); *Rb.* - *Rhodobacter*; *Ro.* - *Roseobacter*; *Rp.* - *Rhodopseudomonas*; *Rs.* - *Rhodospirillum*; *Rv.* - *Rubrivivax*; RubisCO - ribulose 1,5-bisphosphate carboxylase-oxygenase; TMAO-trimethylamine-N-oxide; Tris - tris(hydroxymethyl)aminomethane

transferred by conjugation. Chromosomal mobilization has been induced using broad host range R plasmids in *Rb. capsulatus* and *Rb. sphaeroides* (reviewed in Scolnik and Marrs, 1987; Donohue and Kaplan, 1991; Saunders, 1992; Clewell, 1993). The conversion of these IncP plasmids (RP1, RP4, RK2, R18 and R68) to a form that can induce increased chromosome mobilization activity appears to involve the incorporation of elements capable of transposition, IS insertion sequences or transposable Tn elements. The plasmid R68.45, a derivative of R68, induces chromosome mobilization activity in *Rb. sphaeroides* (Sistrom, 1977; Sistrom et al., 1984) and *Rb. capsulatus* (Yu et al., 1981). Chromosome mobilization is thought to occur following R68.45 integration into the chromosome via transposition-mediated events involving IS21 sequences (Willets et al., 1981). Another conjugative plasmid, RP1::Tn501, has been used to map a number of biosynthetic and antibiotic resistance markers in two linkage groups of *Rb. sphaeroides* (Pemberton and Bowen, 1981). RP1::Tn501 was derived from RP1 via the insertion of the mercury resistance transposon Tn501. Chromosome mobilization activity has been demonstrated in *Rb. capsulatus* with the conjugative plasmids pBLM2 (Marrs, 1981) and pTH10 (Willison

et al., 1985), which appear to initiate chromosome transfer from multiple sites of origin. The plasmid pBLM2 was isolated from a derivative of RP1 for its enhanced sex factor activity. The plasmid pTH10, another mutant RP1 plasmid, contains IS21 and Tn1 sequences and is believed to induce chromosome mobilization activity via pTH10-chromosome co-integrate formation. R' plasmids generated during chromosome mobilization have been useful in the identification of the photosynthetic gene clusters of *Rb. capsulatus* (Marrs, 1981; see also Chapter 50 by Alberti et al.) and *Rb. sphaeroides* (Sistrom et al., 1984; Wu et al., 1991b). Most engineered plasmid systems utilize a mobilizable but not self-transmissible plasmid vector, with the transfer functions provided in *trans* either from a helper plasmid such as pRK2013, a derivative of RK2, in a triparental mating (Ditta et al., 1980) or from a donor strain such as *E. coli* S17-1, in which the transfer genes of RP4 have been integrated into the chromosome (Simon et al., 1983).

2. Transformation

Transformation has the advantage of not requiring counterselection against the donor strain or

mobilization ability of the DNA, but its success usually depends on empirical application of protocols for the preparation of competent cells or electroporation. Competence has been induced in *Rb. sphaeroides* by washing cells with CaCl_2 , polyethylene glycol and high concentrations of Tris (Fornari and Kaplan, 1982; Donohue and Kaplan, 1991), in *Rb. marinus* by CaCl_2 treatment (Matsunaga et al., 1986, 1990) and in *Rs. rubrum* by CaCl_2 and freeze/thaw methods (Fitzmaurice and Roberts, 1991). Conditions for transformation by electroporation have been described for *Rb. sphaeroides* (Donohue and Kaplan, 1991) and *Rp. viridis* (Laußermair and Oesterhelt, 1992).

3. Transduction

Although a number of endogenous phage have been isolated from purple bacteria, none have been shown to be generally useful for transduction (reviewed in Marrs, 1978; Saunders, 1978, 1992; Donohue and Kaplan, 1991). The 'gene transfer agent' or GTA from *Rb. capsulatus* (Marrs, 1974; Solioz et al., 1975; Solioz and Marrs, 1977) consists of phage-like particles that package short (approximately 4.5 kb) linear fragments of DNA. Although DNA transfer by GTA resembles generalized transduction, GTA lacks many typical viral activities. For example, GTA does not transfer to recipients the ability to produce GTA, and the size of the DNA carried by GTA is apparently too small to package all of the genes necessary for its production. Thus, GTA particles represent either a 'pre-phage' particle that confers the advantages of genetic exchange or a defective phage population (reviewed in Marrs, 1978; Saunders, 1978). Most *Rb. capsulatus* strains are GTA donors and recipients (Wall et al., 1975b) and an overproducer mutant has been isolated (Yen et al., 1979). The ability of the GTA to transfer linear fragments of genomic DNA has been very useful in mapping genes and in making replacements of chromosomal DNA in *Rb. capsulatus*.

B. Genetic Markers

Nutritional and antibiotic resistance markers have been developed, particularly for *Rb. capsulatus* and *Rb. sphaeroides* (reviewed in Saunders, 1978; Siström, 1978; see also Siström, 1977; Miller and Kaplan, 1978; Pemberton and Bowen, 1981; Willison

et al., 1985; Pemberton and Harding, 1986, 1987; Choudhary et al., 1994). Antibiotic resistance markers in *Rb. capsulatus* were isolated on complex media in the presence of antibiotics at frequencies in the range of 10^{-6} to 10^{-9} per cell plated (Willison et al., 1985). For example, rifampicin resistance has only been noted at one genetic locus that probably codes for the β -subunit of RNA polymerase. Penicillin resistance found in some strains has been shown to be due to an endogenous β -lactamase in *Rb. sphaeroides* (Bauermann et al., 1989) and *Rb. capsulatus* (Campbell et al., 1989). In addition, exogenous antibiotic resistance genes are widely used to select for recipients of DNA transfer, although not all markers are expressed equally well in purple bacteria (reviewed in Donohue and Kaplan, 1991). Several laboratories have isolated nitrogen fixation (*nif*) mutants of *Rb. capsulatus* (reviewed in Willison, 1993). Many bacteriochlorophyll (*bch*) and carotenoid (*crt*) biosynthesis mutants are easily scored due to their dramatically altered colony color (Yen and Marrs, 1976).

C. Vectors

Broad host range vectors are often used to shuttle DNA fragments between *E. coli* and purple bacteria. Broad host range plasmids that have been engineered for use as DNA vectors contain unique restriction sites for cloning, antibiotic resistance markers, and usually have been reduced in size to facilitate handling. One set of widely used vectors includes derivatives of RK2 such as pRK290, pRK404 and pRK415 (Ditta et al., 1980, 1985; Keen et al., 1988). These vectors are approximately 10–20 kb in size, contain a tetracycline resistance marker, and in some cases have multiple cloning sites and insertional inactivation of the β -galactosidase (*lacZ*) gene. They have been shown to replicate in *Rb. capsulatus* (Klug and Drews, 1984), *Rb. sphaeroides* (Ditta et al., 1985), *Rp. viridis* (Lang and Oesterhelt, 1989b), *Rs. rubrum* (Saegesser et al., 1992) and *Rp. palustris* (Elder et al., 1993). The copy number of pRK404 derivatives has been estimated to be between four and nine in *Rb. sphaeroides* (Davis et al., 1988; Brandner et al., 1989) and eleven and fourteen in *Rs. rubrum* (Saegesser et al., 1992). *Rb. capsulatus* strains can be cured of R plasmids of the P incompatibility group by repeated subculturing in a rich medium lacking calcium and magnesium salts (Magnin et al., 1987). RK2 plasmids are lost from up

to 50% of the cells when *Rb. sphaeroides* is grown for six to eight doublings in the absence of selection (Donohue and Kaplan, 1991). In *Rs. rubrum*, loss of RK2 derivatives was reported after ten generations of anaerobic photosynthetic growth without selection, although the plasmids were retained under aerobic growth conditions (Saegesser et al., 1992). Cosmid derivatives of pRK290 such as pLAFR1, pVK102 and pLA2917 have been used to make libraries of *Rb. capsulatus* (Avtges et al., 1985; Colbeau et al., 1986), *Rb. sphaeroides* (Weaver and Tabita, 1985; Benning and Somerville, 1992a,b; Choudhary et al., 1994) and *Rp. palustris* (Dispensa et al., 1992), and vectors that contain *lacZ* translational fusion sites and an RK2 replicon have been constructed for analysis of promoter regions in *Rb. capsulatus* (Adams et al., 1989; Hübner et al., 1991). Plasmids constructed from the fusion of derivatives of pRK290 and pBR322 that apparently result in a higher copy number in *E. coli* than pRK290 alone have been used for analysis of the *puf* operon in *Rb. capsulatus* (Bylina et al., 1989; Taguchi et al., 1993). Other vectors derived from the broad host range plasmid RSF1010 have been constructed, including a cloning vector, pNH2, modified by the addition of a tetracycline resistance gene containing restriction sites for cloning, that has been used in *Rb. sphaeroides* (Hunter and Turner, 1988), a cosmid vector, pJRD215, that has been used for making libraries of *Rb. capsulatus* (Sganga and Bauer, 1992), *Rb. sphaeroides* (Choudhary et al., 1994) and *Rs. centenum* (Yildiz et al., 1992) and a *lacZ* fusion vector that has been used in *Rb. sphaeroides* (Nano et al., 1984).

Portions of broad host range plasmids have been used to create mobilizable versions of other cloning vectors. For example, mobilizable versions of ColE1 plasmids created by addition of a *mob* site (Simon et al., 1983; Lang and Oesterhelt, 1989b) have been used in purple bacteria (reviewed in Donohue and Kaplan, 1991; Hunter and Mann, 1992). Another system for mobilizing plasmids that has been used in *Rb. capsulatus* involves the supply of the gene products needed to mobilize pBR322 in *trans* from the plasmid pDPT51, which results from the fusion of a promiscuous plasmid with a ColE1 derivative (Taylor et al., 1983). Shuttle vectors for *Rb. marinus* were constructed by combining an endogenous plasmid with *E. coli* cloning vectors (Matsunaga et al., 1986, 1990).

D. Isolation of DNA

Specific protocols for DNA isolation from purple bacteria have been described (Table 1). When isolating DNA from these bacteria, one should keep in mind that endogenous plasmids have been found in *Rs. rubrum*, *Rb. sphaeroides* and *Rb. capsulatus* strains (reviewed in Saunders, 1978; Willison, 1993). *Rs. rubrum* strains contain a single class of 55 kb plasmids. *Rb. sphaeroides* strains contain up to six plasmids and *Rb. capsulatus* strains usually contain one or two plasmids in the 42 to 150 kb size range. Additional purification steps such as selection for antibiotic resistance after transformation into *E. coli* or separation by pulsed field agarose gel electrophoresis may be necessary to isolate recombinant vectors from endogenous plasmids. While normal genomic DNA isolation procedures result in shearing of the DNA into large fragments, intact genomic DNA for use in pulsed field gel electrophoresis can be prepared after first embedding the cells in agarose (McClelland et al., 1987; Suwanto and Kaplan, 1989a; Fonstein et al., 1992). Pulsed field gels are useful for the separation of large restriction fragments generated by rare-cutting restriction enzymes. The high GC content of DNA from many purple bacteria such as *Rb. capsulatus* and *Rb. sphaeroides* tends to result in a small number (usually less than 20 per genome) of restriction sites for enzymes that have a recognition sequence that is AT rich or that contains rarely used codons, such as *AseI*, *DraI*, *SpeI*, *SspI* and *XbaI* (McClelland et al., 1987; Suwanto and Kaplan, 1989a; Fonstein et al., 1992).

III. Gene Mapping

A. Isolation of Independent Events

To begin a genetic analysis of a pool of mutants with a given phenotype, it is desirable to ascertain that the phenotype is due to a single mutation in each strain. To make this more likely, different mutant strains should be derived from different single colonies that presumably arose from different single cells. If mutagens are used, they should be at levels low enough to insure that a reasonable fraction (10% to 50%) of cells survive the treatment. A frequency of reversion to the wild type phenotype in the range of approximately 10^{-6} to 10^{-9} per cell plated is an

indication that a mutant phenotype is due to a single mutation. Reversion can also be induced via recombination systems from a wild type strain (for example, via GTA transduction in *Rb. capsulatus*), and the reversion frequency should match the gene transfer frequency of the specific system. However, some types of single mutations, such as very large deletions or rearrangements, may not revert easily to wild type and thus, may act like the result of multiple mutational events. Also, closely linked mutations may act like a single mutation.

B. Linkage Groups

The next step in a genetic mapping analysis is to sort the new mutations into linkage groups that probably correspond to genes. Linkage tests may be performed using R plasmid-induced conjugation (for example, Willison et al., 1985; Colbeau et al., 1990). In *Rb. capsulatus*, GTA transduction is well suited for these kinds of tests since cotransfer is limited to closely linked markers. The ratio test of Yen and Marrs (1976) has been used in *Rb. capsulatus* to sort fourteen independently isolated *nif* mutants into six linkage groups (Wall and Braddock, 1984; Wall et al., 1984). Since this test requires an independent marker, rifampicin resistant (Rif^r) derivatives of each of their original rifampicin sensitive (Rif^s) nitrogen fixation (Nif^+) mutants were constructed. The transfer of the Rif^r marker was then used to normalize the number of recombinants in pairwise GTA crosses. The expected frequency of transfer of each *Nif* marker was established by determining the ratio ($\text{Nif}^+:\text{Rif}^r$) of the frequency of transfer of the wild type nitrogen fixation marker (Nif^+) to the frequency of transfer of the Rif^r marker in control crosses ($\text{Nif}^+ \text{Rif}^r \times \text{Nif}^- \text{Rif}^s$). In the experimental crosses, one rifampicin resistant, nitrogen fixation mutant ($\text{Nif}_1^- \text{Rif}^r$) was used as a donor and a second rifampicin sensitive, nitrogen fixation mutant ($\text{Nif}_2^- \text{Rif}^s$) was the recipient. If the *nif1* and *nif2* loci are very far apart and therefore are not linked within the 4.5 kb that can be packaged by GTA particles, then the $\text{Nif}^+:\text{Rif}^r$ ratio should be similar to the ratio of the corresponding control crosses. If the two *nif* loci are very near to each other, then it should be more difficult to detect Nif^+ recombinants, and the $\text{Nif}^+:\text{Rif}^r$ ratio in the recombinants will be much less than that of the control crosses. Since the frequencies determined by this type of linkage test are subject to variation, the results must be shown to be statistically significant.

A modernized variant of the classical linkage test was used to determine the extent of linkage of several inhibitor resistance mutations to the *pet* operon of *Rb. capsulatus*, which encodes the three structural genes of the cytochrome bc_1 complex (Daldal et al., 1989). A kanamycin resistance marker was specifically introduced at the 3' end of the *pet* operon, and GTA transduction from the kanamycin resistant, inhibitor sensitive strain into kanamycin sensitive, inhibitor resistant mutants was performed. After selection for transfer of kanamycin resistance to the recipient strain, the frequency of co-transduction of inhibitor sensitivity was tested. Three classes of mutations were observed among mutants resistant to the inhibitor stigmatellin. One group of mutations linked to the kanamycin marker had a co-transduction frequency of approximately 8%, and a second group of linked mutations had a co-transduction frequency of approximately 20%, indicating that these mutations were located closer to the 3' end of *pet* operon than the first group. A third group was not linked to the kanamycin resistance marker (0% co-transduction) and thus were greater than 4.5 kb from the 3' end of the *pet* operon. The *pet* operons from representative isolates whose mutations were shown to be linked to the kanamycin marker were then cloned and sequenced to determine the molecular basis of the inhibitor resistance.

C. Linkage Mapping

The primary requirement for classical genetic mapping is the ability to transfer large stretches of the genome between the mutant strain under study and a tester strain. A second requirement is the presence of selectable markers throughout the genome. One can determine the proximity of the mutation of interest to known markers by conducting two-point crosses. The linear order of three genes and the distances separating them can be determined in three-point crosses. The chromosome of *Rb. capsulatus* can be scanned with six or so widely spaced markers. Thus, if at least two or three markers are present in any tester strain, only two to four tester strains are required as a minimal set. The *hup* (H_2 -uptake hydrogenase) loci in *Rb. capsulatus* have been mapped utilizing the mutant R plasmid, pTH10 (Colbeau et al., 1990). In one mapping cross, an $\text{Ade}^- \text{His}^- \text{Hup}^+ \text{Nif}^+$, pTH10 donor strain was mated to an $\text{Ade}^+ \text{His}^+ \text{Hup}^- \text{Nif}^-$ recipient strain. Since the recovery of recombinants ranges from 10^{-4} to 10^{-6}

per donor cell plated, counterselection against the parental donor and recipient strains was accomplished by requiring adenine biosynthesis (Ade^+) and hydrogenase activity (Hup^+). After selection for $Ade^+ Hup^+$ recombinants, the secondary marker phenotypes, His^- and Nif^+ , were examined. The cotransfer frequency of two genes from the donor into the recipient genome is a measure of the genetic map distance separating these two loci. For the His^- and Hup^+ markers, the cotransfer frequency, defined as the percentage of His^- recombinants in the Hup^+ recombinant population, was measured to be approximately 55%. Similarly, the $Nif^+ Hup^+$ and $His^- Nif^+$ cotransfer frequencies were measured to be approximately 25% and 53%, respectively. Thus, the linear gene order was determined to be *hup-his-nif*. The map distance may be estimated using the equation of Wu (1966) as adapted by Kondorosi et al. (1977):

$$d = 1 - c^{1/3} \quad (1)$$

where d is the map distance in arbitrary units and c is the cotransfer frequency. Map distances calculated in this way show approximate additivity for values of c larger than 0.1. In carrying out crosses of this type, one must keep in mind that the reversion frequencies of these markers to wild type is in the 10^{-7} to 10^{-9} range.

D. Chromosomal Linkage Maps

The circular genetic linkage map of *Rb. capsulatus* (see Chapter 55 in this volume by Vignais et al.) was compiled utilizing derivatives of strain B10 (Willison et al., 1985; Willison, 1993). Data largely from two and three point crosses yielded the positions of approximately 40 genetic loci. Given that the chromosome of *Rb. capsulatus* is approximately 3,700 kb and assuming an average gene size of 1 kb, one might expect to find some 4,000 genetic loci. Undoubtedly, mutations at some of these sites result in a lethal phenotype. The *Rb. capsulatus* map determined by Willison and coworkers is a total of 4.6 arbitrary map units and the chromosome has been determined to be 3,700 kb; this yields an equivalence of approximately 800 kb per map unit. The *Rb. capsulatus* genetic map is largely in agreement with the physical map of *Rb. capsulatus* strain SB 1003 (Fonstein and Haselkorn, 1993; see also Chapter 49 in this volume by Fonstein and Haselkorn) except in the *nifR1-glnA-trp1* region,

which appears to be inverted between the two maps. This may be due to true strain differences, a nonequivalence of marker loci, effects of repeated elements on genetic recombination in the region or a sparsity of genetic loci in the region.

Chromosomal linkage maps for regions of *Rb. sphaeroides* also exist, though these are linear and the allele designations on different maps are not necessarily equivalent (reviewed in Kiley and Kaplan, 1988). Bowen and Pemberton (1985) utilized derivatives of broad host range plasmids coupled to mercury-resistance transposons, pRPI::Tn501 and pR751::Tn813, to map nutritional and antibiotic markers including *crt* and *bch* loci on the *Rb. sphaeroides* RS630 chromosome. Sistro et al. (1984) have generated a linear linkage map of the *Rb. sphaeroides* strain WS2 chromosome utilizing the broad host range, self-mobilizable plasmid R68.45. A physical map of two chromosomes of *Rb. sphaeroides* strain 2.4.1 generated by ordering large restriction fragments has been presented by Suwanto and Kaplan (1989a,b), and a genetic map has been related to a higher resolution physical map of the small chromosome (Choudhary et al., 1994). The origin of transfer from one of the endogenous plasmids of *Rb. sphaeroides* was shown to promote chromosomal transfer, and was used to correlate several genetic markers with the physical map (Suwanto and Kaplan, 1992a,b).

IV. Gene Cloning and Sequencing

A. Genomic Libraries

A DNA library for an organism generally consists of genomic restriction fragments cloned in a vector in *E. coli*. For complete libraries, every fragment should have a reasonable probability of being represented. Based on a statistical distribution, the number of independent clones, N , necessary for a random library to have a probability, P , of having any particular fragment can be estimated by:

$$N = \ln(1-P) / \ln(1-f) \quad (2)$$

where f is the fraction of the genome represented by each cloned fragment (Clarke and Carbon, 1976). The genome sizes, including the chromosomal and endogenous plasmid DNA, of *Rb. sphaeroides* and *Rb. capsulatus* have been estimated to be approxi-

mately 4,400 kb and 3,800 kb, respectively (Suwanto and Kaplan, 1989a; Fonstein and Haselkorn, 1993). After digestion with a restriction enzyme that recognizes a six base sequence and cloning into a plasmid vector, fragments of an average size of 4 kb would be expected to be cloned. Thus, assuming that each clone contains 1/1000 of the genome, for a probability of 99% the library size would have to be approximately 4,600 clones, and for a probability of 90% the library size would have to be approximately 2,300 clones. Larger restriction fragments, usually generated by partial digestion of genomic DNA followed by size fractionation on an agarose gel or sucrose gradient, can be cloned in phage and cosmid vectors. Lambda phage vectors can accept fragments of 10 to 20 kb, and cosmids can accept fragments of 30 to 40 kb, so the number of clones required for a complete library would be correspondingly smaller. A minimal set of 192 clones covering the chromosome and an endogenous plasmid was determined for an ordered, overlapping cosmid library of *Rb. capsulatus* (Fonstein et al., 1992; Fonstein and Haselkorn, 1993). In some cases, where the size of a restriction fragment containing the target gene was determined by hybridization with digests of genomic DNA, fragments of the correct size were isolated and then cloned to create size-enriched libraries. For example, one positive plasmid containing RubisCO genes from *Cm. vinosum* was obtained after screening plasmid DNA from 60 colonies with inserts of 8 to 9.5 kb isolated after agarose gel electrophoresis of a genomic *Bgl*III digest (Kobayashi et al., 1991).

B. Identification of Genes

1. Complementation

The identity of genes contained on restriction fragments cloned in a genomic library may be determined by their ability to complement mutant strains (Table 2). Libraries of *Rb. capsulatus*, *Rb. sphaeroides* and *Rs. rubrum* DNA have been screened by individual mating of several hundred to several thousand members of the library into a target mutant strain (Klug and Drews, 1984; Ahombo et al, 1986; Pemberton and Harding, 1986, 1987; Moore and Kaplan, 1989; Benning and Somerville, 1992a,b; Hustede et al., 1992). The screening can be accomplished by replica plating members of the genomic library from microtiter plates onto lawns of the mutant recipient (Klug and Drews, 1984; Moore

and Kaplan, 1989; Benning and Somerville, 1992a,b). The number of matings that must be performed can be reduced by mating pools of clones from the library, and then isolating the desired cloned fragment from the complemented transconjugant (Avtges et al., 1985; Weaver and Tabita, 1985; Biel et al., 1988; Daniels et al., 1988; Rainey and Tabita, 1989; Xu et al., 1989; Biel and Biel, 1990; Hamblin et al., 1990). Alternatively, each pool from which a complementing clone was observed can be further subdivided and mated again, until individual clones can be tested (Colbeau et al., 1986; Hunter and Coomber, 1988; Hunter and Turner, 1988). Individual crosses are also necessary for plasmids that are not stable in the mutant recipient strain (Hunter and Turner, 1988). Interspecies complementation analysis has also been used to identify genes. For example, libraries of DNA from *Rb. capsulatus* complemented an *E. coli* glutamine synthetase mutant (Scolnik et al., 1983), *Rb. sphaeroides* and *Rs. rubrum* complemented an *Alcaligenes eutrophus* PHB synthase mutant (Hustede et al., 1992), *Rs. centenum* complemented *Rb. capsulatus* photosynthesis mutants (Yildiz et al., 1992), *Cm. vinosum* complemented an *E. coli* chaperonin mutant (Ferreya et al., 1993), *Rb. capsulatus* complemented a *Rb. sphaeroides* cytochrome mutant (Jenny and Daldal, 1993) and *Rb. sphaeroides* complemented a *Pseudomonas aeruginosa recA* mutant (Calero et al., 1994). In addition, resistance to cleavage by *Eco*RI due to the expression in *E. coli* of the gene for the *Rsr*I methyltransferase led to the identification of a clone encoding the methyltransferase gene from *Rb. sphaeroides* (Kaszubska et al., 1989).

Once a clone has been obtained that complements a mutant, the boundaries of the gene and its promoter can be narrowed by testing smaller fragments or making progressive deletions until complementation is no longer observed. The frequency of complementation can be used to distinguish between recombination of a chromosomal point mutation with DNA from the plasmid (marker rescue) and expression of the gene from the plasmid, since recombination occurs at a low frequency. For example, in order to determine the location of nitrogen fixation mutations using fragments of cloned nitrogenase structural genes, the number of transconjugants identified by antibiotic resistance was compared to the number that exhibited the Nif^+ phenotype (Avtges et al., 1983). For complementation from the plasmid, 100% of the antibiotic resistant colonies were Nif^+ ,

whereas marker rescue usually produced Nif^+ colonies at a frequency of 0.5% to 1% of the antibiotic resistant colonies. Similarly, when an *E. coli* strain, harboring a plasmid with a genomic DNA insert that had been identified by hybridization with a heterologous probe as containing a *Rb. capsulatus hup* gene, was mated with a *Rb. capsulatus Hup*⁻ mutant, less than 1% of the transconjugants were Hup^+ , leading to the conclusion that the entire gene was probably not present on the fragment (Leclerc et al., 1988). For mutants with phenotypes that can be distinguished by inspection of colonies, such as the color of *bch* and *crt* mutations, restreaking of transconjugants without selection for plasmid maintenance will either yield unsectored, primarily wild type colonies arising from cells in which recombination has occurred, or sectored colonies arising from cells whose mutation is complemented from the plasmid (Young et al., 1989). Recombination of the complementing DNA fragment can also be tested by using recombination deficient strains such as the *recA* mutants of *Rb. sphaeroides* (Sistrom et al., 1984; Rainey and Tabita, 1989; Calero et al., 1994) or by plasmid curing of the complemented strains (Davis et al., 1988; Tai et al., 1988; Brandner et al., 1989; Xu et al., 1989). The properties of an RNA processing gene in *Rb. capsulatus* expressed in *cis* and in *trans* were compared by forcing recombination of the complementing plasmid into the chromosome by the introduction of an incompatible plasmid (Klug et al., 1994).

2. Heterologous Probes

Once a gene has been cloned from one species, it can often be used as a hybridization probe to identify homologous genes in other species (Table 2). Since the degree of similarity among homologous proteins varies considerably, the evolutionary distance between the probe and the target needs to be considered for successful hybridization. Hybridization among a large number of species has been observed for genes that are highly conserved, such as the genes encoding RubisCO (Shively et al., 1986). The conditions used will affect the amount of hybridization observed, as occasionally genes that might be expected to cross-hybridize do not (for example, Beatty and Cohen, 1983; Coomber and Hunter, 1989). Generally, the heterologous probe is hybridized against colonies or plaques from the gene library, although with an *E. coli* probe for genes encoding ATPase, too much

background hybridization with genomic DNA from the *E. coli* in the library was observed, so isolated DNA from the clones was used for hybridization instead of plaques (Tybulewicz et al., 1984). Heterologous probes have been used to identify DNA fragments in physical genome maps of *Rb. sphaeroides* and *Rb. capsulatus* (Suwanto and Kaplan, 1989a,b; Fonstein et al., 1992; Fonstein and Haselkorn, 1993). Ribosomal RNA has also been used as a hybridization probe (Yu et al., 1982; Dryden and Kaplan, 1990).

3. Oligonucleotide and PCR Probes

If a complete or partial amino acid sequence has been determined for a protein, then a corresponding DNA sequence can be deduced. A synthetic oligonucleotide containing this sequence can then be used as a hybridization probe for the structural gene encoding the protein (Table 2). Due to the degeneracy in the genetic code, the deduced DNA sequence is usually ambiguous, so probes consisting of all the possible coding sequences are synthesized as a mixture. To reduce the complexity of the probe, regions of the amino acid sequence with low codon degeneracy are often selected for the probe sequence. In addition, guesses as to the correct coding sequence can be based on the codon usage for a particular bacterium (Schatt et al., 1989; Majewski and Trebst, 1990; Self et al., 1990; Kerby et al., 1992). For example, a 27 nucleotide nondegenerate probe for ferredoxin in *Rb. capsulatus* was based on the codon usage for a sequence of nine amino acid residues that contained 30 ambiguities (Schatt et al., 1989). Oligonucleotides specific for conserved amino acid sequences of homologous proteins have also been used as hybridization probes (Majewski and Trebst, 1990; Masepohl et al., 1993b). Protein sequences that are reasonably far apart (approximately 70 to 700 residues) can be used as the basis for primers in PCR reactions to amplify the portion of the gene that lies between the two sequences. PCR fragments generated from primers based on consensus sequences have been used as hybridization probes and have also been directly cloned and sequenced (Table 2).

4. Immunological Screening

Screening genomic libraries with an antibody to a particular protein can be used to identify the structural

gene for that protein (Table 2). Since this method requires that the target protein be synthesized in *E. coli* from the cloned gene, libraries are generally constructed in expression vectors. This method may fail if the gene is not expressed in *E. coli*, as was observed during screening for the hydrogenase gene of *Rb. capsulatus* (Colbeau et al., 1986).

C. Sequences

Over 200 genes from purple photosynthetic bacteria have been sequenced, including structural and regulatory genes for a variety of metabolic processes (Table 3). In some cases, the genes for homologous proteins have been sequenced from several species, allowing the identification of conserved residues and the construction of evolutionary trees. Sequencing

DNA that has been cloned from photosynthetic bacteria is performed by standard protocols. The major problem encountered is frequent gel artifacts such as compression due to the high GC content of DNA from many of the purple bacteria. These artifacts usually occur in different places on complementary strands. They can also usually be relieved by measures that reduce the amount of secondary structure in the DNA, such as the use of dGTP analogues during polymerization, the use of thermostable polymerases that enable the reactions to be carried out at higher temperatures, and the addition of formamide to the polyacrylamide gels. The usefulness of being able to amplify by PCR any portion of DNA that has already been sequenced has been demonstrated by the amplification of specific regions of *Rb. capsulatus* and *Rb. sphaeroides* DNA for sequence and size

analysis from mutants (Klug and Jock, 1991; Colbeau et al., 1993; Gong et al., 1994; Kordes et al., 1994), for use in protein binding assays (Klug, 1991; Lee et al., 1993) and for plasmid constructions (Foster-Hartnett and Kranz, 1992; Arondel et al., 1993; Bollivar et al., 1994b). Generation of DNA fragments by PCR was also used to determine the position of a Tn5 insertion in *Rp. palustris* (Dispensa et al., 1992) and to confirm a chromosomal deletion in *Rp. viridis* (Laußermair and Oesterhelt, 1992).

The identification of genes in sequenced regions enables tabulation of the codon usage for an organism (Table 4). The codon usage in turn facilitates identification of other genes by codon preference

profiles of sequences, which have been used to identify ATPase genes in *Rp. blastica* (Tybulewicz et al., 1984) and *Rs. rubrum* (Falk et al., 1985; Falk and Walker, 1988) and pigment synthesis genes (Bauer et al., 1988; Young et al., 1989, 1992; Yang and Bauer, 1990) and fructose metabolism genes (Wu et al., 1991a) in *Rb. capsulatus*. Codon usage information is also useful in designing oligonucleotides for use as hybridization probes and PCR primers, and in site-directed mutagenesis. Evidence has been presented that codon usage may be different for genes expressed under phototrophic and heterotrophic growth conditions in *Rb. capsulatus* (Wu and Saier, 1991).

V. Mutagenesis

A. Enrichment by Antibiotic Selection

Antibiotics such as ampicillin and penicillin that kill actively growing cells have been used to enrich cultures for mutants (reviewed in Marrs et al., 1980). Cultures are subjected to the antibiotics under conditions in which bacteria with the wild type function can grow but those with impaired function will not grow. After this enrichment period, the cells are washed and then screened for the presence of the function. Examples of ampicillin and penicillin selection in photosynthetic bacteria include the isolation of auxotrophs in *Rb. sphaeroides* (Sistrom, 1977) and *Rb. capsulatus* (Willison et al., 1985), nitrogen fixation mutants in *Rb. capsulatus* (Wall et al., 1975a; Avtges et al., 1983; Wall and Braddock, 1984), carbon dioxide fixation mutants in *Rb. sphaeroides* (Weaver and Tabita, 1983), photosynthesis mutants in *Rb. capsulatus* (Chen et al., 1988; Sganga and Bauer, 1992; Mosley et al., 1994), *Rb. sphaeroides* (Hunter and Turner, 1988) and *Rs. centenum* (Yildiz et al., 1991) and hydrogenase mutants in *Rb. capsulatus* (Xu et al., 1989). Other antibiotics have also been used for enrichment of *Rb. sphaeroides* mutants (Schneider et al., 1993). Tetracycline is accumulated in photosynthetically

growing cells, and tetracycline suicide techniques have been used to isolate photosynthetically deficient mutants in *Rb. capsulatus* (Zannoni et al., 1980; Marrs, 1981; Youvan et al., 1983) and *Rs. rubrum* (Johansson and Baltscheffsky, 1980).

B. Chemical Mutagenesis

Mutagens that have been used in photosynthetic bacteria include nitrosoguanidine, ethylmethane sulfonate and UV light (reviewed in Sistrom, 1978; Willison, 1993; Table 5). The survival of cells in a population exposed to a mutagen can be used as a measure of the extent of mutagenesis. For example, a survival curve comparing the survival of the cells to the time of exposure to UV light and to nitrosoguanidine was determined for *Rp. viridis* (Lang and Oesterhelt, 1989a). The degree of mutagenesis in such an experiment can be determined by scoring the frequency of antibiotic resistance mutants, as has been done for nitrosoguanidine mutagenesis of *Rb. sphaeroides* (Benning and Somerville, 1992a). A study of the effects of UV irradiation indicated that *Rb. capsulatus* has a DNA repair system similar to that of *E. coli* (Barbé et al., 1987) and the *recA* gene has been isolated from *Rb. sphaeroides* (Calero et al., 1994). UV irradiation-sensitive mutants that appear to be recombination-deficient have been isolated

from *Rb. capsulatus* (Genther and Wall, 1984) and *Rb. sphaeroides* (Sistrom et al., 1984). In order to increase the frequency of mutation in a given region of DNA, cloned fragments can be subjected to mutagens in vitro and then transferred back into a host strain for screening, as demonstrated by Narro et al. (1990) in studying oxygen regulation of the *puf* operon in *Rb. capsulatus*.

C. Transposon Mutagenesis

Transposons can be used to make polar, random insertion mutations in chromosomal or plasmid DNA (Table 5). Transposons are generally transferred into a cell on a mobilizable suicide vector, where survival of the transposon depends on it having moved to the genomic DNA before the plasmid is lost. The most widely used system of this type is the suicide plasmid pSUP2021::Tn5 (Simon et al., 1983). A derivative of this vector with improved transposition frequencies in *Rs. rubrum* has been constructed (Ghosh et al., 1994). Plasmids that have a temperature sensitive origin of replication and carry derivatives of Tn5 that confer resistance to chloramphenicol (pCHR83) or gentamicin (pCHR84) were used to deliver transposons into *Rs. centenum* (Yildiz et al., 1991). Similarly, the plasmids pJB4J1 and pRK340 have been used to introduce transposons into *Rb. sphaeroides* (Weaver and Tabita, 1983). A restriction fragment containing the transposon can be cloned by selecting for the antibiotic resistance marker on the transposon, and then used as a hybridization probe for the wild type DNA (for example, Sockett and Armitage, 1991; Schüddekopf et al., 1993). Alternatively, the strain with the transposon insertion can be complemented by a genomic library to identify the gene. Additionally, the wild type *nif* genes in *Rb. capsulatus* were obtained after reciprocal exchange with cloned *nif*::Tn5 fragments and isolation of the resulting R' plasmids (Klipp et al., 1988).

Localized transposon mutagenesis can take place in a cloned piece of DNA, which is then transferred back into the species from which the DNA originated (reviewed in Hunter and Mann, 1992; Table 5). The phenotype of the mutation on the plasmid can be revealed either after homologous recombination into the wild type chromosome or by the ability of the mutated plasmid to complement mutant strains. If the transposon is inserted into a piece of DNA for which the restriction map is known, the approximate site of the insertion can be determined by restriction

mapping of the DNA containing the transposon.

D. Interposon Mutagenesis

An antibiotic resistance marker can be inserted into restriction sites in a cloned gene and transferred back into the chromosome by homologous recombination through a double crossover event to create a site-directed chromosomal insertion (reviewed in Donohue and Kaplan, 1991; Table 5). This technique of in vitro insertional mutagenesis has been termed interposon mutagenesis by Prentki and Krisch (1984), who constructed a widely used cassette called the Ω cartridge that consists of a spectinomycin/streptomycin antibiotic resistance gene flanked by transcription and translation termination signals and restriction sites. Other antibiotic resistance markers, including kanamycin and gentamicin, have been used to make such replacements. These types of insertions can be used to define the boundaries of cloned genes, to identify open reading frames, and to create background deletion strains for site-directed mutagenesis experiments.

In *Rb. capsulatus*, transfer of the marker into the chromosome can be mediated by GTA transduction (Scolnik and Haselkorn, 1984; reviewed in Scolnik and Marrs, 1987; Donohue and Kaplan, 1991). Chromosome mobilization or nonreplicating suicide plasmids can also be used to mediate insertion of the interposon into the chromosome. The mostly widely used suicide plasmids are pSUP202 and other derivatives described by Simon et al. (1983), which are mobilizable but are generally unable to replicate in strains outside the enteric bacterial group. Similar mobilizable suicide vectors have been used for interposon mutagenesis in *Rb. capsulatus* (Cauvin et al., 1991; Hübner et al., 1993). A suicide vector derived from R6K is functional in *Rb. sphaeroides* (Penfold and Pemberton, 1992, 1994). An artificial suicide vector created by deletion of the origin of replication from pRK404 was used to construct a chromosomal replacement of the *puf* operon after introduction into *Rp. viridis* by electroporation (Laußermair and Oesterhelt, 1992). Interposons have also been introduced via broad host range vectors in cases where recombination with the chromosome can be forced, such as by the introduction of an incompatible plasmid (Kranz et al., 1990; Lehman et al., 1990; Beckman and Kranz, 1993). In *Rb. capsulatus*, reciprocal exchange of the chromosomal *puf* operon with an interposon constructed in a

pRK404 vector was enriched for by selecting only for the antibiotic resistance of the marker followed by penicillin selection against photosynthetically competent cells (Chen et al., 1988). Chromosomal deletions or insertions that do not involve replacement with an antibiotic resistance marker can be made if the phenotype of the interrupted gene can be selected or screened for, or by replacing a previously inserted marker. For example, mutations and a small deletion were made in the *puf* operon of *Rb. sphaeroides* by replacement of a previously inserted kanamycin resistance marker (DeHoff et al., 1988; Gong et al., 1994; Stilz et al., 1994), and a nonpolar insertion of a 22 base pair fragment in the chromosomal *nifR3* gene of *Rb. capsulatus* was screened for by replacement of a previously inserted polar kanamycin marker (Foster-Hartnett et al., 1993).

E. Oligonucleotide-Directed Mutagenesis

Specific local changes in DNA sequences, such as alteration of the coding sequence of structural genes, can be accomplished by oligonucleotide-directed

mutagenesis (Table 5). In order to study structure-function questions in proteins, a mutagenesis system consisting of a chromosomal deletion of the wild type gene, a shuttle vector in which to transfer mutated copies of the gene back into the deletion strain, and a vehicle for mutagenesis of the DNA is required (Fig. 1). Mutagenesis can be accomplished on small fragments, for example by cloning into single-stranded phage vectors. After the mutagenesis, the fragment can be resequenced, inserted back into the shuttle vector, and mated into the deletion strain. To prevent selection for reversions, growth of the mutant strain should not require the function of the mutated gene.

Other types of alterations can be specifically introduced into DNA. Oligonucleotide-directed mutagenesis has been used to introduce deletions and insertions into the *puf* operon of *Rb. capsulatus* (Klug et al., 1987; Chen et al., 1988; Richter et al., 1992) and to create restriction sites for easier manipulation of DNA (Bylina et al., 1986; Pollock et al., 1988; Adams et al., 1989; Farchaus et al., 1990, 1992; Pille et al., 1990; Robles et al., 1990; Suetsugu

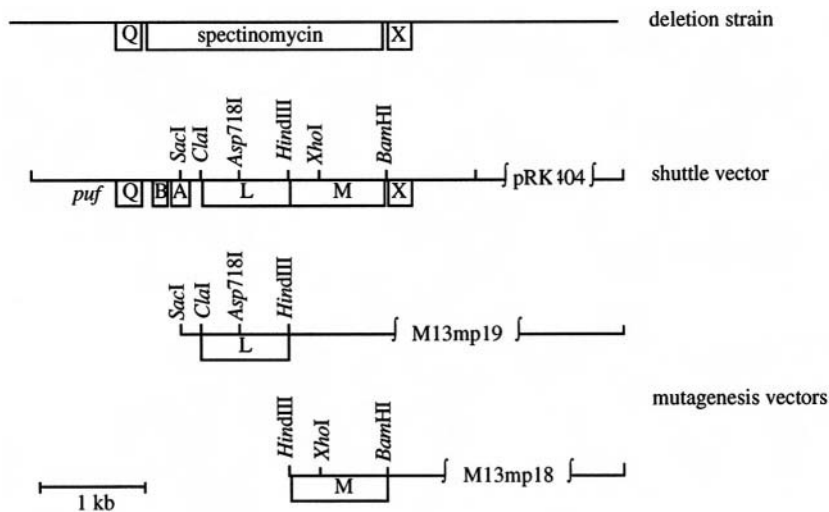

Fig. 1. Example of a mutagenesis system for reaction center genes in *Rb. sphaeroides*. A number of unique restriction sites have been added so that segments of the *pufL* and *pufM* genes can be manipulated independently. Each gene has been cloned into single-stranded M13 bacteriophage vectors to facilitate oligonucleotide-directed mutagenesis experiments. Restriction fragments containing the mutations are then moved into a broad host range plasmid in which the *puf* operon has been cloned, and the resulting shuttle vector is transferred by conjugation into a strain in which the wild type genes on the chromosome have been deleted. The *pufB*, *A*, *L* and *M* genes in the deletion strain have been replaced with an antibiotic resistance marker by interposon mutagenesis. In this deletion strain, the *pucA* and *B* genes, which encode the structural polypeptides of the B800–850 complex, have been deleted as well (Lee et al., 1989b). Since the *SacI* site in the *pufA* gene creates a mutation that results in the loss of the B870 antenna, the only pigmented complex in the complemented deletion strain is the reaction center. (See Chapter 22 in this volume by Hunter for other examples of strains that lack antenna complexes.) The mutant strains can be grown semi-aerobically in the dark to avoid photosynthetic selection pressure while also maintaining expression of the *puf* operon.

et al., 1991; Jones et al., 1992a,b; Shapleigh and Gennis, 1992; Shapleigh et al., 1992b). Mutagenesis (Stocker et al., 1992; Ma et al., 1993; Barz and Oesterhelt, 1994) or the specific addition of restriction sites (Beckman et al., 1992; Dispensa et al., 1992; Burke et al., 1993a; Armengaud et al., 1994; Bollivar et al., 1994a; Gibson and Hunter, 1994; Gibson et al., 1994; Lang et al., 1994) has also been accomplished by PCR reactions. Replacement of DNA segments with small (50 to 60 base pairs) double-stranded fragments consisting of annealed complementary oligonucleotides has been used to create large scale mutations in the reaction center genes from *Rb. capsulatus* (Taguchi et al., 1992), to insert a transcription terminator in the *puf* operon of *Rb. sphaeroides* (Farchaus et al., 1990) and to create small insertions in the gene encoding an RNA polymerase sigma factor in *Rb. capsulatus* (Cullen et al., 1994). This type of cassette mutagenesis can also be used to make simultaneous sets of mutations at several amino acid residues. For example, the antenna and reaction center genes of *Rb. capsulatus* have been mutagenized by incorporating mutations in the chemical synthesis of one strand of short (110 to 120 base pairs) restriction fragments, which were then amplified by PCR reactions using primers from each end of the fragment and subsequently cloned into an expression vector (Goldman and Youvan, 1992; Robles and Youvan, 1993; see also Chapter 61 in this volume by Goldman and Youvan).

F. Suppressors

When selection pressure is put on a mutant strain, reversion to the wild type phenotype may occur. For single site mutations, the reversion is usually at the original mutation site. However, mutations at a second site (suppressor mutations) may be recovered that complement the original mutation. For mutants containing a deletion of the wild type gene, revertants must be due to suppressor mutations in other genes. In *Rb. capsulatus* and *Rb. sphaeroides*, reversion to photosynthetic growth has been used to select suppressors of amino acid changes in the reaction center (Robles et al., 1990; Hanson et al., 1992), *puf* regulatory mutations (Klug and Jock, 1991) and deletions of *pufX* (Lilburn and Beatty, 1992; Lilburn et al., 1992; Barz and Oesterhelt, 1994) and *pucC* (LeBlanc and Beatty, 1993). Additional copies of nitrogenase genes in *Rb. capsulatus* (Scolnik and Haselkorn, 1984; Schneider et al., 1991; Schüddekopff

et al., 1993), cytochrome genes in *Rb. capsulatus* (Daldal et al., 1986; Jenny and Daldal, 1993) and *Rb. sphaeroides* (Rott and Donohue, 1990) and cytochrome *c* oxidase genes in *Rb. sphaeroides* (Shapleigh and Gennis, 1992; Shapleigh et al., 1992a) have also been found after deletion of the normally expressed genes. The ability of homologous genes to recombine under selection in vivo was used to generate a set of chimeric reaction centers in which deletions of the *pufM* gene in *Rb. capsulatus* were repaired by DNA donated from *Rb. sphaeroides* (Taguchi et al., 1993).

VI. Gene Expression

A. Gene Fusions

LacZ gene fusions have been used extensively to study expression in *Rb. capsulatus* and *Rb. sphaeroides* since the amount of the fusion protein can be measured by a quantitative colorimetric assay for β -galactosidase levels. Most commonly, specific translational fusions of the *lacZ* coding region are made near the beginning of a gene, then the construction is transferred back into the purple bacterium. Transcriptional fusions to the *lacZ* gene have also been used. After growth under the appropriate environmental conditions, the activity of β -galactosidase in cell extracts is determined. This technique is useful for identifying regions of DNA that contain promoter or regulatory regions (Belasco et al., 1985; Bauer et al., 1988, 1991; Adams et al., 1989; Tichy et al., 1989; Wellington and Beatty, 1989, 1991; Young et al., 1989; Hornberger et al., 1991; Wellington et al., 1991; Foster-Hartnett and Kranz, 1992; Preker et al., 1992; Beckman and Kranz, 1993; Duport et al., 1992; Foster-Hartnett et al., 1993; Lee and Kaplan, 1992a; LeBlanc and Beatty, 1993; Ma et al., 1993; Saeki et al., 1993; Tadros et al., 1993). *LacZ* gene fusions to open reading frames have helped to establish if the open reading frame is actually translated (Bauer et al., 1988; Foster-Hartnett et al., 1993). Gene fusions have also been used as reporters to define conditions under which genes are expressed (Kranz and Haselkorn, 1986; Bauer and Marrs, 1988; Forrest et al., 1989; Yang and Bauer, 1990; Hornberger et al., 1991; Hübner et al., 1991; Suetsugu et al., 1991; Wright et al., 1991; Colbeau and Vignais, 1992; Duport et al., 1992; Foster-Hartnett and Kranz, 1992; Armstrong et al., 1993; Forkl et al., 1993; Hübner et al., 1993; Buggy et al., 1994a,b;

Calero et al., 1994; Cullen et al., 1994; Eraso and Kaplan, 1994; Foster-Hartnett et al., 1994). As reporters of gene expression, fusions are also useful for studying the effects of mutations on the expression of genes (Moreno-Vivian et al., 1989a; Kranz et al., 1990; Hübner et al., 1991; Richaud et al., 1991; Colbeau and Vignais, 1992; Lee and Kaplan, 1992a,b; Preker et al., 1992; Schilke and Donohue, 1992; Sganga and Bauer, 1992; Colbeau et al., 1993; Gollan et al., 1993; Lee et al., 1993; Masepohl et al., 1993a; Mosley et al., 1994). In addition to assaying the effects of mutations, a *nifH::lacZ* gene fusion was used to isolate constitutive mutants in *Rb. capsulatus* by forcing the bacteria to grow on lactose under conditions where the *nif* genes are repressed (Kranz and Haselkorn, 1986). *LacZ* genes carried by Mu or miniMu bacteriophage transposons have been placed randomly into cloned fragments of DNA (Biel and Marrs, 1983; Avtges et al., 1985; Kranz and Haselkorn, 1985; Kranz, 1989) and have also been introduced into genomic DNA in *Rb. sphaeroides* (Nano and Kaplan, 1984). The expression of the *lac* operon in *Rb. sphaeroides* was studied by Nano and Kaplan (1982).

Promoterless antibiotic resistance genes provide a method for direct selection of regulatory regions. For example, transcriptional gene fusions to a kanamycin resistance marker were used to select for mutants involved in the oxygen regulation of the *puf* operon in *Rb. capsulatus* (Narro et al., 1990) and the *puc* operon in *Rb. sphaeroides* (Lee and Kaplan, 1992a,b) by selecting for kanamycin resistance under conditions where the genes are normally not expressed. A promoterless chloramphenicol transferase gene was used as a probe for promoter activity of DNA fragments in *Rb. sphaeroides* (Benning and Somerville, 1992b; Penfold and Pemberton, 1994). Expression of the *xylE* gene encoding catechol 2,3 dioxygenase has also been used as a reporter for promoter probe vectors in *Rb. sphaeroides* (Dryden and Kaplan, 1993; Xu and Tabita, 1994).

Alkaline phosphatase is a useful marker for cellular location since it is only active when secreted into the bacterial periplasm, and gene fusions with the alkaline phosphatase gene (*phoA*) have been used to study secretion and membrane topology of proteins in *Rb. capsulatus* and *Rb. sphaeroides*. The gene fusions are constructed either randomly on the chromosome or on a plasmid by a *TnphoA* hybrid transposon (Moore and Kaplan, 1989; Brandner et al., 1991), or in specific alkaline phosphatase fusion vectors in

which the *phoA* coding region is joined in frame to the amino terminal portion of a gene containing a potential signal sequence. This construction can be expressed in *E. coli* or in purple bacteria, and the activity of the alkaline phosphatase measured after cell fractionation. These types of fusions have been used to study the gene regions required for the synthesis of cytochrome c_2 (Varga and Kaplan, 1989; Brandner et al., 1991; Beckman et al., 1992; Beckman and Kranz, 1993). The topology of membrane proteins in *Rb. sphaeroides* has also been studied using *phoA* gene fusions (Yun et al., 1991b; Neidle and Kaplan, 1992). The validity of this approach was demonstrated by fusions with the gene encoding the L subunit of the reaction center, which showed that those fusions with high specific activity were in regions that are at or near the periplasmic surface as defined by the X-ray structure (Yun et al., 1991b).

An expression vector, that can be used to make transcriptional or translational fusions and allows a wide range of transcriptional levels by varying the nitrogen source in the medium, has been constructed using the *nifHDK* promoter from *Rb. capsulatus* (Pollock et al., 1988). This system was used to correlate the expression of the *pufQ* gene and the accumulation of bacteriochlorophyll (Bauer and Marrs, 1988) and to demonstrate that transcription of *pucC* is essential for the formation of the B800–850 complex (Tichy et al., 1991). A translational fusion to the beginning of the *nifH* gene in *Rb. capsulatus* was also used to confirm the function of a phytoene desaturase gene cloned from soybean (Bartley et al., 1991). A fructose dependent promoter from *Rb. capsulatus* has been used in another inducible expression vector (Duport et al., 1994).

B. *In vitro* Transcription-Translation

Cell-free transcription-translation systems can be used to study the expression of cloned genes. Cell extracts from *Rb. sphaeroides* capable of *in vitro* transcription-translation were described by Chory and Kaplan (1982) and were shown to have all the components necessary to express RubisCO genes from *Rb. sphaeroides* and *Rs. rubrum* (Chory et al., 1985). This system has been used to localize structural genes and regulatory regions by examination of the products from specific cloned DNA fragments for genes encoding reaction centers (Donohue et al., 1986a), cytochrome c_2 (Donohue et al., 1986b), phosphoribulokinase (Hallenbeck and Kaplan, 1987),

antenna complexes (Kiley and Kaplan, 1987) and ALA synthase (Tai et al., 1988), and also to quantitatively characterize the products of the *puf* operon (Hoger et al., 1986; Kiley et al., 1987). Sensitivity of *Rb. sphaeroides* ribosomes to protein synthesis inhibitors was also studied in a cell-free protein synthesis system (Sánchez et al., 1994). A cell-free translation system from *Rb. capsulatus* was developed to study membrane assembly of proteins, and has been used to study membrane integration of antenna and reaction center proteins (Troschel and Müller, 1990; Troschel et al., 1992) and to define promoter activity for the ALA synthase gene (Hornberger et al., 1991). Signal peptidase, isolated from *Rb. capsulatus* membranes, has been shown to process a *Rb. sphaeroides* cytochrome c_2 precursor synthesized in an *E. coli* cell free transcription-translation system (Wieseler et al., 1992). An *E. coli* cell-free translation system was used to determine the purity of mRNA coding for antenna polypeptides from *Rs. rubrum* mRNA (Bélanger et al., 1985; Bérard et al., 1986), and RNA polymerase from *Rs. rubrum* was used in a partially defined *E. coli* system to define in vitro transcriptional start sites (Leustek et al., 1988). In addition, in vitro transcription systems have been reported using isolated RNA polymerase from *Rb. capsulatus* (Forrest and Beatty, 1987), *Cm. vinosum* (Valle et al., 1988) and *Rb. sphaeroides* (Kansy and Kaplan, 1989; Karls et al., 1994).

C. Interspecies Expression

Some genes cloned from photosynthetic bacteria have been expressed in *E. coli* or other hosts and the products identified by size, antibody reaction, or function. For example, RubisCO genes from *Rs. rubrum* (Somerville and Somerville, 1984; Larimer et al., 1986; Niyogi et al., 1986), *Rb. sphaeroides* (Muller et al., 1985; Gibson and Tabita, 1986) and *Cm. vinosum* (Viale et al., 1985, 1990; Kobayashi et al., 1991) have been expressed in *E. coli*, although expression is dependent on the use of *E. coli* promoters in front of the genes. In a double expression experiment, a regulatory protein from *Cm. vinosum* fused to the amino terminus of *lacZ* was expressed in *E. coli* and shown to affect the transcription of the gene for RubisCO from *Cm. vinosum* that was carried on a different plasmid (Viale et al., 1991). Other genes coding for enzymes involved in CO₂ fixation from *Rb. sphaeroides* have also been expressed in *E. coli* (Gibson and Tabita, 1987, 1988; Hallenbeck and

Kaplan, 1987; Chen et al., 1991). Carotenoid biosynthesis genes from *Rb. sphaeroides* have been expressed in other hosts (Pemberton and Harding, 1987; Penfold and Pemberton, 1991; Hunter et al., 1994; Lang et al., 1994) and a fragment of the *crtI* gene from *Rb. capsulatus* was expressed in *E. coli* in order to generate antibodies (Bartley and Scolnik, 1989). Successful isolation of the PufQ protein from *E. coli* required fusion of the *pufQ* gene from *Rb. capsulatus* with an amino-terminal maltose binding domain and a protease recognition site, with subsequent proteolysis of the resulting fusion protein (Fidai et al., 1993). Additional genes cloned from photosynthetic bacteria that have been expressed in *E. coli* or other hosts include those coding for ALA synthase (Tai et al., 1988; Neidle and Kaplan, 1993b), the *RsrI* restriction endonuclease (Stephenson et al., 1989), thioredoxin (Pille et al., 1990), ferredoxin (Grabau et al., 1991; Jouanneau et al., 1992; Agarwal et al., 1993; Armengaud et al., 1994), reaction centers (Söhlemann et al., 1991), bacteriochlorophyll biosynthesis enzymes (Coomber et al., 1992; Burke et al., 1993a; Bollivar et al., 1994c; Gibson and Hunter, 1994), PHB synthase (Husted et al., 1992; Liebergesell and Steinbüchel, 1992), phosphatidylethanolamine methyltransferase (Arondel et al., 1993), chaperonin (Ferreira et al., 1993) and nitrogenase (Durner et al., 1994). The decay of mRNA from *Rb. capsulatus* genes in *E. coli* was analyzed by Belasco et al. (1985).

The synthesis in other hosts of some proteins can be complicated, as demonstrated by several groups who have attempted to express cytochrome genes in *E. coli* and other species. Cytochrome c_2 from the *Rb. sphaeroides* gene was found in *E. coli* at low levels and only under anaerobic conditions (McEwan et al., 1989) and the cytochrome c_2 gene from *Rs. rubrum* was expressed but the cultures grew very poorly, indicating that the product may be toxic (Self et al., 1990). Expression of *c*-type cytochrome genes from *Rp. viridis* in *E. coli* resulted in aggregates of the apoprotein (Grisshammer et al., 1991), however the mature cytochrome was observed when synthesized in *Paracoccus denitrificans* (Gerhus et al., 1993). Similarly, when the cytochrome c_3 gene from the sulfate-reducing bacterium *Desulfovibrio vulgaris* was expressed in *E. coli* only the apoprotein was observed, but when this gene was expressed in *Rb. sphaeroides* the mature cytochrome was obtained (Cannac et al., 1991). Genes for *c*-type cytochromes from *Rb. capsulatus* have also been expressed in *Rb.*

sphaeroides (Caffrey et al., 1992; Jenny and Daldal, 1993).

RubisCO genes from various other species have been expressed in *Rb. sphaeroides* and *Rs. rubrum* (Falcone and Tabita, 1991, 1993). Other genes from exogenous sources expressed in photosynthetic bacteria include cellulase genes from *Cellulomonas fimi* in *Rb. capsulatus* (Johnson et al., 1986) and a carotenoid biosynthesis enzyme from soybean in *Rb. capsulatus* (Bartley et al., 1991). Genes from purple bacteria can generally be expressed in other related photosynthetic bacteria. For example genes encoding the subunits of the cytochrome *bc₁* complex from *Rb. sphaeroides* and *Rs. rubrum* were expressed in *Rb. capsulatus* (Davidson et al., 1989; Shanker et al., 1992). Hybrid or chimeric reaction centers containing subunits from both *Rb. capsulatus* and *Rb. sphaeroides* have also been obtained (Zilsel et al., 1989; Taguchi et al., 1993).

VII. Conclusions

Given the diversity of metabolic processes in photosynthetic bacteria, the extent of genetic manipulation in these bacteria will almost certainly continue to increase. The variety of species being worked on is steadily expanding, as is the degree of sophistication in the techniques employed. A major change in the last fifteen years is the accessibility of genetic manipulation to a large number of laboratories. For example, the determination of the three dimensional structure of the reaction center has led to detailed mutational analyses of the role of amino acid residues in electron and proton transfer, even by researchers whose primary interests are in spectroscopy and physical chemistry. While some expertise in genetics is still required, the basic manipulations have become standard enough that they are readily obtainable. Those whose primary interest is in molecular biology are usually not limited by the techniques available, since a number of alternative methods exist for realizing most goals. In general, the emphasis has shifted from classical genetic approaches and understanding of recombination processes and genetic exchange mechanisms to more gene-specific topics, with a consequent loss of a more global organismic perspective. One of the most appealing aspects of the genetic approach lies in the possibility of detecting genie interactions that might not be discovered using a strictly molecular biological

approach. It has been said that bacteria are endlessly surprising, so something new can always be expected to emerge from the study of purple bacterial genetics.

Summary

A combination of cosmid genome walking and pulse field gel electrophoresis was used to construct a high resolution physical and genetic map of the 3.8 Mb genome of *Rhodobacter capsulatus* SB1003. The mapping was done by grouping and further mapping of cosmids and bacteriophages from genomic libraries using PFGE-generated DNA fragments and SP6 and T7 specific transcripts corresponding to the ends of the cosmid inserts. Cosmid and phage clones formed two uninterrupted and ordered groups, one corresponding to the chromosome of *Rb. capsulatus*, the other to its 134 kb plasmid. *Cos* site end-labeling and partial *EcoRV* digestion of cosmids were used to construct a high resolution restriction map of the genome. Overlapping of the cosmids was confirmed by the resemblance of the cosmid restriction maps and by direct end-to-end hybridization. 34 genes or gene clusters were located in the ordered gene library and mapped with an accuracy of 1–10 kb. Three *Rb. capsulatus* strains; KB-1, St. Louis and 2.3.1., were chosen out of 14 others for a detailed comparison of their physical maps, which were partially constructed using the minimal cosmid set of *Rb. capsulatus* SB1003 as a source of ordering probes. Blots of the minimal set of 192 cosmids, covering the chromosome and the plasmid, with known map position of each cosmid, gives to *Rb. capsulatus* the same advantages that the Kohara phage panel gives to *E. coli*. Blots of this minimal cosmid set digested with *EcoRV* represent the entire genome split into gene-size pieces, and provide an opportunity for direct high resolution mapping of genes and transcripts.

I. Introduction

Rhodobacter capsulatus is a purple, non-sulfur photosynthetic bacterium. The biochemical versatility to choose between photo- and heterotrophic growth and nitrogen fixation are all packed in a genome that is smaller than that of *E. coli*. Ease of plating and generation of mutations, together with convenient systems for cloning and genetic analysis (Yen and Marrs, 1976; Marrs, 1981; Jonson et al., 1986), summarized in Donohue and Kaplan (1991), makes *Rb. capsulatus* a popular model system for studies of the photosynthetic apparatus and nitrogen fixation. The Gene Transfer Agent (GTA), randomly packing 4.6 kb pieces of any intracellular DNA in phage-like capsids, has been used for insertional mutagenesis, gene replacement and linkage analysis (Yen et al., 1979). Mobilization of the bacterial chromosome by an integrated R' factor produced the current genetic map of *Rb. capsulatus* (Willison, 1985; Willison, 1993; Chapter 55 by Vignais et al.). Though direct plasmid transformation can not be efficiently applied to *Rb. capsulatus*, mobilized shuttle vectors derived from broad host range plasmids RK2 and RSF1010 facilitate manipulations with cloned genes. Efficient random and site-specific mutagenesis with transposons and gene cloning by mutant complementation was done with these vectors, for example Klipp et al., (1988). Using these tools together with powerful biophysical methods, substantial progress was achieved in studying gene control, regulation and protein machinery of photosynthesis and nitrogen fixation (this volume). However, scarcity of data concerning general genetics of *Rb. capsulatus* is already slowing current research, for instance studies on regulation of *nif* and photosynthetic gene expression, where the involvement of general regulatory cascades remains to be integrated. To provide this genetic background, we are developing a broad and fast strategy aimed at producing a dense genetic map and revealing regulatory relations among its elements. The first component of this strategy is the high resolution physical map of *Rb. capsulatus* carrying most of its cloned genes, described in Fonstein and Haselkorn (1993).

II. Low Resolution Physical Mapping of the Genome of *Rhodobacter capsulatus*

To facilitate high resolution mapping of the *Rhodobacter* chromosome via assembly of the minimal cosmid set, covering its entire genome, a low resolution restriction map of its chromosome was constructed. For optimal physical mapping, a restriction endonuclease should cut the bacterial genome into 10–30 pieces. This number of fragments can be well separated and mapped by conventional PFGE. Among the six-base cutters with high-AT recognition sequences, we found *Xba*I (15 fragments), *Ase*I (25 fragments), *Sca*I (14 fragments), *Dra*I (25 fragments) and *Spe*I (3 fragments) to be useful. The first two were chosen for mapping because they yielded a good separation of fragments with uniform distribution in the gels.

The total genomic size of the *Rb. capsulatus* chromosome was estimated by summation of the individual fragment lengths represented in each digest. Those sums for *Xba*I and *Ase*I are respectively 3679 and 3639 kb. This difference is explained in part by the presence of a large plasmid consisting of fragments *Xba*-11, *Xba*-12' and *Xba*-13. Its size is 134 kb. This plasmid has no *Ase*I sites and didn't enter the gel as a separate band in PFGE under the conditions used. The sum of the sizes of *Xba*I-generated fragments differ from the *Ase*I sum by the size of this plasmid.

Macrorestriction DNA fragments generated by PFGE were used as probes for blot hybridization. Groups of *Xba*I, *Ase*I and *Xba*I+*Ase*I-generated fragments were separated by PFGE and transferred to nylon membranes. Filters corresponding to each group were hybridized with a single fragment probe. If, for example, an *Xba*I fragment used as a probe identifies two *Ase*I fragments, it will link them. Using as a second probe one of those *Ase*I fragments, one can step by step map the whole genome. Troubles arise when an *Xba*I fragment overlaps more than three *Ase*I fragments or this overlapping is significantly unequal. In the latter case, the mapping sequence of steps would be interrupted. The other source of mapping troubles was repeated DNA. Using this method several stretches of restriction fragments were assembled, the longest one covering half of the *Rhodobacter* chromosome. Further mapping was done using the cosmid library as a source of clones linking these fragments.

With a specially constructed printing device, individual cosmid clones were replicated onto nylon filters as two ordered sets of 864 clones each. These sets of clones were hybridized with all individual *Xba*I and *Ase*I fragments. Forty-one restriction sites for *Ase*I and *Xba*I were mapped onto the 3.7 Mb circular genome. Complicated cases of ambiguous cosmids that linked three or more restriction fragments, due to internal repeats in the *Rhodobacter* chromosome, were resolved by hybridization with riboprobes prepared by transcription of the ends of the inserts. After such experiments, only two linked restriction fragments typically remained. These cosmids revealed eight groups of repeated sequences.

Five of these were attributed to the duplicated *gyrB* (*parE*), *nifB*, *rrn*, *rpoB* and *anf* genes. The three ways of hybridization used (fragments to fragments, fragments to cosmid sets and riboprobes to sets) make it possible to vary the probe/target ratio, thus distinguishing artifacts connected with different repeated sequences. Comparison of all these data gives the final long-range map without contradictions.

At this stage the cosmid clones were grouped in about 80 subcontigs, corresponding to macro-restriction fragments and restriction sites. They formed two groups, one corresponding to the chromosome of *Rb. capsulatus*, the other to its 134 kb plasmid (Fonstein et al., 1992).

Fig. 1. Physical mapping of cosmids (previously linearized with λ terminase) by partial digestion with *EcoRV* and *cos*-site end-labeling. Lanes M: Takara DNA marker (4.6 – 48.5 kb); lanes 1–11: annealing with *cosL*; lanes 12–22: annealing with *cosR*. Measurement of the fragment sizes gives directly the distance of each *EcoRV* site from the left or right end of each cosmid, respectively.

III. High Resolution Physical Mapping

To start the high resolution mapping, 40 cosmids located on different macrorestriction fragments were chosen. Individual cosmids were cleaved with λ terminase, partially digested with *EcoRV*, annealed to labeled oligonucleotides complementary to *cosL* and *cosR* independently and then separated on 0.3% agarose gels (Fig. 1). The pattern of *EcoRV* sites can be read directly from these gels for each cosmid. Riboprobes generated by SP6- and T7-specific transcription of the ends of the inserts of these cosmids were then used to reveal groups of neighboring cosmids. For the next round of cosmid walking, the overhanging ends of these secondary cosmids were used for transcription and hybridization. Finally, after about 300 riboprobe hybridizations with the first set of 864 cosmids and about the same number of *cos*-mappings, six uninterrupted contigs were mapped with high resolution.

Four of the remaining gaps had a statistical origin and were closed using the second set of 864 clones in similar hybridizations with the probes corresponding to the ends of the contigs. One of the remaining two gaps was linked by phages selected from a λ DASH library, possibly corresponding to DNA unclonable in cosmids. Finally, a minimal uninterrupted set of 186 cosmids mapped with high resolution covered 3.7 Mb of the chromosome of *Rb. capsulatus* (Fig. 2). Only one gap inside fragment *Ase7/Xba8* remained and its size, according to a comparison of the *EcoRV* and *Ase7/Xba8* map, is less than 10 kb.

Thirty-four loci, corresponding to individual cloned genes or large gene clusters were mapped with a resolution of 1–10 kb. A description of these genes and some of their genetic characteristics are presented in Table 1. Another four genes recently cloned from *Rb. capsulatus* and 18 genes, cloned from *Rb. sphaeroides*, whose *Rb. capsulatus* homologues are not yet mapped are in the process of mapping. Using PCR-generated probes, corresponding to 16S and 23S rRNA, and digestion with *CeuI*, a rarely-cutting endonuclease highly specific for eubacterial *rrn* operons (Ralph et al., 1993), the orientation of transcription of three of the *rrn* operons was established (Fig. 2).

IV. Comparison with the Existing Genetic Map

Aligning this physical map with the existing genetic

one (Willison et al., 1985; Willison, 1993; Chapter 55), it is possible to compare eight markers. Their relative positions are the same on both maps, with one exception. On the genetic map, *glnA* is located between *trp* and *nifR1* as is the case on our earlier physical map (Fonstein et al., 1992). However, this region is now reassigned on the new map (Fig. 3). The repeated sequences responsible for our earlier mapping mistake might act the same way in the genetic experiments, altering the apparent order of the genes. Another possible explanation is that these repeated sequences induce real genome rearrangement, and the strains used in the two laboratories now differ.

V. Comparison of the Chromosomal Maps of Different *Rhodobacter* Strains

With regard to strain comparison, the defined positions of the ends of cosmids mapped in the existing ordered library can be used as ordered probes for a variety of closely related strains, drastically simplifying the construction of their high resolution maps. Points where continuity is lost can be attributed to chromosomal rearrangements that can be resolved by the same strategy used in primary mapping.

Pulse field separated restriction patterns of 14 isolates of *Rb. capsulatus* were analyzed and 3 strains, namely B1, St. Louis and 2.3.1. were chosen for detailed comparison. The evolutionary distance between strains 2.3.1 and St. Louis (40–60 % similarity in *EcoRV* fragments) revealed in the study seems to be optimal for the proposed strategy. Cosmid libraries of the chosen *Rhodobacter* strains were hybridized with probes generated by SP6 and T7 – specific transcription from the ends of the inserts of the cosmids of the *Rb. capsulatus* SB 1003 minimal set.

Totally about 80 sequential probes corresponding to six areas of the genome and covering about one third of it were used. Cosmids linking the probes were mapped with high resolution, and assembled in contigs. In preliminary analysis a large number of genome-changing events were revealed. Among them are a deletion that is greater than 60 kb in strain 2.3.1, a set of 1–5 kb deletion/insertions and an inversion/translocation with the ends separated by 400 kb in strains B1 and St. Louis, relative to SB1003 and 2.3.1., and point mutations in the *EcoRV* sites. To get a full descriptive picture of strain diversity we plan to

Fig. 2. Combined high resolution physical and genetic map of the chromosome of *Rb. capsulatus*. Each cosmid is represented by a horizontal line, on which the vertical ticks are the EcoRV sites. The name of each cosmid is on its left, e.g. 1A1, 1A2 etc. There are 40 places where the distribution of EcoRV sites does not permit the precise size of the overlaps to be determined; these are designated by diagonal connecting lines and italicized numbers from 1 to 40. On each cosmid, the L and R cos sites are shown by large and small boxes, respectively. Mapped genes and repeated elements are indicated by boxes above each cosmid. The physical map is read continuously from left to right. Designated gene positions correspond to the EcoRV fragments revealed in blot-hybridizations. In case of the *rrm* operons, their location is fixed by the *CeuI* cleavage site, marked by an arrow. Cosmids 1A1 and 2A12, which are separated by the only remaining gap in the fine structure map, are connected by their hybridization to the restriction fragments Xba-8 and Ase-7 (Fig. 1). Note that the operons *rrmB* and *rrmC* have the same orientation, while *rrmD* has the opposite orientation.

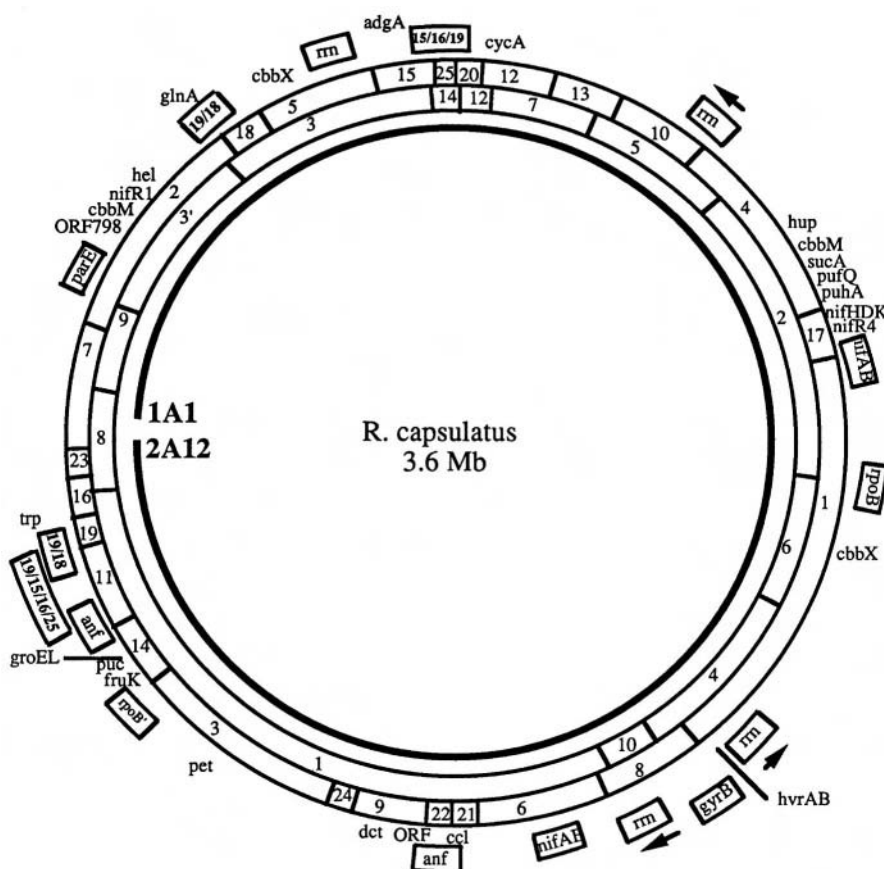

Fig. 3. Corrected long range physical and genetic map of the *Rb. capsulatus* chromosome. The inner circle shows the *Xba*I sites, the outer circle the *Ase*I sites, the numbers in these circles indicating the macro-restriction fragments. The internal arc represents an uninterrupted set of cloned fragments. Numbers at the end of the arc designate cosmids flanking the gap. Boxes represent repeated DNA, attributed to genes or to unidentified (numbered) sequences in the macro-restriction fragments.

complete the mapping of the chromosomes of these three strains to have their ends meet.

VI. Possible Applications of the Minimal Cosmid Set of *Rhodobacter capsulatus* SB1003

An *E. coli* cosmid hybridization panel was used to study the chromosomal localization of coordinately induced multigenic systems (Chuang et al., 1993) by probing with differentially expressed RNAs. Complications, solved by sophisticated computerized image processing, can be avoided by splitting the 40 kb cosmid inserts into smaller pieces, as recently shown in Chuang and Blattner (1993). DNA samples of the 192 cosmids from the *Rb. capsulatus* minimal

set were digested with *Eco*RV, separated in two gels and transferred to nylon membranes (Fig. 4). The resulting blots carry about 1500 *Eco*RV fragments already mapped on the chromosomal restriction map. It divides the entire *Rhodobacter* genome into physically separated gene-size pieces, and should drastically increase specificity during probing with any specific RNAs. This approach should produce reliable data on functional genome architecture and give access to new genes involved in commonly regulated processes.

Acknowledgment

This work was supported by a grant from the Department of Energy (86 ER 13546).

Fig. 4. *EcoRV* restriction patterns of all 192 cosmids from the minimal set, comprising the entire *Rhodobacter* genome. The center and outermost lanes on each gel contained λ DNA standards. The last six lanes on the lower right contain cosmids whose inserts derive from the 134 kb plasmid. The other lanes contain DNA from cosmid 1A1 (upper left) through 2A12 (lower right).

Note Added in Proof

The physical map of Fig. 2 was current in the summer of 1993. A revised version, with 3600 restriction sites mapped, was recently published by Fonstein et al. (1995a). A high-resolution alignment of the maps of three strains of *Rhodobacter capsulatus* was recently published by Fonstein et al. (1995b). The latter work reveals a mosaic chromosome organization, in which chromosomal regions of 15–80 kb with highly polymorphic restriction sites are interspersed with regions in which most of the sites are conserved among all three strains.

Summary

A natural cluster of genes containing nearly all the genetic information specifically required for photosynthesis in *Rhodobacter capsulatus* has been sequenced. Within this 46 kilobase pair cluster are 43 identified genes which include the coding sequences for the structural reaction center polypeptides (RC), the structural light harvest I complex (LHI), as well as the coding sequences for the enzymes required for the biosynthesis of bacteriochlorophyll (BChl) and for the biosynthesis of the carotenoids, spheroidene and spheroidenone.

This cluster and the accompanying DNA sequence have been extremely valuable in the identification of DNA sequences in other organisms, both bacteria and green plants, with comparable functions associated with photosynthesis. These sequence homologies have been tabulated. In addition, these homologies provide evolutionary information relating to reaction centers, light harvesting complexes, carotenoid biosynthesis and chlorophyll biosynthesis. In particular, a strong structural similarity has been identified between some reductive enzymes in the chlorophyll biosynthetic pathways and nitrogen reductases associated with nitrogen fixation. This has led to a new interpretation of Granick's hypothesis, the hypothesis that steps in biosynthetic pathways can be assumed to be linearly associated with the order of evolution of the corresponding activity in time.

Finally, the *Rhodobacter capsulatus* photosynthetic gene cluster and the corresponding sequence will clearly be the source of genes for recombinant constructs, for mutational studies on reaction centers and light harvesting complexes and for the overproduction of enzymatic activities essential for mechanistic biochemistry and for structural studies for many years to come.

*Current address: Department of Molecular, Cellular and Developmental Biology, University of Colorado, Boulder, CO 80309, USA

I. Introduction

Rhodobacter capsulatus (Weaver et al., 1975) has provided a unique route to the study of genes that are essential for photosynthesis, principally by being the first photosynthetic system to lend itself to genetic manipulation. This was made possible largely by the pioneering work of Barry Marrs (1978). His initial discovery of the gene transfer system and his subsequent creation of the R-prime plasmid, pRPS404 (Marrs, 1981), containing nearly all of the genes that are essential for photosynthesis in a natural cluster, provided the means to manipulate and alter these photosynthesis genes in *Escherichia coli*.

We created a large random library of transposon mutants of these genes in *E. coli*, which were conjugated back into *Rb. capsulatus*, where the phenotypes of these insertional mutations were established (Youvan et al., 1982; Zsebo et al., 1984; Zsebo and Hearst, 1984). Simultaneously, the restriction maps for many common restriction enzymes were determined, leading to a high resolution physical DNA map that was superimposed on the somewhat lower resolution genetic map (Taylor et al., 1983; Zsebo et al., 1984; Zsebo and Hearst, 1984). For example, Youvan et al., 1984a, located restriction fragments containing the light harvesting I peptides and the reaction center peptides by identifying colonies of *Rb. capsulatus* which were incapable of performing photosynthesis, but which were capable of fluorescing in the infrared, following conjugation of the randomly mutated R-prime back into *Rb. capsulatus*. Restriction fragments containing transposon inserts in these fluorescent colonies were identified and then sequenced (Youvan et al., 1984a,b). Open reading frames for both LHI peptides were identified by comparing the translated DNA sequence with protein sequences of LHI peptides in *Rb. sphaeroides*, which were kindly provided to us by Professor Herbert Zuber. Reaction center peptides L, M, and H were identified from the amino terminal sequences of these proteins (Sutton et al., 1982; Williams et al., 1983; Worland et al., 1984). The plant analogs of these peptides, the PS II reaction center peptides, were rapidly identified by sequence comparison (Doolittle, 1986; Brutlag et al., 1990) with the bacterial genes (Hearst and Sauer, 1984a,b;

Youvan et al., 1984b; Hearst, 1985, 1986), leading to many fundamental studies.

Since that early achievement, we have completed the sequence of the entire photosynthetic gene cluster of *Rb. capsulatus*, a sequence of 45,959 base pairs. This sequence has provided many additional insights into the photosynthetic systems of plants and in many cases has been the basis for the initial identification of function for newly sequenced plant genes. This 45,959 base pair sequence may be accessed in the EMBL DNA sequence database using accession number Z11165 (Genbank locus RCAPHSYNG). This review consists of a broad description and a summary of the information which has been gleaned from the *Rb. capsulatus* photosynthetic gene cluster DNA sequence by our laboratory.

II. Biosynthetic Pathways

In addition to the reaction center and light harvesting peptides, the gene cluster codes for the biosynthetic enzymes for the carotenoids (Yen and Marrs, 1976; Taylor et al., 1983; Armstrong et al., 1989, 1990a,b,c; 1993b; Schmidt et al., 1989; and see Chapter 53 by Armstrong) and for the bacteriochlorophylls (Taylor et al., 1983; Burke et al., 1993a,b; Armstrong et al., 1993a). Both classes of pigment molecules are essential for normal photosynthesis in plants and photosynthetic bacteria. Sequence similarity between *Rb. capsulatus* sequences and plant genes has provided great insight. Figure 1 displays the carotenoid biosynthetic pathway for *Rb. capsulatus* as well as for the non-photosynthetic bacterium, *Erwinia herbicola* (Hundle et al., 1991, 1992, 1993; Hundle and Hearst, 1991; Armstrong et al., 1993b) We have studied this second system both to provide comparison with the *Rb. capsulatus* genes and because *Erwinia* more closely mimics the plant biosynthetic pathway in that its late products include lycopene (tomato red) and β -carotene (carrot orange). Unlike *Rb. capsulatus*, the *Erwinia* genes can be expressed in *E. coli* allowing mutants to be complimented and identified. Farnesyl pyrophosphate, FPP, is a precursor for many essential structural products in all life forms. The photosynthetic gene cluster contains only the genes needed for the synthesis of carotenoids and carotenoid intermediates beyond FPP. The earliest gene in the pathway codes for CrtE, geranylgeranyl pyro-

Abbreviations: *E. coli* – *Escherichia coli*; *E. herbicola* – *Erwinia herbicola*; *M. polymorpha* – *Marcantia polymorpha*; *N.* – *Neurospora*; *Rb.* – *Rhodobacter*; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*; *S.* – *Saccharomyces*

Fig. 1. The carotenoid biosynthetic pathway.

phosphate (GGPP) synthase. The next codes for CrtB, phytoene synthase (Math et al., 1992). The amino acid sequences of CrtB and CrtE have regions of strong conservation with other enzymes in the isoprene pathway. The CrtE protein also shares sequence identity with several prenyltransferases that catalyze 1'-4 condensations such as GGPP synthase from *Neurospora crassa*, hexaprenyl diphosphate synthase from *Saccharomyces cerevisiae* and FPP synthases from *E. coli*, *S. cerevisiae*, *Rattus rattus* and *Homo sapiens*, (Math et al., 1992). CrtB has regions of similarity with other enzymes which catalyze 1'-1 condensations such as several other known phytoene synthases and a yeast squalene synthase (Math et al., 1992).

The R-prime containing the photosynthesis gene cluster (pRPS404) has a point mutation (*crtD223*) that prevents activity of the mutant CrtD enzyme (Marrs, 1981). Armstrong et al., 1990c, suggested that this mutation corresponded to the first nucleotide of an AGA codon (Arg-13) that is present in the deduced amino acid sequence of *crtD223* at a position which is invariably occupied by a glycine in a consensus sequence for a $\beta\alpha\beta$ fold which has been associated with FAD or NAD(P) cofactor binding. Subsequent sequencing of wild type *Rb. capsulatus* strain B100 genomic DNA has shown a guanine to be present rather than an adenine at nucleotide 37 of *crtD* (Alberti, M., Ma, D. and Burke, D. H. unpublished data). The deduced amino acid translation of the GGA codon found in wild type DNA is therefore glycine, bringing the Val-7 to Val-33 area of CrtD into good agreement with many other reported ADP-binding motifs (Armstrong et al., 1990c), including the deduced CrtD sequence from the corresponding *Rb. sphaeroides* gene (Gari et al., 1992).

Figure 2 displays the biosynthetic pathway for bacteriochlorophyll in *Rb. capsulatus* and for chlorophyll in higher plants. Here protoporphyrin IX, the only naturally occurring porphyrin without a metal, is a precursor for heme, an essential component of the electron transport pathways of non-photosynthetic bacteria. So, as is the case with the carotenoid biosynthesis pathway, the photosynthetic cluster contains only the genes for the biosynthesis of bacteriochlorophyll beyond the branch point between the synthetic pathways of compounds required specifically for photosynthesis and those shared with other functions. There remains some

uncertainty relating to the gene assignments in the bacteriochlorophyll pathway, although considerable progress in gene identification has been made in recent years.

We have made greatest progress with two steps in the bacteriochlorophyll biosynthesis pathway that reduce double bonds to single bonds. The first, monovinyl protochlorophyllide *a* to chlorophyllide *a*, involves gene loci *bchL*, *bchN* and *bchB*, some of these being very recently assigned (Burke et al., 1993b). The second, chlorophyllide *a* to 2-desacetyl-2-vinyl bacteriochlorophyllide *a* (also involved in an alternate route in which BchF acts first), requires the newly assigned three enzymes coded by *bchX*, *bchY* and *bchZ* (Burke et al., 1993a). These were once thought to be a single gene, *bchA* (Yen and Marrs, 1976 and Young et al., 1989). A fourth locus located near the center of the photosynthesis gene cluster, *bchW*, seems also to be required for this step (Bauer et al., 1993b; Bollivar et al., 1994a). There is preliminary evidence for translational coupling in the *bchXYZ* gene cluster (Burke et al., 1993a). The plant and cyanobacterial loci involved with light-independent protochlorophyllide reduction are *chlL(frxC)*, *chlN(gidA)* and *chlB*. This has been demonstrated by disruption of these genes within the chloroplast and cyanobacterial genomes (Ogura et al., 1992; Suzuki and Bauer, 1992, for *chlL(frxC)*, Roitgrund and Mets, 1990; Choquet et al., 1992, for *chlN(gidA)* and Li et al., 1993 and Liu et al., 1993, for *chlB*). Since plant and purple bacterial enzymes show extensive amino acid identity with each other, the genes in plants and bacteria might be expected to play analogous roles. Although the *chlLNB* system is widely distributed among lower plants (Burke et al., 1993d), it appears to have been completely supplanted by a distinct light-dependent activity for the same reaction in higher plants, reviewed in Bauer et al., 1993b. [The light-dependent activity, also prokaryotic in origin, was first observed by Fujita et al., in 1992. The cyanobacterial gene is strongly homologous to the plant gene (Suzuki and Bauer, 1995b).

The subunits of the reduction complexes show a very interesting sequence conservation with genes involved in nitrogen fixation, in which NifH, a [4Fe-4S] cluster protein, donates electrons to NifD and NifK (Hearst et al., 1985; Burke et al., 1993a,b). This has led us to define a new class of chlorophyll and bacteriochlorophyll biosynthetic enzymes called the 'Chlorophyll Iron Proteins' with structural and

Fig. 2. The bacteriochlorophyll and light-independent chlorophyll biosynthetic pathways.

functional similarities to the nitrogenase iron proteins. Chlorophyll (Chl), according to the Granick hypothesis (Granick, 1965), has been viewed as having preceded bacteriochlorophyll (BChl) as the primary photoreceptor pigment in early photosynthetic systems because Chl synthesis requires one fewer enzymatic reduction than BChl (see Fig. 2). A statistical protein sequence analysis of the enzymes catalyzing each reduction has been conducted by Burke et al., 1993c. When nitrogenase iron proteins were used as outgroups, the chlorophyll iron protein tree is rooted on the *bchX* lineage. As a result, the gene duplication that separated *bchX* from *bchL* occurred prior to the speciation event that separated purple bacteria from cyanobacteria. Thus, this rooting strongly suggests that the last common ancestor of photosynthetic eubacteria contained both enzymes and utilized BChl in its reaction center. The Chl-containing reaction centers apparently evolved later, being unique to the cyanobacteria/chloroplast lineage. These arguments also have the enzymes which synthesize modern photosynthetic pigments evolving from nitrogenase enzymes (Burke et al., 1993c).

The conflict between this model and Granick's hypothesis can be explained by postulating that a single enzyme complex once was able to do both ring reduction steps in the early bacterial pathway, converting protochlorophyllide directly to a bacteriochlorin. These two steps have subsequently been replaced by separate and more specific enzymatic activities, only one of which (*chlLNB*) is retained in cyanobacteria and lower plants. Also, the *crtI* locus codes for a desaturase (an enzyme which converts single carbon-carbon bonds into double bonds) in the carotenoid pathway which sequentially oxidizes *three* bonds in the conversion of phytoene to neurosporene in *Rb. capsulatus*. The *crtI* homologue in *E. herbicola* sequentially oxidizes *four* bonds (converting phytoene to lycopene). Thus, alterations in the number of tandemly repeated actions of an enzyme during metabolite synthesis, followed by evolutionary partitioning of each function into separate, specialized enzymatic activities, may be a common feature of enzyme evolution. Plants are thought to require more than a single enzymatic activity for these same four oxidations, although the exact evolutionary relationship between plant and purple bacterial enzymes is not immediately apparent (Pecker et al., 1992).

III. The Genetic Map

Figure 3 contains our most recent map of open reading frames and gene assignments. The gene cluster contains approximately 43 open reading frames, 33 of which have been assigned. The very strongly expressed structural gene for the RC-H subunit is near the left-hand limit of the cluster (low map number), while the genes for the strongly expressed structural genes encoding the LHI $\alpha\beta$ and RC-LM subunits, are near the right-hand limit of the cluster (high map number). These genes are expressed in an outward direction from the remainder of the cluster, a fact that suggested that the superhelical density of the intervening DNA might be altered when reduced oxygen tension induces the transcription of the structural genes. This hypothesis, however, has been convincingly ruled out by Cook et al. (1989). There are five changes in the direction of expression over the entire gene cluster. The relationship between this fact and other elements of gene expression are not yet well established, although some aspects are discussed below. Also shown in Fig. 3 are the locations of the transposon mutations in a random mutant library created by Zsebo and Hearst, 1984. Most of these mutants are still available and are an important source of research materials. The complete description of this library is contained in the Ph. D. thesis of Krisztina M. Zsebo, 1984, University of California, Berkeley.

The map numbers in Fig. 3 correspond to the base pair number (in thousands) designated in the EMBL DNA sequence databank (accession number Z11165). The eight genes for carotenoid biosynthesis are located between 26.7 and 35.8 thousand. *crtA* is the only carotenoid synthesis gene that possibly shares an operon with bacteriochlorophyll biosynthetic genes. The evidence from polar mutants seems to exclude obligatory cotranscription of *crtA* and the downstream *bch* genes (Zsebo and Hearst, 1984; Guiliano et al., 1988). The eighteen bacteriochlorophyll biosynthetic genes are found in three large, multigene domains from 5.1 to 13.6 thousand, from 16.8 to 26.7 thousand (with some potential gaps for genes with unknown functions) and from 36.0 to 41.1 thousand. There is evidence for the carotenoid gene cluster, *crtEF*; the bacteriochlorophyll gene cluster, *bchCXYZ*; and the structural gene cluster, *pufQBALMX*, being in a 'superoperon', that might be driven by a σ^{70} -like promoter before

IV. Functional Assignments of the Open Reading Frames (ORFs) in the Sequence

Table 1 lists all the ORFs in the photosynthetic gene cluster of *Rb. capsulatus* and their sequence positions. The arrows show the direction of expression of each ORF; an arrow to the left indicates that the upper DNA strand is used as template for the messenger RNA, while an arrow to the right indicates that the lower DNA strand serves as template for the mRNA transcript. The table contains the current symbols, eg. *crtC*, given to each of these assigned genes. The number of amino acids coded by the ORF and the corresponding molecular weight of the protein product are also supplied. The enzymatic function or name, when available from the literature, is provided together with the references from which the genetic loci, proposed functions and sequence assignments were obtained. There is ambiguity about the function of some ORFs. For example, Penfold and Pemberton (1994) report strong sequence similarity between the ORF at location 14800 to 16209 in *Rb. capsulatus* and a *Rb. sphaeroides* regulatory gene, *pps*, which maps to the same location and is required for repression of pigment synthesis. Bollivar et al. (1994a), on the other hand, report that an insertion mutation in *Rb. capsulatus* causes no effect on photosynthesis. A transposon insertion within ORF214 defines the *rxCD* locus (Zsebo and Hearst, 1984). The *Rb. capsulatus* strain carrying this transposon is defective in reaction center synthesis, suggesting that the product of ORF214 may be required for the assembly or function of reaction centers; however, more work is needed in order to establish the function of this ORF.

Functional assignment of the early steps in BChI synthesis has proven to be problematic and controversial, due both to the complexity of the system and to the difficulty in properly analyzing the pigments accumulated by mutant strains. The bulk of the evidence currently available suggests that Mg-chelatase is derived from the combined activities of the products of *bchD*, *bchI* and *bchH*, and that *bchM* encodes the methyltransferase. Mg-chelatase activity in plants has been shown to require ATP and to be separable into at least two components (Walker and Weinstein, 1991). The amino acid sequence of BchI

contains a consensus ATP-binding sequence near its N-terminus (Armstrong, et al., 1993a). Only two other proteins within the photosynthesis gene cluster contain ATP-binding sequences. These are BchL and BchX and both are involved in redox reactions of the bacteriochlorophyll biosynthesis pathway. Furthermore, BchI shares a strong sequence identity (49%) with *cs/ch42*, an *Arabidopsis* nuclear encoded chloroplast-localized protein (Armstrong et al., 1993a). *cs/ch42* is required for Mg chelation (Falbel and Staehlin, 1994). When S-adenosyl methionine (SAM) and protoporphyrin IX are added to intact cell preparations from *bchD* and *bchH* transposon mutants of *Rb. sphaeroides*, the *bchD* mutant extracts retained methyltransferase activity, while the *bchH* mutant extracts did not (Richards et al., 1991; Gorchein, personal communication). Nevertheless, mutations in a plant homolog to *bchH*, known as *olive* for the resulting altered pigmentation, resulted in a loss of Mg-chelatase activity, and both *bchH* and *olive* share sequence identities with the cobalt chelatase gene in the vitamin B₁₂ synthesis pathway (Hudson et al., 1993). In vitro Mg-chelatase activity has recently been described using *E. coli* expressed BchH, BchD and BchI subunits derived from *Rb. sphaeroides* genes. Synthesis of each of these gene products was required for activity (Gibson et al., 1995). The deduced amino acid sequence of BchD has an unusual sequence feature: 10 out of 11 residues in a row are prolines (PPPPPPPEPP).

Until recently, no mutant accumulating Mg-protoporphyrin IX had been isolated (e.g., Biel and Marrs, 1983; Burke et al., 1993b), making it difficult to separate genetically the chelatase and methyltransferase activities. This pigment has now been found in *bchM* mutants (Bollivar et al., 1994a). In addition, purified *bchM* product expressed in *E. coli* exhibits methyltransferase activity (Bollivar et al., 1994c). This gene product had been thought, based on an analysis of pigments isolated from *bchM* mutants (Yang and Bauer, 1990), to be involved in the oxidative formation of Ring V, as might have been expected from the high fraction of amino acids shared between the *bchM* gene product and mitochondrial NADH:ubiquinone oxidoreductase (Table 2).

Some sequence similarities between the amino acid translations of the photosynthesis genes and related genes from other species are listed in Table 2. For example, ORFs 477 and 428 code for proteins that have sequence similarity to each other and to the

product of *pucC*, a *Rb. capsulatus* gene required for the accumulation of LHII peptides and which lies outside of this gene cluster (Tichy, et al., 1989). We and others (Bauer et al., 1991) have noticed that if translation of *pucC* is initiated at a position upstream from the originally proposed translation initiation site, additional matches can be made with ORF428 and ORF477.

Rb. capsulatus has a very high GC composition at 65%. It is thus not surprising that such a bias would be reflected in the pattern of codon usage, as shown in Table 3. There are, however, dramatic biases in this pattern which might suggest a functional role, or in an extreme interpretation, the absence of a tRNA which corresponds to the associated anticodon. For example, there are 253 occurrences of CTT as a codon for leucine while there is only one instance of CTA used as a leucine codon. Similar biases exist against all codons of the form NTA. In fact all codons ending in A, i.e. NNA appear to have been selected against. Such an extreme bias may ultimately have a regulatory role, but the evidence at the present time is insufficient.

Table 4 lists the recognition sites for some restriction enzymes. These sites were central to our cloning and sequencing strategies, and have been referred to repeatedly in the literature regarding this gene cluster. This listing may therefore be useful in interpreting such references.

The potential ribosome binding sites for these 43 genes show a clear pattern of translation initiation signals in *Rb. capsulatus*. When fourteen nucleotides of the DNA template for 16S RNA are matched with the nucleotides preceding the genes' start codons (Table 5), there is a core sequence, AAAGGAGG, which occurs two to three times more frequently than predicted in a 65% C+G, 35% A+T random DNA sequence and which precedes the start codon by an interval of 4 to 12 nucleotides. Nucleotides flanking the core sequence occur with random frequency. These observations do not rule out the possibility that a particular message may make use of base complementarity outside this 8 base region to signal translation initiation.

V. Potential Regulatory Sequences

Transcription termination hairpins have been suggested in several locations (Armstrong et al., 1989). Some are presented in Fig. 4. The hairpin

after *puhA*, (between 2810 and 2781), occurs at the end of the RC-H gene and may protect the corresponding mRNA from exonuclease digestion, or it may alter the probability of transcription of downstream genes. The very large hairpin after ORF469/*ppsR* (between 16310 and 16379) provides isolation for an already very isolated open reading frame.

Between map positions 23103 and 23319 there is an enigmatic pair of double hairpins (labeled 'ORF176' and 'ORF284' in Fig. 4) that are almost perfect inverted repeats of each other. These structures occur between the ends of two converging operons involved in the expression of bacteriochlorophyll genes, near the center of the 45959 base photosynthesis gene cluster. Another nearly perfect inverted repeat involves the 90 or so bases following ORF469/*ppsR*, bases 16307 to 16393, that are almost identical (again with opposite polarity) to 90 bases 15 kb distant, 31088–31001, that follow *crtC*. Some of these identical 90 bases are shown in two structures in Fig. 4: 'ORF469/*ppsR*' and the right hand side of '*crtC*'. The symmetrical appearance of these features that show DNA sequence similarity beyond stop codons and what, if any, regulatory or long range interactive role they play awaits further experimentation.

The hairpins labeled '*crtI*' and '*crtB*' have no known function. Perhaps they separate the three genes in this operon serving as a block to exonuclease digestion of messenger RNA in the same way that the structure following *pufA* allows differential expression of LHII $\alpha\beta$ and RC-LM (Belasco et al., 1985; Adams et al., 1989). The hairpin labeled 'ORF 160' is separated by 21 nucleotides from the double hairpin labeled '*crtC*'. These are possible mRNA structures between operons of opposing directions: ORF 160 terminates at 30941, *crtC* terminates at 31176. The structure labeled '*crtF*' is proposed to form right at the end of the coding region of *crtF*, (the TGA stop is within the loop,) and may serve as transcription terminator for the *crtEF* segment of the *crtEFbchXYZpufBALMX* superoperon. The structures labeled '*bchX*' and '*bchY*' are each predicted to occlude the ribosome binding sites and translation initiation sites of their respective downstream genes (*bchY* and *bchZ*). These structures may play a role in regulating the translation of the components of the *bchXYZ* chlorin reductase through translational coupling (Burke et al., 1993a). The last gene known to be involved in the photosynthesis cluster, *pufX*, is

followed by what looks like a transcription terminator.

The entire photosynthetic gene cluster of *Rb. capsulatus* is regulated by oxygen tension at both transcriptional and post-transcriptional levels (Zhu and Hearst, 1986; Zhu et al., 1986; Bauer et al., 1988; Bauer et al., 1993a; Chapter 58 by Bauer). At atmospheric oxygen pressure, the gene cluster is essentially not expressed, although some ORFs are transcribed at low constitutive levels. Upon reduction of oxygen tension to 2 mm Hg, the photosynthetic membrane is formed, reaction centers are made and pigments are synthesized. A two-component sensor/effector system for oxygen regulation of the structural

genes (*puf*, *puh* and *puc*) has been recently described (Sganga and Bauer, 1992; Bauer et al., 1993a; Mosley et al., 1994; Inoue et al., 1995). In bacteria, various sensor/effector systems have been identified as involved in the transcriptional regulation of genes whose expression responds to environmental signals such as nitrogen limitation (Backman et al., 1981), phosphate starvation (Wanner, 1987) and osmoregulation (Csonka, 1989). It is not yet known how many other regulatory proteins are involved in the signal transduction cascade or how reduced oxygen tension is sensed by *Rb. capsulatus*. In addition to the sensor/effector regulatory systems, bacteria some-

times utilize alternative sigma factors to govern the initiation of transcription under environmental stresses (Stock *et al.*, 1989). It seems likely that a novel sigma factor is used to control transcription initiation for the *puh* and *puf* operons in *Rb. capsulatus* (Bauer *et al.*, 1993a).

Despite the fact that the gene cluster on pRPS404 shows no evidence of being expressed in *E. coli*, σ^{70} promoter-likelike sequences have been identified in *Rb. capsulatus*. These are presented in Table 6. Fusion of such a potential promoter sequence (from *bchCXYZ*) to *lacZ* in *Rb. capsulatus* has confirmed that this sequence element is essential for the initiation of transcription of *bchCXYZ* (Ma *et al.*, 1993).

Armstrong has discovered a palindromic motif (Table 7) at six sites in the gene cluster, some of which overlap the potential σ^{70} promoters. A detailed study of the oxygen-dependent, σ^{70} -like promoter upstream of *bchCXYZ* has revealed some additional

details concerning the function of the palindrome motif. It has been shown to bind an oxygen-dependent regulatory protein factor in *Rb. capsulatus* (Ma *et al.*, 1993). These authors have also identified a possible regulatory role for an AT-rich region, the 50 base pairs immediately upstream of the suggested *bchC* σ^{70} -like promoter. Since a σ^{70} -like promoter and this palindrome sequence are found upstream of several other *bch* and *crt* operons, these sequences may be responsible for regulating oxygen-dependent pigment biosynthesis at the level of transcription in *Rb. capsulatus*. This motif is not found upstream of the *puh* and *puf* structural genes, indicating that a different regulatory mechanism is required for the production of the structural polypeptides for the photosynthetic apparatus. Interestingly, this palindrome sequence motif is found preceding the *puc* operon (Youvan and Ismail, 1985) which encodes structural polypeptides of the light harvesting complex II. The significance

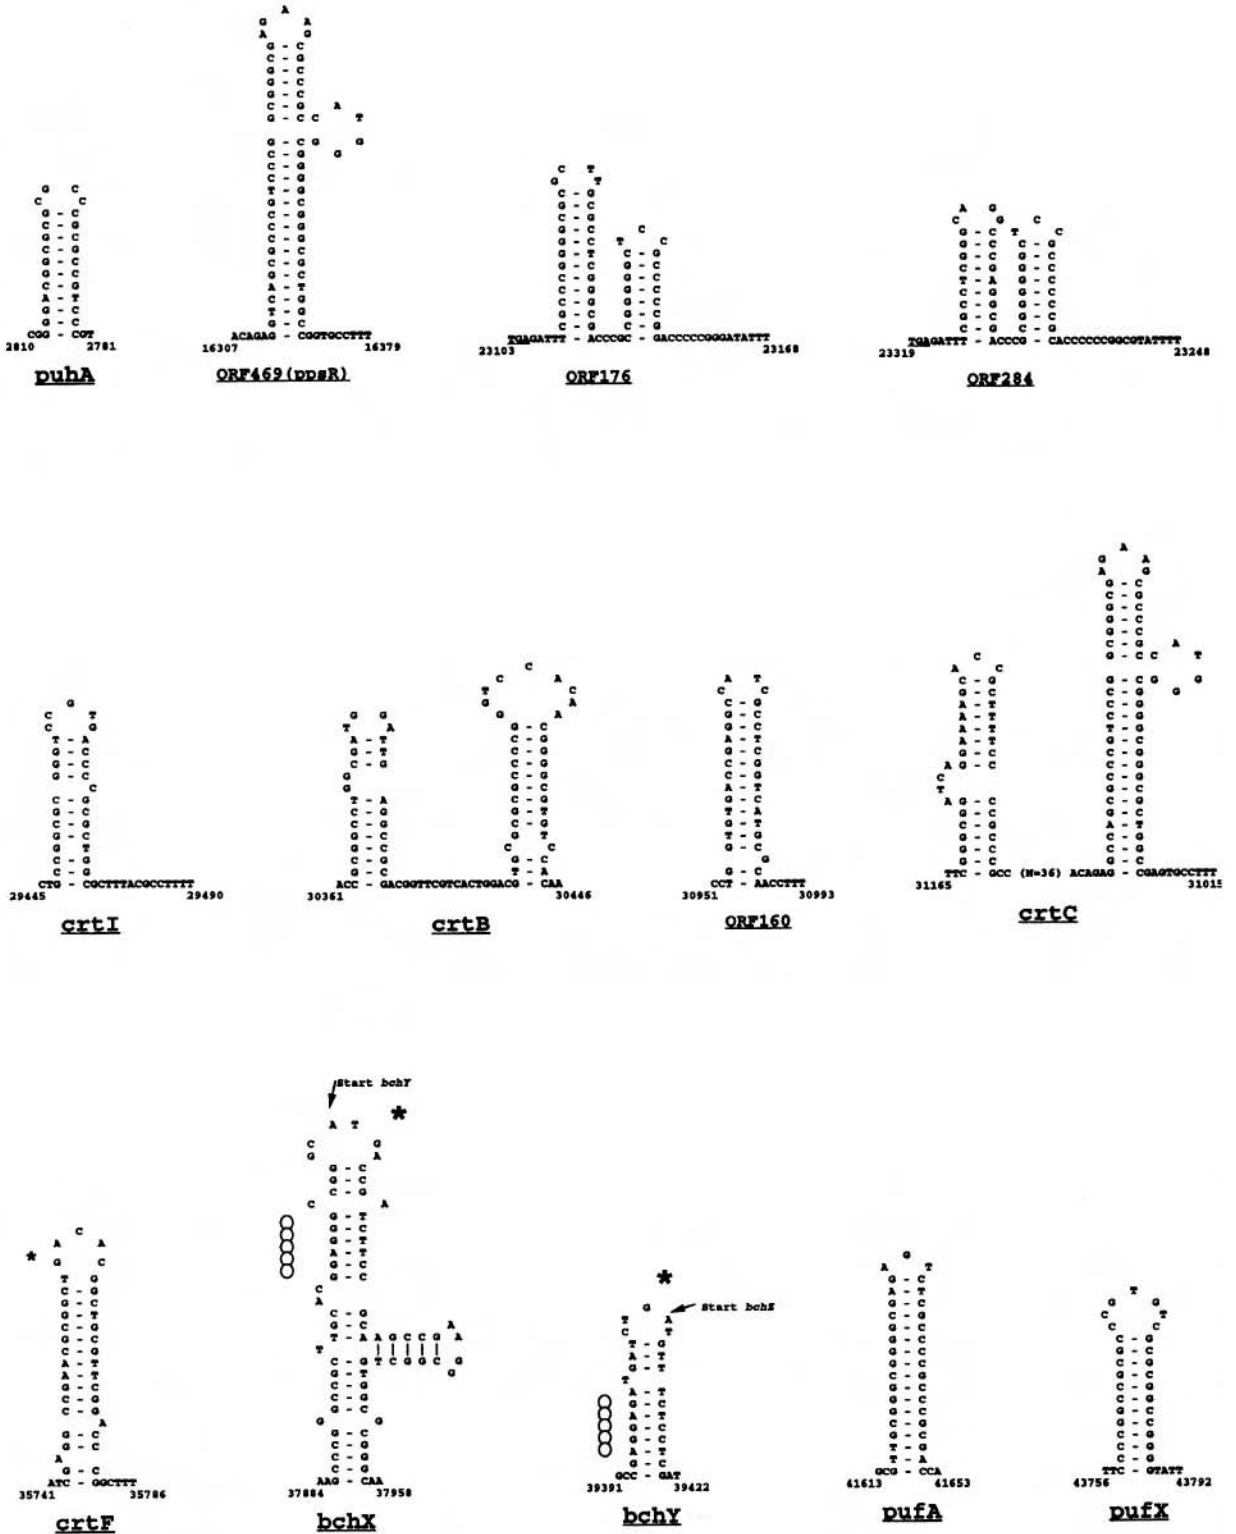

Fig. 4. Potential secondary structures near the ends of the mRNA sequences for some of the genes of the photosynthesis gene cluster. * indicates the 'TGA' stop codon; ○○○○ is the ribosomal binding site for the next gene; start (occluded) 'ATG' is marked by arrow.

Consensus sequence for *E. coli* σ^{70} promoter: **TTGACA** (N = 15 to 19) **TATAAT**

of this palindrome sequence in regulating the *puc* operon has been confirmed in *Rb. sphaeroides* (Lee and Kaplan, 1992a) but remains to be tested in *Rb. capsulatus*. An intriguing question now being investigated is how the regulation between pigment genes and structural genes is coordinated. This coordination has been suggested to involve the *pufQ* gene product (Bauer and Marrs, 1988).

VI. Conclusion

The sequence and function of the photosynthetic gene cluster of the purple bacterium, *Rb. capsulatus*, has provided great insight into the structures of the photosynthesis reaction center and light harvesting proteins, as well as into the assignment of genes in the carotenoid and bacteriochlorophyll biosynthetic

<i>Rb. capsulatus</i> consensus sequence:	+++ + <u>GTGTAARTnnnAnnTTACAC</u>	++	
Consensus sequence for several transcriptional regulatory factors*:	 <u>TGTGT</u> N6-10 <u>ACACA</u>		

Comparison of a palindromic motif found 5' to *Rb. capsulatus* photosynthesis genes. The genes flanking each palindrome are indicated to the left and right, respectively with arrows to show direction of transcription.

Numbers above the sequence shows position in the EMBL DNA database, accession number Z11165.

Numbers above the *pucB* palindrome motif are taken from Youvan and Ismail, 1985. Numbers below are taken from Tichy, et al., 1989 who report a cytosine (position 273) replacing the adenine at position 30.

Complimentary nucleotides in the two halves of the palindromes are underlined.

Nucleotides in the positions shown in bold face in the consensus sequence are capitalized.

Nucleotides that match the consensus are given in bold type.

+ indicates the nucleotide is conserved in all cases.

*Other transcriptional regulatory factors include NifA, AraC, CAP, LacI, GalR, LexA, TrpR, LysR and lclI (Gicquel-Sanzey and Cossart, 1982).

pathways in other organisms. In addition, initial steps in oxygen regulation of this gene cluster have been elucidated. There are vast numbers of issues relating to photosynthesis remaining to be solved in which the sequence of this cluster will have increasing significance. For example, the mechanism of initiation of photosynthetic membrane formation and the sequential steps associated with photosynthetic apparatus assembly are, without a doubt, addressed by these 45,959 bases of DNA.

Acknowledgments

This work has been supported by contract #DE-ACO3-76SF00098 from the U.S. Department of Energy. We wish to thank Bob Rabson of DOE for years of sustained support for research on bacterial photosynthesis. We are grateful for the assistance of G. Armstrong, B. Hundle and D. Ma and the editors, R. E. Blankenship and C.E. Bauer for advice they offered in the writing of this review.

Summary

Purple photosynthetic bacteria assimilate CO₂ primarily via the Calvin reductive pentose phosphate pathway. Depending on the growth conditions, the amount of CO₂ fixation required for growth and the level of Calvin cycle enzymes can vary considerably. Although numerous biochemical studies have demonstrated induction or derepression of the enzymes, the mechanisms underlying this control have remained elusive. Cloning and expression of Calvin cycle structural and regulatory genes from different photosynthetic bacteria have led to significant advances in our understanding of CO₂ fixation at the molecular level. *cbb* genes have been shown to be clustered in several bacteria, including *Rhodobacter sphaeroides*, in which genes within two *cbb* gene clusters appear to be organized within operons thus coordinating expression at the level of transcription. Mutagenesis of *cbb* genes in *Rb. sphaeroides* has revealed independent and interdependent regulatory relationships between the two different operons that appear to be mediated through a common transcriptional regulatory protein, CbbR. Transcriptional regulation and *cbbR* genes have also been demonstrated in *Chromatium vinosum* and *Rhodospirillum rubrum*. Characterization of the CbbR proteins should provide clues to the identity of the molecular signal that serves as sensor of the environment to control expression of enzymes involved in CO₂ assimilation. Alternate routes of CO₂ fixation have unexpectedly been exposed in RubisCO deletion mutants constructed in *Rb. sphaeroides* and *Rs. rubrum* opening new avenues of research in CO₂ fixation in the photosynthetic bacteria. The RubisCO mutants have also been used as host strains for analyzing foreign RubisCO enzymes. In *Cm. vinosum*, two distinct RubisCO coding sequences were identified by hybridization and expression in *E. coli* allowed characterization of both enzymes. Finally, nucleotide sequence comparisons of *cbb* structural and regulatory genes have raised provocative evolutionary questions concerning relationships between photosynthetic bacteria and other organisms.

I. Introduction

Purple photosynthetic bacteria typically display the capacity for growth under a diverse array of environmental conditions. This metabolic versatility relies on the ability to assimilate CO₂ via the Calvin cycle, which is essential in varying capacities, for chemo- and photolithoautotrophic and photoheterotrophic growth. In the two former growth modes, cellular carbon is derived exclusively from CO₂, necessitating a relatively high level of CO₂ fixation and consequently, induced or derepressed synthesis of Calvin cycle enzymes (Tabita, 1988). On the other hand, lower levels of the same enzymes are observed during photoheterotrophic growth, in which CO₂ fixation functions primarily as an electron acceptor to balance excess reducing potential generated through metabolism of organic substrates (Tabita, 1988). Since the amount of CO₂ fixed is proportional to the reduction state of the organic

compound, the level of Calvin cycle enzymes varies accordingly and is generally higher during growth on more reduced substrates (Tabita, 1988). In heterotrophic growth regimens not requiring CO₂ fixation, expression of Calvin cycle enzymes is not observed (Tabita, 1988). The regulatory network involved in the control of CO₂ fixation is expected to be extremely complex to respond to environmental signals such as light, O₂, CO₂ and organic compounds (Tabita, 1988). The situation is complicated further in some purple non-sulfur photosynthetic bacteria by the occurrence of structurally distinct forms of ribulose 1,5-bisphosphate carboxylase/oxygenase (RubisCO) that exhibit unique catalytic and inductive properties (Gibson and Tabita, 1977a,b; Shively et al., 1984; Dow, 1987). The form I RubisCO is the more ubiquitous form of RubisCO and is composed of eight large catalytic subunits and eight small subunits of undetermined function, whereas the form II RubisCO is composed of large subunits only (Tabita, 1988). Although induction of Calvin cycle enzymes has been demonstrated in photosynthetic bacteria by biochemical means, the nature and mechanisms of the molecular signals involved in regulation of CO₂ fixation enzymes has remained elusive. The application of cloning and recombinant DNA technology to this area of metabolism over the

past decade has had far reaching impacts. The intended focus of this chapter is to convey the current understanding of regulation and expression of enzymes involved in CO₂ fixation that has been derived from molecular biological approaches.

II. *cbb* Genes

A. Nomenclature of *cbb* Genes

Historically, different conventions have been used in naming genes encoding enzymes of the Calvin cycle. In photosynthetic bacteria, gene designations were originally assigned according to plant genetic nomenclature, such that three letter designations were chosen according to the enzyme, such as *rbc* for RubisCO, *prk* for phosphoribulokinase (PRK), *fbp* for fructose 1,6-bisphosphatase (FBP) and so on (Tabita et al., 1992). An entirely different system was used by groups studying chemolithoautotrophic bacteria, which employed the prefix, *cfx*, for CO₂ fixation, followed by the first letter of the enzyme encoded by the corresponding gene (Husemann et al., 1988; Meijer et al., 1991). Additional confusion stemmed from the occurrence in some organisms of more than one gene encoding a particular Calvin cycle enzyme and the nomenclature used to distinguish the structurally divergent form I and form II RubisCO large subunit genes (Tabita et al., 1992). Recently, a uniform nomenclature has been proposed by groups studying the reductive pentose phosphate cycle in bacteria that assigns to Calvin cycle genes the prefix *cbb*, for Calvin-Benson-Bassham cycle, followed by the first letter of the corresponding enzyme, if no other enzyme begins with that letter (Tabita et al., 1992). For organisms such as *Rb. sphaeroides*, in which two Calvin cycle gene clusters have been localized to distinct genetic elements (Suwanto and Kaplan, 1989), subscripts I and II, will distinguish between *cbb* genes of each operon. Also pertinent to this chapter, is the situation found in *Cm. vinosum* in which two sets of genes encoding a form I type RubisCO have been identified, both of which are chromosomally encoded (Viale et al., 1989). It has been proposed that these genes be designated *cbbL-1cbbS-1* and *cbbL-2cbbS-2*, respectively (Tabita et al., 1992). Table 1 lists Calvin cycle enzymes and respective gene designations relevant to this chapter.

B. Identification and Isolation of RubisCO Genes

To date, *cbb* genes have been isolated from only a few photosynthetic bacteria including the purple nonsulfur bacteria *Rs. rubrum*, *Rb. sphaeroides*, and *Rb. capsulatus*, and one purple sulfur bacterium, *Cm. vinosum*. Because of the widespread interest in structure-function relationships of RubisCO, these genes were the first of the Calvin cycle genes to be cloned by recombinant DNA techniques. The *cbbM* gene encoding *Rs. rubrum* form II type RubisCO was the first procaryotic RubisCO gene to be isolated and was identified in a lambda expression library by immunological cross-reactivity (Somerville and Somerville, 1984). The first form I RubisCO genes to be isolated from a photosynthetic bacterium, were isolated from *Cm. vinosum* based on hybridization to the *A. nidulans* RubisCO genes (Viale et al., 1985). Subsequently, genes encoding a second form I type RubisCO in *Cm. vinosum* were isolated on the basis of hybridization to the first set of genes (Viale et al., 1989). Both pairs of RubisCO genes are chromosomally encoded but do not appear to be closely linked (Viale et al., 1989). Heterologous hybridization has also been used to isolate clones containing the form I and form II RubisCO genes of *Rb. sphaeroides* (Quivey and Tabita, 1984; Muller et al., 1985; Gibson and Tabita, 1986). Interestingly, the form I and form II RubisCO coding sequences map to distinct genetic elements in this organism (Suwanto and Kaplan, 1989). Form I and form II RubisCO sequences were identified by Southern hybridization analysis of *Rb. capsulatus* and *Rhodospseudomonas palustris* chromosomal DNA (Shively et al., 1986). Corresponding clones containing the form I and form II RubisCO genes from *Rb. capsulatus* have recently been isolated (J. Shively, personal communication).

C. Identification and Isolation of Other *cbb* Genes

One question that naturally arose upon isolation of RubisCO genes was whether or not Calvin cycle genes would be clustered. The availability of DNA sequences flanking the form I and form II *Rb. sphaeroides* RubisCO genes prompted hybridization analysis with probes encoding other Calvin cycle enzymes. In this manner FBP and PRK sequences were found linked to both form I and form II RubisCO coding sequences (Gibson and Tabita, 1987, 1988;

Table 1. Gene designations of bacterial reductive pentose phosphate cycle enzymes and regulatory proteins

Gene	Enzyme	Product
<i>cbbL</i>	form I RubisCO	form I RubisCO large subunit
<i>cbbS</i>		form I RubisCO small subunit
<i>cbbM</i>	form II RubisCO	form II RubisCO large subunit
<i>cbbF</i>	FBP	fructose-1,6-bisphosphatase/sedoheptulose-1,7-bisphosphatase
<i>cbbP</i>	PRK	phosphoribulokinase
<i>cbbA</i>	FBA	fructose-1,6-/sedoheptulose-1,7-bisphosphate aldolase
<i>cbbG</i>	GAP	glyceraldehyde-3-phosphate dehydrogenase
<i>cbbK</i>	PGK	phosphoglycerate kinase
<i>cbbE</i>	EPI	ribulose-5-phosphate-3-epimerase
<i>cbbT</i>	TKL	transketolase
<i>cbbR</i>	CbbR	transcriptional activator protein
<i>cbbz</i>	PGP	phosphoglycolate phosphatase

Hallenbeck and Kaplan, 1987) and a sequence within a form II RubisCO clone hybridized to a gene probe encoding glyceraldehyde 3-phosphate dehydrogenase (GAP)(Gibson and Tabita, 1988). Additional genes have been identified in the *Rb. sphaeroides* gene clusters primarily on the basis of nucleotide sequence comparisons. Protein database searches with deduced amino acid sequences from regions situated immediately upstream of the RubisCO genes in both clusters showed similarity to a class II fructose 1,6-bisphosphate aldolase (FBA) sequence from *E. coli* (Chen et al., 1991; Gibson et al., 1991). Similarly, the clue to the identity of the gene encoding transketolase (TKL) that is encoded within the form II cluster was its similarity to the sequence of dihydroxyacetone synthetase, an enzyme involved in methanol assimilation in yeast (Chen et al., 1991). The reaction this enzyme catalyzes is functionally similar to the TKL reaction in the Calvin cycle (Janowicz et al., 1985). Preliminary sequence determination revealed additional genes downstream of the form I RubisCO coding sequence that are similar to *cbbX*, *cbbY* and *cbbZ* in chemolithotrophic bacteria (J. Gibson, unpublished). Of these three genes, only *cbbZ* has been identified as the gene encoding phosphoglycolate phosphatase (Schäferjohann et al., 1993). Although the function of the *cbbX* and *cbbY* gene products are not known, the location of the genes within *cbb* transcriptional units in chemolithotrophic bacteria suggests a role in CO₂ fixation (Meijer et al., 1991; Kusian et al., 1992). Finally, sequence similarity to the LysR family of transcriptional

regulatory proteins allowed identification of *cbbR*, a regulatory gene that is linked to the form I genes (Gibson and Tabita, 1993).

Calvin cycle genes are known to be clustered in two other photosynthetic bacteria, *Rs. rubrum* and *Rb. capsulatus*. In *Rs. rubrum*, *cbb* sequences linked to the RubisCO gene include *cbbE*, *cbbF*, *cbbP*, *cbbT*, *cbbA* and *cbbR*, all of which were identified by Southern hybridization and/or DNA sequence comparisons (Falcone and Tabita, 1993b; R. Ghosh, personal communication). Similar to *Rb. sphaeroides*, *Rb. capsulatus* has been shown to express two types of RubisCO (Gibson and Tabita, 1977b). Interestingly, hybridization analysis of clones containing the form I and form II RubisCO genes revealed *cbb* structural genes encoding FBP, PRK, and FBA linked to *cbbM* but not to *cbbL* or *cbbS* (J. Shively, personal communication). A potential regulatory gene was also found linked to the form II cluster by hybridization to *cbbR* genes from *Rb. sphaeroides* and *Rs. rubrum* (G. Paoli and F. R. Tabita, personal communication). No other *cbb* genes have been localized to DNA sequences flanking the form I RubisCO genes. Finally, as mentioned previously, two apparently unlinked sets of genes encoding distinct L₈S₈ RubisCO enzymes have been identified in *Cm. vinosum* (Viale et al., 1989). Although no other *cbb* structural genes have been identified in this organism, a CbbR sequence has been shown to be linked to one set of RubisCO genes (Viale et al., 1991).

D. *cbb* Gene Organization

In *Rb. sphaeroides*, the nucleotide sequence of the regions flanking the RubisCO genes confirmed the gene order determined from combined restriction nuclease mapping and Southern hybridizations and established the location of genes for which no probes were available (Gibson et al., 1990, 1991; Chen et al., 1991). In addition, sequence analysis showed that genes within each cluster were oriented in the same direction and closely spaced suggesting they formed a single transcriptional unit. Potential regulatory features were also revealed such as the overlap of stop codons with ribosome binding sites of the following gene pairs: *cbbF*_I-*cbbP*_I; *cbbF*_{II}-*cbbP*_{II}; *cbbT*_{II}-*cbbG*_{II} and *cbbL*_I-*cbbS*_I.

The arrangement of genes common to both clusters is somewhat conserved as shown in Fig. 1. The major distinctions include the 3 kbp region in the form II cluster encoding TKL and GAP that is noticeably absent from the form I cluster (Chen et al., 1991) and

the regulatory gene, *cbbR*, that is divergently oriented with respect to *cbbF*_I (Gibson and Tabita, 1993). For comparison, the gene arrangement of *cbb* sequences from a nonphotosynthetic bacterium *Alcaligenes eutrophus*, is also shown in Fig. 1. This organism contains two sets of *cbb* genes that are plasmid and chromosomally encoded and, for the most part are exact duplicates of each other (Husemann et al., 1988). It is noteworthy that the gene arrangement between organisms is similar. In spite of the different location of RubisCO genes, the gene order of other *cbb* structural genes that are present (*cbbF*_I*cbbP*_I*cbbT*_I*cbbG*_I*cbbA*_I) is maintained. Several genes that have been identified in *A. eutrophus* are either absent in the *Rb. sphaeroides* *cbb* clusters or have not yet been identified. These include *cbbE* and *cbbK* (Bowien et al., 1993).

Mapping of Calvin cycle genes in *Rs. rubrum* revealed similarities as well as differences in *cbb* gene arrangement compared to other organisms (Fig. 1). In contrast to RubisCO genes in *Rb.*

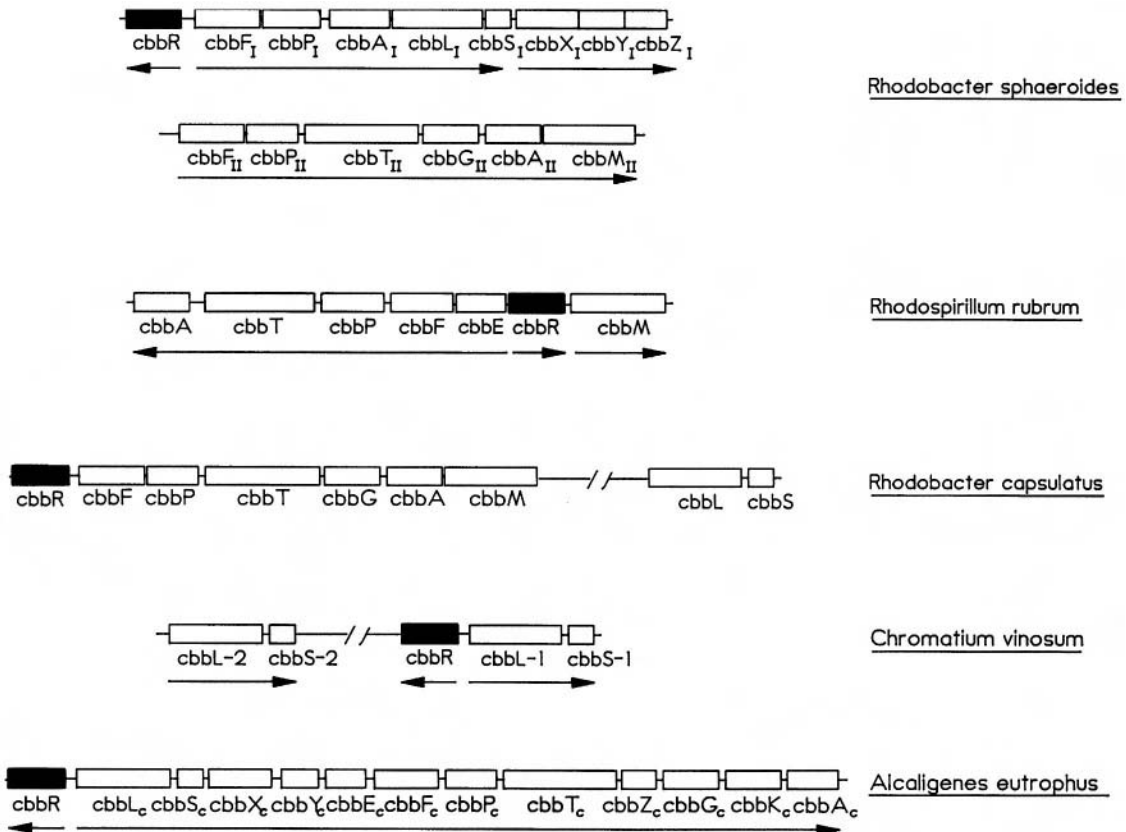

Fig. 1. *cbb* gene organization. For *cbb* genes of *Rs. rubrum* and *cbbX*_I, *cbbY*_I and *cbbZ*_I, arrows indicate gene orientation only. In other cases, arrows denote transcriptional units. Gene designations for known Calvin cycle enzymes are indicated in Table 1. The functions of the proteins encoded by *cbbX* and *cbbY* are not known. The subscript C for *A. eutrophus* genes denote a chromosomal location.

sphaeroides, the *cbbM* gene is transcribed separately from other Calvin cycle genes (Falcone and Tabita, 1993b). The presumptive regulatory gene, *cbbR*, is immediately upstream from *cbbM*, but opposed to other CbbR coding sequences, is transcriptionally oriented in the same direction as the RubisCO gene (Falcone and Tabita, 1993b). Primary sequence determination of the region upstream of *cbbR* revealed additional *cbb* sequences divergently oriented with respect to *cbbR* and *cbbM* arranged in the following order: *cbbEcbbFcbbPcbbTcbbA* (Falcone and Tabita, 1993b; R. Ghosh, personal communication). The ribulose 5-phosphate-3-epimerase (PPE) coding sequence occupies the same position relative to *cbbF* in the *A. eutrophus cbb* cluster (Kusian et al., 1992).

In *Rb. capsulatus*, mapping of *cbb* genes linked to *cbbM* have thus far revealed a pattern identical to that of the form II cluster of *Rb. sphaeroides*, except that the *cbbR* homolog has been localized to a region upstream of the form II RubisCO gene (Fig. 1) (J. Shively; G. Paoli and F. R. Tabita, personal communication). The transcriptional orientation of these genes has not been determined. At present, the form I RubisCO genes appear to be isolated with respect to other Calvin cycle genes. Also illustrated in Fig. 1 are the *Cm. vinosum* RubisCO operons.

E. Amino Acid Sequence Comparisons

1. RubisCO

The deduced amino acid sequences of the form II type RubisCO proteins from *Rs. rubrum* and *Rb. sphaeroides* share 85% identity at the amino acid level (Nargang et al., 1984; Wagner et al., 1988). The relatively high degree of identity shared between the form II RubisCO enzymes is in sharp contrast to that calculated for the form II RubisCO and the large subunit of form I type RubisCO (Nargang et al., 1984; Wagner et al., 1988). Even when large subunit amino acid sequences of the form I and form II RubisCO proteins from *Rb. sphaeroides* are compared, only 23% identical residues are shared and most of these are centered around regions that have been shown to be important in either activation or catalysis (Gibson et al., 1991). Virtually the same degree of identity is observed when form II RubisCO sequences are compared to form I RubisCO large subunit sequences independent of the source of RubisCO. Numerous sequences are available for the form I type RubisCO, most of which are derived

from eucaryotic algae and higher plants. Comparison of the photosynthetic bacterial form I RubisCO sequences from *Cm. vinosum* and *Rb. sphaeroides* with RubisCO sequences from other organisms has revealed interesting evolutionary relationships. First, deduced amino acid sequences of genes encoding the two RubisCO large and small subunits from *Cm. vinosum* share approximately the same degree of identity, 80% and 45%, respectively, with each other as with the amino acid sequences from cyanobacterial, green algal and terrestrial plants (Kobayashi et al., 1991). Significantly less identity, 52% between large and 24% between small subunits, is observed when either RubisCO of *Cm. vinosum* is compared to the form I RubisCO of *Rb. sphaeroides*. The *Rb. sphaeroides* form I RubisCO subunits are, in turn, more similar to those from the chemolithoautotrophic bacteria, and somewhat surprisingly, to algae belonging to the genera *Rhodophyta* and *Chromophyta* (Gibson et al., 1991; Hwang and Tabita, 1991). These comparisons revealed a previously unknown evolutionary relatedness between purple non-sulfur bacteria and non-green algae.

2. FBA, FBP, PRK

At present, sequence information for other *cbb* structural genes from photosynthetic bacteria is limited to coding sequences from *Rb. sphaeroides* and the PPE sequence of *Rs. rubrum* (Gibson et al., 1990, 1991; Chen et al., 1991; Falcone and Tabita, 1993). Comparison of the deduced amino acid sequences of gene pairs in *Rb. sphaeroides* encoding FBP, PRK and FBA is interesting from an evolutionary standpoint because, in contrast to the extreme divergence of the RubisCO genes, these sequences are highly conserved. The form I and form II FBP, PRK and FBA sequences share 66%, 86%, and 81% identical amino acid residues, respectively. Comparison of the FBP and PRK sequences to corresponding gene products from the closely related chemolithoautotrophic bacteria revealed about 20% less identity for both sequences (Gibson et al., 1990, 1991).

3. CbbR

The nucleotide sequences of several *cbbR* genes have been determined and it is interesting to note that the CbbR deduced amino acid sequences from photosynthetic and nonphotosynthetic bacteria share 40-50% identity independent of the divergence noted

between RubisCO genes (Meijer et al.; 1991; Viale et al., 1991; Windhovel and Bowien, 1991; Falcone and Tabita, 1993; Gibson and Tabita, 1993; Kusano and Sugawara, 1993). Identity shared between CbbR sequences is higher than that noted between CbbR and other members of the LysR family and extends beyond the helix-turn-helix motif at the amino terminal portion of the coding sequence. It is tempting to speculate that the conserved central regions of the CbbR proteins represent sequences involved in binding a common inducer, which would implicate similar signals in the regulation of Calvin cycle gene expression in different bacteria.

III. Regulation of *cbb* Gene Expression

A. *Rs. rubrum*

The influence of culture conditions on expression of RubisCO in *Rs. rubrum* was first noted by Anderson and Fuller (1967). Initial investigations showed that the level of RubisCO attained under photolithoautotrophic growth conditions with CO₂ as the sole carbon source and H₂ as the electron donor was more than 30-fold greater than that observed in cells grown photoheterotrophically with malate as carbon source. In addition, the reduction state of the organic carbon compound was shown to affect the level of RubisCO. Cells cultured on a relatively reduced substrate such as butyrate, in which exogenous bicarbonate in the media is essential for growth, expressed RubisCO at a level intermediate between that observed with either malate or CO₂ as carbon source (Tabita, 1988). During photolithoautotrophic growth, the concentration of CO₂ in the media has a profound effect on expression of RubisCO (Sarles and Tabita, 1983).

The regulation of RubisCO in *Rs. rubrum* in response to the carbon source supplied in growth media appears to be mediated, at least in part, at the level of transcription. An investigation by Leustek et al. (1988), quantitated levels of RubisCO activity and mRNA following a shift from photoheterotrophic growth on malate, to growth in an atmosphere of hydrogen containing either 1.5% CO₂ or 10% CO₂. The level of mRNA initially paralleled the increase in RubisCO specific activity in cultures grown at both concentrations of CO₂, and was four to five-fold higher in cells grown at the lower CO₂ concentration. However, later in the growth phase the specific activity of RubisCO continued to increase whereas the level

of mRNA decreased until the activity of RubisCO in the cultures grown on 1.5% CO₂ was ten to thirty fold higher than the malate grown culture, although the mRNA levels had only increased 5-6 fold. Regulation at the level of translation was one possibility suggested by the authors to explain the discoordinate levels of enzyme activity and mRNA.

Northern blots of RNA extracted from cells grown under different conditions probed with a *cbbM* probe revealed, in all cases, a 1.4 kbp transcript that corresponds well to the size of the *cbbM* gene (Leustek et al., 1988). The transcriptional start site of the *cbbM* message was determined by S1 nuclease mapping of RNA isolated from *Rs. rubrum* and from *E. coli* transformed with the plasmid pRR117 that carries the *Rs. rubrum* RubisCO gene. In mRNA isolated from *Rs. rubrum*, a single transcriptional start site was detected that was situated 28 bp upstream from the *cbbM* translation initiation codon, regardless of growth condition. Interestingly, inspection of the sequence surrounding this start site showed it to be located within a region of dyad symmetry (Nargang et al., 1984). Three different start sites were mapped when the mRNA was isolated from *E. coli* harboring pRR117, none of which correspond to that mapped using *Rs. rubrum* RNA. Two of these start sites are preceded by typical *E. coli* -10, -35 consensus promoter sequences. It should be mentioned that although *cbbM* transcripts were observed in RNA isolated from *E. coli* carrying pRR117, no RubisCO protein could be detected.

B. *Rb. sphaeroides*

Regulation of RubisCO synthesis in *Rb. sphaeroides* in response to environmental factors was first demonstrated by Lascelles (1960) and has since been shown to be affected by such determinants as light, the concentration of O₂, CO₂, organic substrates, and alternate electron acceptors (Tabita, 1988; Hallenbeck et al., 1990a,b; Wang et al., 1993). In addition to the daunting number of environmental stimuli that affect CO₂ assimilation in this organism, the study of regulation is further complicated by the presence of at least two copies of genes encoding many of the Calvin cycle enzymes (Quivey and Tabita, 1984; Gibson and Tabita, 1986, 1987, 1988). Most of the initial work focused on the structurally and catalytically distinct form I and form II RubisCO enzymes present in this organism (Gibson and Tabita, 1977a). Induction of the form I and form II RubisCO

during photolithoautotrophic growth was examined by Jouanneau and Tabita (1986). During photoheterotrophic growth on malate, although the levels of both forms of RubisCO are relatively low, the form II RubisCO is the more abundant enzyme. In an experiment in which the amount of the form I and form II RubisCO was quantitated following a shift from photoheterotrophic growth on malate to photolithoautotrophic growth in the presence of 1.5% CO₂/98.5% H₂, the level of the form I enzyme increased 17-fold replacing the form II enzyme as the predominant RubisCO. The level of the form II enzyme also increased, but only four fold. The difference in the extent of induction was one of the first indications that expression of the two enzymes was subject to independent regulation. The abundance of the form I RubisCO during growth in the presence of a low CO₂ concentration coupled with the higher affinity of this enzyme for the substrate CO₂ also led to the proposal that the form I enzyme was specialized to function in conditions of CO₂ limitation.

Zhu and Kaplan (1985) first demonstrated regulation of RubisCO at the level of transcription in *Rb. sphaeroides* by examining the effects of light, O₂, and carbon substrate on *cbbM*_{II} mRNA levels. The level of the form II RubisCO transcript was highest in cells grown in high light, and when cultures were shifted from light to dark, the level of form II RubisCO mRNA decreased. Virtually no *cbbM*_{II} transcript was detected in aerobically grown cells. In most cases, RubisCO activity paralleled the changes in mRNA levels. The greatest deviation was noted in malate and succinate cultures in which the level of the form II RubisCO transcript was 80-90% of that measured in cells cultured on butyrate, but the RubisCO specific activity was only 5-10% of butyrate grown cells. This discrepancy is most easily explained by the fact that the RubisCO activity measurement includes the activity of the form I RubisCO which can be quite high in butyrate grown cultures, whereas only the form II mRNA was quantitated in these experiments.

The original proposal that during photoheterotrophic growth, CO₂ fixation functions as an electron sink for excess reducing equivalents (Muller, 1933; Van Niel, 1936) was addressed in studies by Hallenbeck et al. (1990a,b) that examined the effect of CO₂ concentration on expression of PRK and RubisCO. In these investigations, photosynthetic growth of *Rb. sphaeroides* on succinate in cultures bubbled with argon was not observed, but growth did

result under these conditions if cultures were supplied with either exogenous CO₂. Increasing the concentration of CO₂ in the media was shown to coordinately repress synthesis of RubisCO and PRK and the activities of both enzymes were inversely proportional with respect to growth rate and CO₂ concentration (Hallenbeck, 1989a). To distinguish between a direct effect of CO₂ on RubisCO and PRK synthesis and an indirect effect caused by perturbation of the redox balance, dimethyl sulfoxide (DMSO), an alternate electron acceptor, was added to the growth medium. Cultures supplemented with DMSO grew in the absence of exogenous CO₂ and exhibited reduced activities of PRK and RubisCO compared to cultures grown with limiting CO₂. Increasing the concentration of CO₂ in the presence of DMSO resulted in even greater repression of both PRK and RubisCO activities. Quantitation of RubisCO mRNA showed that the effects of DMSO and CO₂ concentration on PRK and RubisCO expression were exerted at the level of transcription because decreases in form I and form II RubisCO transcripts correlated well with the decreases in overall enzyme activity.

Northern hybridization of RNA isolated from *Rb. sphaeroides* detected mRNA species capable of encoding only one, or in the case of *cbbLcbbS*, two genes when probed with various *cbb* probes (Hallenbeck et al., 1990a,b; Gibson et al., 1991). Although the hybridization results revealed individual transcripts for the Calvin cycle enzymes, the results of insertional mutagenesis discussed below argue for cotranscription of genes within each cluster (Hallenbeck et al., 1990a,b; Gibson et al., 1990, 1991).

C. *Cm. vinosum*

In *Cm. vinosum*, RubisCO biosynthesis has been shown to be regulated by O₂, CO₂, reduced sulfur compounds, and organic compounds (Kobayashi and Akazawa, 1982). The effect of various environmental factors on transcription of RubisCO genes was determined in cultures after shift from photoheterotrophic growth, in which RubisCO synthesis is repressed, to derepressing growth conditions (Valle et al., 1988). RubisCO protein and mRNA levels were shown to increase coordinately following a shift to autotrophic media containing CO₂ as the sole carbon source. The absence of CO₂ and the presence of a reduced sulfur compound in the autotrophic media following the shift further enhanced RubisCO

protein and mRNA levels. Increased RubisCO synthesis was also observed when cultures were transferred to photoheterotrophic growth conditions in the presence of a reduced sulfur compound. Transcripts were detected of 2.0 kbp, 1.5 kbp, and 1.3 kbp in Northern blots hybridized with *Cm. vinosum* RubisCO genes.

IV. Mutational Analysis

A. Autotrophic Mutants of *Rb. sphaeroides*

The first selection scheme for mutations affecting carbon dioxide assimilation in *Rb. sphaeroides* was designed to select strains incapable of derepressing RubisCO in growth modes that usually resulted in high levels of Calvin cycle enzymes. Hence, mutants were isolated that were incapable of growing either photoheterotrophically in butyrate-bicarbonate medium or photolithoautotrophically, yet were unaffected in photoheterotrophic growth on malate (Weaver and Tabita, 1983). The mutants initially appeared to affect regulation of Calvin cycle enzymes, because in spite of the inability to derepress form I RubisCO during carbon starvation, a condition known to induce the form I enzyme in the wild type strain, the level of the form II RubisCO was normal (Weaver and Tabita, 1983). The discoordinate induction pattern in the mutant suggested independent pathways existed for regulating synthesis of the two RubisCO enzymes. Subsequent mutagenesis experiments yielded additional mutants with the same growth phenotype, but only one was incapable of derepressing form I RubisCO (Rainey and Tabita, 1989). Distinct DNA fragments from a *Rb. sphaeroides* library were found to complement three of the mutant strains and, interestingly, all three complementing fragments mapped to endogenous plasmid DNA instead of chromosomal DNA (Rainey and Tabita, 1989). The exact nature of the mutations is not understood, but based on subsequent work with RubisCO mutants described below, the growth phenotype is apparently not directly related to expression of Calvin cycle enzymes.

B. Mutations in *cbb* Structural Genes

1. *Rb. sphaeroides*

Gene replacement techniques have been used to

obtain mutations in all of the known *cbb* structural genes in *Rb. sphaeroides* (Falcone et al., 1988; Hallenbeck et al., 1990a,b; Gibson et al., 1990, 1991). Double mutants have also been constructed in which both genes encoding RubisCO, PRK and FBA were inactivated (Hallenbeck et al., 1990a, b; Falcone and Tabita, 1991). Mutations were found to be polar on expression of downstream genes, such that all insertions eliminated expression of the corresponding RubisCO enzyme, and provided strong evidence for cotranscription of genes within each cluster (Hallenbeck et al., 1990a,b; Gibson et al., 1990, 1991). Strains containing single mutations were able to grow under photoheterotrophic as well as photolithoautotrophic growth conditions, demonstrating that neither form I nor form II enzymes are absolutely necessary for phototrophic growth (Falcone et al., 1988; Hallenbeck et al., 1990a,b; Gibson et al., 1991). Differences in growth characteristics were observed in some mutants, however. In general, these differences were more pronounced in the *cbbP*_I and *cbbA*_I mutants grown in the presence of low concentrations of CO₂, which assumed a wild type growth phenotype when the CO₂ concentration was increased (Hallenbeck et al., 1990a,b). Similarly, the relatively severe growth defects observed in *cbbP*_{II} and *cbbA*_{II} mutants in standing cultures were alleviated by addition of DMSO to culture media (Hallenbeck et al., 1990a,b). Double mutants were unable to grow photosynthetically unless cultures were supplemented with DMSO, providing direct evidence for the role CO₂ fixation plays as electron acceptor during photoheterotrophic growth (Hallenbeck et al., 1990a,b; Falcone and Tabita, 1991). It should be mentioned that the double RubisCO deletion mutant gained the capacity for photoheterotrophic growth after a prolonged incubation of two months (Wang et al., 1993). The genetic basis of the phenotype is not known, but most likely results from activation of a silent gene that in some way turns on an alternate pathway of CO₂ fixation.

Measurement of Calvin cycle enzyme activities and mRNA levels in the single mutants revealed an interesting interdependence in gene expression of the two gene clusters (Falcone et al., 1988; Hallenbeck et al., 1990a,b; Gibson et al., 1991). Altered expression of RubisCO and PRK were observed in the single PRK and FBA mutants grown under photoheterotrophic conditions in which the concentration of CO₂ was varied in the presence and absence of DMSO

(Hallenbeck et al., 1990a,b). The most dramatic case was exemplified by the *cbbP_{II}* mutant where levels of PRK and RubisCO increased 1427-fold and 193-fold, respectively. Activities varied considerably between different mutants depending on the culture conditions (Hallenbeck et al., 1990a,b). The presence of DMSO caused severe repression of synthesis of the form II enzymes in the *cbbP_I* mutant, but the level of form I enzymes was shown to increase in the *cbbP_{II}* mutant (Hallenbeck et al., 1990b). The form I and form II RubisCO mRNA levels measured in the PRK mutants correlated well with RubisCO activity suggesting that the differences in enzyme activity reflect alterations at the level of transcription (Hallenbeck, et al, 1990a,b).

Actual RubisCO protein levels were measured in FBP and RubisCO mutants following photoheterotrophic and photolithoautotrophic growth. In contrast to activity, the immunological determination of RubisCO protein individually measures the level of form I and form II RubisCO allowing a direct comparison to levels expressed in the wild type strain (Gibson et al., 1991). In all of the mutants, increased expression of RubisCO from the unaltered gene cluster was observed (Table 2). Overexpression was most pronounced in the *cbbF_I* mutant grown photolithoautotrophically in which the level of form II RubisCO increased 10-fold over that observed in the wild type strain and comprised 21% of the soluble protein (Gibson et al., 1991). Differential expression of RubisCO, PRK and FBP within each cluster was also evident from activities measured in the single mutants under different growth conditions (Table 2).

The construction and analysis of mutants in *cbb* genes substantiated previous proposals and provided invaluable insight into the nature of coordinated regulation of CO₂ fixation genes in *Rb. sphaeroides*. Polarity of the insertions on expression of downstream gene expression is evidence for cotranscription of genes within a cluster, thus providing a simple means of achieving stoichiometric amounts of *cbb* gene products. Collectively, these data illustrate two important facets of *cbb* gene regulation in *Rb. sphaeroides*: 1) the alteration of PRK and RubisCO synthesis shows that expression of one set of genes can respond to disruption of gene expression from the other operon, and 2) the different extent of induction of PRK and RubisCO demonstrates differential expression of genes within an operon. At present, posttranscriptional processing of a polycistronic message and differential stability of resultant

transcripts is consistent with all of the data concerning expression of Calvin cycle enzymes in *Rb. sphaeroides*. This form of regulation has been described in other systems including that of the *puf* operon in *Rb. capsulatus* (Klug et al., 1987).

2. *Rs. rubrum*

Only two *cbb* mutations have been described in *Rs. rubrum*. A RubisCO deletion strain obtained by insertional mutagenesis unexpectedly retained the ability to grow photoheterotrophically, but was incapable of photolithoautotrophic growth (Falcone and Tabita, 1993b). As for the RubisCO deletion mutant of *Rb. sphaeroides*, photosynthetic growth in the absence of a functional Calvin cycle suggests the existence of an alternative pathway of CO₂ fixation. A second mutant obtained by transposon mutagenesis, was originally selected for alterations in electron transport (Ghosh et al., 1991). The mutant is characterized by impaired ability to grow phototrophically and reduced cytochrome *c*₂ content. However, sequence determination of regions flanking the transposon, surprisingly revealed that the mutation was in a gene corresponding to *cbbA* (R. Ghosh, personal communication). Although the effect of the mutation on electron transport is not clear, it is particularly interesting in light of the role CO₂ fixation normally plays during photoheterotrophic growth.

V. Transcriptional Regulatory Genes

A. *Cm. vinosum*

In *Cm. vinosum*, an open reading frame (ORF) located 226 bp upstream from and divergently oriented to *cbbL-1cbbS-1*, originally termed *rbcR*, was identified by nucleotide sequence analysis (Viale et al. 1991). No such homolog was detected upstream from *cbbL-2cbbS-2*. Since, at present, no genetic system is available for expression of genes in *Cm. vinosum*, the potential for CbbR regulation of RubisCO genes was investigated in *E. coli* (Viale et al., 1991). An expression clone was constructed in which the amino terminal portion of *lacZ* was fused to the initiation codon of CbbR and synthesis of the resultant fusion protein was directed by the *lac* promoter of the vector. RubisCO activity was lower in *E. coli* cells cotransformed with the *cbbR* construct and a plasmid containing the *cbbL-1cbbS-1* operon under control

of its own promoter than in *E. coli* cells containing the RubisCO plasmid alone. Because a reduction in RubisCO activity was observed in the presence of CbbR, the authors suggest a negative transcriptional regulatory function for the *Cm. vinosum* CbbR protein which would account for the lowered RubisCO expression observed during photoheterotrophic versus photolithoautotrophic growth. This proposal should be regarded as tentative since the promoter recognized in *E. coli* may not be the same as that in *Cm. vinosum* and gene dosage can alter properties of regulatory molecules.

B. *Rb. sphaeroides*

1. *cbbR*

As mentioned previously, nucleotide sequence determination of the region located upstream of the form I *cbb* cluster in *Rb. sphaeroides* revealed a divergently oriented gene, called *cbbR*, that showed significant identity to the LysR family of transcriptional regulatory proteins (Gibson and Tabita, 1993). Evidence that suggested CbbR regulated expression of both *cbb* operons was obtained from studies of a strain in which the *cbbR* gene was inactivated by insertional mutagenesis (Gibson and Tabita, 1993). The *cbbR* mutant was impaired in photoheterotrophic growth and was completely incapable of growing photolithoautotrophically in a CO₂/H₂ atmosphere. In cells grown photoheterotrophically on malate, no expression of form I RubisCO could be detected and the synthesis of the

form II RubisCO was reduced to approximately 30% of the wild type strain (Table 3). The *cbbR* mutant could be complemented to a wild type growth phenotype with plasmids containing the form I and form II gene clusters. Normal levels of form I and form II RubisCO were observed only in the mutant carrying the plasmid encoded form I genes, which include *cbbR* (Table 3). No form I RubisCO was detected in the strain complemented with the form II genes, and although normal levels of RubisCO were measured in photoheterotrophically grown cells, no derepression or induction of RubisCO was evident in photolithoautotrophically grown cultures (Table 3). When the mutant was complemented with *cbbR*, a normal induction pattern for RubisCO was restored (Table 3). However, immunological analysis revealed that only 10% the normal level of form I RubisCO was present in photolithoautotrophic cultures and the apparent wild type activity was due to overexpression of form II RubisCO (Table 3). The inability of plasmid encoded CbbR to restore normal synthesis of the form I enzymes is not clear, but may be due to gene dosage effects. The complete absence of detectable form I RubisCO in the *cbbR* mutant suggests that CbbR is essential for transcription of the form I genes and it is evident that the CbbR gene product is required for maximum induction of the form II proteins during photolithoautotrophic growth. The low level of form II RubisCO in photoheterotrophically grown cells that is observed in the absence of CbbR may be due simply to a constitutive level of expression or may result from the involvement of additional regulatory factors. On the basis of

Table 3. RubisCO levels in wild type and *cbbR* mutant and plasmid-complemented strains

complementation results, the overexpression of the form II enzymes observed in response to loss of the form I gene products is mediated by CbbR as well, and can account for the apparent communication previously observed between the two operons. Interestingly, the promoters controlling expression of three open reading frames situated immediately upstream of *cbbF*_{II} appear to be influenced by CbbR as shown by transcriptional fusions to the *xyIE* gene (Xu and Tabita, 1994).

2. Aerobic Expression

In the course of examining the effect of the *cbbR* mutation on expression of the genes within the form I and form II operons, RubisCO activity was measured in aerobically grown cells of the mutant strain which carried plasmids containing the form I operon, the form II operon or *cbbR*. Significantly higher levels of RubisCO were observed in the *cbbR* mutant carrying the form II cosmid. The elevated activity was unrelated to the *cbbR* background because the same level of activity was observed in the RubisCO deletion strain harboring the form II plasmid which carries a wild type *cbbR* locus (Gibson and Tabita, 1993). This evidence, though preliminary, raises the possibility of a low copy number negative regulatory factor involved in repression of the form II genes in the presence of oxygen.

C. *Rs. rubrum*

A *cbbR* gene has been identified upstream of the RubisCO gene in *Rs. rubrum* (Falcone and Tabita, 1993b). Unlike other *cbbR* genes that have been described, the *cbbR* gene in *Rs. rubrum* is unique in that it is oriented in the same direction as the RubisCO gene but divergent to an operon comprised of other Calvin cycle genes (Falcone and Tabita, 1993b). Evidence for the function of the *Rs. rubrum* CbbR gene product comes primarily from plasmid directed expression of RubisCO from the *cbbM* promoter in *Rb. sphaeroides*. Phenotypic complementation of the *Rb. sphaeroides* RubisCO deletion mutant with the *Rs. rubrum* RubisCO could be accomplished only if sufficient sequence upstream of the *cbbM* gene was present that contained the entire CbbR coding sequence (Falcone and Tabita, 1993b). These data implicated *cbbR* as a requirement for expression of *Rs. rubrum* RubisCO. However, complementation of the *Rs. rubrum* RubisCO deletion strain was not achieved using either the *cbbRcbbM* containing fragment that complemented the *Rb. sphaeroides* RubisCO mutant or a series of plasmid constructs containing additional sequence upstream and downstream of the RubisCO gene. In spite of the inability of these plasmids to complement the strain to a wild type growth phenotype, expression of RubisCO was observed in *Rs. rubrum* when 2 kbp

DNA upstream from RubisCO was present, encoding the divergently oriented *cbbE* in addition to *cbbR*. In one case, RubisCO comprised up to 20% of the soluble protein, suggesting that the reason for lack of complementation was not due to insufficient RubisCO, but may instead result from an imbalance in levels of Calvin cycle enzymes.

D. Regulatory Features of Sequences 5' to *cbbR*

LysR regulated promoters have typically been mapped to the region separating the LysR coding sequence from the genes it regulates (Henikoff et al., 1988). The 5'-end of the *Rs. rubrum cbbM* transcript, which maps to the intergenic region between *cbbM* and *cbbR* fits this model (Leustek et al., 1988; Falcone and Tabita, 1993). Although other promoters for the photosynthetic bacterial *cbb* genes have not been located, several features of the intergenic regions are notable. All of the intergenic regions are A+T rich compared to the relatively high G+C content of the coding regions and contain T-N₁₁-A motifs common to LysR DNA binding sites (Viale et al., 1991; Falcone and Tabita, 1993b; Gibson and Tabita, 1993). In *Cm. vinosum*, the sequences, 5'-ATATTGCTT-3' and 5'-ATGTGGTTT-3', were also noted that share significant similarity with consensus sequences described for other LysR intergenic regions (Viale et al., 1991).

VI. Expression of *cbb* Genes in Heterologous Systems

A. *E. coli*

The *Rs. rubrum* form II type RubisCO was the first Calvin cycle enzyme to be synthesized as a fully functional protein in *E. coli* (Somerville and Somerville, 1984). High level expression has been attained by placing the *cbbM* gene under transcriptional control of the *lac* promoter (Somerville and Somerville, 1984; Pierce and Gutteridge, 1985). Characterization of the purified protein produced in *E. coli* showed it to be comparable in specific activity and migration in SDS gels to the enzyme isolated from *Rs. rubrum*, although later experiments showed the plasmid encoded enzyme was actually a fusion protein that contained an additional 25 amino acid

residues of *lacZ* at its amino terminus. The plasmid was later reconstructed to eliminate the gene fusion without any apparent effect on activity (Larimer et al., 1986). The form I and form II RubisCO from *Rb. sphaeroides* and both of the form I type enzymes from *Cm. vinosum* have been successfully expressed in *E. coli* and purified recombinant proteins were subsequently shown to be identical to the authentic enzyme with respect to various catalytic and immunological properties (Quivey and Tabita, 1984; Muller et al., 1985; Viale et al., 1985, 1989, 1990; Gibson and Tabita, 1986). Almost all of the other *cbb* structural genes have been expressed and demonstrated to be fully functional enzymes in *E. coli* (Gibson and Tabita, 1987, 1988; Hallenbeck, 1987; Chen et al., 1991). These include the FBP, PRK, TKL, and GAP enzymes from *Rb. sphaeroides*. It should be mentioned that expression of TKL directed by the *lac* promoter in *E. coli* and actual measurement of TKL activity confirmed the identity of this gene (Chen et al., 1991). In addition, expression of the two PRK enzymes from *Rb. sphaeroides* in *E. coli* made possible the ability to characterize each enzyme individually before mutants were available in *Rb. sphaeroides*, because both enzymes copurify in extracts of *Rb. sphaeroides* (Gibson and Tabita, 1987). Attempts to assay FBA expressed in *E. coli* have been unsuccessful (Gibson et al., 1991).

To date, the only photosynthetic bacterial Calvin cycle enzyme synthesized from its own promoter in *E. coli* is the *Cm. vinosum* RubisCO encoded by *cbbL-1cbbS-1* (Viale et al., 1990). It has not been determined whether or not *E. coli* polymerase recognizes the same signals as *Cm. vinosum* polymerase. In this context, it is interesting to note that although two RubisCO coding sequences have been identified in *Cm. vinosum*, apparently only one is expressed to a measurable extent (Viale et al., 1990). Amino terminal sequence data of RubisCO purified from *Cm. vinosum* indicated only a single RubisCO was present, corresponding to the *cbbL-1cbbS-1* gene product (Viale et al., 1990). Individual expression of the two sets of genes in *E. coli* resulted in functional RubisCO with distinct catalytic properties (Viale et al., 1990). The properties of the *cbbL-1cbbS-1* gene product were the same as the enzyme isolated from *Cm. vinosum*, further supporting the notion that only one set of RubisCO genes is expressed in the native organism.

B. Expression of *cbb* Genes in Heterologous Photosynthetic Bacteria

An interesting experiment was performed by Pierce et al. (1989) in which a cyanobacterial L_8S_8 RubisCO was replaced in vivo with the *Rs. rubrum* L_2 RubisCO. Initial attempts to inactivate the RubisCO genes in *Synechocystis* 6803 were unsuccessful leading to the supposition that RubisCO was essential even during growth on glucose. A variation of this experiment was carried out in which the *Synechocystis* RubisCO genes were actually replaced with the *cbbM* gene encoding the *Rs. rubrum* RubisCO fused to the cyanobacterial RubisCO promoter. The resultant cyanorubrum strain, was extremely sensitive to the ratio of oxygen to carbon dioxide and grew in the absence of glucose, provided the atmosphere was supplemented with 5% CO_2 . The cyanobacterial RubisCO has a low affinity for the substrate CO_2 which is offset in part because the enzyme is housed in structures called carboxysomes, postulated to contain a specialized carbonic anhydrase to provide CO_2 at the active site (Reinhold et al., 1987). Carboxysomes were not observed in the cyanorubrum strain, a factor that may account for the observed phenotype. The construction of the cyanorubrum strain provided a unique opportunity to examine the physiological consequences of replacing the native RubisCO with a foreign enzyme.

Falcone and Tabita have utilized a RubisCO deletion strain of *Rb. sphaeroides* as a host with which to examine the effects of expression of heterologous or mutated RubisCO enzymes on the physiology of this organism as well as a means to analyze regulation of foreign *cbb* promoters (Tabita et al., 1990; Falcone and Tabita, 1991, 1993a). For the former, a broad-host range expression vector was constructed into which genes of interest could be inserted downstream from the *Rs. rubrum cbbM* promoter (Falcone and Tabita, 1991). This promoter was shown to be regulated in an expected manner in *Rb. sphaeroides* by first analyzing synthesis of the *Rs. rubrum* RubisCO itself under different growth conditions (Falcone and Tabita, 1991). Subsequently, the *Rs. rubrum* RubisCO gene was replaced with the form I and form II RubisCO genes from *Rb. sphaeroides* and the cyanobacterial *rbcLrbcS* genes from *Synechococcus* PCC6301. All of the RubisCO constructs were able to complement the RubisCO deletion mutant of *Rb. sphaeroides* to photo-

heterotrophic and photolithoautotrophic growth (Falcone and Tabita, 1991). Interestingly, however, the mutant harboring the cyanobacterial RubisCO genes exhibited a pronounced lag and markedly longer growth rate during photosynthetic growth on malate when cultures were bubbled with argon, although in standing cultures growth was comparable to that of the other complemented strains. The difference in growth can be attributed to the higher concentration of CO_2 in the standing culture. The growth phenotype therefore reflects the properties of the cyanobacterial RubisCO which has an unusually low affinity for CO_2 normally compensated for in its native host by carboxysomes and a CO_2 concentrating mechanism and thus illustrates the potential of using the *Rb. sphaeroides* RubisCO mutant for screening RubisCO enzymes with altered catalytic properties (Reinhold et al., 1987; Kaplan et al., 1989).

Expression of foreign *cbb* genes directed by homologous promoters was also examined in the RubisCO deletion strain (Falcone and Tabita, 1993a). In addition to the *Rs. rubrum* RubisCO, *cbb* genes from two nonphotosynthetic bacteria, *Xanthobacter flavus* and *Bradyrhizobium japonicum*, were expressed from their own promoters in the *Rb. sphaeroides* mutant. In contrast to the normal regulation that was observed for the *Rs. rubrum* promoter, the *Xanthobacter* and *Bradyrhizobium cbb* genes were regulated in a fashion exactly opposite to that for *Rb. sphaeroides* as more RubisCO was measured in cells cultured under photoheterotrophic than photolithoautotrophic growth conditions.

C. In vitro Transcription

1. *Rb. sphaeroides*

The inability to express RubisCO genes in *E. coli* from native promoters led to the development of in vitro transcription systems as an alternative for examining regulatory factors governing synthesis of RubisCO in photosynthetic bacteria. This approach, which has thus far met with limited success, was first used in *Rb. sphaeroides*. Plasmid encoded form II RubisCO genes from *Rs. rubrum* and *Rb. sphaeroides* were expressed in an *Rb. sphaeroides* coupled transcription-translation system using RubisCO activity as a measure of transcription (Chory et al., 1985). In vitro synthesis and assembly of the *Rb. sphaeroides* form II RubisCO was reported from a

cloned DNA fragment containing only a few hundred base pairs 5' to *cbbM*_{II}. This result suggests an internal promoter for the form II RubisCO is present, a result in conflict with data derived from mutagenesis and complementation studies that are discussed above.

2. *Rs. rubrum*

The 5' end of *Rs. rubrum* RubisCO mRNA synthesized in an in vitro transcription system with either *E. coli* or *Rs. rubrum* RNA polymerase was determined by S1 mapping procedures (Leustek et al., 1988). Regardless of the source of polymerase, the same three 5'-ends were observed corresponding to those mapped when RNA was isolated from *E. coli* harboring plasmid encoded *cbbM*, but not when RNA was isolated from *Rs. rubrum*. The discrepancy between apparent in vitro and in vivo transcriptional start sites may reflect the absence of factors in vitro that are required for recognition of the RubisCO promoter.

3. *Cm. vinosum*

Expression of the first set of RubisCO genes isolated from *Cm. vinosum* in *E. coli* was dependent on an *E. coli* promoter, suggesting that the native promoter, if present, was not recognized by *E. coli* RNA polymerase. Transcription was measured by hybridizing ³²P-labeled RNA synthesized in vitro to DNA fragments representing vector, *rbcL* and *rbcS* sequences blotted to nitrocellulose. With *E. coli* RNA polymerase, RubisCO RNA was only detected when synthesis was directed by the *E. coli tac* promoter. RNA synthesized in a homologous system with purified *Cm. vinosum* RNA polymerase hybridized to RubisCO genes, but the results are difficult to interpret since the plasmid used as template also contained the *tac* promoter and no control plasmid DNA lacking this promoter was used to determine whether or not it is functional in this system.

VII. Conclusions

As indicated throughout this review, expression of Calvin cycle enzymes is affected by a wide variety of environmental factors. This is not surprising given the central, yet varied role CO₂ fixation plays in

cellular metabolism in photosynthetic bacteria. Over the past ten years, cloning and expression of DNA coding for Calvin cycle enzymes have provided the basis for significant advances made in our understanding of the molecular biology underlying the regulation of this important pathway. Gene replacement technology has enabled analysis of the individual roles of the two forms of RubisCO in *Rb. sphaeroides* and revealed different facets of regulation involved in coordinating expression of two different sets of Calvin cycle genes. Numerous studies have targeted transcription as a major determinant in control of Calvin cycle gene expression in phototrophic bacteria. The identification of CbbR proteins as members of the LysR family of transcriptional regulators offer the first clues into the nature of the transcriptional regulation. Deletion of RubisCO genes in *Rs. rubrum* and *Rb. sphaeroides* surprisingly unmasked alternative means of assimilating CO₂, further demonstrating the metabolic versatility of photosynthetic bacteria. Sequencing of structural and regulatory Calvin cycle genes has revealed intriguing relationships between photosynthetic bacteria and other organisms. Although numerous regulatory and evolutionary features have emerged from these studies, many questions remain unanswered. Foremost among future avenues of research will be the elucidation of promoter sequences involved in regulation of *cbb* operons and the signal(s) through which transcriptional activation or repression is mediated. Biochemical analysis of the transcriptional regulatory proteins will also be required for a complete understanding of the molecular processes involved in gene expression. Although not dealt with in this review, post-transcriptional factors affecting synthesis, assembly and activity of Calvin cycle enzymes must also be considered in examining the overall control of CO₂ assimilation. Translation is an area that remains to be explored. However, post-translational mechanisms affecting assembly and activity of RubisCO have already been identified and is discussed in Chapter 41 by F.R. Tabita. Ultimately, the question of how the regulation of CO₂ fixation is coordinated with other areas of metabolism will need to be addressed.

Acknowledgments

I gratefully acknowledge R. Ghosh, J. Shively, and G. Paoli for permission to cite unpublished results. I

would also like to thank G. Paoli, T. Wahlund and F.R. Tabita for their critical review of this manuscript. Support from Support from Public Health Service Grant GM-45404 from the National Institutes of Health is acknowledged.

Summary

This chapter focuses on recent advances in the genetic analysis of the common tetrapyrrole pathway and on the factors that regulate BChl biosynthesis. The genes for several steps in tetrapyrrole biosynthesis have been cloned, and the rest of the genes should be cloned in the near future.

This is an extremely complex pathway, with four different branches. Unlike most pathways where the endproducts are functionally very similar, the endproducts of this pathway serve very different functions, and are required in vastly different amounts. For this reason, the common tetrapyrrole pathway can be expected to have multiple layers of regulation, each one modulating carbon-flow to a different extent. The presence of oxygen, for example, has to block the magnesium branch and dramatically reduce carbon-flow over the common pathway without reducing the synthesis of the other three endproducts.

Three different environmental factors have been identified which alter the carbon-flow over the common tetrapyrrole pathway: oxygen, heme and *c*-type cytochromes. A fourth factor, light intensity, regulates BChl degradation rather than BChl synthesis. These factors appear to act independently of one another to ensure the smooth functioning of this pathway under a variety of environmental conditions.

I. Introduction

The purple non-sulfur photosynthetic bacteria synthesize four tetrapyrrole endproducts: heme, BChl, siroheme and vitamin B-12. These compounds are all derived from ALA via a multiply branched pathway (Fig. 1). The first branchpoint in this pathway is at uroporphyrinogen III. A small amount of uroporphyrinogen III is methylated, committing it to the synthesis of siroheme and vitamin B-12. Siroheme is the cofactor of enzymes such as sulfite reductase (Murphy and Siegel, 1973) and nitrite reductase (Murphy et al., 1974), while vitamin B-12 is the cofactor of homocysteine methyltransferase (Davis and Mingioli, 1950). Neither *Rb. capsulatus* nor *Rb. sphaeroides* appear to have the vitamin B-12-independent pathway for methionine biosynthesis (Cauthen et al., 1967; Biel, unpublished). While a small amount of the uroporphyrinogen III is diverted to these compounds, the vast majority is decarboxylated to coproporphyrinogen III, a precursor of protoporphyrin IX. At this point, either iron or magnesium is chelated into the porphyrin ring. The various hemes are formed from iron protoporphyrin, while BChl is derived from magnesium protoporphyrin.

Considerable effort has gone into understanding how various environmental factors influence tetrapyrrole biosynthesis. The factor that has the largest effect, and has received the most scrutiny, is oxygen tension. In *Rb. sphaeroides*, heme synthesis is unaffected by oxygen tension (Lascelles, 1978). However, the presence of as little as 2% oxygen dramatically reduces the BChl content of *Rb. capsulatus* and *Rb. sphaeroides* (Arnheim and Oelze, 1983; Clark et al., 1984).

In the last decade, there has been an explosion of information on BChl synthesis and how various factors regulate it. The *bch* genes, encoding the enzymes of the magnesium branch, have been cloned, physically mapped and sequenced (Chapter 50 by Alberti et al., Taylor et al., 1983; Biel and Marrs, 1983; Zsebo et al., 1984; Yang and Bauer, 1990; Bollivar and Bauer, 1992; Burke et al., 1993a; Bollivar et al., 1994a,b), and the enzymatic activities of a few of the enzymes are known (Bollivar et al., 1994c). A few of the *hem* genes, encoding the enzymes of the common tetrapyrrole pathway, have also been cloned.

These advances have facilitated several studies into the regulation of BChl biosynthesis. It has become clear that the regulation of BChl synthesis is much more complex than initially realized. While it was previously assumed that the observed regulation by oxygen and heme was part of a single control mechanism, it now appears that these factors act independently of each other. In fact, this is such an important biosynthetic pathway that it now seems probable that there are multiple, independent, regulatory systems that act to modulate the intracellular levels of BChl and heme.

This review will detail the information known about the genetics of the common tetrapyrrole pathway, i.e. the pathway from succinyl CoA and glycine to protoporphyrin IX (Fig. 1). Additional information regarding the genetic analysis of the mg-tetrapyrrole branch can be obtained in Chapter 50 by Alberti et al. as well as in a review by Bauer et al., (1993). The current state of information on regulation of BChl biosynthesis by oxygen, heme, *c*-type cytochromes, and light will also be covered in this review.

II. Genetics of Protoporphyrin Biosynthesis

The *hemA* gene has been the most extensively studied of the *hem* genes in purple photosynthetic bacteria. Lascelles and Altshuler (1969) were the first to describe a *hemA* mutant in *Rb. sphaeroides*. The mutant H-5 requires exogenous ALA for both heme and BChl production, indicating that a single ALA synthase makes ALA for both pathways. However, the mutant was isolated following nitrosoguanidine mutagenesis, and may have multiple mutations. This possibility was supported by the cloning of two different genes encoding ALA synthase, *hemA* and *hemT*, from *Rb. sphaeroides* (Tai et al., 1988). Either one of the genes allows strain H-5 to grow both aerobically in the dark and photosynthetically (Neidle and Kaplan, 1993). Thus it appears that the enzyme produced by either *hemA* or *hemT* can supply all of the ALA needed for both heme and BChl production.

Wright et al. (1987) isolated a *Rb. capsulatus* strain with a Tn5 insertion in *hemA*. This strain requires exogenous ALA for aerobic growth and BChl synthesis. The *hemA* gene was cloned and subsequently sequenced (Biel et al., 1988; Hornberger, et al., 1990; Wright et al., 1991). The observation that *hemA* mutants are unable to

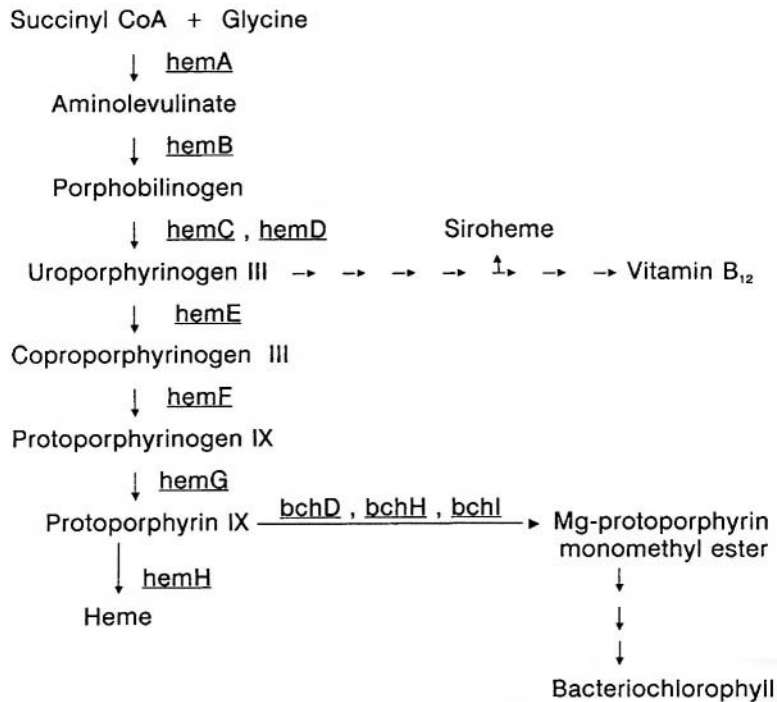

Fig. 1. The common tetrapyrrole pathway.

synthesize heme or BChl suggests that unlike the situation in *Rb. sphaeroides*, there is only one gene for ALA synthase in *Rb. capsulatus*.

The condensation of two ALA molecules to form the monopyrrole porphobilinogen is catalyzed by porphobilinogen synthase, the product of the *hemB* gene. This gene has been cloned from *Rb. sphaeroides* (Delaunay et al., 1991) and from *Rb. capsulatus* (K. Indest and A. Biel, unpublished). Both clones were isolated by complementation of an *E. coli hemB* mutant. The porphobilinogen synthase encoded by the *Rb. capsulatus hemB* gene is 43 kDa and is 54% identical to the enzyme from *Bradyrhizobium japonicum* (Chauhan and O'Brian, 1993). There are no reports of *hemB* mutants in either *Rb. capsulatus* or *Rb. sphaeroides*.

Coomber et al. (1992) isolated a *Rb. sphaeroides* mutant that accumulates coproporphyrin and does not make BChl, but does grow aerobically. They cloned a gene that complements this mutation and determined that the amino acid sequence, derived from the DNA sequence, is 44.7% similar to that of the yeast *hem13* gene, which encodes an aerobic coproporphyrinogen oxidase. The authors suggested that *Rb. sphaeroides* has two coproporphyrinogen

oxidases, one for BChl synthesis and one for heme synthesis, and that the mutation inactivated the enzyme responsible for BChl synthesis. If this mutation is indeed in the *hemF* gene, the phenotype would suggest that the heme and BChl branches diverge at coproporphyrinogen instead of protoporphyrin. This would imply that there are two enzyme complexes, consisting of at least coproporphyrinogen oxidase and protoporphyrinogen oxidase, with one complex leading to heme and the other to BChl.

In *Rb. capsulatus*, the *hemE* gene has been cloned by complementation of an *E. coli hemE* mutant (G. Ineichen and A. Biel, unpublished). The predicted amino acid sequence is 34% identical to uroporphyrinogen decarboxylase from yeast (Garey et al., 1992) and from *Bacillus subtilis* (Hansson and Kederstedt, 1992). The *hemH* gene, which encodes ferrochelatase, has also been cloned from *Rb. capsulatus* (E. Kanazierova and A. Biel, unpublished).

None of the other *hem* genes have as yet been cloned from either *Rb. capsulatus* or *Rb. sphaeroides*. However, the existence of a *hemD* mutant of *E. coli* (Sasarman et al., 1987) and strains with insertions or point mutations in each of the *Salmonella typhimurium hem* genes (Xu et al., 1992) should allow the rest

of the *Rhodobacter hem* genes to be cloned by complementation of these mutations.

As the cloning and sequencing of the *Rb. capsulatus bch* genes is discussed in Chapter 50 by Alberti et al., it will not be included in this review.

III. Regulation of BChl Biosynthesis

A. Regulation by Oxygen

A thorough review of BChl biosynthesis and its regulation in *Rb. sphaeroides* was published in 1982 (Rebeiz and Lascelles, 1982). The authors proposed a simple model to explain how oxygen might regulate BChl synthesis. It was suggested that oxygen inhibits magnesium chelatase, resulting in an increase in the protoporphyrin IX pool. Ferrochelatase would convert protoporphyrin IX to heme, which would feedback inhibit aminolevulinate synthase (Fig. 1). The decrease in aminolevulinate synthase activity would prevent further synthesis of protoporphyrin IX and would explain how oxygen inhibits the production of BChl without overproducing any of the tetrapyrrole intermediates (Lascelles, 1978).

This model predicts that oxygen, either directly or indirectly, regulates two steps in the synthesis of BChl. According to this theory, the first regulated step is the formation of ALA, which can be greatly modulated depending on the amount of BChl needed, but cannot be shut off because of the constant need for heme. The second regulated step is the conversion of protoporphyrin to Mg-protoporphyrin monomethyl ester.

A recent study suggests that, as predicted, oxygen regulates the conversion of protoporphyrin to Mg-protoporphyrin monomethyl ester. A *Rb. capsulatus bchE* strain, which accumulates Mg-protoporphyrin monomethyl ester, was grown under either 23% or 3% oxygen and pigment accumulation was measured (Biel, 1992). Under high oxygen tensions no Mg-protoporphyrin monomethyl ester accumulated. Since heme synthesis must continue under these conditions, these results indicate that oxygen controls the formation of Mg-protoporphyrin monomethyl ester from protoporphyrin.

The *pufQ* gene product is essential for BChl synthesis from protoporphyrin, although its role is unclear (Bauer and Marrs, 1988). It is intriguing, however, that transcription of *pufQ* is 30-fold higher in anaerobically grown cultures than in cultures grown

aerobically (Bauer et al., 1988; Chapter 58). Thereby implying that transcription of *pufQ* may have a role in this control.

Studies on the regulation of BChl biosynthesis by oxygen were facilitated by the isolation of an **R'-factor**, derived from RP1, which carried the entire *Rb. capsulatus* photosynthesis region (Marrs, 1981). A genetic and physical map of the photosynthesis region of the *Rb. capsulatus* chromosome, showing the positions of the genes for BChl and carotenoid biosynthesis, was then developed (Taylor et al., 1983; Zsebo and Hearst, 1984) and refined by interposon mutagenesis (Yang and Bauer, 1990; Bollivar et al., 1994a,b). Fusions between the *lacZ* gene and several of the *bch* genes were also constructed and used to determine that transcription of the *bch* genes was two- to three-fold lower in cultures grown with 20% oxygen than in those grown with 2% oxygen (Biel and Marrs, 1983; Young et al., 1989; Yang and Bauer, 1990). These results have been confirmed by measuring *bch* mRNA levels in *Rb. capsulatus* and *Rb. sphaeroides* (Clark et al., 1984; Hunter and Coomber, 1988; Armstrong et al., 1993). While transcription of the *bch* genes is regulated by oxygen tension, the magnitude of that regulation cannot account for the 50-fold lower BChl levels seen in aerobically grown cultures compared to anaerobically grown ones. In an effort to determine how oxygen regulates transcription of the *bch* promoters, Ma et al. (1993) analyzed the *bchCXYZ* promoter region. They found that it shared sequence similarity to the *E. coli* σ^{70} consensus promoter and that deletion of a 50bp AT-rich region immediately upstream of the -35 region rendered the promoter uninducible by oxygen. There is also a report of a *trans*-acting repressor in *Rb. sphaeroides* and *Rb. capsulatus* which controls expression of *bch* genes (Penfold and Pemberton, 1994; Ponnampalam et al., 1995).

When the synthesis of BChl from protoporphyrin is inhibited by oxygen, carbon-flow over the common tetrapyrrole pathway has to be reduced to prevent the overproduction of protoporphyrin. Regulation of the common tetrapyrrole pathway by oxygen was demonstrated by growing a *Rb. capsulatus bchH* mutant under high and low oxygen tensions and measuring protoporphyrin accumulation (Biel and Marrs, 1983). The low-oxygen grown culture had dramatically higher protoporphyrin levels than the high-oxygen grown culture. While this observation suggests that oxygen regulates carbon-flow over the common tetrapyrrole pathway, it does not rule out

the possibility that protoporphyrin synthesis is the same under both oxygen tensions, but that under high oxygen the excess protoporphyrin is degraded. However, since a *bchH* mutant accumulates protoporphyrin when grown under high oxygen in the presence of exogenous porphobilinogen, it seems likely that oxygen does indeed regulate the synthesis of protoporphyrin (Biel, 1992).

Mutants which accumulate coproporphyrin have been isolated in both *Rb. capsulatus* and *Rb. sphaeroides* (Biel and Biel, 1990; Coomber et al., 1992). Coproporphyrin is accumulated by both mutants only when they are grown under low oxygen tension, suggesting that oxygen controls one of the steps in the formation of coproporphyrin.

Since the formation of ALA has been considered to be the first step in the common tetrapyrrole pathway, it seemed plausible that this would be the step at which oxygen acts. Evidence in support of this are the observations, made in *Rb. sphaeroides*, that ALA is rate-limiting for heme synthesis (Lascelles and Hatch, 1969), and that ALA synthase is inhibited by heme in vitro (Burnham and Lascelles, 1963).

There is no direct evidence, however, that oxygen influences ALA synthase activity. In *Rb. capsulatus*, cultures grown aerobically have the same ALA synthase activity as cultures grown photosynthetically (Biel, 1992), while in *Rb. sphaeroides*, ALA synthase specific activity varies less than five-fold with oxygen tension (Lascelles, 1959; Oelze and Arnheim, 1983). Since the *Rb. sphaeroides* enzyme is activated by trisulfides, the observed ALA synthase specific activity may not reflect the true in vivo situation (Marriott et al., 1969). Transcription of the *Rb. capsulatus hemA* gene is regulated only two-fold by oxygen (Hornberger et al., 1991; Wright et al., 1991).

If oxygen either directly or indirectly inhibits ALA formation, the addition of exogenous ALA to an aerobically growing culture should result in increased carbon-flow over the common tetrapyrrole pathway. This was tested by growing a *Rb. capsulatus bchH* mutant under high and low oxygen tensions in the presence of 1.0mM ALA and measuring the accumulation of protoporphyrin (Biel, 1992). Surprisingly, even in the presence of exogenous ALA, protoporphyrin levels were much higher in the low-oxygen grown culture than in the high-oxygen grown culture, suggesting that oxygen regulates some step after the formation of ALA. When the experiment was repeated with exogenous porphobilinogen, both the high- and low-oxygen grown cultures accumulated

protoporphyrin, indicating that oxygen regulates the conversion of ALA to porphobilinogen.

An implication of this result is that either aerobically growing cells must accumulate ALA, which has not been reported, or the ALA must be metabolized by some other pathway. There are several reports in different organisms suggesting that ALA is not committed to tetrapyrrole biosynthesis. Shemin and Russell (1953), in reporting that ALA is a precursor of protoporphyrin, also indicated that ALA is incorporated into purines. Further evidence for the incorporation of ALA into purines was presented by Nemeth et al. (1957). Shigesada (1972) demonstrated that in photosynthetically grown *Rhodospirillum rubrum* the major metabolites of [4-¹⁴C]ALA were not tetrapyrroles, but were instead δ -amino- γ -hydroxyvalerate, α -hydroxyglutarate and glutamate.

While the evidence presented above suggests that oxygen regulates the formation of porphobilinogen from ALA, the mechanism of this regulation is unclear. Now that the *hemB* gene has been cloned from both *Rb. capsulatus* and *Rb. sphaeroides*, it will be a simple matter to determine if oxygen regulates *hemB* transcription. It will be more difficult to determine if oxygen regulates the activity of porphobilinogen synthase. Lascelles (1959) measured porphobilinogen synthase specific activities in *Rb. sphaeroides* cultures grown under low and high oxygen tensions and found that porphobilinogen synthase activity was four-fold higher in the low-oxygen grown culture than in the high-oxygen grown culture. Porphobilinogen synthase activity does not seem to be regulated in *Rb. capsulatus* (A. Biel, unpublished). These assays may not represent the true in vivo situation, however, since no attempt was made in these studies to maintain the original oxygen tension of the culture while making the extracts. Thus if the porphobilinogen synthase in photosynthetic bacteria is oxygen-labile, as has been reported for the mammalian enzyme (Tsukamoto et al., 1979), the observed activity from anaerobically grown cultures may be considerably less than the actual in vivo activity.

B. Regulation by Heme

It has been demonstrated convincingly that hemin inhibits *Rb. sphaeroides* ALA synthase in vitro (Burnham and Lascelles, 1963; Yubisui and Yoneyama, 1972). Porphobilinogen synthase of *Rb. sphaeroides* is also very sensitive to inhibition by

hemin, with 50% inhibition occurring at 33 μM (Burnham and Lascelles, 1963; Nandi et al., 1968). In contrast, the porphobilinogen synthase of *Rb. capsulatus* is insensitive to inhibition by hemin (Nandi and Shemin, 1973). One other *Rb. sphaeroides* enzyme, ferrochelatase, has been shown to be strongly inhibited by hemin, with 50% inhibition occurring at 10 μM (Jones and Jones, 1970).

In spite of these observations, the manner in which heme might regulate tetrapyrrole biosynthesis, and the physiological significance of that regulation are not clear. The role of heme in regulating tetrapyrrole biosynthesis has been investigated by starving cells for heme and monitoring the production of various tetrapyrroles. The first method used to produce heme-deficient cells was to incubate cell suspensions in iron-limited media. Cell suspensions of either *Rb. capsulatus* or *Rb. sphaeroides* incubated in the light for 24 h in iron-deficient media accumulated large amounts of coproporphyrin while synthesizing less than half the normal amount of BChl (Lascelles, 1956; Burnham and Lascelles, 1963; Cooper, 1963; A. Biel, unpublished). Jones (1963) reported that *Rb. sphaeroides* also accumulated Mg-protoporphyrin monomethyl ester when starved for iron.

A second, more specific, method for producing heme-deficient cells has been used in both *Rb. capsulatus* and *Rb. sphaeroides* (Houghton et al., 1982; A. Biel, unpublished). Cell suspensions were incubated in the presence of N-methylprotoporphyrin, an inhibitor of ferrochelatase, in the presence of excess iron. In both *Rb. capsulatus* and *Rb. sphaeroides*, N-methylprotoporphyrin had no effect on BChl production, while dramatically increasing the production of Mg-protoporphyrin monomethyl ester. Incubation of the cell suspensions with N-methylprotoporphyrin did not result in accumulation of coproporphyrin.

While both sets of experiments suggest that heme deficiency causes increased carbon-flow over the common tetrapyrrole pathway, it also appears that iron-limitation reduces the conversion of coproporphyrinogen to Mg-protoporphyrin monomethyl ester. It has been suggested that the increased carbon-flow over the common tetrapyrrole pathway is due to a loss of the normal feed-back inhibition of ALA synthase by heme (Lascelles, 1978; Houghton et al., 1982), however, there are no published reports on the level of ALA synthase in heme-deficient cells. *Rb. capsulatus* grown under 3% oxygen in the presence of N-methylprotoporphyrin had 1.4-fold more ALA

synthase activity than a similar culture grown in the absence of the inhibitor (A. Biel, unpublished). It is not yet known if this increase in ALA synthase activity alone is enough to account for the increased porphyrin accumulation.

Complicating the picture is the observation that when *bch* mutants of *Rb. capsulatus* or *Rb. sphaeroides* are incubated with N-methylprotoporphyrin the pigment that accumulates is not Mg-protoporphyrin monomethyl ester, but is the pigment characteristic of the mutant (Houghton et al., 1982; A. Biel, unpublished). Houghton et al. (1982) suggested that BChl acts as an inhibitor of the conversion of Mg-protoporphyrin monomethyl ester to Mg-2,4-divinyl pheoporphyrin a_3 monomethyl ester, and that in *bch* mutants the absence of BChl allows carbon-flow to continue until the block in the pathway is reached.

It is evident that a considerable amount of work needs to be done to determine the role of heme in regulating the common tetrapyrrole pathway. The isolation of ALA synthase mutants that are insensitive to feed-back inhibition by heme might be very useful in elucidating the role of ALA synthase in heme-mediated regulation of this pathway. Presumably, these mutants would accumulate higher than normal amounts of Mg-protoporphyrin monomethyl ester, which would not be increased by heme-deficiency. These mutants will also help to determine if oxygen and heme act independently on the common tetrapyrrole pathway, as suggested by the results presented above. If, in fact, regulation by oxygen is totally independent from regulation by heme, the accumulation of Mg-protoporphyrin monomethyl ester should still be regulated by oxygen.

C. Regulation by c-type Cytochromes

Several different mutants have been isolated in *Rb. capsulatus* whose phenotypes suggest a link between c-type cytochrome biosynthesis and carbon-flow over the common tetrapyrrole pathway. Daldal et al. (1987) found that *Rb. capsulatus* *petB* and *petC* mutants, which lack the cytochrome bc_1 complex, accumulate an uncharacterized pigment. Kranz (1989) isolated mutants with alterations in three different genes (*helA*, *helB* and *helC*) required for biosynthesis of c-type cytochromes. These mutants also accumulated an uncharacterized pigment. Biel and Biel (1990) isolated a Tn5 insertion mutant that completely lacks c-type cytochromes. Beckman et al. (1992) have

sequenced the gene mutated in this strain. The gene has been designated *cII1*, and has been shown to be involved in *c*-type cytochrome biosynthesis. This mutant accumulated nine-fold more protoporphyrin and 18-fold more coproporphyrin than the parental strain and only 19% of the normal amount of BChl. Porphyrin production in this mutant is still subject to the normal regulation by oxygen (Biel, 1991). Growth of the mutant in an iron-limited medium increases porphyrin accumulation almost three-fold (A. Biel, unpublished), suggesting that whatever regulatory mechanism has been disrupted by this mutation, it is separate from heme-mediated regulation.

The phenotypes of these mutants suggest that *Rb. capsulatus* monitors the level of one or more *c*-type cytochromes and modulates carbon-flow over the common tetrapyrrole pathway in response to changes in that level. It is unclear whether the total pool of *c*-type cytochromes is monitored, or whether it is the level of a specific *c*-type cytochrome which regulates the pathway. How carbon-flow over the common tetrapyrrole pathway is regulated is also unknown. By analyzing the cytochrome *c*-less mutant it should be possible to determine if the activities of any of the enzymes in the pathway are increased and whether transcription of the *hemA* and *hemB* genes are altered.

D. Regulation by Light

Cohen-Bazire et al. (1957) demonstrated that BChl levels were inversely proportional to light intensity in photosynthetically grown cultures. They also found that aerobically grown cultures produced very little BChl, regardless of the light intensity. It was assumed that the decreased levels of BChl found in high-light grown cultures was due to inhibition of BChl synthesis, and it was proposed that oxygen and light controlled the state of oxidation of some electron transport chain component, which in turn regulated the synthesis of BChl.

Arnheim and Oelze (1983) investigated the formation of BChl in chemostats where growth was limited by oxygen or light. They found that in *Rb. sphaeroides* the two factors acted independently of one another, and suggested that oxygen and light use separate mechanisms to control BChl formation. Oelze and Arnheim (1983) showed that while aminolevulinic synthase levels respond to changes in oxygen tension, changes in light intensity have no effect on enzyme activity. These results suggest that a single regulatory mechanism, such as that proposed

by Cohen-Bazire et al. (1957), can not account for regulation by both oxygen and light. This conclusion was further strengthened when it was observed that while oxygen regulated transcription of the *bch* genes in *Rb. capsulatus*, light intensity had no effect on transcription (Biel and Marrs, 1983).

These studies indicated that oxygen and light independently regulated BChl accumulation. The assumption was made that both oxygen and light regulated the synthesis of BChl. However, several pieces of evidence suggest that in *Rb. capsulatus* light intensity controls the rate of BChl degradation rather than the rate of synthesis (Biel, 1986). A *bch*⁺ strain, grown under 3% oxygen either in darkness or with a light intensity of 850 W m⁻² accumulated nine times more BChl in the dark than in bright light. On the other hand, a *bchG* mutant, which synthesizes bacteriochlorophyllide *a* but cannot convert it to BChl, accumulated the same amount of bacteriochlorophyllide *a* per mg of protein under the two conditions, indicating that light intensity does not alter the synthesis of bacteriochlorophyllide *a*. This experiment does not rule out the possibility that light prevents the conversion of bacteriochlorophyllide *a* to BChl. However, when tetrapyrrole formation from [¹⁴C]ALA was followed it was determined that bright light caused an increase in BChl degradation. In a *bch*⁺ strain grown in the dark, [¹⁴C]ALA was rapidly converted to BChl. When grown in bright light, the [¹⁴C]ALA was converted to a colorless compound that co-migrated with BChl on silica gel TLC plates developed with either 70% ethanol or two other solvent systems. Spectroscopy and fluorimetry indicated that this compound was not a normal BChl precursor, suggesting that the compound was a degradation product of BChl. Interestingly, BChl formed by a culture grown in the dark was not degraded when the culture was shifted to bright light. Perhaps insertion of BChl into pigment-protein complexes stabilizes the BChl. Synthesis of the proteins for these complexes are known to be regulated by light intensity (Klug et al., 1985; Zhu and Hearst, 1986).

IV. Conclusions

Oxygen tension is the environmental factor with the most influence on this pathway. It prevents the conversion of protoporphyrin to Mg-protoporphyrin monomethyl ester. The *PufQ* protein appears to be

involved in regulating this step, but how this regulation occurs is unknown. Oxygen also reduces carbon-flow over the common tetrapyrrole pathway. Recent evidence suggests that the site of regulation is not the formation of ALA, but rather its conversion to porphobilinogen. A considerable amount of work remains to be done to confirm this and to determine the mechanism by which oxygen regulates this step.

Heme-deprivation also causes an increase in carbon-flow over the common tetrapyrrole pathway. It is likely that regulation by heme is separate from regulation by oxygen. The isolation and characterization of a mutant with a feed-back resistant ALA synthase should help to determine if heme controls the common tetrapyrrole pathway by regulating ALA synthase activity.

This pathway is also regulated by *c*-type cytochromes. Cytochromes can be considered to be the true endproducts of the heme pathway; therefore it seems likely that the cell would monitor the level of some type of cytochrome and regulate tetrapyrrole synthesis in response to changes in the level of that cytochrome. The mechanism by which *c*-type cytochromes regulate heme synthesis are as yet totally unexplored.

In one area at least, the regulation of BChl is simpler than previously thought. Light intensity regulates the intracellular level of BChl by altering the rate of BChl degradation, rather than its rate of synthesis. Thus the brighter the light, the faster degradation occurs.

With the application of genetic approaches and molecular biological tools to this area tremendous strides have been made in the last decade. We have not yet answered the questions, but have defined them so that they can be answered. In the next decade a picture should begin to emerge of how the bacterial cell regulates such an extraordinarily complex pathway with such precision.

Summary

Carotenoids comprise a large class of natural pigments that are ubiquitous in photosynthetic organisms and are essential for photooxidative protection. A large collection of anoxygenic photosynthetic bacterial carotenoid biosynthesis mutants with novel color phenotypes have been isolated over the past 40 years. Genes involved in carotenoid biosynthesis have recently been mapped, cloned and sequenced. Seven clustered genes (*crtA*, *crtB*, *crtC*, *crtD*, *crtE*, *crtF*, *crtI*) are required for carotenoid biosynthesis in *Rhodobacter (Rb.) capsulatus* and *Rb. sphaeroides*. The *crt* gene products participate in reactions that convert FPP to spheroidene/spheroidenone. The proposed requirement for the products of *Rb. capsulatus* ORF160 and ORF 469 in carotenoid biosynthesis conflicts with experiments using their respective *Rb. sphaeroides* homologs. Nucleotide sequences have been determined for all of the *Rb. capsulatus crt* genes and for *crtD*, *crtI*, *crtB* and a portion of *crtC* in *Rb. sphaeroides*. The *Rb. capsulatus crtEF* and *crtIB* genes appear to form multigene operons, the former within the global context of a superoperon in the photosynthesis gene cluster.

Carotenoid pigment accumulation in *Rhodobacter* clearly responds to environmental stimuli, particularly light intensity and oxygen tension, and correlates with the presence and extent of the photosynthetic membrane. mRNA accumulation studies using gene-specific probes and promoter-reporter gene fusions indicate upregulation of *Rb. capsulatus crtA*, *crtC*, *crtD*, *crtE*, *crtF* and ORF 160, but not *crtB* and *crtI*, by anaerobiosis. Transcriptional regulation thus does not appear to limit the biosynthetic capacity for the conversion of GGPP to neurosporene.

Most information available on the *Rhodobacter* carotenoid biosynthesis enzymes has been deduced from the predicted amino acids sequences, rather than from biochemical or immunological studies. The carotenoid prenyltransferases (CrtB and CrtE) and phytoene dehydrogenase (CrtI) catalyze the early biosynthetic reactions in the carotenoid pathway that are conserved in other organisms. CrtI is, however, replaced in oxygenic photosynthetic organisms by a structurally distinct but functionally similar protein called CrtP/Pds. The CrtB, CrtC, CrtD, CrtE, CrtF and CrtI enzymes share conserved sequence motifs with other proteins of related function.

I. Introduction

A. Scope of This Chapter

The study of the genetics of carotenoid biosynthesis has blossomed in recent years, spurred in large part by the broad application of research results obtained

Abbreviations: BChl – bacteriochlorophyll; BChlide – bacteriochlorophyllide; DMAPP – dimethylallyl pyrophosphate; *E. coli* – *Escherichia coli*; *E. herbicola* – *Erwinia herbicola*; FPP – farnesyl pyrophosphate; GGPP – geranylgeranyl pyrophosphate; GPP – geranyl pyrophosphate; IPP – isopentenyl pyrophosphate; kb – kilobase; LH I – light-harvesting I; LH II – light-harvesting II; LH – light-harvesting; *M. xanthus* – *Myxococcus xanthus*; *N. crassa* – *Neurospora crassa*; ORF – open reading frame; *P.* – *Paracoccus*; PPPP – prephytoene pyrophosphate; *Rb.* – *Rhodobacter*; RC – reaction center; *Rs.* – *Rhodospirillum*; SAH – S-adenosylhomocysteine; SAM – S-adenosylmethionine

with the anoxygenic photosynthetic bacteria to other organisms (reviewed in Armstrong, 1994). These advances have been achieved almost exclusively with two closely related, genetically amenable and metabolically versatile species of purple nonsulfur photosynthetic bacteria, *Rhodobacter capsulatus* and *Rhodobacter sphaeroides* (*Rhodopseudomonas capsulata* and *Rhodopseudomonas sphaeroides*, respectively, in earlier literature (Imhoff et al., 1984)). General aspects of the genetics of photosynthetic bacteria have been reviewed (Scolnik and Marrs, 1987). This chapter will focus primarily, though not exclusively, on developments since 1976 in the genetics of *Rb. capsulatus* and *Rb. sphaeroides* carotenoid biosynthesis.

Other chapters in this volume address topics such as the range of carotenoid structures and biosynthetic

pathways encountered in the anoxygenic photosynthetic prokaryotes, the chemical and physical properties of carotenoids in their dual functions of photooxidative protection of the photosynthetic apparatus and light harvesting in the pigment-protein antenna and reaction center complexes, detailed features of the nucleotide sequence of the *Rb. capsulatus* carotenoid biosynthesis gene cluster, and those aspects of the regulation of carotenoid biosynthesis genes relating to the global organization of photosynthesis gene clusters.

B. General Background

Carotenoids comprise a diverse class of yellow, orange and red natural pigments that serve a variety of roles in photosynthetic and nonphotosynthetic prokaryotic and eukaryotic organisms. During the last 40 years the significance of carotenoid biosynthesis for photosynthesis has become evident. Biological functions of carotenoids in photooxidative protection, light absorption and the structural integrity of the photosynthetic membrane have been established in the anoxygenic photosynthetic bacteria (reviewed in Cogdell and Frank, 1987).

Carotenoid and bacteriochlorophyll (BChl) pigment molecules associate noncovalently but specifically with the photosynthetic reaction center (RC) and the light-harvesting (LH) antennapigment-protein complexes (reviewed in Hawthornthwaite and Cogdell, 1991). In anoxygenic photosynthetic bacteria the formation of these complexes and the accompanying pigments is normally induced by anaerobic or low oxygen growth conditions. The LH antenna complexes serve as the major sites for the binding of lipophilic carotenoids in the photosynthetic membrane.

II. Early Developments in the Genetics of Carotenoid Biosynthesis

A. *Rb. sphaeroides* Mutants

The birth of the genetics of photosynthetic bacteria can be dated to the isolation of carotenoid pigment mutants of *Rb. sphaeroides* (Griffiths and Stanier, 1956). These bacteria are normally brown under anaerobic conditions and become reddish-purple upon exposure to oxygen. In this classic study, both ultraviolet-induced and spontaneous mutants were studied and classified according to the colors of the

bacterial colonies. Griffiths and Stanier (1956) observed several classes of mutants, including brown, green and blue-green strains that contained BChl but lacked the normal carotenoid complement. A detailed examination of the properties of a blue-green phytoene-accumulating mutant (UV-33) provided the basis for our understanding of one of the crucial functions of carotenoids that absorb visible light, namely photooxidative protection of the organism against the deadly combination of photons, endogenous sensitizers (BChl in this case) and oxygen (Griffiths et al., 1955; Sistrof et al., 1956). The effects of light and oxygen on the formation of photosynthetic pigments in *Rb. sphaeroides* wild type and a spontaneous green mutant (Ga) were also documented in an elegant physiological study (Cohen-Bazire et al., 1957).

B. Elucidation of Biosynthetic Pathways

In the 20 years thereafter, research on carotenoid biosynthesis emphasized the identification of biosynthetic intermediates from wild type, mutant and chemically inhibited bacterial cultures (reviewed in Goodwin, 1980). Many of these early studies were performed with *Rb. sphaeroides* or *Rs. rubrum*. The classification of carotenoid pigment mutants and proposals for biosynthetic pathways in species of anoxygenic photosynthetic bacteria, based on the chemical relationships between the characterized biosynthetic intermediates, are described in detail elsewhere (Liaaen-Jensen et al., 1961; reviewed in Schmidt, 1978). In *Rb. sphaeroides* and *Rb. capsulatus*, a carotenoid biosynthetic pathway leading to the synthesis of spheroidene and spheroidenone was proposed (Fig. 1). The absence of a viable genetic system among the anoxygenic photosynthetic prokaryotes posed a major obstacle to further advances.

III. Mapping, Cloning and Sequencing of Carotenoid Biosynthesis Genes

A. *Rb. capsulatus*

1. Genetic Mapping

With the discovery of genetic recombination in *Rb. capsulatus*, mediated by a virus-like particle termed the gene transfer agent (Marrs 1974), the genetic mapping of carotenoid biosynthesis mutations in a

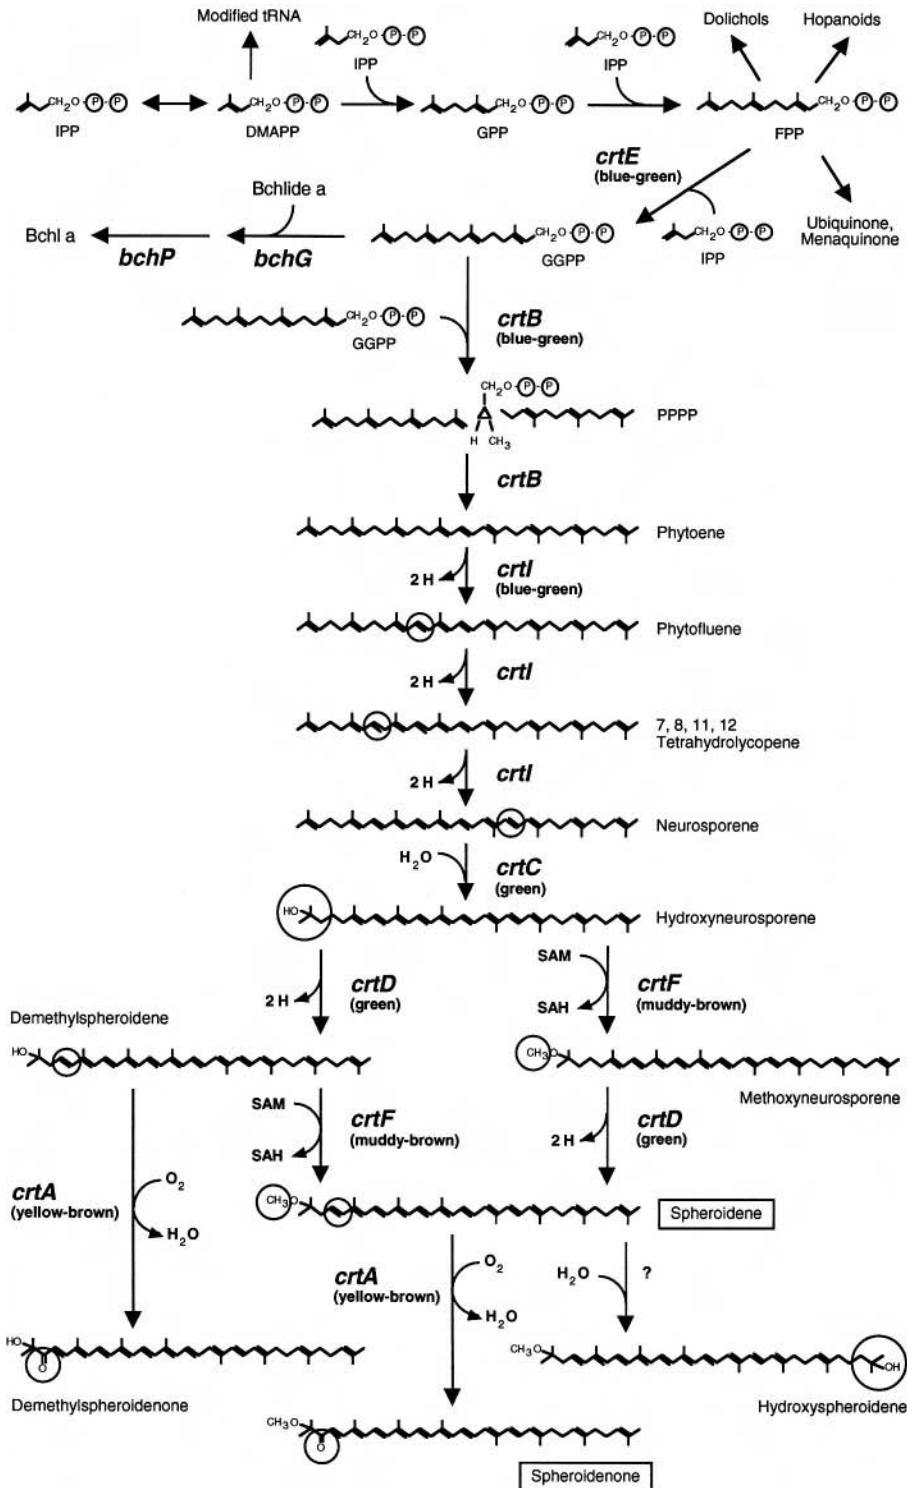

Fig. 1. Rhodobacter isoprenoid and carotenoid biosynthesis. Other biosynthetic pathways dependent on intermediates in general isoprenoid metabolism are indicated (Ourisson et al., 1987; Sherman et al., 1989; Bauer et al., 1993a). Starting with phytoene, the first stable compound unique to the C₄₀ carotenoid branch of isoprenoid metabolism, the biosynthetic conversions are highlighted (circles). Intermediates up to neurosporene are common to most carotenogenic organisms. Spheroidene and spheroidenone (boxed) are the major *Rhodobacter* wild type carotenoids accumulated in the absence and presence, respectively, of oxygen in the growth medium. See Goodwin (1980) for the semisystematic nomenclature of the carotenoids and a general review of biosynthetic pathways. Specific genetic

photosynthetic prokaryote became possible (Yen and Marts, 1976). Carotenoid (*crt*) and BChl (*bch*) biosynthesis genes were shown to be genetically linked. Five genetically distinct classes of *Rb. capsulatus crt* mutants displaying three altered color phenotypes (*crtB* or *crtE*, blue-green; *crtC* or *crtD*, green; *crtA*, yellow) were isolated (Yen and Marts, 1976). The *Rb. capsulatus* mutants corresponded phenotypically to the blue-green, green and brown mutants previously reported in *Rb. sphaeroides* (Griffiths and Stanier, 1956). An additional class of muddy-brown mutants defined a new genetic locus, *crtF*, linked to the other *crt* genes (Scolnik et al., 1980). A carotenoid metabolic grid connecting *crtA*, *crtC*, *crtD* and *crtF* with specific biosynthetic conversions (Fig. 1) was proposed on the basis of a study of the carotenoid intermediates accumulated in *Rb. capsulatus* mutants. Another new locus associated with the green phenotype, *crtG*, was also identified and some of the previously reported *crtC* mutations (Yen and Marts, 1976) were reassigned to it (Scolnik et al., 1980). *crtG* and *crtD* were subsequently demonstrated to be identical (Marrs, 1982).

The biosynthetic intermediates accumulated in *Rb. capsulatus crtB* and *crtE* mutants were not defined in the construction of the metabolic grid (Yen and Marts, 1976; Scolnik et al., 1980). It was, however, recognized that these blue-green strains did not accumulate phytoene, whereas the prototypical *Rb. sphaeroides* UV-33 mutant did (Griffiths and Stanier, 1956; Sistrom et al., 1956). An *Rb. capsulatus crtH* blue-green mutant that accumulated phytoene was also mentioned in the literature but was not described in detail (Marrs 1982).

2. Physical Mapping

Shortly after the assignments of *crtA*, *crtC*, *crtD* and *crtF* to the biosynthetic grid (Scolnik et al., 1980), an R-prime plasmid, pRPS404, containing a 46 kilobase pair (kb) region of the *Rb. capsulatus* chromosome from strain SB 1003 was described (Marrs, 1981). This R-prime complemented all genetic defects in

photosynthesis known at that time, including blockages in carotenoid and BChl biosynthesis, upon its introduction into *Rb. capsulatus* mutants. The *puc* operon, encoding the LH II (B800–850) peripheral antenna complex, was subsequently found to lie outside of the region carried on pRPS404 (Kaufmann et al., 1984). The isolation of pRPS404 ushered in a period of intensive research to physically map, subclone and sequence genes for the photosynthetic RC and LH I (B875) pigment-protein complexes, encoded by the *puf* and *puh* operons, and the photosynthetic pigment biosynthesis enzymes, encoded by various *crt* and *bch* operons (see Burke et al., 1991; Chapter 50 by Alberti et al. and references therein).

The *crtB* locus was the first carotenoid biosynthesis function to be physically mapped on pRPS404 by a conjugation-mediated marker rescue technique (Taylor et al., 1983). Shortly thereafter, transposon mutagenesis of pRPS404 and the physical mapping of the *crtA*, *crtE*, *crtI* and *crtJ* genetic loci were also reported (Zsebo and Hearst, 1984). *crtI* and *crtJ* had not been previously described and were identified in this study by their blue-green mutant phenotypes typical of early blockages in carotenoid biosynthesis (Fig. 1). *crtJ* was surrounded by *bch* genes and was located about 12 kb away from the other *crt* genes, which formed a subcluster within the photosynthesis gene cluster (Zsebo and Hearst, 1984). The *crtC*, *crtD*, and *crtF* genes were physically mapped by interposon (i.e. antibiotic resistance cartridge) mutagenesis and in vivo complementation (Giuliano et al., 1988).

3. Assignments of Biosynthetic Blockages in Blue-Green Mutants

The phenotypes of the new *Rb. capsulatus crtI* and *crtJ* mutants coincided with those of *crtB* and *crtE* blue-green mutants both with respect to the absence of visibly absorbing carotenoids and in the pleiotropic loss of a spectroscopically detectable LH II antenna complex (Kaufmann et al., 1984; Zsebo and Hearst, 1984). Subsequently, several point mutants that

defects in carotenoid biosynthesis result in mutant color phenotypes reflecting the presence of BChl and the particular carotenoid intermediate(s) accumulated. Compounds starting with asymmetrical ζ -carotene (7, 8, 11, 12 tetrahydrolycopene) that have 7 or more conjugated double bonds absorb visible light and contribute to the overall color. *bch* genes associated with BChl biosynthesis are discussed elsewhere (Bauer et al., 1993a; Bollivar et al., 1994). *crt* genes and product functions are as follows: *crtA*, monooxygenation; *crtB*, 1'-2-3 prenylpyrophosphate condensation and 1'-1 rearrangement; *crtC*, hydration; *crtD*, 3,4 dehydrogenation; *crtE*, 1'-4 prenylpyrophosphate condensation; *crtF*, O-methylation; *crtI*, dehydrogenation. The biosynthetic functions ascribed to *crt* gene products have been deduced from precursor accumulation studies, or from in vivo or in vitro complementation of mutant phenotypes. Enzymatic activities of most of the proteins have not yet been demonstrated.

accumulated phytoene were examined and found to be complemented *in vivo* by DNA from the *crtI* region (Giuliano et al., 1986). A cell-free extract from a *crtI* mutant failed to synthesize colored carotenoids but could be complemented *in vitro* by a *crtB* mutant extract, thus defining a function for *crtI* in the biosynthetic pathway (Fig. 1).

Blue-green *crtB*, *crtE*, *crtI* and *crtJ* mutants were studied further using a cell-free *Rb. capsulatus* *in vitro* carotenoid biosynthesis system capable of converting ¹⁴C-labeled IPP to phytoene (Armstrong et al., 1990c). Both *in vitro* and *in vivo* accumulation of phytoene were demonstrated in a *crtI* transposon mutant, in agreement with earlier results using point mutants (Giuliano et al., 1986). Although the updated biosynthetic pathway gives the all-*trans* carotenoid structures for convenience (Fig. 1), 15-*cis* and all-*trans* phytoene were present in roughly equal amounts in the *crtI* transposon mutant (Armstrong et al., 1990c).

The cell-free system also indicated an *in vitro* accumulation of GGPP in *crtB* and *crtJ* mutants, and GGPP plus PPPP in a *crtE* mutant. Provisional biosynthetic functions of PPPP synthesis and phytoene synthesis were therefore ascribed to the *Rb. capsulatus crtB* and *crtE* gene products, respectively (Armstrong et al., 1990c). These assignments were made under the assumption that blue-green mutants could not be defective in GGPP synthesis because this compound is essential for the synthesis of the phytyl side chain of BChl *a* in the *Rhodospirillaceae* (Fig. 1) (Biel and Marrs, 1983; Rüdiger and Schoch, 1991; Bauer et al., 1993a). Subsequent comparisons of the deduced amino acid sequences for CrtE and CrtB with those of prenyltransferases and squalene synthases led to revised proposals that CrtE might rather be the GGPP synthase and that CrtB alone might convert GGPP to phytoene via PPPP (Carattoli et al., 1991; Math et al., 1992; Kuntz et al., 1992). *In vivo* complementation and precursor accumulation studies with prokaryotic homologs of CrtB and CrtE from other organisms confirmed this hypothesis (Chamovitz et al., 1992; Math et al., 1992; Sandmann and Misawa, 1992). The complementation of an *Rb. capsulatus crtB* mutant, but not a *crtE* mutant, with a tomato phytoene synthase cDNA was also demonstrated (Bartley et al., 1992). These results together imply that a *crtE* mutant should accumulate FPP (Fig. 1) (see section VI. A).

Although a *crtJ* transposon mutant accumulated GGPP *in vitro*, *crtJ* was not definitively assigned to the biosynthetic pathway for several reasons

(Armstrong et al., 1990c). Previous observations had suggested that this mutation could not be complemented *in trans* in *Rb. capsulatus* (Zsebo, 1984), the *crtJ* gene had not yet been characterized in detail, and an unidentified substance was found to accumulate along with GGPP in the *in vitro* assay (Armstrong et al., 1990c). It has also been recently demonstrated that a site-directed insertion mutation in *crtJ* does not affect carotenoid biosynthesis (Bollivar et al., 1994).

4. Nucleotide Sequences

Physical mapping of pRPS404 culminated in the nucleotide sequence determination of an 11 kb region of the *Rb. capsulatus* photosynthesis gene cluster containing a subcluster of eight genes devoted to carotenoid biosynthesis (Fig. 2) (Armstrong et al., 1989). Independent nucleotide sequencing of *crtI* and the 3' portion of *crtF* confirmed these results (Bartley and Scolnik, 1989; Young et al., 1989). The existing genetic-physical maps of the *crt* gene cluster (Taylor et al., 1983; Zsebo and Hearst, 1984; Giuliano et al., 1986, 1988) and the high resolution mapping of previously described and newly generated transposon mutations (Armstrong et al., 1990c) permitted the alignment of open reading frames (ORFs) present in the DNA sequence with the known genetic loci (Armstrong et al., 1989). The only difficulty in this analysis came with the discovery of a previously unknown ORF located between the convergently oriented *crtB* and *crtC* genes, and predicted to be transcribed in the same direction as *crtB* (Fig. 2). An interposon mutation resulting in a *crtC* mutant phenotype (Giuliano et al., 1988) was proposed to interrupt the new ORF because of the location of a restriction site at which the interposon had been reported to be inserted (Armstrong et al., 1989). This ORF was therefore named *crtK* (Armstrong et al., 1989), to reflect the green phenotype of neurosporene accumulation reported for the interposon mutant (Giuliano et al., 1988). As with *crtJ*, the assignment of *crtK* to the biosynthetic pathway remained provisional pending a more detailed characterization of the gene function. The nucleotide sequence of the entire 46 kb *Rb. capsulatus* photosynthesis gene cluster from pRPS404, including *crtJ*, has recently become available (Burke et al., 1991; Chapter 50 by Alberti et al.).

Because pRPS404 carries the *crtD223* point mutation, the *crtD* gene sequence determined was that of the mutant allele (Armstrong et al., 1989;

Fig. 2. *Rhodobacter* carotenoid biosynthesis gene clusters. Only sequenced regions are shown. *crt* genes, *bch* genes and genes of uncertain function are shaded gray, black and white, respectively. For simplicity of illustration, genes encoded in the regions flanking ORF 469/*pps*, 3' to *bchl* and 3' to *bchC* are not shown. Gene orientations are as indicated. The region of the *Rb. capsulatus* photosynthesis gene cluster depicted represents nucleotide positions 14800 to 16209 for ORF 469/*pps* and positions 25861 through 36868 for *bchl* through *bchC* (Armstrong et al., 1989; Burke et al., 1991). A sequencing error which revealed the existence of *bchl* is indicated (white triangle) (Armstrong et al., 1993b; Young et al., 1992). Possible σ^{70} -type promoters (P), palindromic regulatory sequences (R) (Armstrong et al., 1989) and operons are shown (arrows) (Giuliano et al., 1988; Young et al., 1989; Armstrong et al., 1990c, 1993b). Of the *Rb. capsulatus* genes depicted, most display increased (2- to 12-fold) mRNA accumulation during photosynthetic adaptation (Armstrong et al., 1993b). The exceptions are *crtI* and *crtB*, whose mRNA levels remain constant, and ORF 469/*pps* and *bchl*, which have not been tested. In *Rb. sphaeroides*, *crtD*, a portion of *crtC* and *bchC* have been sequenced (Gari et al., 1992b; McGlynn and Hunter, 1993). *crtA*, *crtB*, *crtE*, *crtF* and *crtI* have been physically mapped and are organized as shown for *Rb. capsulatus* (Pemberton and Harding, 1986; Coomber et al., 1990; Gari et al., 1992a).

Burke et al., 1991). Based on sequence homologies between CrtD and other proteins (see section V. B.), a specific proposal was made that the *crtD223* allele arose from a nucleotide exchange of G to A in the first position of codon 13, causing a mutation of Gly to Arg at a critical location within a putative CrtD ADP-binding fold (Armstrong et al., 1990a). Recent sequencing of a portion of the wild type *crtD* gene from genomic DNA of *Rb. capsulatus* strain B100 confirms this proposal, although the presence of additional mutations in other portions of the *crtD223* nucleotide sequence cannot be excluded (M. Alberti, personal communication).

The *Rb. capsulatus crtA* gene was recently resequenced and a frameshift error was discovered with respect to the originally reported wild type sequence (Armstrong et al., 1989, 1993b; Young et al., 1992). The results of high resolution mapping of *crtA* and *bchl* transposon mutations resulting in drastically different phenotypes motivated this effort (Armstrong et al., 1990c). The *crtA* mutant synthesized BChl while the *bchl* mutant did not, although the mutations were physically mapped to the 5' and 3' ends of the same ORF, respectively. In addition, higher plant (Koncz et al., 1990) and algal (Orsat et al., 1992) proteins were found to be homologous to the C-terminus but not the N-terminus of the predicted CrtA protein (Armstrong et al., 1993b). Correction of the frameshift splits the long ORF originally proposed to encode CrtA into 5' and

3' ORFs corresponding to *crtA* and *bchl*, respectively (Fig. 2). The ORF downstream of *bchl*, originally termed ORF H (Armstrong et al., 1989), appears to correspond to *bchD*. Evidence discussed elsewhere in detail suggests that *bchD*-*bchl* and the *Arabidopsis thaliana bchl* counterpart encode components of the Mg-chelatase, an enzyme which inserts Mg into protoporphyrin IX in the first committed step of BChl/Chl synthesis (Koncz et al., 1990, 1992; Armstrong et al., 1993b).

The translation start for *crtI* also lies farther 5' than originally reported (Armstrong et al., 1989); this fact became clear by extending the alignment of the deduced sequences for CrtI and CrtD (Armstrong et al., 1990b), and for CrtI and *Neurospora crassa* Al-1, the fungal phytoene dehydrogenase (Bartley and Scolnik, 1989; Schmidhauser et al., 1990). This result was confirmed by complementation of an *Rb. capsulatus crtI* mutant with a construct using an upstream ATG start codon for translation of *crtI* mRNA (Bartley et al., 1990).

B. *Rb. sphaeroides*

1. Genetic and Physical Mapping

In parallel to the efforts with *Rb. capsulatus*, a genetic exchange system based on broad host range plasmid-mediated chromosome transfer was developed in *Rb. sphaeroides* (Sistrom, 1977; Pemberton and Bowen,

1981). This system was used to demonstrate the genetic clustering of photosynthesis genes, including *Rb. sphaeroides crtA*, *crtB*, *crtC*, *crtD*, *crtE* and *crtF*, which were identified by analogy to the corresponding *Rb. capsulatus* mutant genotypes and phenotypes. Two overlapping cosmids that between them complemented all of the *crt* mutations were isolated and used to construct a rough physical map of the *crt* genes in *Rb. sphaeroides* wild type strain RS6258 (Pemberton et al., 1986).

Transposon mutagenesis of *Rb. sphaeroides* wild type strain 8253 using a Tn5-suicide plasmid allowed the isolation of a number of mutants with photosynthesis gene defects (Coomber et al., 1990). Mutant complementation and pigment characterization led to the construction of a high-resolution genetic-physical map of the photosynthesis gene cluster, similar to that established earlier in *Rb. capsulatus* (Zsebo and Hearst, 1984). *Rb. sphaeroides crtA*, *crtB*, *crtC*, *crtD*, *crtE* and *crtI* mutants were characterized but no *crtF* mutants were isolated (Coomber et al., 1990). A physical map of the *Rb. sphaeroides crtA*, *crtB*, *crtC*, *crtD*, *crtE* and *crtF* genes from the prototypical wild type strain 2.4.1 (Griffiths and Stanier, 1956; Cohen-Bazire et al., 1957) has recently been reported (Garí et al., 1992a). Thus, the combined results of the genetic and physical mapping from three different strains of *Rb. sphaeroides* revealed the existence of a *crt* gene cluster equivalent in organization and composition to that found in *Rb. capsulatus* (Fig. 2).

2. Gene Assignments and Nucleotide Sequences

The nucleotide sequences of *crtD* and the 5' portion of *crtC* from *Rb. sphaeroides* have recently been published (Garí et al., 1992b). *Rb. sphaeroides* and *Rb. capsulatus crtD* display 63% nucleotide sequence identity. An *Rb. sphaeroides* equivalent of *Rb. capsulatus crtK* has also been identified and sequenced (S. Kaplan, personal communication). *Rb. sphaeroides* CrtK plays, however, no role in carotenoid biosynthesis. The designation ORF 160 therefore replaces *crtK/oxyA* throughout the remainder of this chapter to emphasize this fact. Another *Rb. sphaeroides* gene, *pps*, has been recently sequenced (Penfold and Pemberton, 1994) and shown to be equivalent to *Rb. capsulatus crtJ* (Burke et al., 1991). The *pps* gene plays a role in the suppression of both BChl and carotenoid pigment levels when introduced in *trans* to a functional photosynthetic

pigment gene cluster (Penfold and Pemberton, 1991, 1994). Recent experiments have demonstrated that *Rb. capsulatus crtJ* is not required for carotenoid biosynthesis and that the original *crtJ* transposon mutant described (Zsebo and Hearst, 1984) probably contains a second site *crt* mutation resulting in the observed blue-green phenotype (Bollivar et al., 1994). The nomenclature ORF 469/*pps* therefore replaces *crtJ* throughout the remainder of this chapter (see section IV. A. 2.).

C. *Rs. centenum* and *Rs. rubrum*

1. Genetic and Physical Mapping

Rhodospirillum centenum has recently been introduced as another suitable system in which to explore the genetics of bacterial photosynthesis (Yildiz et al., 1991, 1992). Work is in progress to obtain photosynthetic pigment mutants and to map the corresponding genes. Thus far, several *crtI*-like phytoene accumulating mutants have been isolated (Yildiz et al., 1991) and heterologous in vivo complementation of an *Rb. capsulatus crtF* mutant with a portion of the *Rs. centenum* photosynthesis gene cluster has been demonstrated (Yildiz et al., 1992). *Rs. centenum* and *Rs. rubrum*, two closely related species, use a carotenoid biosynthetic pathway thought to partially overlap that of the more distantly related *Rb. capsulatus* and *Rb. sphaeroides* (Fig. 1). Divergence at the level of neurosporene or hydroxyspheroidene gives rise to spirilloxanthin as the end product (Schmidt, 1978). Thus, homologs of *Rhodobacter crtB*, *crtC*, *crtD*, *crtE*, *crtF* and *crtI* might be expected in *Rs. centenum* and *Rs. rubrum*. Preliminary mapping of the photosynthesis gene cluster in the latter bacterium has also been described (Sägesser, 1992; Bauer et al., 1993a).

D. Genomic Organization

1. Operons and Superoperons

The nucleotide sequence of the *Rb. capsulatus crt* gene cluster (Fig. 2) revealed gene orientations and suggested the possible existence of several operons (*crtDC*, *crtEF*, *crtIBORF 160*, *crtA*) (Armstrong et al., 1989). In *Rb. sphaeroides*, the orientations of most of the *crt* genes remain to be established although nucleotide sequencing of *crtD*, *crtI*, *crtB* and the 5' coding region of *crtC* has revealed a gene arrangement identical to *Rb. capsulatus* (Garí et al., 1992b; Lang

et al., 1994). The phenotypes resulting from interposon and transposon mutations in *Rhodobacter crtD* and *crtC* indicate that these genes do not form an obligate operon (Giuliano et al., 1988; Coomber et al., 1990; Garí et al. 1992a). Transcription of *crtF* requires the presence of the *crtE* 5' noncoding region, suggesting the existence of a *crtEF* operon (Young et al., 1989). The situation with *crtIBORF* 160 is somewhat more complicated; cotranscription of ORF 160 with *crtIB* does not seem to be obligatory, because the patterns of *crtIB* and ORF 160 mRNA accumulation differ substantially upon a shift from aerobic to photosynthetic growth conditions (see section IV C.3.) (Armstrong et al., 1993b). Differential stabilities of various portions of the same transcript cannot be excluded, however (Belasco et al., 1985). With respect to a *crtIB* operon, *Rb. capsulatus crtI* point mutants accumulate phytoene (Giuliano et al., 1986) while *crtI* interposon mutants do not (Giuliano et al., 1988). Both kinds of phenotypes are observed among *Rhodobacter crtI* transposon mutants (Armstrong et al., 1990c; Coomber et al., 1990). The simplest explanation for these results, in agreement with the physical organization of these genes (Fig. 2) is that *crtIB* form an operon and that not all *crtI* insertion mutations are polar (Armstrong et al., 1993b; Lang et al., 1994). Cotranscription of *crtA* with *bchl* does not seem to be obligatory, as *crtA* transposon and interposon mutants produce BChl and grow photosynthetically (Giuliano et al., 1988; Armstrong et al., 1990c), in contrast to a BChl-deficient *bchl* transposon mutant (Zsebo and Hearst, 1984).

The *Rb. capsulatus* photosynthesis gene cluster consists of a series of operons embedded within superoperons, which seems to provide for a low level of expression of pigment biosynthesis enzymes and pigment-binding polypeptides during aerobic growth (reviewed in Wellington et al., 1992). This mechanism apparently enables the bacteria to adapt more rapidly during a transition to anaerobic photosynthetic conditions. *crtEF* was shown to be the 5'-most operon in a superoperon encompassing *crtEFbchCXYZ-pufQBALMX* (Young et al., 1989; Burke et al., 1993; Chapter 57 by Beatty). The participation of *crtD*, *crtC*, ORF 160, *crtIB* in superoperons of the type mentioned above seems to be excluded because of the physical arrangement of the genes. *crtA*, on the other hand, could potentially contribute to a superoperon containing downstream *bch* genes (see section III. A. 4.).

2. Carotenoid Biosynthesis Gene Clusters

Data thus far in *Rhodobacter* indicate that the *crtA*, *crtB*, *crtC*, *crtD*, *crtE*, *crtF* and *crtI* genes are clustered, that this *crt* subcluster is embedded within a larger cluster of genes devoted to photosynthesis, and that the overall gene organization is very similar in two species (Fig. 2). Partial genetic-physical maps in *Rs. centenum* and *Rs. rubrum* support these conclusions (Bauer et al., 1993a). Carotenoid biosynthesis gene clusters are also found in nonphotosynthetic bacteria, including *Erwinia* species (Armstrong et al., 1990a; Misawa et al., 1990; Hundle et al., 1991; Armstrong, 1994).

All of the *crt* gene clusters described thus far contain *crtE*, *crtB* and *crtI* homologs that encode enzymes catalyzing the early reactions in carotenoid biosynthesis common to most carotenogenic organisms (Fig. 1) (Armstrong et al., 1990a). A comparison of the *crt* gene clusters from the nonphotosynthetic and photosynthetic bacteria reveals that the location and transcriptional orientation of the *crtE* gene, encoding GGPP synthase, varies between species. On the other hand, the arrangement of the *crtI* and *crtB* genes, encoding phytoene dehydrogenase and phytoene synthase, respectively, is identical to that observed in photosynthetic bacteria (Fig. 2). Furthermore, in the cyanobacterium *Synechococcus* PCC7942 this arrangement of the cognate genes encoding phytoene dehydrogenase (*crtP*) and phytoene synthase (*crtB*) has also been conserved (Chamovitz et al., 1992), although the phytoene dehydrogenases encoded by *crtI* and *crtP* are proposed to have evolved independently (Pecker et al., 1992). Whether the conserved physical arrangement of *crtI/crtP* and *crtB* has a functional significance has not been tested.

IV. Regulation of Carotenoid Biosynthesis

A. Carotenoid Accumulation

1. Environmental Factors

In anoxygenic photosynthetic bacteria, anaerobiosis initiates a variety of processes, including pigment, protein and lipid synthesis, accompanied by changes in gene expression (reviewed in Kiley and Kaplan, 1988). These processes culminate in the formation of a functional photosynthetic membrane. Because

the coordination of membrane development ensures that the supplies of the individual components remain in balance, abnormalities in carotenoid or BChl accumulation can have pleiotropic effects on the accumulation of the RC and LH pigment-binding polypeptides or on the spectral characteristics of these complexes (Griffiths and Stanier, 1956; Marrs, 1982; Dierstein, 1983; Kaufmann et al., 1984; Zsebo and Hearst, 1984; Klug et al., 1985; Bartley and Scolnik, 1989; Yildiz et al., 1991).

The accumulation of BChl and carotenoid pigments can be influenced by environmental stimuli, particularly oxygen and light, in the anoxygenic photosynthetic bacteria. The classic study of Cohen-Bazire et al. (1957) demonstrated that both oxygen and light strongly influence carotenoid accumulation in *Rb. sphaeroides*, results which also apply to *Rb. capsulatus*. In these species a down shift in light intensity with photosynthetically growing cells triggers transient increases in carotenoid accumulation until a new steady-state with a higher specific carotenoid content has been achieved. A downshift in oxygen tension using dark aerobically grown cells produces much the same result, with or without accompanying illumination. Low oxygen tension thus initiates photosynthetic membrane synthesis, while a reduction in light intensity expands the size of the photosynthetic light-harvesting antenna (Kiley and Kaplan, 1988).

Steady-state BChl concentrations increase dramatically in *Rb. capsulatus* cells grown under decreasing oxygen tensions from 20 to 0% (Clark et al., 1984). The accompanying several-fold increase in carotenoid content has been argued to be an indirect effect of oxygen on BChl or some other component of the photosynthetic membrane (Clark et al., 1984; Biel and Marrs, 1985). Only marginal increases in carotenoid content were seen in *bch* mutants of *Rb. capsulatus* shifted to low oxygen tension (Biel and Marrs, 1985). Two problems prevent a straightforward interpretation of these data, however. First, *bch* mutations in *Rb. capsulatus* or *Rb. sphaeroides* reduce carotenoid content to about 25% of the wild type levels (Biel and Marrs, 1985; Penfold and Pemberton, 1991). In the anoxygenic photosynthetic bacteria nothing is known about carotenoid turnover or the binding sites of the carotenoids found in cells lacking a photosynthetic membrane, such as *bch* mutants or the wild type cultured aerobically under 20% oxygen tension. As *bch* mutants lack BChl, and hence stable LH I and LH II antenna

complexes (Dierstein, 1983; Zsebo and Hearst, 1984; Klug et al., 1985), the major known carotenoid binding sites in the photosynthetic membrane no longer exist. Furthermore, the concentration of potential endogenous photosensitizers (i.e. BChl precursors) which might interact with the carotenoid pool differs between *bch* mutants and the wild type. Therefore, the assumption of similar carotenoid turnover rates cannot be made with confidence.

Little is known about the influence of environmental factors other than light intensity and oxygen tension on carotenoid biosynthesis and accumulation. Both iron excess and iron deficiency in the growth medium alter the carotenoid composition in *Rb. capsulatus* (Nelis and De Leenheer, 1989a). A novel mixture of *cis* and all-*trans* isomers of spheroidenone (Fig. 1) has been tentatively identified in axenically grown cultures subjected to iron excess.

2. Genetic Factors

Spontaneous green mutants of *Rb. sphaeroides*, exemplified by strain Ga, have been known from the inception of genetic studies with photosynthetic bacteria (Cohen-Bazire et al., 1957). Ga accumulates methoxyneurosporene, hydroxyneurosporene and neurosporene (Fig. 1), and therefore is classified as a *crtD* mutant (Scolnik et al., 1980). In a survey of wild type isolates of *Rb. capsulatus*, one of 33 strains examined displayed an *in vivo* absorption spectrum typical for a green *crtD* or *crtC* mutant (Weaver et al., 1975). Various researchers have been unable to discern any differences in growth rates or pigment-protein complexes, other than carotenoid composition, distinguishing *crtD* mutants and wild type strains accumulating spheroidene and spheroidenone (eg. Cohen-Bazire et al., 1957; Marrs, 1982; Armstrong et al., 1990c). Any selective advantage imparted by the synthesis of these wild type carotenoids may thus be subtle and/or function only under certain growth conditions. The molecular basis for the high frequency (10^{-5}) appearance and reversion of spontaneous green *crtD* mutants in the *Rb. sphaeroides* wild type strain 2.4.1 has recently been elucidated (Gari et al., 1992a). The reversible addition of a G residue to a stretch of seven G's found within the 5' coding region of *crtD* leads to a frameshift mutation. Interestingly, this mechanism appears to be strain-specific.

In contrast to the weak or nonexistent selection against *crtD* mutations, *crtF* mutations are subject to strong negative selective pressure (Taylor et al., 1983).

Two classes of secondary mutations appear in *Rb. capsulatus crtF* mutants, namely earlier blockages in carotenoid biosynthesis, and *bch* or other mutations which completely abolish the accumulation of photosynthetic pigment-protein complexes. Although the biological significance of this phenomenon is not clear, the apparent negative selection against the accumulation of demethylspheroidene and demethylspheroidenone in *crtF* mutants may explain why this gene escaped detection in random transposon mutagenesis schemes used in *Rhodobacter* (Zsebo and Hearst, 1984; Coomber et al., 1990).

With respect to regulatory genes, no mutant with a genetic defect leading to a quantitative change in carotenoid levels independent of other components of the photosynthetic membrane has been described. The *Rb. sphaeroides pps* gene, homologous to *Rb. capsulatus* ORF 469, represses both BChl and carotenoid pigment accumulation when expressed in *trans* to a functional photosynthetic gene cluster resident in or introduced into *Rb. capsulatus*, *Rb. sphaeroides* or *Paracoccus denitrificans* (Penfold and Pemberton, 1991, 1994). In addition, the repression of carotenoids functions even in a *bch* mutant background and therefore independently of BChl.

An *Rb. sphaeroides* mutant, TA-R, displayed inappropriate regulation of both BChl and carotenoid accumulation by derepressing pigment synthesis under dark aerobic conditions (Lascelles and Wertlieb, 1971). More recently the *Rb. sphaeroides* T1_a mutant, which is defective at a locus termed *oxyB*, was found to accumulate spectroscopically intact LH II antenna complexes containing BChl and carotenoids under aerobic growth conditions (Lee and Kaplan, 1992b). Because the stability of the photosynthetic LH and RC pigment-protein complexes depends on interactions between BChl, carotenoids and various polypeptides, it is difficult to predict what the targets of these regulatory genes might be. *Rs. centenum* provides an interesting experimental system because this bacterium possesses a functional photosynthetic membrane with all of the usual pigment and protein components when cultured under high oxygen tension (Yildiz et al., 1991). Wild type *Rs. centenum* thus resembles the *Rb. sphaeroides* TA-R and T1_a mutants.

The function of ORF 160, which was originally thought to have a biosynthetic role in carotenoid synthesis, is unknown (S. Kaplan, personal communication). Interestingly, *Rb. capsulatus* ORF 160 mRNA increases 8-fold in response to the shift

from aerobic growth to anaerobic photosynthesis (see section IV. C. 3.) (Armstrong et al., 1993b).

B. Carotenoid Biosynthesis Enzymes

Virtually nothing is known about the regulation of carotenoid biosynthesis enzyme levels or activities in the anoxygenic photosynthetic bacteria. The biochemical intractability of the membrane-bound enzymes which convert phytoene into later carotenoids have hindered attempts at enzyme purification (reviewed in Bramley, 1985). No carotenoid biosynthesis enzyme from these organisms has yet been purified to homogeneity.

CrtI from *Rb. capsulatus* and *Rb. sphaeroides* has been overexpressed in *Escherichia coli* (Schmidt et al., 1989; Bartley and Scolnik, 1989; Lang et al., 1994). Antibodies raised against a CrtI-LacZ fusion protein (Schmidt et al., 1989) as well as a truncated version of CrtI have been described (Bartley and Scolnik, 1989). In vitro phytoene dehydrogenation in solubilized membranes of *Aphanocapsa* PCC 6714 was inhibited by the antibody against the *Rb. capsulatus* CrtI-lacZ fusion protein (Schmidt et al., 1989). Inducible overexpression of CrtI in a *crtI* blue-green mutant of this organism produced some surprising results (Bartley and Scolnik, 1989). The uninduced bacteria carrying the expression construct contained immunologically negligible levels of CrtI, compared to the wild type, yet these cells displayed wild type pigmentation. Furthermore, the massive induced overexpression of CrtI had no effect on carotenoid levels. The roughly constant in vivo accumulation of carotenoids over a large range of CrtI concentrations strongly suggests that this enzyme does not catalyze a rate-limiting step in *Rb. capsulatus* carotenoid biosynthesis. Curiously, overproduction of CrtI resulted in higher than normal levels of BChl and LH II complex (Bartley and Scolnik, 1989). Whether this represents a specific interaction of CrtI with the LH II complex or results from unspecific interactions is unknown. The *crtI* mutant used for the in vivo complementation also carried a *crtF* mutation, so that this result was obtained in a situation leading to the synthesis of *crtF*-type carotenoids (Fig. 1). Recently, Lang et al. (1994) have also overexpressed the *Rb. sphaeroides crtI* gene product in *E. coli* and shown that a cell free extract will catalyze three desaturations of phytoene to give neurosporene. The reaction was shown to be ATP-dependent.

With respect to cofactor requirements for

carotenoid biosynthesis (Schmidt, 1978), *CrtA* in *Rhodobacter* mediates the conversion of (demethyl)-spheroidene to (demethyl)spheroidenone under aerobic conditions in a reaction requiring molecular oxygen (Fig. 1). The O-methylation of carotenoids, mediated by *CrtF*, requires SAM as a cofactor. Both oxygen and endogenous SAM levels could therefore provide regulatory points for carotenoid biosynthesis. The function of the aerobic conversion of spheroidene to spheroidenone is not known. Because *crtD* mutants of *Rhodobacter* never synthesize spheroidene and yet seem subject to little or no selective disadvantage compared to the wild type, the significance of the reactions carried out by *CrtA*, and for that matter *CrtD*, remains unclear. The *Rb. capsulatus ahcY* gene, which encodes an enzyme required for the conversion of SAH to SAM, has been shown to be essential for the presence of normal levels of BChl and LH complexes (Sganga et al., 1992). The proposal has therefore been made that the intracellular ratio of SAM:SAH affects BChl biosynthesis at the level of the methylation of Mg-protoporphyrin IX. It is conceivable that the O-methylation of carotenoids could also be controlled by a similar phenomenon.

Finally, the metabolic balance between isoprenoid requirements for carotenoid and BChl biosynthesis must be regulated in some fashion (Fig. 1). Whether the branch point in these pathways occurs at the level of GGPP, as commonly assumed, or even earlier is discussed in section VI. A.

C. *crt* Gene Regulation

1. Regulation of Other Photosynthesis Genes

The fundamental mechanisms underlying the regulation of *crt* genes in photosynthetic bacteria are unknown. In comparison, much progress has been made in studies of the regulation of the synthesis of structural polypeptides of the photosynthetic membrane in response to light and oxygen tension. One current model for the anaerobic induction of mRNAs from the highly expressed *Rb. capsulatus puf*, *puh* and *puc* operons incorporates a membrane-bound oxygen sensor (RegB) and a cytoplasmic regulator (RegA) (reviewed in Bauer et al., 1993b and by Bauer in Chapter 58). This model does not explain the moderate anaerobic induction of *crt* and *bch* pigment biosynthesis operons, however (Biel and Marrs, 1983; Giuliano et al., 1988; Armstrong and Hearst, 1989; Young et al., 1989; Sganga and

Bauer, 1992; Armstrong et al., 1993b; Ma et al., 1993).

2. Promoter Activities

E. coli σ^{70} promoter-like sequences are present in the 5' noncoding regions of *Rb. capsulatus crtD*, *crtI* and *bchC* (Armstrong et al., 1989; Young et al., 1989; Ma et al., 1993). Because σ^{70} promoter-like sequences are not found 5' to the *regA*-regulated operons, the proposal has been made that differences in promoter structure between the *puf*, *puh* and *puc* genes versus the *crt* and *bch* genes may account for the *regA*-independent regulation of the latter (Sganga and Bauer, 1992; Bauer et al., 1993b; Ma et al., 1993; Chapter 58 by Bauer). Little is known experimentally about the structure of *bch* and *crt* promoters, however. Site-directed mutagenesis of a putative σ^{70} promoter for the *bchCXYZ* operon confirms that transcription initiation requires this sequence (Ma et al., 1993). On the other hand, no *crt* promoter has yet been functionally defined in any detail. Furthermore, given our current knowledge of the operon structure of the *crt* gene cluster, *crtD* and *crtI* σ^{70} promoter-like sequences would only be sufficient to direct transcription of *crtD* and *crtIB* (Fig. 2). No obvious recognition sites for alternative σ subunits have yet been observed in the 5' noncoding regions of other *crt* genes (*crtA*, *crtC*, *crtEF*). A palindromic sequence resembling the consensus binding site for many prokaryotic DNA-binding regulatory proteins has been identified in 5' noncoding regions of *Rb. capsulatus crtD*, *crtE*, *crtI*, *crtA*, *bchC*, and the *puc* operon (Fig. 2) (Armstrong et al., 1989; Ma et al., 1993). The palindrome seems to play a role in the regulation of the *bchC* promoter (Ma et al., 1993) and the *Rb. sphaeroides puc* promoter (Lee and Kaplan, 1992a), probably in conjunction with other *cis* elements in both cases, and could be a functional element in *crt* promoters.

The activities of several *Rb. capsulatus crt* promoters have been studied using translational or transcriptional fusions to the *E. coli lacZ* gene, although the regulatory sequences have not yet been defined in detail. Translational fusions of a *crtE* promoter fragment to *lacZ* yielded a 3-fold upregulation in response to anaerobiosis (Young et al., 1989). This promoter has been proposed to contain two transcription initiation sites, one anaerobically induced and the other constitutive (Giuliano et al., 1988). DNA fragments containing the *crtA* or *crtI*

promoters were transcriptionally fused to the *lacZ* gene and demonstrated to be upregulated 2-fold or unregulated, respectively, during the adaptation from aerobic to anaerobic photosynthetic growth (Armstrong et al., 1993b). These limited data indicate modest oxygen regulation of several *crt* promoters and are qualitatively consistent with the patterns of mRNA accumulation (see below) for the corresponding genes during the adaptation from aerobic to anaerobic photosynthetic growth (Armstrong et al., 1993b). While the *crtA* promoter seems to be only 2-fold inducible by anaerobiosis, the amount of *crtA* mRNA increases about 12-fold; several possible explanations exist, including posttranscriptional regulation.

pRPS404 carries all of the known *Rb. capsulatus* *crt* genes but does not direct carotenoid accumulation in the noncarotenogenic bacteria *E. coli* and *Pseudomonas fluorescens* (Marrs, 1981). On the other hand, introduction of the *Rb. sphaeroides* *crt* gene cluster into several species of phylogenetically related noncarotenogenic bacteria (*P. denitrificans*, *Agrobacterium tumefaciens*, *Agrobacterium radiobacter*, *Azotomonas insolita*) results in carotenoid production (Pemberton and Harding, 1987). The *Rb. sphaeroides* *pps* gene exerts a negative effect on carotenoid and BChl levels when supplied in *trans* to chromosomal or plasmid-borne pigment biosynthesis genes in *Rb. capsulatus* and *P. denitrificans* (Penfold and Pemberton, 1991, 1994), and *Rs. centenum* DNA complements an *Rb. capsulatus* *crtF* mutation in vivo (Yildiz et al., 1992). Thus, successful heterologous expression of *crt* genes may depend on the evolutionary distance between the species involved.

3. mRNA Accumulation

The regulation of *crt* mRNA accumulation has thus far been examined only in *Rb. capsulatus*. Early mRNA accumulation studies performed before the *crt* genes had been sequenced utilized hybridization probes which overlapped several genes. These studies indicated little or no induction of *crt* and *bch* mRNA levels, in contrast to the 10 to 40-fold induction of *puf*, *puh* and *puc* mRNAs, during shifts from aerobic growth to low oxygen or anaerobic photosynthetic conditions (Clark et al., 1984; Klug et al., 1985; Zhu and Hearst, 1986). The most defined results, in terms of the DNA probes used, indicated qualitative upregulation of the *crtA*, *crtC*, *crtE* mRNAs and

constant levels of *crtI* mRNA in response to the removal of oxygen from a bacterial culture maintained under continuous illumination (Giuliano et al., 1988). Two *crtE* mRNA species were found, one of which appeared only under anaerobic conditions.

A more quantitative study to determine the temporal patterns of *crt* mRNA accumulation with gene-specific probes has also been performed (Armstrong et al., 1993b). The shift from aerobic to anaerobic photosynthetic growth induced transient 2- to 12-fold increases in mRNA accumulation for *crtA*, *crtC*, *crtD*, *crtE*, *crtF* and ORF 160, temporally coordinated with increases in mRNAs from other photosynthesis genes (3–5 fold for *bch*; 6- to 8-fold for *puf* and *puc*; 25-fold for *puc*) (Armstrong and Hearst, 1989; Cook et al., 1989; Armstrong et al., 1993b). mRNA levels for *crtB* and *crtI* remained constant, however. Light did not qualitatively affect the accumulation of *crtA* mRNA. The *crt* mRNAs that increased under anaerobic conditions encode biosynthetic enzymes either early (*crtE*) or late (*crtC*, *crtD*, *crtF*, *crtA*) in the biosynthetic pathway. This suggests that transcriptional regulation of the *crt* genes could play a role in boosting overall biosynthetic capability for the synthesis of GGPP and for the conversion of neurosporene to the final products (Fig. 1). The 12-fold induction of *crtA* mRNA by anaerobiosis (Armstrong et al., 1993b) is particularly noteworthy because CrtA requires molecular oxygen as a cofactor (Schmidt, 1978). An earlier study supplied some evidence that *crtA* mRNA also increases 2-fold in response to a shift from anaerobic photosynthetic to aerobic conditions, although a gene-specific probe was not used (Zhu et al., 1986). In contrast to the lack of regulation of *crtI* mRNA accumulation in *Rb. capsulatus* (Giuliano et al., 1988; Armstrong et al., 1993b), *Rb. sphaeroides* *crtI* mRNA has recently been reported to increase in abundance during anaerobiosis (Lang et al., 1994).

A striking result from the above investigations is the quantitative similarity in the anaerobic accumulation of mRNAs from several *crt* operons compared to the *puf* and *puh* operons (Cook et al., 1989; Armstrong et al., 1993b). Comparisons with other studies, even those using the same approaches, are complicated by differences in the growth conditions, strains, and experimental techniques used. Nonetheless, the current conventional wisdom regarding the regulation of photosynthesis genes says that expression of the *puf*, *puh*, and *puc* operons occurs at much higher levels and is subject to a more stringent

control by oxygen than is observed for *crt* and *bch* operons (Bauer et al., 1993b; Chapter 58 by Bauer). While the former premise is unquestionably correct (Young et al., 1989; Sganga and Bauer, 1992), the latter may not always hold true (Cook et al., 1989; Armstrong et al., 1993b).

V. Functional and Structural Conservation of the *crt* Gene Products

A. The Utility of Deduced Amino Acid Sequences

Almost nothing is known directly about the *crt* gene products because the later reactions in carotenoid biosynthesis occur in membranes and the corresponding enzymes have not proven amenable to isolation, purification or characterization (Bramley, 1985). At the time that the sequence of the *Rb. capsulatus crt* gene cluster was published, no other nucleotide sequences for carotenoid biosynthesis genes had been described in the literature (Armstrong et al., 1989). Much has since been learned by comparison of the deduced amino acid sequences of the *Rb. capsulatus* carotenoid biosynthesis enzymes with each other and with other protein sequences present in the databases (eg. Armstrong et al., 1993a; Armstrong, 1994). Probable homology between two sequences can, in general, be said to exist when the overall identity exceeds approximately 25% for sequence alignments of a few hundred amino acids. By this criterion, homologs of *Rb. capsulatus* CrtB, CrtC, CrtD, CrtE, CrtF, CrtI and ORF 160 exist in other organisms (Table 1). CrtB, CrtD, CrtE, CrtF, CrtI and ORF 469/Pps also contain specific local sequence motifs probably related to the structures and functions of these proteins (see below) (Armstrong et al., 1993a). On a cautionary note, the deduced characteristics of all of the *crt* gene products must ultimately be confirmed by studying the purified proteins. *Rb. capsulatus* CrtI has been overexpressed (see section IV B.), though not as an active enzyme (Bartley and Scolnik, 1989; Schmidt et al., 1989). In vivo complementation of carotenoid biosynthetic mutants of *Rb. capsulatus* with heterologous eukaryotic cDNAs has been used successfully to study the conservation of phytoene dehydrogenase and phytoene synthase enzyme functions (Bartley et al., 1990, 1991, 1992). More recently, enzymatic activity has been demonstrated for *Rb. sphaeroides* CrtI that has been overexpressed in *E. coli* (Lang et al., 1994).

B. Dehydrogenases (CrtD, CrtI)

Rb. capsulatus CrtI and CrtD, the phytoene and methoxyneurosporene dehydrogenases, respectively, were the first two carotenoid biosynthesis enzymes demonstrated to share conserved features with other proteins, in this case with each other (Armstrong et al., 1989). CrtI and CrtD dehydrogenate distinct but related carotenoid intermediates and were therefore expected to exhibit some sequence similarity. Phytoene is an intermediate in carotenoid biosynthesis in most organisms (Fig. 1), whereas methoxyneurosporene and hydroxyneurosporene are restricted to a few species of bacteria (Goodwin, 1980).

Comparison of the deduced amino acid sequences for CrtI and CrtD revealed 27% overall sequence identity (Table 1), with two highly conserved regions found at the respective N- and C-termini of the proteins (Armstrong et al., 1989). Shortly thereafter, deduced phytoene dehydrogenase sequences from two nonphotosynthetic bacteria, *Erwinia herbicola* and *Erwinia uredovora* (Armstrong et al., 1990a; Misawa et al., 1990), and a fungus, *N. crassa* (Bartley et al., 1990), were found to be conserved with *Rb. capsulatus* CrtI and, to a lesser extent, with CrtD. These findings supported the proposed conserved nature of the early enzymes of carotenoid biosynthesis in photosynthetic and nonphotosynthetic prokaryotes and eukaryotes, as hypothesized in the comparison of the *Rb. capsulatus* and *Ec. herbicola crt* gene products (Armstrong et al., 1990a). Recently, the characterization of the *Rb. sphaeroides crtD* gene (Garí et al., 1992b) and genes encoding carotenoid dehydrogenases from *Myxococcus xanthus* have been reported (Table 1). The *Rb. capsulatus* and *Rb. sphaeroides* CrtD proteins are 55.6% identical. Other carotenoid dehydrogenases display between 26–30% sequence identity with *Rb. capsulatus* CrtD, whereas identities of other phytoene dehydrogenases with *Rb. capsulatus* CrtI range from 25–40%. *N. crassa* A1-1 (Schmidhauser et al., 1990), was shown to complement an *Rb. capsulatus crtI* carotenoid biosynthesis mutant in vivo, producing novel fungal carotenoids in the bacterium (Bartley et al., 1990). Despite this functional complementation, antibodies raised against A1-1 or CrtI did not crossreact with the heterologous enzyme. Antibodies raised against an *Rb. capsulatus* CrtI-LacZ fusion protein crossreacted weakly with antigens from cyanobacteria, algae and higher plants (Schmidt et al., 1989), although a bell pepper phytoene dehydrogenase antibody did not recognize antigens in a bacterial extract (Huguency et al., 1992).

A revision of the originally proposed *Rb. capsulatus* *crtI* translation start (Hartley and Scolnik, 1989; Armstrong et al., 1990b) exposed the presence of putative ADP-binding folds predicted to have $\beta\alpha\beta$ structures within the conserved N-terminal sequences of the carotenoid dehydrogenases (Table 2) (Armstrong et al., 1990a; Bartley et al., 1990). ADP-binding folds interact with FAD or NAD(P) cofactors in other types of dehydrogenases that contain this structural motif (Scrutton et al., 1990). Conserved features of the *Rhodobacter*, *Erwinia*, and *N. crassa* carotenoid dehydrogenases are illustrated in sequence alignments presented elsewhere (Armstrong et al., 1993a).

Deduced protein sequences for phytoene dehydrogenases from oxygenic photosynthetic organisms, including cyanobacteria, soybean, tomato and bell pepper have recently been reported (Bartley et al., 1991, 1992; Huguency et al., 1992; Pecker et al., 1992). These proteins show little overall sequence identity to the *Rb. capsulatus*, *Erwinia*, *M. xanthus* and *N. crassa* phytoene dehydrogenases, however. Sequence conservation between the anoxygenic photosynthetic /nonphotosynthetic microbial carotenoid dehydrogenases (CrtI-type and CrtD-type) and the oxygenic photosynthetic phytoene dehydrogenases (CrtP/Pds-type) seems to be restricted to the N-terminal ADP-binding fold (Huguency et al., 1992; Pecker et al., 1992). A major functional difference between these classes of proteins can be seen in the extent of the dehydrogenation of the carotenoid products. CrtI-type phytoene dehydrogenases introduce three or four double bonds consecutively, yielding neurosporene in *Rhodobacter* or lycopene in other organisms, respectively (Bartley et al., 1990). The CrtP/Pds-type phytoene dehydrogenases introduce two double bonds to produce symmetrical ζ -carotene, which is subsequently converted to lycopene by a dehydrogenase distinct from Pds (Bartley et al., 1991; Pecker et al., 1992). The proposal that CrtI-type and CrtP/Pds-type phytoene dehydrogenases represent two functionally similar but evolutionarily independent proteins remains to be established (see section III. D. 2.) (Pecker et al., 1992). It is not known whether the *Rhodobacter* carotenoid dehydrogenases bind FAD or NAD(P) either as a cofactor or for structural reasons, although the bell pepper Pds has recently been isolated with bound FAD (Huguency et al., 1992).

C. Prenyltransferases (CrtB, CrtE)

Rb. capsulatus CrtE and CrtB, the putative GGPP and phytoene synthases, respectively, both utilize isoprenoid pyrophosphate substrates but carry out different types of condensation reactions (Fig. 1). Initial uncertainty as to the biosynthetic functions of CrtE and CrtB in the synthesis of phytoene has now been resolved in experiments with homologous proteins from other prokaryotes (see section III. A. 3.) (Chamovitz et al., 1992; Math et al., 1992; Sandmann and Misawa, 1992). CrtE, CrtB and CrtI were shown to be conserved within the *crt* gene clusters of *Rb. capsulatus* and *Erwinia* species (Armstrong et al., 1989, 1990a; Misawa et al., 1990), presumably because these gene products catalyze reactions in the early portion of the carotenoid biosynthetic pathway common to most organisms (Fig. 1). The *Rb. capsulatus* and *Erwinia* CrtB and CrtE proteins share 30–35% and 27–30% sequence identities, respectively, and thus are not as highly conserved as the CrtI proteins (Table 1).

The prokaryotic CrtB proteins were also found to share about 29% sequence identity with the tomato pTOM5 protein (Armstrong et al., 1990a), encoded by a fruit ripening-associated cDNA of unknown function (Ray et al., 1987). Sequence alignments of these proteins have been presented elsewhere (Armstrong et al., 1993a). Biochemical analysis of transgenic tomato plants expressing an antisense pTOM5 mRNA (Bramley et al., 1992) and in vivo complementation of an *Rb. capsulatus* *crtB* mutant with a pTOM5-related cDNA confirmed the role of this protein as a phytoene synthase (Bartley et al., 1992). Other phytoene synthase sequences have been identified in the *M. xanthus* carotenoid gene cluster and in two species of cyanobacteria (Table 1). Both photosynthetic and nonphotosynthetic organisms have CrtB homologs that are between 27–35% identical to *Rb. capsulatus* CrtB.

The *Rb. capsulatus* and *Erwinia* CrtE proteins were recently found to share sequence identity with several other proteins, including a possible GGPP synthase from *Cyanaphora paradoxa*, FPP synthase from *E. coli*, a sporulation protein from *Bacillus subtilis*, and a hypothetical *E. coli* protein (Table 1). Features of the sequence alignments of these proteins are detailed elsewhere (Armstrong et al., 1993a). *Rb. capsulatus* and *Erwinia* CrtE also share extensive sequence identity with the GGPP synthase from bell pepper (Table 1). The sequence identities of *Rb.*

⁶ Sequence alignments were obtained using the FASTA computer program (Genetics Computer Group (GCG) software package (version 7.0; April, 1991)). Only sequences that yielded a length-dependent *opt* score of at least 10% of the maximum value at 100% identity are listed.

⁷ deduced from a partial nucleotide sequence of the corresponding gene

⁸ deduced from the nucleotide sequence of the *crtD223* mutant allele carried on plasmid pRPS404

capsulatus CrtE with the related proteins range between 26–36%.

Ashby and Edwards (1990) first reported the conservation of two aspartate-rich sequence motifs, termed domains I and II, in eukaryotic prenyltransferases that carry out 1'-4 condensations between homoallylic IPP and allylic prenylpyrophosphates (Fig. 1); only domain II was found in the yeast MOD5 protein, which modifies tRNA by addition of the allylic substrate DMAPP, suggesting that domain II might be the allylic binding site. Both the aspartates and arginine residues found in domain I are thought to be important for prenyltransferase substrate binding and/or catalysis (Ashby and Edwards, 1990; Carattoli et al., 1991; Kuntz et al., 1992; Joly and Edwards, 1993).

In addition to proteins with global sequence identity to *Rb. capsulatus* CrtB and CrtE (Table 1), other proteins exhibit local sequence conservation concentrated in aspartate-rich motifs resembling domains I and II (Table 2) (Armstrong et al., 1993a). *Rb. capsulatus* CrtB, which carries out a 1'-2-3 prenylpyrophosphate condensation of two molecules of GGPP and a 1'-1 rearrangement (Fig. 1), shares a domain II-related sequence not only with phytoene synthases from other organisms but also with squalene synthases from yeast, rat and human (Math et al., 1992; Robinson et al., 1993). Squalene synthase carries out a condensation and rearrangement reminiscent of phytoene synthase but uses two molecules of FPP to produce squalene, a key intermediate in eukaryotic sterol biosynthesis

Table 2. Conserved sequence motifs related to protein structure and function

Proposed function of the motif ¹	Consensus sequence ²	Protein ³	Location within protein ⁴
FAD/NAD(P) binding <i>βαβ</i> fold	(V/I)(V/I)G(A/G)GXGG(L/I)X ₂ AX ₂ (L/A)X ₃ GX ₂	Rc-CrtD ⁵	9 - 41
	(V/T)X(V/L)X(E/D)X ₃ GG	Rs-CrtD	10 - 42
		Rc-CrtI	13 - 45
Prenyl pyrophosphate binding (domain IIa)	(L/M)GX(A/F)XQX(T/S)NIXRDX ₂ (E/D)D	Rc-CrtB	156 - 172
Prenyl pyrophosphate binding (domain I)	(E/S)X ₂ (H/Q)X ₂ (S/F)LX ₂ DDX _{2/4} DX ₄ RRG	Rc-CrtE	70 - 93
Prenyl pyrophosphate binding (domain II)	GX ₂ (F/Y)QX ₂ DDX ₂ (D/N)	Rc-CrtE	201 - 212
SAM-binding	D(L/V)GG(G/A)XG(A/N)X ₈ (Y/H)PX ₆ (F/Y)D(L/I) PX(V/M)	Rc-CrtF	234 - 263

¹ Domains I and II denote regions found in prenyltransferases catalyzing 1'-4 condensations. Domain IIa is used here to denote a region found in prenyltransferases catalyzing 1'-2-3 condensations and 1'-1 rearrangements.

² Consensus sequences reflect the alignments listed in Table 1, modifying domains I and II as previously defined (Ashby and Edwards, 1990; Armstrong et al., 1993a); X = any amino acid.

³ species abbreviations as in Table 1

⁴ inclusive amino acid residues

⁵ The Rc-CrtD sequence contains a mutation which changes Gly-13 in the wild type sequence to Arg-13 (see section III. A. 4.)

(Robinson et al., 1993). *Rb. capsulatus* CrtE, which catalyzes the 1'-4 condensation between homoallylic IPP and allylic FPP, and its homologs possess both domains I and II (Tables 1 and 2). Local sequence conservation of domains I and II from *Rb. capsulatus* CrtE is seen in the *N. crassa* GGPP synthase (AI-3) (Carattoli et al., 1991) and in several other eukaryotic prenyltransferases (Armstrong et al., 1993a), which otherwise exhibit little similarity to CrtE. The functional significance of the conserved aspartate and arginine residues found in domains I and II of *Rb. capsulatus* CrtE and CrtB remains to be demonstrated.

D. Hydratases (CrtC)

Virtually nothing is known about carotenoid hydratases. *Rb. capsulatus* CrtC, hydroxyneurosporene synthase (Fig. 1), shows 80% sequence identity with a partial CrtC sequence from *Rb. sphaeroides* (Armstrong et al., 1989; Garí et al., 1992b). In addition, a 28% identical *M. xanthus* protein is thought to encode the same enzyme (Table 1). No information is yet available on sequence motifs important for the structure or function of the carotenoid hydratases.

E. O-methyltransferases (CrtF)

Rb. capsulatus CrtF, the hydroxyneurosporene-O-methyltransferase, catalyzes the SAM-dependent methylation of hydroxyneurosporene or demethylspheroidene in a few species of bacteria (Goodwin, 1980). Recently, a number of noncarotenogenic O-methyltransferases that display sequence identities of 22–30% with CrtF have been described (Table 1). Putative SAM-binding sites found in RNA, DNA and other SAM-dependent methylases have been proposed (Haydock et al., 1991). The SAM-binding sequence motif is highly reminiscent of the ADP-binding fold found in FAD and NAD(P)-containing proteins (Scrutton et al., 1990), including the carotenoid dehydrogenases. A sequence motif which is strictly conserved and may represent a SAM-binding site in *Rb. capsulatus* CrtF and in other noncarotenogenic O-methyltransferases is given in Table 2. Biochemical evidence is not yet available to confirm the binding of SAM to CrtF.

F. ORF 469 and ORF 160

Rb. capsulatus ORF 469 and ORF 160 were originally thought to be involved in carotenoid biosynthesis

(Zsebo and Hearst, 1984; Giuliano et al., 1988; Armstrong et al., 1989; 1990c; Burke et al., 1991). Ongoing studies with *Rb. sphaeroides* and *Rb. capsulatus* indicate other functions for these gene products, however (see Sections III.B.2. and IV.A.2.) (Penfold and Pemberton, 1991, 1994; Gomelsky and Kaplan, 1995; Ponnampalam et al., 1995).

ORF 469/Pps is a negative regulator of BChl and carotenoid photopigment accumulation in *Rb. sphaeroides* (Penfold and Pemberton, 1991, 1994). Comparison of *Rb. capsulatus* and *Rb. sphaeroides* ORF 469/Pps to other protein sequences present in the databases reveals no homologs or global conservation of the amino acid sequence, but does identify one interesting sequence motif. Residues at the C-terminus of CrtJ/Pps resemble conserved helix-turn-helix DNA-binding motifs found in prokaryotic transcriptional regulatory proteins (Penfold and Pemberton, 1994). The exact function of ORF 469/Pps will require further study, but this identification of a possible DNA-binding motif could explain the apparent regulatory function in *Rb. sphaeroides* and *Rb. capsulatus* (Penfold and Pemberton, 1991, 1994; Gomelsky and Kaplan, 1995; Ponnampalam et al., 1995).

Intriguingly, *Rb. capsulatus* ORF 160 (Armstrong et al., 1989) has been observed to share significant sequence identity with mammalian benzodiazepine receptor proteins (Baker and Fanestil, 1991). The responses mediated by the mammalian receptors are diverse and not well understood. Nevertheless, their 35–38% sequence identities with ORF 160 (Table 1) are impressive considering the evolutionary gap between anoxygenic photosynthetic bacteria and mammals.

VI. Perspectives for the Future

A. Unsolved Problems in Carotenoid Biosynthesis

Recent advances in our understanding of the genetics of carotenoid biosynthesis in anoxygenic photosynthetic bacteria have been dramatic, but leave many questions unanswered. Our knowledge is confined to a few species of purple nonsulfur bacteria for which carotenoid mutants and systems for genetic transfer exist. Much is now known about the structure and organization of the *crt* genes and the properties of *crt* mutants in *Rb. capsulatus* and *Rb. sphaeroides*.

On the other hand, detailed studies of the regulation of *crt* genes remain in their infancy, and, outside of *Rb. capsulatus* CrtI, no biochemical or immunological data exist with respect to the *crt* gene products. The functions of several specific biosynthetic conversions are unknown. *Rhodobacter* possess CrtA, an enzyme which catalyzes a specific conversion in the presence of oxygen, yet this system is inactive with no apparent ill effects in mutants lacking CrtD activity. By the same token, a selective advantage of wild type versus *crtD*-type carotenoids is not evident. The scope for groundbreaking research into these areas remains enormous.

Another specific issue which deserves more attention is the nature of the branch point between carotenoid and BChl biosynthesis in the general isoprenoid pathway. *Rb. capsulatus* CrtE and CrtB correspond to GGPP synthase and phytoene synthase, respectively (see Section III.A.3). This situation, however, poses a problem with respect to the synthesis of the phytol side chain of the BChl molecule (Rüdiger and Schoch, 1991). If, as currently accepted, only one pathway exists for the synthesis of GGPP (Fig. 1), then *crtE* mutants of *Rb. capsulatus* should be blocked in both carotenoid and BChl synthesis, and hence should not have a blue-green phenotype, accumulate GGPP, or be photosynthetically viable (Armstrong et al., 1990c). As this is not the case, one could postulate that only leaky *crtE* mutants can be isolated, as has been reported for *al-3* (GGPP synthase) mutants of *N. crassa* (Sandmann et al., 1993). This possibility seems highly unlikely in *Rhodobacter*, however, when one considers that a gross disruption of the *crtE* gene with a transposon or interposon should completely abolish CrtE enzymatic activity (Zsebo and Hearst, 1984; Giuliano et al., 1988; Armstrong et al., 1990c; Coomber et al., 1990). A more plausible explanation for BChl synthesis in a *crtE* mutant background would be to postulate a branch point for BChl and carotenoid biosynthesis before GGPP, at the level of FPP for example (Fig. 1). This alternative would require either (1) the ability of farnesol to directly replace geranylgeraniol in the esterification of BChlide *a* or (2) the existence of a second GGPP synthase specific for BChl biosynthesis. Esterification of BChlide with alcohols not derived from GGPP can occur in some anoxygenic photosynthetic bacteria, but has not been observed in the BChl *a*-accumulating *Rhodospirillaceae*, which use phytol or less frequently geranylgeraniol for this purpose (Rüdiger and Schoch, 1991). At present it is not

possible to decide between these alternatives. It is interesting in retrospect to note that the *Rb. capsulatus crtE* transposon mutant studied in an in vitro cell-free phytoene synthesis system (Armstrong et al., 1990c), accumulated substantially larger amounts of FPP than the *crtB*, *crtI* and *crtJ* blue-green mutants examined in parallel (A. Schmidt, personal communication).

B. Biotechnological Applications

Carotenoids are highly visible natural pigments and have a wide variety of commercial uses, such as food colorants, pigmenters for fish and poultry feed, and provitamin A (reviewed in Nelis and De Leenheer, 1989b). *Rb. capsulatus* has been studied as a potential source of the red ketocarotenoid spheroidenone for eventual use as a natural coloring agent. One strategy of biotechnological interest would be to grow *Rb. capsulatus* in a continuous-flow bioreactor for biomass or single cell protein production, while simultaneously enhancing carotenoid content. Preliminary experiments to investigate the potential for reliable characterization of the accumulated pigments have demonstrated that iron concentration in the growth medium can be used to manipulate spheroidenone content (Nelis and De Leenheer, 1989a, 1989b).

In light of recent developments in the genetics of anoxygenic photosynthetic bacterial carotenoid biosynthesis, manipulation of carotenoid levels or content through genetic engineering may be an attractive option. Heterologous systems for the production of novel carotenoids in a prokaryotic host organism by introduction of a foreign prokaryotic or eukaryotic carotenoid biosynthesis gene(s) have been described (Pemberton and Harding, 1986, 1987; Bartley et al., 1990, 1991, 1992; Misawa et al., 1990, 1991; Hundle et al., 1991; Penfold and Pemberton, 1991; Chamovitz et al., 1992; Math et al., 1992; Sandmann and Misawa, 1992). One could thus envision the construction of hybrid carotenoid biosynthetic pathways with anoxygenic photosynthetic bacteria serving either as hosts or gene donors to obtain large scale microbial production of desirable natural pigments.

Acknowledgments

I would like to thank those researchers who contributed manuscripts or unpublished data, Marie

Alberti and Donald Burke for their advice, and Catharina Maulbecker-Armstrong for valuable consultations during the preparation of this chapter.

Summary

At the present little is known on the genetics of green sulfur, green filamentous and heliobacteria. Since, based upon the 16S RNA phylogenetic tree, none of these bacteria are closely affiliated with the cyanobacteria or purple nonsulfur bacteria it is unlikely that preexisting genetic techniques from other photosynthetic bacteria can be used directly. However, due to the improvement in the methods available and the introduction of new techniques for molecular cloning and genetic manipulation of other prokaryotes, progress in these three bacterial groups should be relatively rapid. In this chapter, I have attempted to summarize all that is currently known on the properties of the nucleic acids and their genes. Potentially relevant physiological and biochemical

aspects of these bacteria have also been gathered and are presented here. Genes cloned and sequenced as of November, 1994, have been tabulated and the codon frequency based upon these data has been calculated for each of these bacterial groups. One cannot yet speak of the genetic analysis of these bacteria but rather the building of the foundation to do this type of work.

I. Some Relevant Physiological and Biochemical Characteristics

A. Species Used in the Laboratory and Culture Conditions

1. Green Sulfur Bacteria

Although several species of green sulfur bacteria have been isolated and characterized, only three have been used thus far for genetic and molecular cloning work: *Chlorobium vibrioforme*, *Chlorobium limicola*, and

. The thiosulfate-utilizing strains of *Cb. limicola* and *Cb. vibrioforme*, designated forma specialis (f. sp.) *thiosulfatophilum* (DSM 249, 254, 257 for the former strain and DSM 263 or NCIB 8327 for the latter strain) (Pfennig, 1989) are often used.

All *Chlorobium* species are obligate anaerobic phototrophs. They are usually grown in a thiosulfate-acetate-bicarbonate medium (Sirevåg and Ormerod, 1970, Schmidt, 1980, Rieble et al., 1989, Wahlund et al., 1991) at 23–28 °C with the exception of 44–48 °C for *Cb. tepidum*.

2. Green Filamentous Bacteria

The thermophilic facultative phototroph, *Chloroflexus aurantiacus*, is the only species of filamentous and green bacteria to be biochemically genetically studied to any great extent. It is the only species which can be grown as an axenic culture at the moment. Strains J-10-fl (ATCC 29366, DSM 635), OK-70-fl (ATCC 29365, DSM 636) and B3 have been used most frequently.

Cf. aurantiacus is usually grown in a complex medium containing salts, yeast extract and glycylglycine as a buffering agent (Castenholz and Pierson, 1981; Kaulen and Klemme, 1983; and the DSM medium No. 87). Glycylglycine, which is relatively

expensive especially when large volumes of cells are to be grown, has been successfully replaced by 10 mM Tris (Bingham and Darbyshire, 1982; Cox et al., 1988; Rolstad et al., 1988) or 0.1% (w/w) K-phosphate (pH 8.0) (Ivanosky et al., 1993). Madigan et al. (1974) developed defined media for aerobic and anaerobic growth. The growth temperature is usually between 48 and 55 °C. Conditions for aerobic cultivation as well as for a high to low O₂ concentration shift of the culture to induce the biosynthesis of the photosynthetic apparatus have been described by Foster et al. (1986). Cell densities achieved under dark, aerobic growth conditions are very low; this is most probably due to the low solubility of O₂ in the growth medium at 50–55 °C.

The filamentous nature and gliding movement of *Cf. aurantiacus* presents problems for the isolation of colonies. Filaments can be broken up into shorter pieces by sonication but at the expense of cell viability (Pierson et al., 1984). Under anaerobic growth conditions, cells can be partially immobilized by embedding them in soft agar (Pierson et al., 1984). Another possibility, although untested, would be to plate cells onto nitrocellulose filters laid on top of the agar surface. This would allow growth of cells under aerobic conditions. In any case, target 'colonies' must be picked and restreaked a few times to ensure that they are monoclonal.

3. Heliobacteria

In biochemical and genetic work, *Heliobacillus mobilis* (ATCC 43427) has been used preferentially over the first described heliobacteria, *Heliobacterium chlorum* (ATCC 35205, DSM 3682), perhaps because it 'grows more robustly and shows a much lower tendency to sphaeroplast and lyse' (Beer-Romero et al., 1988). Two endospore-forming species, *Hb. gestii* and *Hb. fasciculum* have been described (Ormerod et al., 1990). All species are strict anaerobic phototrophs. *Hb. chlorum* can be maintained on ATCC medium No. 112 (DSM medium No. 370) under strict anaerobic conditions between 35–37 °C (Gest and Favinger, 1983); however, it has been reported to grow more rapidly on American Type Culture Collection (ATCC) medium No. 1552 (van

Abbreviations: ATCC – American Type Culture Collection; BChl – bacteriochlorophyll; *Cb.* – *Chlorobium*; *Cf.* – *Chloroflexus*; DSM – Deutsche Sammlung für Mikroorganismen; *Hb.* – *Heliobacterium*; *Hc.* – *Heliobacillus*; NTG – N-methyl-N'-nitro-N-nitrosoguanidine; ORF – open reading frame; *Rb.* – *Rhodobacter*; REMI – Restriction enzyme-mediated integration

de Meent et al., 1990). *Hc. mobilis* can be grown under strict anaerobic conditions between 40 and 42°C using a defined medium developed by Beer-Romero and Gest (1987), ATCC medium No. 112 plus 1.1 g sodium pyruvate per liter (Beer-Romero et al., 1988) or ATCC medium No. 1552 (van de Meent et al., 1990).

B. Inhibition of Bacteriochlorophyll Synthesis

Green sulfur and green filamentous bacteria contain very large amounts of BChl *c*, *d* or *e* as light-harvesting pigments. The synthesis of BChl *d* and *e* can be specifically inhibited in *Cb. vibrioforme* with anesthetic gases (Ormerod et al., 1990). It has not been reported whether these gases have any effect on BChl *c* synthesis. Gabaculin (3-amino, 2,3-dihydrobenzoic acid) has been used to inhibit the biosynthesis of BChl *a* and *c* in *Cf. aurantiacus* (Kern and Klemme, 1989); this antibiotic was first used in cyanobacteria.

C. Antibiotic Sensitivities and Resistances

Pierson et al. (1984) tested photoheterotrophically grown *Cf. aurantiacus* J-10-fl for sensitivity to carbenicillin, penicillin and ampicillin. For concentrations up to 100 µg ml⁻¹ carbenicillin was observed to have no effect on cell growth. On the other hand, *Cf. aurantiacus* was shown to be very sensitive to penicillin in that cell recovery was not predictable after exposure to penicillin at 100 U ml⁻¹ under nongrowth conditions (anaerobic dark). The authors found that the best condition for growth inhibition and subsequent cell recovery was obtained using 30–50 µg ml⁻¹ ampicillin (see also III.A).

From John Ormerod's work (1988) on the natural transformability of *Chlorobium* (see III.B) one can deduce that *Cb. limicola* is normally sensitive to streptomycin and kanamycin whereas *Cb. vibrioforme* is streptomycin sensitive (Kjærulff et al., 1993).

Hc. mobilis is apparently kanamycin sensitive (Vermaas and Vu, 1993; see Section III.B).

II. The Genome

A. General

The G + C mole % content of DNA from *Chlorobium* species used for molecular cloning work ranges from 51 to 58.1% (Pfennig, 1989; Imhoff, 1992). The

reported values for *Cf. aurantiacus* are 53.1 to 54.9% and for *Hc. mobilis* is 50.3% (Pierson and Castenholz, 1974; Beer-Romero and Gest, 1987; Imhoff, 1992). The genome size and presence of special structures such as the two circular chromosomes found in *Rhodobacter sphaeroides* (Suwanto and Kaplan, 1989) have not been reported for green bacteria. The presence of endogenous plasmids and bacteriophages have also not been reported. Genome sizes of other photosynthetic bacteria and cyanobacteria range between 1.6 × 10⁹ to 8.6 × 10⁹ daltons (Saunders, 1992).

B. DNA Restriction and Modification Systems

Thus far the activity and/or isolation of specific endogenous restriction endonucleases has been reported for only *Cf. aurantiacus*. Two type II restriction enzymes, *CauI* and *CauII*, were isolated by Bingham and Darbyshire (1982). The recognition sites were determined by Molemans et al. (1982) to be identical to that of *AvaII* (GG A/T CC) and *NciI* (CC C/G GG), respectively. A third restriction endonuclease, *Cau-B3-1*, was isolated and characterized more recently by Kramarov et al. (1987). The recognition sequence and cleavage site is identical to that of *BspE1*, T¹CCGGA. This enzyme was also found to be sensitive to methylation of adenine in the recognition sequence. A fourth restriction enzyme, *CauIII*, with the recognition sequence CTGCAG has been reported (Kessler and Manta, 1990). Methylases responsible for modifying the cognate nucleotide sequences to prevent self-restriction have not been described.

Cf. aurantiacus apparently has a *dam*-like methylation system since *Sau3AI* will digest chromosomal DNA isolated from the bacterium whereas *MboI* will not (Shiozawa et al., 1989). Several other restriction enzymes apparently also do not restrict *Cf. aurantiacus* DNA even though the recognition sequence for these enzymes has been found in cloned and nucleotide sequenced DNA. These enzymes include *BamHI*, *EcoRV*, *HindIII*, *SacI*, *SalI* and *XbaI* (Robinson and Redlinger, 1987; Shiozawa et al., 1989, unpublished; Dracheva et al., 1991). The apparent lack of activity of these enzymes could be due to DNA modification or to a low frequency of the respective recognition sites. There are two arguments for the latter case: For mammalian DNA, *SalI* is considered to be a rare cutting restriction enzyme with an average fragment length of 100,000 bp (see Sambrook et al., 1989). *XbaI* has been used to

map the chromosomal DNA of *Rb. capsulatus* since this enzyme acts infrequently in this species (Fonstein and Haselkorn, 1993). The enzyme *Dra*III has been used to map *Rb. sphaeroides* DNA (Suwanto and Kaplan, 1989). No recognition sites for this enzyme has been found in over 15,000 bp sequenced in *Cf. aurantiacus* and in over 13,000 bp sequenced in *Chlorobium*. One complicating factor is that *Xba*I is *dam* methylation sensitive. *Dam* methylation of the *Xba*I recognition sequence (TCTAGA) occurs when the dinucleotide TC immediately follows the restriction site.

C. Genes Cloned and Sequenced

The genes cloned and sequenced as of November, 1994, are presented in Table 1 for *Chlorobium* species, in Table 2 for *Cf. aurantiacus* and in Table 3 for heliobacteria. Where available, the Genbank/EMBL data bank accession numbers are also given. In some cases, the sequence data was neither published nor available from the data bases; this is also indicated in the tables. Also indicated in the tables is whether the transcriptional organization of the genes has been analyzed.

The gene designations suggested at the EMBO Workshop on Green and Heliobacteria in Denmark August 1993 have been adopted (Bryant, 1994). An additional modification was made: The two loci of the *puf* operon in *Cf. aurantiacus* and the *psc* in *Chlorobium* species are differentiated by an Arabic number immediately following the gene locus designation as has been done for the *atp1* and *atp2* operons in cyanobacteria. This differential designation was also going to be applied to the chlorosome genes of *Chlorobium* and *Chloroflexus* but there are already three *cs*m gene loci of which only one seems to occur in both bacterial groups. As more chlorosome genes are identified and sequenced, the present nomenclature system will quickly become overly complicated. As soon as functional properties can be definitively associated with these gene products, I suggest that new gene locus designations be developed.

D. Gene and Transcriptional Organization

1. *Chloroflexus aurantiacus*

At the moment the best characterized genes in these three bacterial groups are those of the *puf1* and *puf2*

operons and the *cs*mA gene of *Cf. aurantiacus*. The organization of the *Cf. aurantiacus puf* operon differs greatly from that of purple nonsulfur bacteria. Whereas the *puf* operon in purple nonsulfur bacteria forms a contiguous region of the genome and is transcribed as a single mRNA before it is processed, in *Cf. aurantiacus* the *puf* operon is divided between two loci which are separated by at least 3 kb. *Puf1* encodes the L and M subunits of the photochemical reaction center while *puf2* encodes the β and α subunits of the B806–866 light-harvesting complex and the tetraheme cytochrome *c*-554 (Shiozawa et al., 1990; Watanabe et al., 1992, 1995). How the molar relationships between the reaction center and the light-harvesting complex and between the reaction center and cytochrome *c*-554 are regulated in vivo is not known. In photoheterotrophically grown *Rb. capsulatus* differential mRNA stability is probably the major factor in maintaining the molar ratio of the *pufB* and *A* gene products to the *pufL* and *M* gene products (Klug, 1993).

The 5' end of the *puf1* mRNA begins about 130 nt upstream from the ATG start codon of *puf1L*. In the DNA region just upstream of the region corresponding to the 5' end of the *puf1* mRNA are nucleotide sequences with very high similarity to the *E. coli* RNA polymerase σ^{70} consensus sequence. In addition, an octanucleotide sequence is repeated three times and there are two regions of inverted symmetry upstream of the putative promoter region which could be regulatory protein binding sites. The electrophoretic mobility of radioactively labeled DNA fragments from this potential promoter-regulatory region after incubation with cellular extracts of *Cf. aurantiacus* is reduced, indicating DNA-protein interaction(s) (Shiozawa et al., 1990 and unpublished). The identity of the protein(s) interacting with the DNA probes is not known.

Puf2 may actually represent two semi-independent operons: one composed of *puf2B* and *puf2A*, the genes encoding the subunits of the B806–866 light-harvesting complex, and the second composed of *puf2C*, the gene encoding the tetraheme cytochrome *c*-554 (Watanabe et al., 1992, 1995). A putative σ^{70} promoter sequence precedes both *puf2B* (centered – 149 bp from the start codon) and *puf2C* (centered – 119 bp from the start codon). The predominant mRNA encoding *puf2B* and *puf2A* is 0.5 kb long; however, a minor transcript 2.1 kb long and encoding both genes is also observed. For *puf2C* two transcripts are observed: the 1.5 kb mRNA encodes only *puf2C*

while the 2.1 kb mRNA encodes all three *puf2* genes. Primer extension experiments show that the 1.5 kb mRNA was actually composed of two species: one having a 5' terminus just downstream of the putative promoter sequence and the second, 88 nt longer, with its terminus in the potential stemloop region immediately following the stop codon of *puf2A*. There are two possible explanations for these results: All of *puf2C* is transcribed as a 2.1 kb message which later is subject to endonuclease processing. The original endonucleolytic products would be the 0.5 kb *puf2B-puf2A* mRNA and the longer 1.5 kb mRNA. Subsequent endo- or exonucleolytic activity would yield the slightly shorter 1.5 kb product. A second possible explanation is that some *puf2C* is transcribed as the 2.1 kb message, some of which is later processed to the 1.5 kb mRNA having the 5' terminus in the putative stemloop region of *puf2A*. The second shorter 1.5 kb mRNA results from the transcription of *puf2C* from the putative promoter just upstream of the mapped 5' terminus. The banding pattern from primer

extension experiments support this latter explanation since no extension products between the two termini are observed (Watanabe et al., 1992, 1995). Capping experiments in conjunction with nuclease mapping would help to clarify the origin of the two 1.5 kb mRNAs.

In *Cf. aurantiacus*, the 5.7 kD chlorosome protein which is encoded by the *csmA* gene is transcribed as a monocistronic message. Just upstream of the 5' end of the mRNA which was determined by primer extension are nucleotide sequences which have similarity to the alternate σ^{54} consensus sequence (Theroux et al., 1990). Two potential open reading frames (ORFs) are found upstream and downstream of *csmA* which have sequence similarity to two similarly positioned ORFs in *Cm. vibrioforme* 8327D and *Cb. tepidum* (Chung and Bryant, 1992; Chung et al., 1994; see the following section).

Two other chlorosome genes have been cloned and sequenced from *Cf. aurantiacus* recently (Niedermeier et al., 1994). The genes for the 11 and 18 kD

proteins have been designated *csmM* and *csmN*, respectively, and are not in the direct vicinity of the *csmA* gene. The two genes are transcribed into one mRNA having the approximate size of their combined gene lengths. About 185 bp upstream of the ATG start codon of the *csmM* gene are nucleotide sequences resembling the σ^{70} consensus sequence.

Nucleotide sequences which could form stemloops are almost always found downstream of all stop codons of the putative final gene of a transcript in *Chloroflexus*. In *puf1* the G+C-rich region of dyad symmetry and the dA-rich region (on the DNA template strand for mRNA synthesis) is typical of rho-independent termination. A region of dyad symmetry is also found immediately following the stop codon of the cytochrome *c-554* gene (*puf2C*) but the only dA-rich sequence proximal to this region is part of the putative stemloop or is 30 bp further downstream. Thus, it is not clear whether this is a rho-independent termination site.

The region of dyad symmetry between *puf2A* (α -subunit of the B806–866 complex) and *puf2C* lacks the poly A region on the template strand. Intercistronic stemloops have been observed, for example, in the *puf* operon of *Rb. capsulatus* and *sphaeroides* and have been shown to contribute to the stability of the message 5' to the stemloop (Belasco and Chen, 1988; Klug, 1993). The intercistronic stemloop of *puf2* may also have a similar function but this must be proven. The termination signal/mechanism of the *csmA* and *csmM-csmN* transcripts are not clear. In the former case, a region of strong dyad symmetry is present, but a dA-rich sequence is absent. In the case of the *csmM-csmN* operon only a region of weak dyad symmetry is found 3' of the *csmN* stop codon. Whether transcription in both could be terminated by a rho-like protein factor is also difficult to say. There seems to be no consensus sequence or structural features common to all rho-dependent termination sites (Beebe and Burke, 1992; Richardson, 1993). Most recently it has been suggested that a relatively G-poor and C-rich region on the transcript is required for rho binding (see Richardson, 1993). While there are nucleotide regions 50 to 100 bp upstream of the stop codon which may be described as such, whether these have a functional significance is conjecture at the moment.

2. *Chlorobium* Species

The first gene sequenced in a *Chlorobium* species

was *hemA* which encodes glutamyl tRNA reductase, the first enzyme of the five carbon δ -amino levulinic acid biosynthetic pathway (Majumdar et al., 1991). In the same paper, data for the 5' end of the gene downstream, of *hemA* was also published. The deduced amino acid sequence was 42 and 46% identical to that of porphobilinogen deaminase from *E. coli* and *B. subtilis*, respectively. Subsequently, this gene, *hemC*, and *hemD* (uroporphyrinogen II cosynthase) were completely sequenced (Majumdar and Wyche; see Table 1). Based upon the size of the mRNA as seen on Northern blots, all three genes are transcribed together and form an operon (Majumdar et al., 1991). The short intercistronic space between *hemA* and *hemC*, 76 bp, and the 1 bp overlap between *hemC* and *hemD* supports this idea. A putative Pribnow box is found just 6 bp upstream of the start codon of *hemA*; two possible sequences which could correspond to the -35 consensus sequence of the RNA polymerase σ^{70} subunit were found 20 and 21 bp upstream of the Pribnow box. It is also possible that the true promoter lays further upstream and beyond the cloned DNA fragment.

The region 3' of the termination codon of each of three genes has some interesting characteristics, although the significance or function of these features is not known presently. There are stretches of DNA that are extremely dA+dT-rich, especially immediately after *hemA* and *hemD*. Twenty bp downstream of the *hemA* termination codon is a potential polyadenylation signal (Majumdar et al., 1991). Polyadenylation is typical of the 3' terminus of eukaryotic mRNA and has also been observed in other bacteria although this is the first time a signal sequence in the genomic DNA has been described. Another unusual feature of this operon is that a region of very strong dyad symmetry is centered about 90 bp into the *hemD* gene. It is not known whether a transcription termination signal occurs after the stop codon of *hemD*; the DNA fragment sequenced ends about 25 bp after the stop codon.

The genes encoding the reaction center polypeptide and the Fe-S binding polypeptide form an operon in *Cb. limicola* which has been designated *psc1* (photosystem *Chlorobium*-type; Bryant, 1994) and the genes, *A* and *B*, respectively (Büttner et al., 1992). The genes are preceded by a putative σ^{70} promoter sequence centered about 320 bp upstream of the ATG start codon. Beginning 31 bp downstream of the *psc1B* stop codon is a region of strong dyad symmetry with a interesting motif which is

found in other *Chlorobium* genes: a run of dA begins the potential stemloop and a run of dT terminates and continues beyond the structure. Such termination stemloops have been observed in other prokaryotic operons and, in some cases, have been shown to be bi-directional termination sites (Platt, 1986). A third ORF which showed sequence identity to the yeast enzyme dolichyl-phosphate-D-mannose synthase (EC 2.4.1.83, Genbank/EBML data bank accession no. A32122) was found on the cloned 4.8 kb *EagI* fragment. This ORF is located 303 bp downstream of the Fe-S binding protein compared to the 85 bp separating *psc1A* and *psc1B* and is transcribed in the same direction as but independently of the *psc1* genes (Büttner et al., 1992). A possible promoter sequence is found 68 bp upstream of the ATG start codon of *dpm1* and there is a region of dyad symmetry which encompasses the 3' terminus of the gene.

The β - and ϵ -subunits of F-ATPase in *Cb. limicola* which have been designated *atp2 β* and *atp2 ϵ* most likely form an operon as in the cyanobacteria (Xie et al., 1993). The authors did not specifically mention the location of possible promoter sequences; the closest σ^{70} promoter-like sequences I could find were in the noncoding region preceding *atp2 β* and centered around -315 bp from the start codon. Twenty-two bp downstream of the *atp2 ϵ* stop codon is a region of interrupted dyad symmetry. A run of dA begins and a run of dT ends this potential transcription termination structure (see preceding paragraph).

Coincidentally the gene encoding the enzyme phosphoenol pyruvate carboxykinase also lies on the cloned 4.5 kB *BamHI* fragment. The gene, *pepck*, is almost 1 kb upstream of *atp2 β* and is transcribed in the opposite direction. A potential σ^{70} promoter sequence is located between bp -38 and -67 from the start codon and the nucleotide sequences for a potential termination stemloop with a run of dA and dT forming the 3' and 5' termini are found 26 bp downstream of the stop codon.

The gene homologous to *csmA* in *Cf. aurantiacus* has been identified, cloned and sequenced in two *Chlorobium* species (Chung and Bryant, 1992, 1993). In both *Cb. tepidum* and *Cb. vibrioforme*, the *csmA* gene is preceded by a gene, now called *csmC*, which encodes the 14 kDa protein found in *Chlorobium* chlorosomes. In *Cb. tepidum* *csmCA* is transcribed as a single albeit not abundant transcript. A more abundant transcript which encodes only *csmA* is also found. Nucleotide sequences resembling the *E. coli* σ^{70} consensus sequence are found upstream of the 5'

end of the *csmCA* mRNA. Surrounding the *csmCA* operon are conserved ORFs which also appear to be related to ORFs upstream and downstream of the *csmA* gene in *Cf. aurantiacus*.

The gene encoding the Olson-Gerola 7.5-kDa chlorosome protein in *Cb. vibrioforme* and *Cb. tepidum* has also been cloned and sequenced (Chung and Bryant, 1992, 1993). The *csmB* gene appears to be transcribed as a monocistron. An analogous protein in *Cf. aurantiacus* has not yet been identified. The *csmCA* and *csmB* represent two different loci on the genomic DNA of *Chlorobium* species. The distance separating these two loci is presently not known.

Psc2C which encodes the monoheme cytochrome *c-551* of *Cb. vibrioforme* was identified in the genomic DNA, cloned and sequenced (Okkels et al., 1992). Centered 52 bp upstream of the start codon of the gene are nucleotide sequences resembling the consensus sequence of the σ^{70} subunit of the RNA polymerase and 45 bp downstream of the stop codon a region having the properties of a rho-independent termination site are found. Northern blot analysis also support the idea that the *psc2C* gene is transcribed as a monocistron.

The gene encoding the Fenna-Matthews-Olson protein, the polypeptide component of the water soluble BChl-protein of *Chlorobium* species, is apparently also transcribed as a monocistron in *Cb. tepidum* (Dracheva et al., 1992). This belief is based upon the presence of sequences having similarity to the RNA polymerase σ^{70} promoter sequence upstream of the start codon of *fmoA* (nt 95-123 in Dracheva et al., 1992) and the presence of a region of dyad symmetry with poly (dA) and poly (dT) beginning and ending this region just downstream of the gene stop codon.

3. *Heliobacillus mobilis*

Thus far, the only gene cloned and sequenced from heliobacteria is *pshA* (photosystem heliobacteria-type; Bryant, 1994), the gene encoding the reaction center polypeptide of *Hc. mobilis* (Liebl et al., 1993). The published nucleotide sequence begins -14 bp from the *pshA* start codon; the nucleotide sequence submitted to the GenBank/EMBL data bank (accession no. L19604) began over 700 bp upstream. Therefore, a visual search for promoter sequences was made. A potential Pribnow box starting -91 bp from the start codon was found; however, a reasonable -35 consensus sequence was not found 16 to 20

bases further upstream. Another possible promoter is centered -145 bp from the ATG start codon; here potential -24 and -12 sequences for a σ^{54} promoter are found. A potential G+C-rich stemloop followed by a dT-rich stretch is found starting 26 bp downstream of the stop codon. An ORF begins 147 bp downstream of *pshA*. A Pribnow box is found 38 bp upstream and, again, a -35 consensus sequence could not be identified. Beginning 28 bp downstream from the stop codon a region of dyad symmetry is found; this region is not followed by a dT-rich region. Northern blot analysis suggest that the message for *pshA* is monocistronic.

E. Translation Signals

A ribosome-binding site or Shine-Dalgarno sequence is found 8 to 12 bp upstream of the start codon of all *Cf. aurantiacus* genes thus far sequenced. The *pshA* and downstream ORF from *Hc. mobilis* were also preceded by a ribosome-binding site. In *Chlorobium* species, Shine-Dalgarno sequences just upstream or just following the start codon are seen in the *psc1* operon and in the *dpm1* and *fmoA* genes. On the other hand, ribosome-binding sites in these more typical locations have not been found in the *hemACD* and the *atp2 β ϵ* operons and in the *psc2C* and *pepck* genes. In the GenBank/EMBL submission of the complete *hemACD* sequence (accession no. M96364) Majumdar and Wyche suggest that the ribosome-binding sites lie within the genes. This has been observed in other bacteria, for instance the archaea (Zillig et al., 1988). I have found possible ribosome-binding sequences within 70 bp of the start codons of the *atp2 β ϵ* operon, but was unsuccessful in my search of the *psc2C* and *pepck* genes.

F. Codon frequency

The codon frequency for each of the three bacterial groups was calculated. The data are presented in Tables 4 through 6 and demonstrate that the codon frequencies do not parallel that of *E. coli*, *Rhodobacter* (Wu and Saier, Jr., 1991) or one another. The frequency for which a degenerate codon having a G or C as the third base was used over the other codons was also determined. As found previously for other prokaryotes and eukaryotes, the G/C content of the third base in a codon correlated with the G/C composition of the genome (D'Onofrio and Bernardi, 1992). Thus, *Chlorobium* species had the highest

G/C frequency for the third codon position (0.70), followed by *Cf. aurantiacus* (0.66) and last by *Hc. mobilis* (0.60).

G. Summary

Almost of the genes or operons studied thus far from these three groups of bacteria have nucleotide sequences resembling the consensus motif of the σ^{70} subunit of *E. coli* RNA polymerase upstream of the start codons. Whether these putative promoter sequences are functional and the location and identity of *cis*-acting regulatory sequences, where applicable, must be demonstrated.

In most cases it appears that transcription is terminated by rho (like)-independent stemloop structures. Several of the *Chlorobium* genes have an additional characteristic—the stems of the putative termination stemloops begin with a 6–7 nt long stretch of poly (dA)-poly (dT). In *hemA* a polyadenylation signal was found at the 3' end of the gene.

Chlorobium genes are unusual in another aspect in that about half of the genes now known have ribosome-binding sites well after the translation start codon. While this phenomenon has been observed in other bacteria, it is not always clear what the function or advantage of such binding sites are.

It is too early to say whether the genes required for photosynthesis in green sulfur, green filamentous or heliobacteria are organized into a cluster such as seen in purple nonsulfur bacteria. There does seem to be a tendency for genes that are functionally related to be grouped together into an operon. An exception here seems to be *Cf. aurantiacus* and its divided *puf* operon. The separation of the genes encoding the L and M subunits of the reaction center from the light-harvesting component to which the reaction center is most tightly coupled and the cytochrome responsible for re-reducing the oxidized special BChl pair may be an indication that *Chloroflexus* or its predecessor may have received these genes by lateral gene transfer from a purple nonsulfur bacterium or its predecessor. Blankenship (1992) has suggested that *Cf. aurantiacus* is a photosynthetic chimera. Whether this organism also received its light-harvesting apparatus and BChl synthesis genes from a green sulfur bacterium in the same manner is too early to say.

III. Genetic Manipulation

A. Chemical and UV Light Mutagenesis

1. *Chloroflexus aurantiacus*

UV light radiation or treatment with N-methyl-N'-nitro-N-nitrosoguanidine (NTG) was used by Pierson et al. (1984) to generate BChl *c*- and carotenoid-deficient mutants of *Cf. aurantiacus*. Either before or after the mutagenesis step, the cellular filaments were sonicated briefly to facilitate the isolation of colonies. Ampicillin sensitivity under anaerobic light (emission maximum at 740 nm where BChl *c* and not BChl *a* absorbs) growth conditions was used to reduce the number of wild type cells after NTG mutagenesis. One BChl *c* + carotenoid-deficient, one carotenoid-deficient and several BChl *c*-deficient mutants were isolated and partially characterized. Many of the mutants reverted and had to be re-isolated.

B. Transformation

1. *Chlorobium* Species

In 1988 Ormerod reported that *Cb. limicola* 8327 could be transformed by the addition of a crude DNA extract from a spontaneous streptomycin resistant mutant of the same *Chlorobium* strain. The cells were transformable in all growth phases. DNA uptake was light dependent and strain and species specific: *Cb. limicola* strain Tassajara was not transformed by the DNA from the streptomycin resistant 8327 strain. Likewise both *Cb. limicola* strains 8327 and Tassajara were not transformed to kanamycin resistance by DNA extracts from R6845 and R1822 plasmid-containing *Rb. capsulatus*. Conjugation attempts with *Rb. capsulatus* containing either of the two plasmids or *E. coli* containing RP 4 were also unsuccessful.

Kjærulff et al. (1994) have described the transformation of *Cb. vibrioforme* through electroporation. The DNA construct used contained a full copy of the *psc2C* gene encoding the monoheme cytochrome *c*-551 and the streptomycin adenyltransferase gene as a selectable marker. The transformation was dependent upon the presence of *Cb. vibrioforme* DNA indicating that homologous recombination was necessary.

2. *Heliobacillus mobilis*

Vermaas and Vu (1993) have been able to transform CaCl₂/RbCl-treated *Hc. mobilis* cells to kanamycin resistance with the broad-host range plasmid pFD666 which carries the neomycin phosphotransferase gene from Tn5.

Very recently, Wahlund and Madigan (1995) described methods for the conjugal transfer of two IncQ group plasmids into *Chlorobium tepidum* from *E. coli* and for the growth of this bacterium on agar.

3. Restriction Enzyme-Mediated Integration of Plasmid DNA into Chromosomal DNA

The method Restriction Enzyme-Mediated Integration (REMI) of plasmid DNA into chromosomal DNA was originally described for *Saccharomyces cerevisiae* (Schiestl and Petes, 1991) and was successfully used in *Dictyostelium discoideum* for identifying developmental genes (Kuspa and Loomis, 1992). Genomic regions interrupted by the presence of plasmid DNA can be easily identified and cloned as long as a restriction enzyme known to digest the host DNA but not the plasmid DNA is available (Kuspa and Loomis, 1992). REMI could probably be adapted to photosynthetic bacteria, especially those which can be cultivated under aerobic conditions, to identify structural, metabolic, and regulatory genes required for photosynthesis. If transformation methods utilizing broad-host range plasmids does not work for *Cf. aurantiacus*, then REMI would be a good alternative method to attempt.

IV. Concluding Remarks

At this time more than a dozen genes from *Chlorobium* species, eight from *Cf. aurantiacus*, and two from *Hc. mobilis* have been cloned and sequenced. In a few cases, analysis of the transcriptional organization of the genes has been initiated. For the *Cf. aurantiacus puf1* operon work on the promoter region and *cis*-acting regulatory elements has begun. Transformation systems have been established for *Cb. vibrioforme* and *Hc. mobilis* which means site-directed mutagenesis of the known genes can be carried out and the effect on the encoded proteins analyzed. Because both of these bacteria are obligate photoanaerobes and have no alternate growth

possibilities, gene disruption experiments on essential genes or regulatory elements cannot be carried out. A transformation system for *Cf. aurantiacus* will probably be developed relatively soon despite the basic microbiological problems that have to be resolved concomitantly.

Acknowledgments

I would like to thank the many colleagues who sent me reprints and/or preprints of their work. This work was supported by the Deutsche Forschungsgemeinschaft (SFB 143).

Summary

In bacteria, the genes for hydrogenase (*hup* and *hyp*) are generally clustered, and the sequence of these clustered genes has been determined in several species. Among the photosynthetic bacteria, the organization of the *hup* and *hyp* genes has been the most studied in *Rhodobacter capsulatus*, and the nucleotide sequence of the entire *hup/hyp* gene cluster has been determined. This cluster includes the structural genes for the H₂-uptake [NiFe]hydrogenase (*hupSLC*) and the large number of accessory and regulatory genes. The possible roles of these genes, and the existence of other types of hydrogenase in the photosynthetic bacteria, are discussed. Hydrogenase gene expression in *Rb. capsulatus* is controlled by two main factors, namely molecular hydrogen and oxygen. Several regulatory genes have been identified in the *hup/hyp* gene cluster of *Rb. capsulatus*. The products of two of them, *hupR* and *hupT*, belong to the superfamily of two-component regulatory systems. In

addition, an IHF-like protein isolated from *Rb. capsulatus* has been shown to be required for in vivo hydrogenase synthesis. A molecular model of the interaction between the IHF binding site present in the promoter region of the hydrogenase structural operon and the IHF protein of *Rb. capsulatus* is presented.

I. Introduction

The potential for use of H₂ as a primary or secondary source of energy, and the possibility of transforming solar radiation into stable chemical energy, in the form of hydrogen gas, have greatly stimulated the study of H₂ metabolism in photosynthetic organisms, in particular in photosynthetic procaryotes. Many review articles on H₂ metabolism and on biotechnological aspects of hydrogen production in cyanobacteria and in photosynthetic bacteria have been published in the last 15 years. Numerous relevant references may be found in the reviews of Vignais et al. (1985) and of Sasikala et al. (1993).

A. The Discovery of Hydrogen Utilization and Production by the Photosynthetic Bacteria

1. Hydrogen Consumption for Autotrophic Growth

Early studies had shown that photosynthetic bacteria, such as *Chromatium*, can use molecular hydrogen as sole electron donor during photoautotrophic growth. The capacity to oxidize H₂ was later associated to the presence of the hydrogenase enzyme (Gest, 1952). Anaerobic photoautotrophic growth with H₂ as electron donor was demonstrated for *Rhodospirillum rubrum*, *Rhodopseudomonas palustris*, *Rhodopseudomonas gelatinosa*, and *Rhodopseudomonas capsulata* (now *Rhodobacter capsulatus*) (cf. Vignais et al., 1985). Under photoautotrophic conditions, *Rb. capsulatus* strains showed the fastest growth rates among purple non-sulfur bacteria (Klemme, 1968). *Rb. capsulatus* is also able to grow chemoautotrophically under aerobic conditions; under these conditions, H₂ serves as the source of energy and reducing power, O₂ as the terminal electron acceptor for energy transduction and CO₂ as the sole carbon source (Madigan and Gest, 1979; Seifert and Pfennig, 1979; Colbeau et al., 1980).

2. Photoproduction of Molecular Hydrogen

Photochemical production of molecular hydrogen by a photosynthetic bacterium, *Rs. rubrum*, was first observed by Gest and Kamen (1949a,b), who noted that photoevolution of H₂ proceeded readily under an atmosphere of 100% H₂ but did not occur under an atmosphere of N₂; addition of ammonium chloride or of high concentrations of yeast extract to the culture medium stimulated growth but inhibited H₂ production. Subsequent experiments with the isotope ¹⁵N indicated clearly that *Rs. rubrum* contained a N₂-fixing system (Gest and Kamen, 1949b; Gest et al., 1950) as did the purple sulfur bacterium *Chromatium*, and the green bacterium *Chlorobium* (Lindstrom et al., 1949) and several other species of purple nonsulfur bacteria including *Rp. palustris*, *Rhodopseudomonas sphaeroides* (now *Rhodobacter sphaeroides*), *Rb. capsulata* and *Rp. gelatinosa* (later termed *Rhodocyclus gelatinosus*) (Lindstrom et al., 1951). Since H₂ production did not occur when N₂ fixation was repressed, there appeared to be a close relationship between these two processes. While studying nitrogen fixation by cell-free extracts of *Rs. rubrum*, Bulen et al. (1965a) demonstrated that ATP and a low potential reductant were required for the production of H₂ by these extracts as well as for N₂ fixation, and that H₂ evolution was irreversible, independent of the partial pressure of H₂ and insensitive to CO. Bulen et al. (1965b) concluded that the same enzyme, nitrogenase, catalyzes both N₂ reduction and ATP-dependent H₂ evolution.

The evidence that in purple nonsulfur bacteria photoevolution of hydrogen is mediated by nitrogenase was summarized by Meyer et al. (1978), namely: 1) H₂ evolution, like nitrogen fixation, was strongly stimulated by light and inhibited by nitrogen, the natural substrate of nitrogenase (Gest and Kamen, 1949b; Jouanneau et al., 1984, 1985); 2) unlike with classical hydrogenases, H₂ evolution in *Rb. capsulatus* was not inhibited by carbon monoxide (Jouanneau et al., 1980) similarly to ATP-dependent H₂ evolution by nitrogenase (Winter and Burris, 1968); 3) H₂ evolution was inhibited by ammonia and the biosynthesis of the H₂ evolving enzyme was repressed in the presence of ammonia (Ormerod et al., 1961;

Abbreviations: *A. eutrophus* – *Alcaligenes eutrophus*; *B. japonicum* – *Bradyrhizobium japonicum*; *E. coli* – *Escherichia coli*; IHF – integration host factor; *Rb.* – *Rhodobacter*; *Rc.* – *Rhodocyclus*; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*; *Tc. roseopersicina* – *Thiocapsa roseopersicina*

Gogotov et al., 1974); 4) *Nif*⁻ strains of *Rb. capsulatus*, which lack nitrogenase activity, were incapable of H₂ evolution (Wall et al., 1975); 5) molybdenum-starved cells of *Rs. rubrum* displayed a large decrease in their ability to evolve hydrogen (Paschinger, 1974); since nitrogenases are molybdo-enzymes whereas hydrogenases are not, H₂ evolution in this bacterium could be clearly attributed to nitrogenase. Light-stimulated nitrogenase-mediated H₂ evolution was then recognized as a general property of photosynthetic bacteria (early reviews by Gest, 1972; Yoch, 1978; Meyer et al., 1978). In accordance with its high N₂ fixation capacity (Madigan et al., 1984), *Rb. capsulatus* has been found to be one of the most efficient H₂ producers (under nitrogen limited growth conditions) (Hillmer and Gest, 1977a, b). By means of its hydrogenase, *Rb. capsulatus* cells can recycle H₂ electrons to nitrogenase, which is a way for the cells to avoid energy loss in the form of H₂ (Meyer et al., 1978).

3. Production of Molecular Hydrogen in the Dark

Purple bacteria have also the capacity to ferment their endogenous substrates in the dark with production of organic acids, CO₂ and H₂ (van Niel, 1944; see Uffen, 1978 for review). Dark, fermentative H₂ production results from breakdown of formate to CO₂ and H₂ by formic hydrogenlyase (Gest, 1954). Gas production from formate by the formic hydrogenlyase reaction is not influenced by light but is completely inhibited by carbon monoxide (Gorrell and Uffen, 1977, 1978). This is a typical fermentative type of H₂ production, which is quite distinct from the CO-insensitive, ATP-dependent, production of H₂, mediated by nitrogenase.

The formic hydrogenlyase system is particularly well studied in *Escherichia coli*; it is hydrogenase 3, the product of the *hycE* gene, which transfers electrons to protons and releases H₂ (Sauter et al., 1992). A gene homolog to *hycE* has not been yet identified in a photosynthetic bacterium. *Rs. rubrum* should be a good candidate to look for it. *Rs. rubrum* can produce H₂ in the presence of ammonia, via a fermentative type of hydrogenase, and can also grow under autotrophic conditions with H₂ and CO₂ via non-fermentative pathways involving an adaptively synthesized H₂-uptake hydrogenase (Voelskow and Schön, 1980; see also Kern et al., 1994). Thus, in *Rs. rubrum*, three enzymes interact in H₂ metabolism according to the growth conditions: two hydrogenases

and nitrogenase. It is not known yet whether the hydrogenase which, with carbon monoxide dehydrogenase, evolves H₂ during anaerobic oxidation of CO (Bonam et al., 1989) represents an additional type of enzyme. Our knowledge of those enzymes, at the biochemical and genetic level, is less advanced in *Rs. rubrum*, for fewer genetic tools have been developed for it than for *Rb. capsulatus* or for *Rb. sphaeroides*.

B. Genetics of Hydrogen Production and Utilization in Photosynthetic Bacteria

The development of good genetic systems to study nonsulfur purple photosynthetic bacteria (Marrs, 1974; Taylor et al., 1983; Willison et al., 1985; Donohue and Kaplan, 1991) has intensified research in this group of bacteria (reviewed by Scolnik and Marrs, 1987). Genetic studies of H₂ metabolism in the photosynthetic bacteria, undertaken only recently, are mainly restricted to members of the Rhodospirillaceae, in particular to *Rb. capsulatus*, which was the first phototrophic bacteria for which an useful genetic exchange system was discovered (Marrs, 1974). Another interesting feature of *Rb. capsulatus* is that, like *Pseudomonas* spp., it can exchange plasmids of the R type by means of conjugation, a property which has greatly contributed to the development of genetic studies in *Rb. capsulatus* (reviewed by Donohue and Kaplan, 1991; and in Chapter 48 by Williams and Taguchi).

The development of methods for the genetic analysis of the mutants affected in the enzyme systems involved in H₂ metabolism (nitrogenase and hydrogenase) has permitted the genetic mapping of *nif* (nitrogen fixation) and *hup* (hydrogen uptake) genes on the *Rb. capsulatus* chromosome, using R plasmid-mediated conjugation (Willison et al., 1985; Willison, 1993) (Fig. 1), has led to the identification of gene clusters necessary for the biosynthesis of nitrogenase (Klipp et al., 1988) and of hydrogenase (Colbeau et al., 1993) and has provided information on the regulation of H₂ metabolism in the photosynthetic bacteria (see below).

This chapter focuses on the organization and expression of genes necessary for the expression of the H₂ uptake hydrogenase (*hup*) genes. The capacity of *Rb. capsulatus* to grow lithoautotrophically (Aut⁺ phenotype) has been used as a primary selective test to distinguish strains with an active hydrogenase (Hup⁺ phenotype) from hydrogenase-deficient strains (Hup⁻ and Aut⁻ phenotypes).

Fig. 1. Genetic linkage map of the *Rhodospirillum rubrum* chromosome. The position of genetic markers on the chromosome was determined by conjugation, using the mutant R plasmid, pTH10 (Willison et al., 1985). The positions of the *hup/hyp* gene cluster and the *himA* gene (characterized by the *aut-4* mutation) are shown. The *himA* gene is closely linked to the *nif* gene cluster containing the nitrogenase structural genes (*nifHDK*) and the *nifR₄* regulatory gene (for further details, see Willison, 1993). The figures inside the circle show the genetic map distance in arbitrary units, with the position of the *tyr-1* marker arbitrarily chosen as zero. Physical mapping of the *Rb. capsulatus* chromosome has shown its size to be 3.7 Mbp (Fonstein and Haselkorn, 1993). The physical map shows good agreement with the genetic map for several markers, except that the positions of the *glnA* and *nifR₁* genes are inverted with respect to *trp-1* and *adgA*. (See Chapter 49 by Haselkorn) (Adapted from Willison, 1993). The *adgA* gene has recently been shown to code for NH₃-dependent NAD synthetase (Willison and Tissot, 1994).

II. Hydrogenases of Photosynthetic Bacteria Belong to the Class of [NiFe]Hydrogenases

All hydrogenases catalyze the simple, reversible reaction of proton reduction leading to the formation of H₂ gas: $2\text{H}^+ + 2\text{e} \leftrightarrow \text{H}_2$. In addition to Fe-S clusters, the hydrogenase enzymes found in *Chromatium vinosum* (Albracht et al., 1983), in *Thiocapsa roseopersicina* (Gogotov, 1986; Bagyinka et al., 1993), as well as in *Rb. capsulatus* (Takakuwa and Wall, 1981; Colbeau and Vignais, 1983) have been shown to require Ni for activity and to contain Ni at their active site. They belong to class I of [NiFe]hydrogenases, are heterodimers (30 kDa and 65 kDa) and have a common evolutionary origin (Wu and Mandrand., 1993). The term [NiFe] is very appropriate because the crystal structure of the [NiFe] hydrogenase from *Desulfovibrio gigas* (Volbeda et al., 1995) revealed that the active site contains a nickel atom and an iron atom.

A. Mapping of *hup* Genes on the Chromosome of *Rb. capsulatus*

In contrast to *Alcaligenes eutrophus* (Eberz et al., 1986) and *Rhizobium leguminosarum* (Brewin et al., 1980), in which hydrogenase genes reside on a megaplasmid, in *Rb. capsulatus*, the hydrogenase is chromosomally encoded (Colbeau et al., 1990). *Hup*⁻/*Aut*⁻ mutants obtained by chemical mutagenesis (Willison et al., 1984; Colbeau et al., 1986) were used to map the *hup* loci on the genetic map of the *Rb. capsulatus* chromosome. The *hup* mutations used in the mapping experiments were found to be clustered on the chromosome in the proximity of the *his-2* marker. On the other hand, the mutation *aut-4* carried by the IR4 mutant (Willison et al., 1984), in the *himA* gene (Toussaint et al., 1991) maps close to the *nifR₄* gene, which is contiguous to the *nifHDK* structural genes of nitrogenase (Colbeau et al., 1990) (Fig. 1).

B. Organization of Hydrogenase Genes

1. Isolation of the *hup* Gene Clusters

By complementing *Hup*⁻ mutants with cosmids from gene banks of *Rb. capsulatus*, genomic DNA fragments containing *hup* determinants were isolated (Colbeau et al., 1986; Xu et al., 1989; Colbeau et al., 1990; Xu and Wall, 1991). The sequencing of those fragments revealed the presence of the cluster of *hup* genes (Leclerc et al., 1988; Richaud et al., 1990; Xu and Wall, 1991; Richaud et al., 1991; Colbeau et al., 1993) depicted in Fig. 2. The same approach, led to the isolation of the hydrogenase structural genes from *Rc. gelatinosus* (Uffen et al., 1990) and to the identification of several homologous *hup* genes in *Tc. roseopersicina* (Colbeau et al., 1994).

2. The Structural Hydrogenase Genes, *hupSLC*

The small and large subunits of hydrogenase are encoded by the *hupS* and the *hupL* genes, respectively. In *Rb. capsulatus*, *hupS* is capable of encoding a protein of 34,256 Da with 13 Cys residues, and the *hupL* gene can encode a protein of 65,839 Da containing 10 Cys residues. These proteins share a high degree of identity, more than 80 and nearly 70% with the small and large subunits, respectively, of the [NiFe]hydrogenases belonging to group I in the classification of Wu and Mandrand (1993) (cf. Colbeau et al., 1993).

The *hupS* gene is preceded by a sequence capable of encoding a signal peptide of 45 amino acids, which is found not only in genes encoding periplasmic hydrogenases but also is highly conserved among the membrane-bound hydrogenases (cf. Vignais and Toussaint, 1993). All the putative cleavable signal

(or leader) peptides found at the N-terminal end of the small hydrogenase subunit contain a strictly conserved "RRXFXK" consensus element and are cleaved after an alanine residue which suggests a conserved mechanism for the function of these signal peptides (Voordouw, 1992). Apparently, those signal peptides may function in some cases for membrane integration, since *Rb. capsulatus* hydrogenase is an intrinsic membrane protein (Colbeau et al., 1983) and in other cases for protein export to the periplasm. A nucleotide sequence capable of encoding a putative signal peptide has been identified at the 5' end of the *hupS* gene of *Rb. capsulatus* (Leclerc et al., 1988), of *Rc. gelatinosus* (Uffen et al., 1990) and of *Tc. roseopersicina* (Colbeau et al., 1994).

Downstream from *hupL* is the *hupC* gene (formerly termed *hupM*) which, in *Rb. capsulatus*, has been shown to be expressed only from the promoter of *hupSL* and therefore to belong to the same *hupSL* transcriptional unit (Cauvin et al., 1991). Inactivation of the *hupC* (*hupM*) gene, by interposon mutagenesis, resulted in mutants which could still synthesize an active hydrogenase assayable with artificial electron acceptors (methylene blue or benzylviologen), but which could not grow autotrophically, respire with H₂, or recycle electrons to nitrogenase. In other words, in those mutants the hydrogenase was no longer functionally competent. Introduction of plasmid-borne copies of the *hupC* (*hupM*) gene into the mutant cells restored an Aut⁺ phenotype in the transconjugants and full activity to the hydrogenase enzyme (Cauvin et al., 1991). The third gene of the *hupSLC* operon is thought to encode a cytochrome *b* which links the hydrogenase to the respiratory chain, as has been demonstrated in *Wolinella succinogenes* (Dross et al., 1992).

Fig. 2. Organization of genes in the *hup/hyp* gene cluster of *Rb. capsulatus* (Colbeau et al., 1993). The scheme shows also that the hydrogenase gene cluster is flanked by genes involved in chemotaxis: the product of ORF19 shares sequence similarities with *E. coli* CheB and CheR proteins, and the *mcpA* and *mcpB* genes are capable of encoding chemoreceptors of the methyl-accepting type (V. Michotey, B. Toussaint, P. Richaud and P. M. Vignais, unpublished).

3. Hydrogenase Gene Organization and Accessory Genes

The cloning and sequencing of hydrogenase gene clusters led to the surprising discovery that the number of genes necessary for hydrogenase synthesis is nearly as large as the number of *nif* genes required for the biosynthesis of nitrogenase. In the latter case, several *nif* genes have been shown to be involved in the synthesis and insertion of the metallic centers in the enzyme complex which remains in the cytoplasm as a soluble oligomeric enzyme. The membrane-bound and the periplasmic hydrogenases may require additional helper (chaperone ?) proteins and signal peptidase for membrane integration or export to the periplasm.

Comparative studies of the products of the genes which encode [NiFe]hydrogenase in various organisms suggest that there is a common core of at least 18 genes, whose products are necessary for effective hydrogenase biosynthesis. Since homologous genes have been termed differently in the various organisms, the organisation and the name of the clustered genes so far identified are indicated in Table 1. In Fig. 3, the size of the products of the best known hydrogenase gene clusters is given.

Immediately downstream from the structural hydrogenase operon *hupSLC* is *hupD*, which can encode a product homologous to *E. coli* HyaD (Table 1, Fig. 3). Inactivation of *E. coli* *hyaD* results in deficiency in processing of both the large and the small subunits of *E. coli* hydrogenase 1 (Menon et al., 1991). The *hyaD* product has been recently identified as a protease involved in hydrogenase maturation (Rosmann et al., 1995).

In *E. coli*, an operon necessary for the activity of the three hydrogenase isoenzymes has been cloned and sequenced. It comprises five *hyp* (for hydrogenase pleiotropic) genes, *hypABCDE* (Lutz et al., 1991). The products of the *hypB*, *hypD* and *hypE* genes are involved in the processing of the large subunits of hydrogenases 1 and 2 (Lutz et al., 1991); the *hypA* and *hypC* gene products appear to adjust the activity of hydrogenase 3, relative to those of hydrogenases 1 and 2 involved in respiration (Jacobi et al., 1992). The product of *hypB* has been recently shown by Maier et al. (1993) to catalyze some step in nickel incorporation into the 3 hydrogenases and to have GTPase activity. Homologs of the *E. coli* *hyp* operon genes have been found in the photosynthetic

bacterium, *Rb. capsulatus* (Xu and Wall, 1991; Colbeau et al., 1993) (Table 1, Figs. 2, 3) but the exact function of their products has not yet been identified.

Genes encoding a product homologous to HypF of *Rb. capsulatus* (Colbeau et al., 1993) have been found within the *hyp* operon in *R. leguminosarum* and in *Azotobacter vinelandii* (Table 1, Fig. 3). The predicted HypF proteins contain at their N-terminal end two Cys-rich clusters which resemble zinc-finger motifs, a structure which could conceivably enable the proteins to chelate nickel atoms. The HypF protein, like HypB, is currently thought to play a role in nickel metabolism in relation with hydrogenase biosynthesis. In *Rb. capsulatus*, it has been shown also to participate in the H₂-stimulation of hydrogenase gene expression (Colbeau et al., 1993).

In summary, identification of the *hup/hyp* gene organisation has laid a firm foundation for further studies on hydrogenase biosynthesis. The gene organisation is strikingly similar in these clusters and it is anticipated that homologous genes encode proteins with analogous functions. The absence of some of the genes gives also interesting clues as to the minimum requirement for the synthesis of an effective enzyme and for the genes likely involved in specific regulation. For example, in *Tc. roseopersicina*, the *hupFG* genes appear to be lacking (Table 1), (unless they are localized elsewhere on the chromosome). The major challenge now is, on the one hand, to identify the role of those conserved genes and, on the other hand, to determine the specificity of each hydrogenase gene cluster, in terms of genes leading to the assembly of hydrogenase complexes capable of interacting with specific electron acceptors/donors, in terms of regulatory genes participating to bacterial signaling systems leading to the adaptive cellular responses to specific growth or stress conditions.

III. Regulation of Hydrogenase Genes

The remarkable metabolic versatility of the purple, nonsulfur bacteria, which permits their adaptability to environmental changes, no doubt depends on multiple regulatory circuits. Regulation of hydrogenase gene expression in response to environmental stimuli has so far been studied only in *Rb. capsulatus*.

Table 1. Gene products homologs to those encoded by the *hup* and *hyp* genes from *Rb. capsulatus*, identified in other bacteria. The Hup and Hyp proteins are ordered horizontally according to the order of their genes in the hydrogenase gene cluster in each bacterium. Empty slots mean that the corresponding gene is missing in the species. Only in *E. coli* are the hydrogenase genes dispersed on the chromosome. In *R. leguminosarum* and *A. eutrophus* the cluster of genes is plasmid-borne.

A. Environmental Factors Affecting Hydrogenase Synthesis

A translational fusion of the *E. coli lacZ* gene to the *Rb. capsulatus hupSLC* promoter has been constructed and used to identify the Hup⁻ mutants mutated in regulatory genes and the environmental stimuli to

which those regulatory genes responded (Colbeau and Vignais, 1992). The plasmid-borne *HupS::lacZ* fusion was transferred to the wild type strain B10 and to various Hup⁻ mutants. The expression of β -galactosidase and that of the chromosomally encoded hydrogenase were then measured under various physiological conditions. The factors found to affect

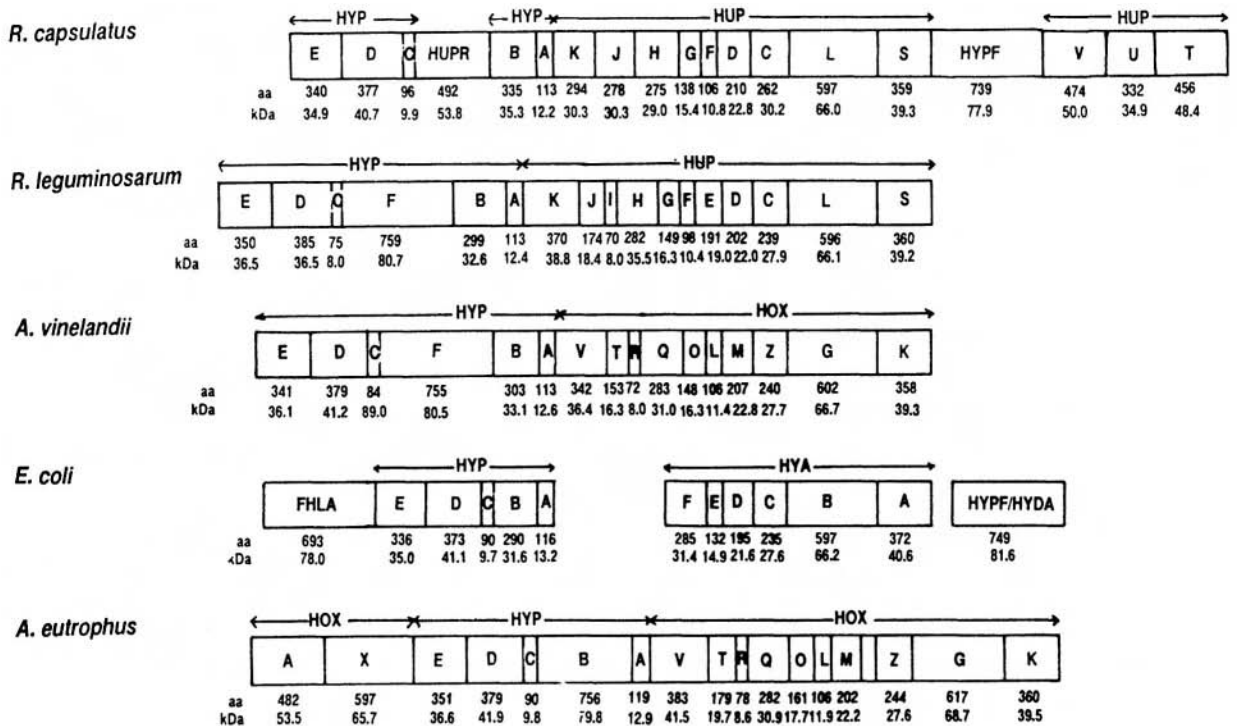

Fig. 3. Comparison of deduced hydrogenase gene products. Only the most completely sequenced clusters are shown. The size of boxes is proportional to the size (in kDa) of the predicted gene products. See legend to Table 1 for source of data.

hydrogenase expression were the following:

1. Molecular Hydrogen Stimulates Hydrogenase Gene Expression in *Rb. capsulatus*

Molecular hydrogen was the factor which, in the wild-type strain B10, stimulated most the expression of β -galactosidase and of hydrogenase. The highest expression was observed under conditions which favor expression of nitrogenase (anaerobiosis, light and malate-glutamate medium) or in darkness in the presence of H_2 plus O_2 . Since H_2 is evolved by nitrogenase, $NifR_4^-$ mutants devoid of nitrogenase (Ahombo et al., 1986) were used to check whether the increased hydrogenase expression observed under nitrogenase-derepressing conditions was really due to H_2 and not a result of activation of the *nif* or *ntf* regulatory circuit. The *nifR₄* gene of *Rb. capsulatus* encodes a protein homologous with the sigma factor σ^{54} , product of the *ntfA* (*rpoN*) gene in other bacteria (Jones and Haselkorn, 1989; Alias et al., 1989). It was found that hydrogenase and β -galactosidase were still expressed in $NifR_4^-$ mutants

in a H_2 -stimulatable way (Colbeau and Vignais, 1992). Therefore, firstly, the observed stimulation was indeed due to the presence of H_2 , and secondly, hydrogenase expression in *Rb. capsulatus* had no absolute requirement for the factor σ^{54} encoded by *nifR₄*. The possibility cannot be excluded that there is another factor σ^{54} in *Rb. capsulatus*, as was found in *Bradyrhizobium japonicum* (Kullik et al., 1991) and in *Rb. sphaeroides* (Meijer and Tabita, 1992).

2. Oxygen Control

From the use of DNA gyrase inhibitors, Kranz and Haselkorn (1986) have suggested that O_2 regulation of *nif* gene expression was exerted at the level of DNA supercoiling. It is interesting to note that O_2 regulation of hydrogenase synthesis is unaffected by DNA gyrase inhibitors such as novobiocin (Willison et al., 1990). Rather unexpectedly, since hydrogenase enzymes are O_2 -labile and unlike nitrogenase, hydrogenase and β -galactosidase expressed from the *hupS::lacZ* fusion were still synthesized at high levels in the form of active enzymes in the presence of

oxygen provided that H₂ be present (Colbeau and Vignais, 1992). Elsen et al. (1993) have even been able to obtain mutants (HupT⁻, see below) which overexpress active hydrogenase in the presence of oxygen, indicating that the HupT protein is involved in (O₂)-repression.

B. Transcriptional Regulation and Regulatory Genes

1. The *hupR* Gene Encodes a Response Regulator of the NtrC Subfamily

Measurement of β -galactosidase and of hydrogenase activity showed that both activities in the Hup⁻ mutant RCC8, harboring the *hupS::lacZ* fusion, were decreased to 4% of those found in the wild-type strain B10 (Colbeau and Vignais, 1992). This finding indicated that the mutation in RCC8 affects a transcriptional factor required for the expression of both enzymes. The gene, *hupR*, complementing the mutation was isolated and sequenced, together with the mutated *hupR* gene from mutant RCC8. The *hupR* gene is capable of encoding a transcriptional activator belonging to the NtrC subfamily (Richaud et al., 1991) of the superfamily of two-component regulatory systems (reviewed by Stock et al., 1989, 1991; Albright et al., 1989; Bourret et al., 1991; Parkinson and Kofoid, 1992; Parkinson, 1993). These activators act by catalyzing the isomerization of the closed RNA polymerase-DNA complex at the transcriptional start site, into an open complex, at the expense of ATP. The mutated *hupR* gene in strain RCC8 contains a point mutation in the codon of one of the amino acids belonging to the putative ATP-binding site of the HupR protein (Richaud et al., 1991). These data support the contention that HupR plays the role of a response regulator in the transcription of the *hupSLC* operon. The HupR protein shares an overall 43% identity with the HoxA protein of *A. eutrophus* shown to be a transcriptional regulator in the expression of *A. eutrophus* hydrogenase (Eberz and Friedrich, 1991).

2. The *hupT* Gene Product of *Rb. capsulatus* Represses Hydrogenase Synthesis

The *hupT* gene is located upstream from the structural *hupSLC* genes, while *hupR* is downstream in the middle of the *hup* genes (Fig. 2). Amino acid sequence

comparisons have indicated that the predicted HupT protein (456 amino acids, 48.4 kDa) belongs to the superfamily of sensor kinases which, in two-component regulatory systems, function in tandem with a response regulator. It is predicted to be a soluble sensor-kinase, since it lacks the hydrophobic region thought to maintain the protein in the membrane, as do *Rb. capsulatus* NifR₂ and *Klebsiella pneumoniae* NtrB with which it shares sequence similarities. HupT is expected to be a kinase molecule capable of autophosphorylation and a putative nucleotide binding site has indeed been identified in the deduced amino acid sequence (Elsen et al., 1993). HupT shares sequence similarities with components of signal transduction systems responding to O₂ such as FixL of *Rhizobium meliloti* (although no significant similarity exists with the fragment of FixL shown to bind heme and to bind oxygen (Monson et al., 1992)), or ArcB of *E. coli* which represses the *arc* modulon under anaerobiosis (Iuchi et al., 1990). However, while ArcB participates in anaerobic repression, *hupT* appears to be involved in regulation by the carbon status of the cell (S. Elsen, unpublished results). It is also of interest to note that HupT does not share sequence similarity with HoxX, the putative sensor protein thought to function in tandem with the response regulator HoxA (homologous to *Rb. capsulatus* HupR, Table 1), in *A. eutrophus* and *B. japonicum* (cf. Elsen et al., 1993).

Two other genes, *hupU* and *hupV*, contiguous with and downstream from *hupT*, belong to the same *hupTUV* operon (Fig. 2). HupU, capable of encoding a protein of 34.9 kDa, and *hupV* a protein of 50.0 kDa, share sequence similarities with the small and the large subunits of [NiFe] hydrogenases, respectively. The strongest similarity is observed with the periplasmic hydrogenase of *Desulfovibrio baculatus*, but the *hupU* gene does not comprise a sequence for a signal peptide (Elsen et al., 1993; S. Elsen, A. Colbeau and P. M. Vignais, unpublished data).

Insertional inactivation of the *hupT* gene leads to deregulation of transcriptional control so that the structural hydrogenase operon *hupSLC* becomes overexpressed in cells grown aerobically or anaerobically, either in the presence or in the absence of ammonia. The HupT⁻ mutants are Hup^e (constitutive) mutants in which hydrogenase is maximally expressed under conditions (presence of ammonia, presence of oxygen) where hydrogenase activity is minimum in the wild-type strain B10. This indicates

that the HupT protein participates in the *repression* of hydrogenase expression. This repression is restored when plasmid-borne copies of the wild-type gene are introduced in the HupT⁻ mutants (Elsen et al., 1993). It is to note that, in contrast, mutation in the *hupR* gene resulted instead in a decrease in transcription and in activity of hydrogenase indicating that the HupR protein is rather a positive transcriptional factor (Colbeau and Vignais, 1992).

Therefore, although the *hupR* gene product presents features of response regulators and the product of *hupT* those of sensor kinases indicating that they belong to the superfamily of two-component regulatory systems, it remains to be demonstrated that the two proteins form a matched pair of regulatory proteins.

3. An IHF-like Protein Activates *in vivo* Transcription of the *hupSLC* Operon

By complementation of the Hup⁻ mutant IR4, a gene called *himA* of *Rb. capsulatus* has been isolated and sequenced (Toussaint et al., 1991). The gene is capable of encoding a protein sharing 45% identical amino acids with the α -subunit of the Integration Host Factor (IHF) of *E. coli*. An IHF consensus sequence, identified in the promoter of the *hupSLC* operon, was shown to bind *E. coli* IHF by gel retardation assays, and therefore to be a true IHF binding site. Similarly, the IHF-like protein recently isolated from *Rb. capsulatus* has been shown to bind to the same IHF binding site. Like *E. coli* IHF, *Rb. capsulatus* IHF is a heterodimeric protein (10 and 11 kDa). The *hip* gene which encodes the β subunit has been isolated from *Rb. capsulatus* and sequenced; its products shares 46% identical amino acids with *E. coli* IHF β subunit. Foot-printing analyses have shown that *Rb. capsulatus* IHF and *E. coli* IHF on the one hand, and that the IHF protein isolated from the *himA* mutant IR4 on the other hand, do not interact exactly in the same manner with the IHF binding site of the *hupS* promoter region (Toussaint et al., 1993). A molecular model of the interaction between *Rb. capsulatus* IHF protein and DNA from the *hupS* promoter region is shown in Fig. 4. In this model, where DNA is strongly bent by the IHF molecule, Arg-8 is able to interact with the phosphate-ribose backbone of DNA in the flanking region of the IHF binding site (Toussaint et al., 1991, 1994). It has been shown earlier that the replacement of Arg-8 by Cys-8 in mutant IR4 affects hydrogenase transcription (Colbeau and Vignais, 1992).

Fig. 4. A three-dimensional model of *Rb. capsulatus* IHF bound to its binding site on the *hupSLC* promoter. Coordinates of the protein atoms were deduced from the crystal structure of HU of *Bacillus stearothermophilus* (Tanaka et al., 1984; White et al., 1989). The 40 bp IHF site has been modeled taking into account DNA bending. The position of IHF to its site was deduced from Dnase I foot-printing data (Toussaint et al., 1993). Arg-8 is replaced by a Cys in the IR4 mutant. The model has been assembled and refined by Laurent David using the Quanta 3 program of Molecular Simulation.

4. Sigma Factors

The *nifR₄* gene codes for a protein showing sequence homology to the *ntrA* gene product (σ^{54}) of other Gram-negative bacteria (Alias et al., 1989; Jones and Haselkorn, 1989). The *nifR₄* gene is located adjacent to, and downstream from, the nitrogenase structural genes (*nifHDK*) (Fig. 1) and is transcribed from its own promoter (Ahombo et al., 1986). Studies with a *nifR₄::lacZ* gene fusion have shown that transcription of the *nifR₄* gene requires the presence of the *nifR₁*/*nifR₂* (*ntrC/ntrB*) genes and of *nifA* and that the *nifR₄* gene product is also required for its own synthesis (Hübner et al., 1991). The *nifR₄* gene is therefore different from its homolog, *ntrA*, in other Gram-negative bacteria, which is generally expressed constitutively (reviewed by Thöny and Hennecke, 1989). A further difference is that in *Rb. capsulatus*, the *nifR₄* gene is exclusively involved in the regulation of nitrogen fixation, whereas in other Gram-negative bacteria, many of which are not nitrogen fixing (e.g., *E. coli*, *Pseudomonas putida*, and *A. eutrophus*) *ntrA* may be involved in the regulation of the uptake and utilization of alternative nitrogen sources, of some carbon sources, and of H₂ (Thöny and Hennecke, 1989).

As described above, nitrogen fixation and hydrogen

uptake are interrelated, since the H_2 evolved by nitrogenase may induce the synthesis of hydrogenase, and under some conditions, hydrogenase activity may allow the recycling of electrons from H_2 to nitrogenase. However, a relationship at the genetic level has not been established, and the *nifR₄* gene product is not required for hydrogenase gene expression (Colbeau and Vignais, 1992). Transcriptional analysis of the *hupS* promoter by primer extension or nuclease S1 protection has allowed us to determine the transcriptional start site of *hupSLC* operon. There is no direct evidence of the occurrence of the (-24)GG-N₁₀-GC(-12) consensus sequence in the promoter. On the other hand, around positions -10 and -35 we can observe the presence of hexamers, GAGAAT and TTGGCG, which contain respectively 4/6 and 5/6 of nucleotides identical to -10 -35 *E. coli* boxes recognized by sigma factor 70 (σ^{70}) (Delic-Attree I, unpublished results). Although IHF is usually implicated in transcription from σ^{54} -associated RNA polymerase, it has already been shown that expression of the *E. coli nar* and *ompF* genes (Rabin et al., 1992; Ramani et al., 1992) utilizes IHF and σ^{70} -associated RNA polymerase. Nevertheless, the fact that expression of hydrogenase genes is dependent on the response regulator HupR suggests that an alternative sigma factor for RNA polymerase may also be required. (It should be noted that no additional genes homologous to *nifR₄* have been identified in *Rb. capsulatus* by DNA-DNA hybridization). The possible existence of a sigma factor other than NifR₄ has also been invoked for the regulation of the expression of the *nifA* genes in *Rb. capsulatus* (Hübner et al., 1991). In *Rb. capsulatus*, the *nifA* gene is unusually present in two copies, both of which are active (Masepohl et al., 1988). The expression of both copies of *nifA* is dependent on the *ntrBC* homologs, *nifR₂*, and *nifR₁*, but is independent of *nifR₄*, suggesting that an additional, alternative sigma factor is required for their expression (Hübner et al., 1991).

IV. Conclusions and Perspectives

The identification of the genes necessary for hydrogenase expression in several organisms, the striking similarity of the proteins encoded by homologous genes, should accelerate our understanding of the function of those proteins and of the mechanisms of *hup* gene control and regulation. Among the photosynthetic bacteria, it is in *Rb. capsulatus* that the molecular biology of hydrogenase

is the most advanced.

With respect to the environmental stimuli which have been shown to affect hydrogenase gene expression in *Rb. capsulatus*, there are clearly two main factors—namely the availability of molecular hydrogen and the levels of O_2 in the immediate environment. Synthesis of hydrogenase is stimulated by H_2 and is repressed in presence of O_2 alone, but is maximal in the presence of H_2 plus O_2 .

One significant environmental factor that has received little attention until recently in terms of possible regulatory effects, is the availability of metals such as nickel. The lack of data may result from technical difficulties in addressing the problem (it is difficult to deplete *Rb. capsulatus* cells of nickel, for example), rather than from a lack of interest in the subject.

Hup gene regulation presents features typical of prokaryotic gene regulation in that it depends upon regulatory proteins belonging to the widespread family of two-component regulatory systems. It may also present other specific features since analysis of the *hup* promoter structure appears to indicate that σ^{70} rather than RpoN (σ^{54}) may be involved in *hup* gene transcription. There is still much to be learned from further studies of these systems, with respect to the detailed molecular mechanisms of activation of gene transcription, to the identification of environmental factors affecting *hup* gene expression and in the understanding of the processes of signal transduction that link gene expression to environmental changes.

Particular questions which are likely to be addressed in future studies are as follows:

- (i) How is hydrogenase synthesis regulated by H_2 and by O_2 ? At what level does regulation occur, and are specific DNA recognition sequences involved?
- (ii) Are nickel ions directly involved in regulation of expression? If they are, can they play the role of H_2 detector? In the *hup* gene cluster, which gene can encode a protein able to bind Ni and become a transcriptional activator?
- (iii) Does *Rb. capsulatus* contain alternative sigma factors for RNA polymerase in addition to the constitutive sigma factor (σ^{70}) and σ^{54} (NifR₄/NtrA/RpoN). If it does, are these factors involved in the expression of the *hup* genes?

(iv) How are modulated the interactions between IHF and DNA? Are there additional proteins which help in the binding of IHF to its site? If yes, what are they? Is it the participation of this type of helper proteins that explains the lack of effect of the *himA* mutation, in the IR4 mutant, on *nif* gene expression?

(v) The predicted HupR and HupT proteins belong to the superfamily of two-component regulatory systems. Does the putative response regulator HupR function in tandem with the putative sensor kinase HupT? What are the signals to which each of them respond? Does HupR activate transcription in the phosphorylated form? If HupR and HupT do not form a matched pair, what are the other partners?

Elucidation of the answers to these questions will require studies both at the cellular level and *in vitro*, using purified components of the different regulatory gene networks.

Acknowledgments

The authors gratefully thank Drs J. Meyer and J.C. Willison for critical reading of the manuscript and J. Boyer for expert assistance in the preparation of the manuscript.

Summary

Some prokaryotes can reduce atmospheric dinitrogen to ammonia as a source of fixed nitrogen. The biological process of nitrogen fixation (*nif*) requires significant sources of reductant and energy. Moreover, in the anoxygenic photosynthetic bacterium, *Rhodobacter capsulatus*, at least 34 proteins are involved in this process including nitrogenase, the molybdenum-containing enzyme that catalyzes this reduction. If ammonia or other source of fixed nitrogen is already present in the environment it becomes unnecessary and wasteful to express nitrogen fixation (*nif*) genes and reduce dinitrogen. Additionally, nitrogenase is irreversibly inactivated by oxygen, making nitrogen fixation possible only under anaerobic (or microaerobic) conditions in anoxygenic photosynthetic bacteria. Therefore, *Rb. capsulatus*, and other anoxygenic photosynthetic bacteria, have developed specific nitrogen and oxygen-sensing systems that activate transcription of *nif* genes only under conditions of limiting nitrogen and oxygen. This chapter reviews the current state of knowledge about the transcriptional control of *nif* genes primarily in the best studied phototroph, *Rb. capsulatus*. This remarkable

regulatory system involves a cascade of protein factors: UTase → GlnB → NtrB → NtrC → NifA and RpoN → transcriptional activation of other *nif* genes. Some of these factors sense nitrogen and some oxygen. The molecular basis for the activity of each of these proteins is discussed. Additional control in *Rb. capsulatus* is at the level of molybdenum; recently an alternative nitrogenase (*anf*) that appears to contain no molybdenum (but iron instead) has been discovered in *Rb. capsulatus*. Synthesis of *anf* is repressed by molybdenum but is still under the control of nitrogen and oxygen. Studies on this alternative system have contributed to our understanding of *anf* and molybdenum-based gene regulation. Anoxygenic photosynthetic bacteria rapidly fix nitrogen in the presence of light as the energy source representing one of the few ways to directly and efficiently convert the energy from sunlight into the fixation of atmospheric dinitrogen. However, there is no evidence that anoxygenic photosynthetic bacteria show any specific *nif* gene regulation in response to light, but they do exhibit amazing metabolic diversity. These capabilities include the use of a variety of sources of nitrogen and carbon under aerobic and anaerobic growth conditions. Additionally, within the aquatic habitats where photosynthetic bacteria are found, rapidly changing environmental conditions make rapid and diverse gene regulation necessary. Studies on *nif* genes in photosynthetic bacteria will continue to contribute to our own understanding of *nif* regulation in general and to our knowledge of basic mechanisms of transcriptional control.

I. Introduction: Nitrogen Fixation (*nif*) Genes; Transcriptional Control by Fixed Nitrogen and Oxygen

Nitrogen fixation is the reduction of atmospheric dinitrogen to ammonia. Although all organisms on earth require fixed nitrogen for survival and growth, only a select group of prokaryotes have been shown to fix dinitrogen biologically. Anoxygenic photosynthetic bacteria comprise a large class of microorganisms that are capable of carrying out this process. Other chapters in this book describe (1) the historical perspectives and microbiology of nitrogen fixation in anoxygenic phototrophs (Chapter 42 by Madigan) and (2) the biochemical aspects and enzymology of nitrogen fixation (Chapter 43 by Ludden and Roberts). The present chapter concerns the transcriptional regulation of genes required for nitrogen fixation in photosynthetic bacteria. Biological nitrogen fixation is an energy-intensive process with a major requirement for reductant and ATP. The molybdenum-containing nitrogenase enzyme composed of three polypeptides has been isolated from a number of phototrophs as have the genes that encode them (*nifHDK*). However, *Rhodobacter capsulatus* has been the model anoxygenic photosynthetic bacterium for the analysis

of *nif* gene regulation and *nif* gene organization. In *Rb. capsulatus* two major clusters of *nif* genes encoding up to 34 gene products involved in nitrogen fixation have been discovered (see Fig. 1 and references in legend). Many of these *nif* genes have homologs that were described initially in *Klebsiella pneumoniae* and subsequently in other diazotrophs. An overview on the genetic organization of *nif* genes in the five best studied diazotrophs (including *Rb. capsulatus*) has recently been published (Merrick, 1993). Non-regulatory genes in *Rb. capsulatus* include the structural genes *nifHDK*; *nifE*, *nifN*, *nifX*, *nifV*, and *nifB* for synthesis of the MoFe cofactor; *nifY*, *nifU* and *NifS* for processing of the nitrogenase MoFe protein component; and *nifQ* for Mo processing. Interestingly, *Rb. capsulatus* has duplications of at least three genes, *nifU*, *nifA*, and *nifB*, although the reason for this redundancy remains obscure. Other *nif* genes or orfs within the *nif* clusters may be involved in aspects of nitrogen fixation tailored to a specific bacterial physiology. For example, photosynthetic bacteria may utilize an electron transport pathway to nitrogenase that requires specific proteins dedicated to its various reducing environments. Thus, some of the *Rb. capsulatus* orfs at the *nifENX* cluster encode ferredoxin-like proteins, potentially involved in the electron transfer reaction to nitrogenase (Moreno-Vivian et al., 1989). Three genes within the two *nif* clusters in *Rb. capsulatus* are involved in transcriptional regulation: *nifA1*, *nifA2* and *rpoN*. Two other loci in *Rb. capsulatus* encode the regulatory genes *glnB*, *ntrB* and *ntrC* (see Fig. 1). These regulatory genes, the proteins they encode, and their functions will be described in detail.

Abbreviations: Atase – adenylyltransferase; *E. coli* – *Escherichia coli*; IHF – integration host factor; *K. pneumoniae* – *Klebsiella pneumoniae*; *Rb. capsulatus* – *Rhodobacter capsulatus*; *Rb. sphaeroides* – *Rhodobacter sphaeroides*; RNAP – RNA polymerase; UAS – upstream activating sequences; UTase – uridylyltransferase

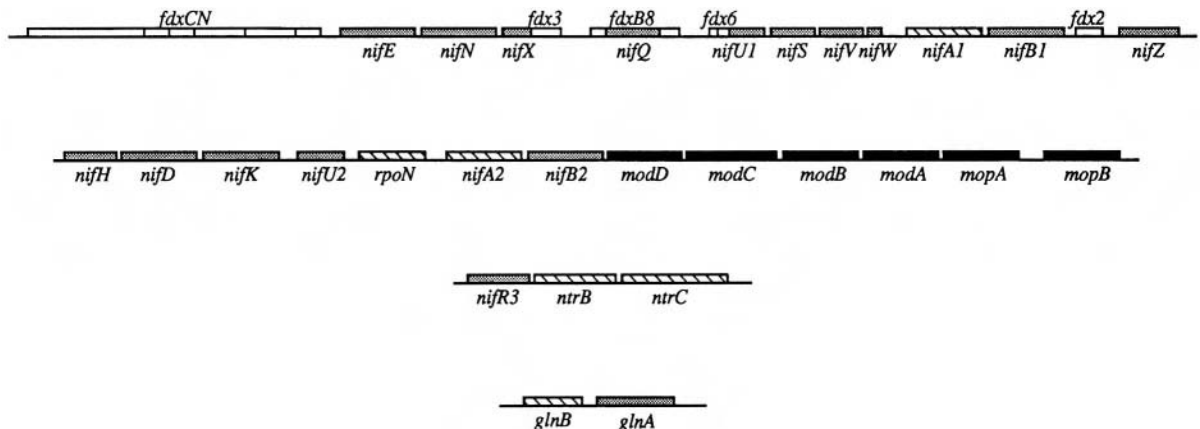

Fig. 1. Organization of *nif* genes in *Rhodospirillum rubrum*. Four separate loci contain at least 40 genes that are involved in nitrogen fixation in *Rb. capsulatus*. The *glnBA* locus (Kranz et al., 1990), *nifR3ntrBntrC* locus (Kranz and Haselkorn, 1985; and Foster-Hartnett et al., 1993), *nifHDKU2-rpoN-nifA2B2* locus (Avtges et al., 1983; Klipp et al., 1988; and Masephol et al., 1988), the molybdenum uptake locus (Wang et al., 1993) and the locus that contains the *nifENX* genes (e.g. Moreno-Vivian et al., 1989; see Merrick, 1993 for review) are shown. *nif* genes are lightly shaded, regulatory genes are hatched, *fdx* genes are not shaded, and genes involved in molybdenum uptake or repression are in black. The spacing between the genes is not to scale.

Transcription of *nif* genes is controlled by fixed nitrogen and oxygen. The biosynthesis requirement of at least 34 proteins involved in nitrogen fixation along with the energy needs to carry out the reduction reaction itself make this biological process one of the most costly enzymatic reactions in the cell. Consequently, microorganisms have evolved remarkable mechanisms to turn on *nif* genes only when they are needed and to repress transcription of *nif* genes when they are not. When free-living, nitrogen-fixing bacteria are faced with environmental conditions abundant in fixed nitrogen (e.g. ammonia) there is no need to synthesize ammonia within the cell. Thus, exogenous ammonia, or a fixed nitrogen source which is easily transported and assimilated (e.g. into amino acids, purines, pyrimidines) leads to repression of *nif* genes. Additionally, oxygen reacts with nitrogenase and irreversibly inactivates this enzyme. Nitrogen-fixing bacteria have therefore developed mechanisms to (1) keep oxygen out of the cell, such as the formation of heterocysts in filamentous oxygenic cyanobacteria (see Haselkorn et al., 1986 for review), (2) protect their nitrogenase from oxygen, such as the rapid oxidase activities of *Azotobacter* species (Maier and Moshiri, 1993 for review) and/or (3) repress the expression of *nif* genes when oxygen levels are high. *Rb. capsulatus*, like all free-living unicellular diazotrophs, has evolved mechanisms to activate transcription of *nif* genes only when the concentration of these two effectors

(fixed nitrogen and oxygen) are low (for review, see Kranz and Foster-Hartnett, 1990). Although *Rb. capsulatus* has been used as the model phototroph to study these mechanisms, there are clear similarities to the gene regulatory controls used by other microorganisms (non phototrophs); these will be discussed and compared.

II. General Models Describing *nif* Regulatory Mechanisms

A. *Rhodospirillum rubrum*

Before detailing the individual sensing and activator proteins involved in *nif* transcriptional control, an overview on the strategies used by *Rb. capsulatus* to accomplish this regulation will be presented (see Fig. 2). Briefly, an enzyme called uridylyltransferase (UTase) is predicted to control the uridylylation of another protein, GlnB, depending on the levels of fixed nitrogen in the cell. Under nitrogen-deficient conditions, UTase uridylylates GlnB; uridylylated GlnB would no longer interact with NtrB, NtrB consequently functioning only as a kinase. The substrate of the NtrB kinase, NtrC, is phosphorylated under this condition. (Under nitrogen-sufficient conditions a GlnB/NtrB complex is predicted to act as an NtrC~P phosphatase.) NtrC~P is predicted to be an ATPase which, upon binding to DNA upstream,

Fig. 2. Transcription regulatory cascade of nitrogen fixation genes in *Rhodospirillum rubrum*; oxygen and nitrogen control in a phototroph. Details of the cascade are described in the text. UTase, uridylyltransferase; RNAP, RNA polymerase; IHF, integration host factor. UTase is proposed to sense the ratio of glutamate to 2-ketoglutarate, compounds that reflect endogenous levels of fixed nitrogen. When the ratio is low, UTase essentially inactivates GlnB by the covalent addition of uridylylmonophosphate, UMP. Under these conditions, NtrB acts as a kinase that phosphorylates NtrC, a proposed transcriptional activator. The NtrC protein has three domains: An N-terminal regulatory domain, a central ATP-binding activation domain, and a C-terminal helix-turn-helix domain that is shown to bind to DNA over 100 bp upstream of the *nifA1* and *nifA2* promoters (i.e. UAS). Phosphorylated NtrC is proposed to activate transcription of the *nifA1* and *nifA2* genes via an unknown sigma factor. The *rpoN* gene is also regulated; a primary promoter is responsible for nitrogen-independent, low levels of *rpoN* expression, and an autoactivated secondary promoter increases the expression of *rpoN* under nitrogen-limiting conditions. NifA, a DNA binding transcriptional activator, and RpoN, a *nif*-specific sigma factor, together catalyze transcriptional activation of *nifHDK* and other *nif* genes, possibly in an IHF-stimulated manner. Oxygen control probably takes place at the level of NifA activity and possibly at the *rpoN* promoter.

transcriptionally activates the *nifA1* and *nifA2* genes. Transcriptional activation of *nifA1* and *nifA2* results in the nitrogen-dependent increase in NifA protein. NifA itself is predicted to possess ATPase activity (like the NtrC class of proteins) and act as a transcriptional activator of all other *nif* genes,

including *nifHDK*. The transcriptional activation of *nif* genes by NifA additionally requires an RNA polymerase (RNAP) alternative sigma factor called RpoN. The *Rb. capsulatus* *rpoN*-encoded sigma factor is interesting because of its physical location (i.e. *nifHDK*-linkage), its expression, and its struc-

tural properties when compared to RpoN proteins from other microorganisms. Expression of the *Rb. capsulatus rpoN* gene is autoactivated (by RpoN and NifA) at a secondary promoter upstream of *nifU2*. This secondary promoter results in a more rapid and higher maximal induction of other *nif* genes which is physiologically beneficial under certain environmental conditions (see IIIf below). Oxygen regulation is not as well understood as nitrogen control, although it is thought that the NifA protein itself may be oxygen sensitive and that other oxygen-sensing control may be mediated through DNA supercoiling (see VI, Future Studies).

The activation of *nifHDK* and other *nif* genes by NifA and RNAP/RpoN may be enhanced by the DNA binding protein, integration host factor (IHF). Santero et al. (1992) have shown that the *K. pneumoniae nifHDK* promoter region is activated in vitro to 20-fold higher levels when IHF is added. This is proposed to occur by IHF-induced bending of the DNA such that the interaction frequency of RNAP/RpoN with the NifA protein, bound at upstream activating sequences (UAS), is increased. Hoover et al. (1990) have shown that *E. coli* IHF binds to the appropriate DNA within the *Rb. capsulatus nifH* upstream region, thus suggestive that a similar IHF protein and interactions may occur in *Rb. capsulatus*.

B. Other Anoxygenic Phototrophs

Concerning trans-acting factors involved in *nif* gene regulation in other phototrophs, to our knowledge, only *Rb. sphaeroides* has so far been investigated. In that organism, two *rpoN* genes and an *ntrC* gene appear to be present (see below).

III. Regulatory Components Related to Other Bacterial Proteins

A. Uridylyltransferase (= UTase = GlnD)

Studies on mutants in the enteric *glnD* gene suggested that *glnD* was involved in nitrogen control because *glnD* mutants lost their ability to deadenylate glutamine synthetase in response to the nitrogen source (e.g. Bancroft et al., 1978; Bloom et al., 1978; Foor et al., 1978). Consequently, these mutants are glutamine auxotrophs. Early studies on nitrogen control proteins in *E. coli* involved the analysis of the enzyme encoded by *glnD*, UTase (e.g. Adler et al.,

1975). Biochemical experiments on the purified *E. coli* UTase indicated that (1) UTase covalently uridylylates and deuridylylates the GlnB protein (via UTP) and (2) UTase activity is allosterically effected by glutamine (which activates deuridylylation) or 2-ketoglutarate (which activates uridylylation). Since the ratio of glutamine to 2-ketoglutarate reflects the general nitrogen status of the cell, allosteric modulation of UTase by these molecules is the key sensing element of the nitrogen regulatory system in enteric bacteria. The substrate of UTase action, GlnB, is a protein of approximately 12,000 daltons (behaving as a tetramer), and the *Rb. capsulatus glnB* gene has been isolated and sequenced (Kranz et al., 1990; see below). Although the UTase gene has only been isolated and sequenced from *E. coli* and *Azotobacter vinelandii* (Conteras et al., 1991), its presence in *Rb. capsulatus* has been postulated because of the conservation of its substrate, GlnB particularly within the site of uridylylation. Cloning and inactivation of the *glnD* gene in *Rb. capsulatus* is still required to confirm this aspect of the nitrogen fixation regulatory cascade. It is important to note however that the phenotype of an *Rb. capsulatus glnD* mutant would, by the model, be predicted to be a Nif⁻ regulatory mutant because NtrC would always be dephosphorylated. However, if the *Rb. capsulatus glnD* gene is involved in other nitrogen-control systems the phenotype of a *glnD* strain is impossible to predict. Moreover, since some regulatory genes have already been shown to be duplicated in *Rb. capsulatus* (*nifA*; Klipp et al., 1988) and *Rb. sphaeroides* (*rpoN*; Meijer and Tabita, 1992) isolation of a double mutant in *glnD* genes, if duplicated, would be unlikely by traditional mutagenesis procedures.

B. glnB

Uridylylation of GlnB, in response to nitrogen limitation essentially inactivates the GlnB protein which allows NtrB to function in its kinase mode only (e.g. Ninfa and Magasanik, 1986; Keener and Kustu, 1988). Consequently, inactivation of the *glnB* gene would be predicted to also 'release' the NtrB protein such that it is continually a kinase, irrespective of fixed nitrogen levels. Thus, by this model, *Rb. capsulatus glnB* mutants would be Nif-constitutive with respect to nitrogen concentrations (i.e. Nif^{c:NH₄}). In fact, isolation of *Rb. capsulatus glnB* mutants and the *glnB* gene were isolated using this premise. *Rb. capsulatus* Nif^{c:NH₄} mutants were isolated by using a

lactose-selection technique and *nifH-lacZ* fusions (see Kranz and Haselkorn, 1986). Analysis of a cosmid that returned some of these $\text{Nif}^{\text{c:NH}_4}$ back to normal regulation (i.e. nitrogen repression) yielded the *glnB* gene (Kranz et al., 1990). Analysis of this locus indicated that *glnA*, encoding glutamine synthetase, was downstream from the *glnB* gene. Inactivation by Tn5 mutagenesis of the chromosomal *glnB* orf resulted in a glutamine auxotroph, presumably because of polarity on *glnA*. These *Rb. capsulatus glnB* transposon mutants are Nif^{c} with respect to glutamine or ammonia anaerobically but still repress synthesis of nitrogenase under aerobic conditions. Recently, transcription of the *glnBA* operon has been studied using *lacZ* fusions and primer extension (Foster-Hartnett and Kranz, 1994). These results show that (1) two promoters are upstream of *glnB*: *glnBP1* is repressed by NtrC and *glnBP2* is activated by NtrC and (2) a third promoter within *glnB* for *glnA* transcription may exist. Additionally, activation of *glnBP2* is independent of RpoN, and purified *Rb. capsulatus* NtrC binds to tandem binding sites greater than 100 bps upstream of the *glnBP2* transcription start site (but overlapping *glnBP1*). These results add a third promoter, *glnBP2*, to a short list that includes *nifA1* and *nifA2* which require NtrC for activation but not RpoN. Like *nifA1* and *nifA2*, *glnBP2* is not an RpoN-type promoter (Foster-Hartnett and Kranz, 1994). In enteric bacteria, *glnB* is present at a different locus than *glnA*, while *glnA* is in a complex *glnA-ntrB-ntrC* operon (see below). Additionally, in enteric bacteria, *glnB* has been shown to interact with adenylyltransferase (ATase), which adenylylates or deadenylylates glutamine synthetase depending on this interaction (i.e. nitrogen status; Stadman et al., 1980). It has not been shown whether the *Rb. capsulatus glnB* mutants are altered in their glutamine synthetase modification system, although the glutamine synthetase enzyme is apparently modified (Johansson and Gest, 1977). To summarize, in enteric bacteria the GlnB protein is a multi-faceted protein which interacts with a variety of protein substrates (e.g. NtrB, ATase and UTase) to alter their enzymatic properties. Recently it has been proposed that GlnB may interact directly with the NifA protein in *Azospirillum brasilense*, based on genetic studies (deZamaroczy et al., 1993). Thus, the versatility of GlnB as a modulator of protein activity may be greater than originally thought (see also III below).

C. ntrB

Under nitrogensufficient conditions, the GlnB protein is not uridylylated and interacts with NtrB by an unknown mechanism. Consequently, a phosphatase activity of the NtrB protein is induced resulting in dephosphorylation of the NtrC protein (e.g. Ninfa and Magasanik, 1986; Keener and Kustu, 1988). When GlnB is uridylylated by UTase (under nitrogen-limiting conditions) or the *glnB* gene is mutated (under nitrogen-limiting or sufficient conditions) NtrB only phosphorylates the NtrC protein. The *Rb. capsulatus* NtrB and NtrC proteins thus comprise a pair of the previously reviewed two-component bacterial regulatory systems (e.g. Gross et al, 1989; Stock et al, 1990). These aspects of the regulatory model are consistent with the phenotype of *Rb. capsulatus ntrB* mutants (and *ntrC* mutants); such mutants are Nif^- and unable to activate a *nifH-lacZ* fusion in *Rb. capsulatus* (Kranz and Haselkorn, 1985). The *ntrB* gene in *Rb. capsulatus* is not located in *glnA-ntrB-ntrC* operon as in the enteric bacteria. Rather, the *Rb. capsulatus ntrB* gene is located in a *nifR3-ntrB-ntrC* operon (Foster-Hartnett et al., 1993). (Note: *Rb. capsulatus ntrB* and *ntrC* were previously called *nifR2* and *nifR1* respectively.) Although the function of NifR3 is unknown (see below) the *Rb. capsulatus* NtrB sequence was predicted to be an NtrC kinase because of the phenotype of *ntrB* strains and the conservation between this protein and other kinases of the NtrB-class of protein (Jones and Haselkorn, 1988). This includes a completely conserved histidine residue which accepts the phosphate group from ATP (in an autophosphorylation reaction) and subsequently transfers this phosphate group to NtrC. Recently, the *Rb. capsulatus* NtrB, purified as a fusion protein to the maltose binding protein, has been shown to autophosphorylate and transfer the phosphate to NtrC (Cullen and Kranz, unpublished).

D. ntrC

As noted above, *Rb. capsulatus ntrC* mutants were originally isolated as Nif^- colonies (Wall and Braddock, 1984) and later shown to be *nif* regulatory mutants using a *nifH-lacZ* reporter (Kranz and Haselkorn, 1985). The *Rb. capsulatus ntrC* gene was cloned by complementation of these mutants to a Nif^+ phenotype by a wild-type DNA library (Avtges et al., 1985). Southern hybridization experiments

with these DNA fragments showed that this gene was *ntrC* (Kranz and Haselkorn, 1985), and sequence analysis of this DNA showed orfs that encode NtrB- and NtrC-like proteins (Jones and Haselkorn, 1989). Recent studies have shown that the *ntrC* gene is required for the activation of both *nifA1-lacZ* and *nifA2-lacZ* fusions (Foster-Hartnett and Kranz, 1992; Preker et al., 1992). Accordingly, nitrogen control is mediated through the *nifA* regulatory genes via an NtrC-dependent process. Under nitrogen-deficient conditions, phosphorylated NtrC activates the transcription of *nifA1* and *nifA2*. Surprisingly, primer extension analyses (Foster-Hartnett and Kranz, 1992) have indicated that the *nifA1* and *nifA2* promoters do not possess the consensus RpoN-recognition sequences (i.e. GG N₁₀ GC). In all other cases, members of the NtrC-class of protein activate RNAP containing the alternative RpoN sigma factor at such promoters (see Kustu et al., 1989; North et al., 1993). Moreover, RpoN⁻ strains of *Rb. capsulatus* are still able to activate *nifA1* and *nifA2* in an NtrC-dependent manner. This is true for both deletions and point mutations in the *Rb. capsulatus rpoN* gene.

Recent surveys (Collado-Vides et al., 1991) of promoters within *E. coli* have defined two types: One class uses the housekeeping type of sigma factor (σ^{70}) and another set uses the RpoN (σ^{54}) type of sigma factor (and is always activated by an NtrC-type activator). The σ^{70} class of promoters, when activators are used, typically require DNA ≤ 70 bps upstream of the transcription start site for activation. The second, RpoN/NtrC class typically requires > 100 bp upstream for activation 'at a distance'. Studies performed on the *E. coli* and *Salmonella typhimurium* NtrC systems were in fact the first cases of 'enhancer' like activities discovered in procaryotic systems, describing this activation at a distance phenomenon (Reitzer and Magasanik, 1986; Reitzer et al., 1989; Su et al., 1990; Wedel et al., 1990). For *Rb. capsulatus*, deletion analysis has shown that DNA between -114 and -139 upstream of the transcriptional start site is required for NtrC-dependent *nifA2* activation (Foster-Hartnett and Kranz, 1992) and between -134 and -144 are required for *nifA1* activation (Foster-Hartnett et al., 1994). Thus, the *nifA1* and *nifA2* promoters of *Rb. capsulatus* fit the pattern of NtrC-activatable genes (i.e. > 100 bp required) but clearly do not possess the RpoN-type of promoter. Very recently, Foster-Hartnett et al. (1994) have shown by DNase I footprint analysis that the purified *Rb. capsulatus* NtrC binds to tandem recognition sites in the same

distal regions determined to be important for in vivo activation. Thus, *Rb. capsulatus* NtrC clearly activates the *nifA1* and *nifA2* promoters (and *glnBP2*) directly by binding to tandem distant sites in an RpoN-independent manner.

A comparison of selected members of the NtrC class of proteins define three regions important for function (Fig. 3; see reviews by North et al., 1993, and Mopett and Segovia, 1993, for details and extended references). First, the N-terminus of all NtrC proteins, including the *Rb. capsulatus* NtrC, possess the aspartate residues which are phosphorylated by NtrB. Second, the C-terminus of all, including the *Rb. capsulatus* NtrC, possess a typical helix-turn-helix motif that is required for binding DNA upstream of the promoters that each activates (i.e. UAS). Additionally, as proposed by North et al. (1993), the C-terminus contains extended sequence similarity to each other and to the DNA binding protein FIS. *Rb. capsulatus* NtrC also has this extended identity to FIS (Foster-Hartnett et al., 1993) and it has been proposed that this region may be involved in dimerization of NtrC to form active dimers or oligomers. In fact, recent data is suggestive that phosphorylation of the N-terminus catalyzes not only ATP-dependent hydrolysis (see next), but also oligomerization of NtrC protein (Weiss et al., 1992), both of which are required for the transcriptional activation of RNAP/RpoN. Third, the central domain of all true NtrC-type proteins contain a consensus ATP-binding motif. This domain is even present in extended members of the NtrC family, such as NifA, that do not possess the N-terminal phosphorylation or FIS-like C-terminus. The central domain of the *Rb. capsulatus* NtrC protein clearly possesses the ATP binding site or 'Walker motif' (Walker et al., 1982). Studies by Weiss et al. (1991) and Austin and Dixon (1992) have shown that the hydrolysis of ATP by NtrC is required for open complex formation by the RNAP-RpoN holoenzyme; this directly distinguishes the NtrC-class of transcriptional activators from other known bacterial activator proteins. Recently, the ATP-binding site was altered by site-directed mutagenesis (of the *Rb. capsulatus* NtrC protein); this NtrC was shown to be completely inactive for *nifA1* and *nifA2* expression yet was still able to bind upstream (Foster-Hartnett et al., 1994). Thus, by these criterion, the *Rb. capsulatus* NtrC protein fits the paradigm of an RNAP/RpoN activator. However, a region between the 'Walker motif' and C-terminal domain is conserved within the other

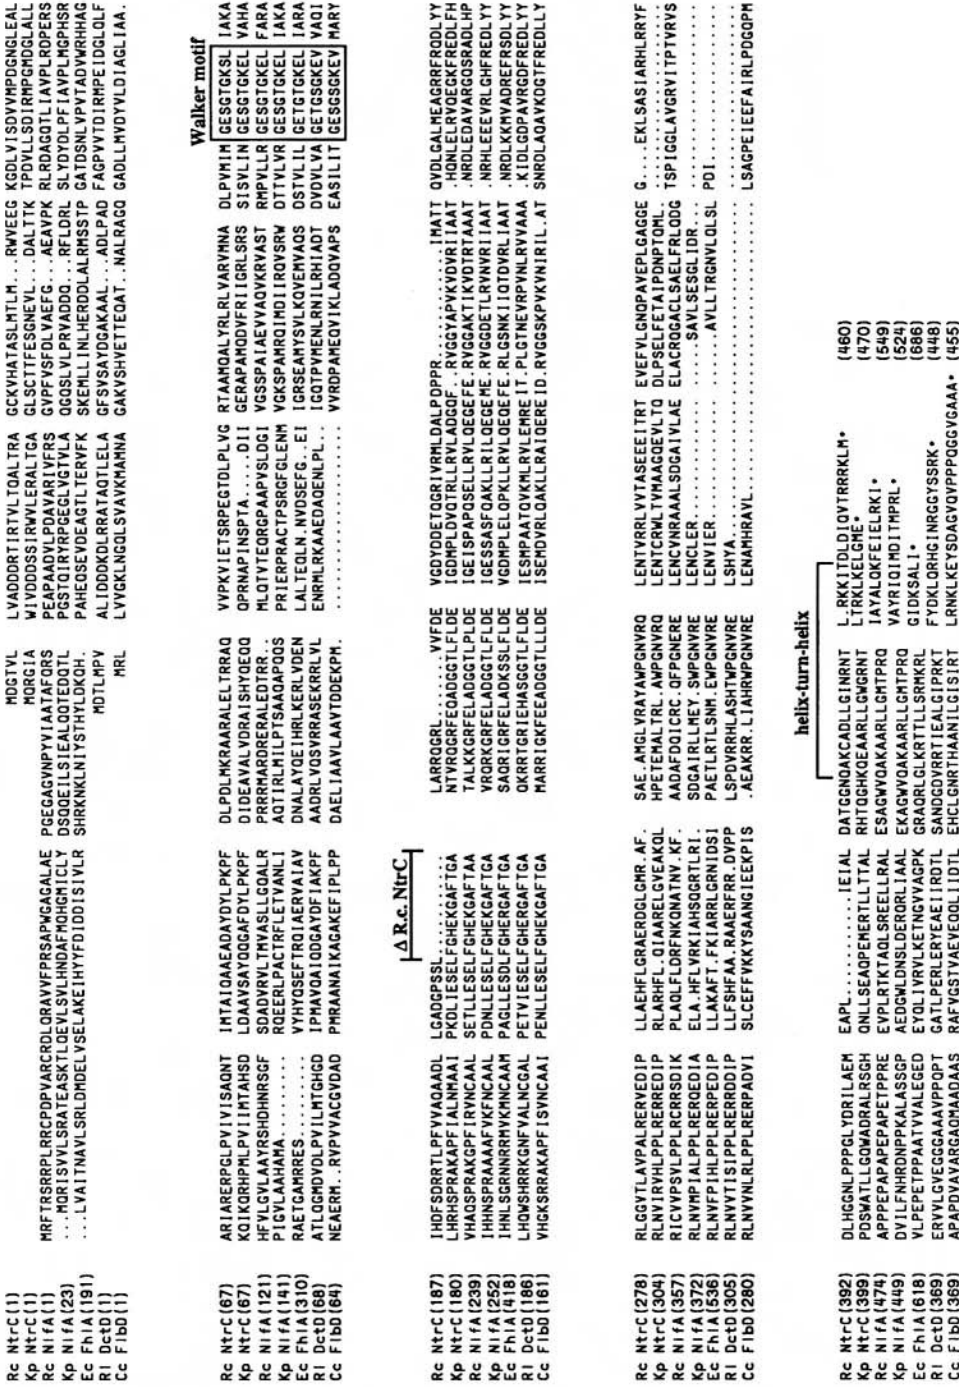

Fig. 3. Comparison of different NtrC-like proteins. The amino acid sequences of *Rb. capsulatus* NifA (Rc NifA; Masephol et al., 1988), *Rb. capsulatus* NtrC (Rc NtrC; Jones and Haselkorn, 1989) *K. pneumoniae* NifA (Kp NifA; Drummond et al., 1986), *K. pneumoniae* NtrC (Kp NtrC; Buikema et al., 1985), *E. coli* FhA (Ec FhA; Maupin and Shammugam, 1990), *Rhizobium leguminosarum* DctD (R1 DctD; Ronson et al., 1987), and *Caulobacter crescentus* F1bD (Cc F1bD; Ramakrishnan and Newton, 1990) are shown. The N-terminus of the *E. coli* FhA and *K. pneumoniae* NifA are not shown. The nucleotide binding site, or Walker motif (Walker et al., 1982), is boxed. An asterisk defines the aspartate residue (D54) which has been shown to be phosphorylated by the NtrB protein in *E. coli* NtrC (Sanders et al., 1992). The helix-turn-helix region, proposed to be involved in DNA binding, is marked. The natural deletion observed in the *Rb. capsulatus* NtrC but not in RpoN-dependent, ATP-dependent NtrC-type activators is also shown; see text for details. Note: Only select proteins of the NtrC-class of proteins are shown; the above mentioned natural deletion is the only observed difference in the *Rb. capsulatus* NtrC as compared to the NtrC-class of proteins so far sequenced. Initially, GCG bestfit comparisons were used to align these sequences in a pairwise fashion; subsequent alignments were performed manually.

members of the NtrC proteins but not *Rb. capsulatus* (Fig. 3). This domain may contact the RpoN/RNAP holoenzyme. Because the exact mechanisms by which NtrC~P activates transcription of RNAP/RpoN is unknown it is premature to conclude that this region interacts specifically with RpoN. Clearly, analysis of members of the NtrC-class of proteins that activate RNAP containing sigma factors other than RpoN will aid in understanding the basic molecular mechanisms behind the activation process. Do other photosynthetic bacteria contain unique NtrC members and what can be learned by analyzing exceptions to the rules? Section F below describes properties of RpoN which further distinguish the NtrC-class of protein activator systems.

E. *nifA*

Transcription of the *Rb. capsulatus nifA1* and *nifA2* genes depend upon an NtrC-mediated mechanism. Although this transcriptional activation is repressed by fixed nitrogen, it is oxygen insensitive (Foster-Hartnett and Kranz, 1992). Therefore oxygen repression occurs at a later stage in the regulatory cascade. This is in contrast to the regulatory cascade in *K. pneumoniae* in which a *nifLA* operon is activated by the nitrogen sensing NtrC/RpoN system only under anaerobic conditions (Dixon et al., 1980). Aerobic repression of the *K. pneumoniae nifLA* promoter is thought to occur by a DNA supercoiling mechanism whereby anaerobically grown cells show an increase in DNA negative supercoiling, a requirement for *nifLA* activation (see Whitehall et al., 1992 and references therein). The suggestion that an increase in supercoiling is required for *nifLA* activation by NtrC/RpoN/RNAP is based on results of in vivo analyses of *K. pneumoniae nif* expression and recent in vitro transcription experiments with the purified NtrC/RpoN/RNAP components.

The *Rb. capsulatus nifA1* and *nifA2* are thought to have identical orfs but differ significantly upstream of their proposed translational start sites. The *Rb. capsulatus nifA1* and *nifA2* genes were discovered by using the *K. pneumoniae nifA* gene as a probe in Southern hybridization experiments (Klipp et al., 1988). Inactivation of either *nifA1* or *nifA2* results in an *Rb. capsulatus Nif⁺* phenotype but inactivation of both *nifA1* and *nifA2* yields a *Nif⁻ Rb. capsulatus* strain that is unable to synthesize nitrogenase polypeptides (Masepohl et al., 1988). As indicated earlier, the physiological advantage of possessing

duplicated *nifA* genes has yet to be determined.

The NifA protein from *Rb. capsulatus*, like all NifA proteins from a diverse array of diazotrophs, is a member of the NtrC class of proteins. The *Rb. capsulatus* NifA protein contains the typical NtrC-like central domain with the consensus ATP-binding site (see Fig. 3). NifA also has a C-terminal helix-turn-helix motif, presumably required for binding to the DNA with the sequence TGT-N₁₀-ACA, a typical NifA binding site (Morett et al., 1988). This consensus (or a similar binding site) has been discovered upstream of a number of NifA/RpoN activated genes in *Rb. capsulatus* (e.g. *nifH*, *nifU2*; see review by Kranz and Foster-Hartnett, 1990; Preker et al., 1992). The NifA proteins show little similarity in their C-terminus to FIS, possibly suggestive that although ATPase activity may be necessary for transcriptional activation, oligomerization may not (North et al., 1993). *Rb. capsulatus* NifA protein contains cysteine residues that are conserved among most members of the NifA family including the symbiotic organisms *Bradyrhizobium* and *Rhizobium* (Masepohl et al., 1988). It has been proposed that these cysteine residues may chelate an oxygen sensitive metal, thus explaining the oxygen sensitive NifA activity observed in these NifA proteins (Fischer and Hennecke, 1987). Interestingly, the *K. pneumoniae* and *Azotobacter* NifA proteins do not have these conserved cysteines and are not oxygen sensitive (Huala and Ausubel, 1989 and references therein). Rather, in these organisms another protein called NifL senses oxygen and by an unknown mechanism inactivates the NifA protein. Thus, one point of oxygen control within the *Rb. capsulatus nif* regulatory cascade may be the sensitivity of the NifA proteins to oxygen. Very recently, Kustu and colleagues have synthesized a Mal-NifA (from *K. pneumoniae*) fusion protein that retains in vitro activation activity, thus overcoming previous problems with the overproduction of inactive NifA protein (Lee et al., 1993). The in vitro transcription studies indicate that NifA-mediated activation requires the hydrolysis of any nucleotide triphosphate. Accordingly, although the basic mechanism of RNAP/RpoN activation by NifA may be similar to that of NtrC, specific hydrolysis of ATP is not essential, as it is with the enteric NtrC.

Another form of control in the *Rb. capsulatus* regulatory cascade may exist and Hubner et al. (1993) have placed the *Rb. capsulatus nifA1* gene behind constitutively expressed promoters to

eradicate the NtrC-dependent nitrogen control. This construct was able to complement an *Rb. capsulatus nifA1/nifA2* double mutant to a Nif⁺ phenotype. However, a *nifH-lacZ* fusion in this strain is still only partially repressed by ammonia. The authors propose that a novel mechanism of nitrogen control is mediated at the level of the NifA protein. Future studies will be needed to determine if this residual control is mediated by the GlnB sensing system.

F. *rpoN*

As with the NifA proteins in other diazotrophs, it is thought that the *Rb. capsulatus* NifA protein binds upstream of *nif* promoters and activates RNAP containing the RpoN sigma factor. (Section III F-3 below describes promoters activated by *Rb. capsulatus* RpoN.) The *rpoN* gene (previously called *nifR4*) in *Rb. capsulatus* was isolated (Avtges et al., 1985) by complementation of Nif⁻ regulatory mutants (Wall et al., 1984). Surprisingly, this gene was mapped to the *nifHDK* locus, the first case of an *rpoN* gene with physical linkage to *nif* genes. In fact, previous results on other microorganisms have shown that the *rpoN*-encoded sigma factor is typically not associated only with nitrogen or *nif* control but with a wide variety of physiological responses (e.g. dicarboxylic acid transport; Ronson et al., 1987; flagellar synthesis; Helmann, 1989, for review). The *Rb. capsulatus rpoN* gene was subsequently sequenced by Jones and Haselkorn (1988) and Alias et al. (1989).

Since the regulated expression of *rpoN* in a cell could naturally control the levels of expression of all genes that it activates, it is important to understand the controls exerted on the *rpoN* promoter(s). Moreover, the RpoN genes from many different prokaryotes have been cloned and sequenced. The wide interest in this sigma factor stems from the unique aspects of NtrC-mediated activation, the plethora of environmental systems it controls, and the fact that RpoN is not homologous to the large family of sigma-70 factors that have been characterized. Such interest warrants a discussion on the expression and structure of the RpoN protein from anoxygenic phototrophs.

1. Expression of *rpoN*

Initial results with *Rb. capsulatus rpoN-lacZ* fusions indicated that *rpoN* expression is at least five-fold

repressed by fixed nitrogen or oxygen (Kranz and Haselkorn, 1985). This repression can now be explained by the following mechanism:

(1) A primary promoter directly upstream of *rpoN* is responsible for nitrogen-independent basal levels of expression of *rpoN*. Expression from this promoter is lower than can be detected using a *rpoN-lacZ* reporter (Foster-Hartnett and Kranz, 1992). However, this promoter is responsible for sufficient *rpoN* expression to yield a Nif⁺ phenotype under normal laboratory growth conditions (see below).

(2) Upon induction of the *nifA1* and *nifA2* genes (by nitrogen-limitation) a secondary promoter, upstream of *nifU2*, that depends on NifA and RpoN, results in *nifU2-rpoN* expression in the cell (Preker et al., 1992). This raises *rpoN-lacZ* expression to measurable β galactosidase levels, at least 20- to 100-fold higher than with the primary promoter alone (i.e. above background).

An *Rb. capsulatus* strain was created (Cullen et al., 1994) that has a transcriptional terminator upstream of the *rpoN* primary promoter but downstream of the secondary promoter (and between the *rpoN* and *nifU2* genes). This strain only expresses *rpoN* via the primary promoter, and it was used to show that the secondary, autoactivated promoter is responsible for a more rapid induction of nitrogenase (with a maximal expression of approximately 3-fold higher levels when the secondary promoter is not terminated). Importantly, although this strain is Nif⁺ under normal laboratory growth conditions, it is Nif⁻ when NaCl (> 50 mM) is added or Fe is limited (< 400 nM) in the media (Cullen et al., 1994). Thus, the physiological role of the secondary promoter may be to increase levels of Nif proteins such that under stress conditions limitations on nitrogen fixation are overcome.

2. Structure of the RpoN Protein

Recent models for the enteric RpoN sigma factor have suggested that five domains are characteristic of RpoN proteins (Fig. 4):

(1) a glutamine rich N-terminus (Sasse-Dwight and Gralla, 1990),

- (2) two hydrophobic heptad repeats that may form a DNA binding 'intramolecular leucine zipper' (Sasse-Dwight and Gralla, 1990),
- (3) an acidic central domain located between the two leucine zippers (Sasse-Dwight and Gralla, 1990),
- (4) a C-terminal helix-turn-helix motif involved in DNA binding (Coppard and Merrick, 1991; Merrick and Chambers, 1992), and
- (5) a C-terminal 'RpoN box' composed of 8 amino acids that are completely conserved among all RpoN proteins (Merrick, 1993).

Some of these domains are reminiscent of eucaryotic domains that are required for transcriptional activation (Courey and Tijan, 1988; Harrison, 1991; Hahn, 1993). An alignment of the *Rb. capsulatus* RpoN with the 13 other RpoN proteins that have been sequenced is shown in Fig. 4. Recent results by Merrick and Chambers (1992) have shown that the helix-turn-helix domain in the *K. pneumoniae* RpoN is important in binding to the -13 region of the promoter (GC of the GG N₁₀ GC consensus). Using linker mutagenesis, Cullen et al. (1994) have shown that the *Rb. capsulatus* RpoN helix-turn-helix is also required for function, as is the RpoN box (unknown function). A deletion of the N-terminal glutamine region (Δ 2-24) also completely inactivated the *Rb. capsulatus* RpoN protein.

A recent model proposed that the 2 leucine zipper domains interact, forming a DNA binding region, that loops out the acidic domain (Sasse-Dwight and Gralla, 1990). According to the model, the acidic domain is then involved in melting the promoter to form an open complex. This model has recently been reevaluated (Merrick and Chambers, 1992; Cullen et al., 1994) for the following reasons: (1) The *Rb. capsulatus* RpoN protein (and the recently sequenced *Rb. sphaeroides* RpoN) are lacking an acidic domain yet presumably still require the NifA protein for transcriptional activation; (2) linkers in the second 'leucine zipper' of the *Rb. capsulatus* RpoN protein resulted in RpoN alleles that retained function. However, the spacing in bona-fide leucine zipper proteins is critical; insertions within the zippers would disrupt such structures. Thus, although these hydrophobic heptad repeats may form α helices, they probably do not form typical leucine zippers.

Very recently, Tintut et al. (1994) have provided evidence that these hydrophobic-repeats may be involved in binding to the RNAP. In summary, the RpoN proteins from diverse microorganisms, including two photosynthetic bacteria, contain domains that are reminiscent of eucaryotic motifs important in transcription. However, only the role of the helix-turn-helix domain and heptad repeats have been critically investigated. Other domains in this sigma factor require further analyses to determine their role in transcriptional activation mediated by an ATP-dependent activator like NtrC.

3. Promoters Activated by RpoN

Promoters that have been shown (or proposed) to be activated by RpoN in *Rb. capsulatus* possess the consensus sequence GG-N₁₀-GC from -24 to -12 upstream of the transcriptional start site. S1 nuclease mapping (Pollock et al., 1988) and primer extension analyses (Foster-Hartnett and Kranz, 1992) of the *nifH* promoter and the *nifU2* promoter (Preker et al., 1992) have confirmed this suggestion. Additionally, some promoters have been shown to require RpoN for activation using *Rb. capsulatus* RpoN⁻ strains. As mentioned above, an AT rich region, centered between the putative NifA binding site and the *nifH* promoter, may be involved in the binding of an IHF-like protein to facilitate NifA interaction with RpoN/RNAP.

IV. Regulatory Components Unique to Anoxygenic Phototrophs (Or Are They)?

A. RNA Polymerase Sigma Factors

One of the most interesting aspects of the *Rb. capsulatus* *nif* regulatory cascade is the possibility that NtrC activates *nifA1*, *nifA2*, *glnBP2* and perhaps other genes (Rapp et al., 1986; Schuddlekopf et al., 1993) by a mechanism that may require ATP hydrolysis but not the RNAP sigma factor RpoN. If such is the case, then unique sigma factors are yet to be discovered. Alternatively, could the *Rb. capsulatus* NtrC protein activate a σ^{70} -type RNAP? Analyses of these alternative mechanisms would clearly contribute to our basic understanding of transcriptional activation.

An interesting difference between *Rb. capsulatus* and *Rb. sphaeroides* is that two *rpoN* genes may be present in *Rb. sphaeroides* (Meijer and Tabita, 1992).

Fig. 4. Comparison of the amino acid sequences of RpoN. The RpoN amino acid sequences of *Rb. capsulatus* (Rc), *Rb. sphaeroides* (Rs), *Bacillus subtilis* (Bs), *Thiobacillus ferrooxidans* (Tf), *K. pneumoniae* (Kp), *E. coli* (Ec), *Salmonella typhimurium* (St), *Bradyrhizobium japonicum* (Bj-1 and Bj-2), *Pseudomonas putida* (Pp), *Azotobacter vinelandii* (Av), and *Rhizobium meliloti* (Rm, Rm104A14, and RmNGR234) are aligned by size. The glutamine rich region (Q-rich region), acidic domain, helix-turn-helix, and RpoN box are labeled. The hydrophobic residues that form the backbone of the two hydrophobic heptad repeats (i.e. 'leucine zippers') are boxed. See text for details. The references for these sequences are as follows: Rc, Jones and Haselkorn, 1989; Rs, Meijer and Tabita, 1992; Bs, Debarbouille et al., 1991; Tf, Berger et al., 1990; Kp, Merrick and Gibbins, 1985; Ec, Sasse-Dwight and Gralla, 1990; St, Popham et al., 1991; Bj-1 and Bj-2, Kullik et al., 1989; Av, Merrick et al., 1989; Pp, Kohler et al., 1989 and Inouye et al., 1991; Rm, Ronson et al., 1987; Rm104A14, Shatters et al., 1989; and Rm NGR234, vanStooten et al., 1990.

The *Rb. sphaeroides* *nif*-linked *rpoN* is not essential for a Nif^+ phenotype yet the *Rb. capsulatus* *rpoN* is required. Presumably, the second copy of *rpoN* in *Rb. sphaeroides*, detected by Southern blot analysis, is sufficient. A second *rpoN* in *Rb. capsulatus* has not been detected by Southern blot analysis using various *rpoN* genes as probes (see review by Kranz and Foster-Hartnett, 1990). However, Colbeau and Vignais (1992) have recently suggested that because the *hupS* gene is still activated in an *Rb. capsulatus* RpoN^- strain and because it contains a consensus RpoN -type promoter, that a second *rpoN* gene may be present in *Rb. capsulatus*. Nevertheless, primer extension results have not been reported for the *hupS* gene in an RpoN^- background to confirm this idea. Results from the *nifA1* and *nifA2* primer extension experiments rule out the possibility of RpoN -type promoters for those genes. Possibly, photosynthetic bacteria have evolved a larger repertoire of sigma factors to respond more rapidly and with greater metabolic versatility to their changing environments. In this respect, having a single RpoN that can be activated by the large class of NtrC -like proteins places some limitations on versatility. This is particularly true if the NtrC -like proteins can activate from long distances (i.e. as enhancers), thus placing upper limits on the numbers of NtrC -like activation systems that are possible on a bacterial chromosome. From ecological or evolutionary perspectives and to contribute to our basic understanding about mechanisms of transcriptional activation, it will be important to determine what alternative sigma factors are present in these microorganisms.

B. *nifR3*

The *Rb. capsulatus* *nifR3* gene is directly upstream of *ntrB-ntrC* in an *nifR3-ntrB-ntrC* operon. *nifR3* was originally defined by Tn5 and mini-*Mu* chromosomal insertions that resulted in a Nif^- regulatory phenotype (i.e. could not activate a *nifH-lacZ* fusion; Kranz and Haselkorn, 1985 and Avtges et al., 1985). Although the original sequence of this region yielded no *nifR3* orf, additional sequence analysis has confirmed the existence of an orf upstream of *ntrB* (Foster-Hartnett et al., 1993). Insertional and deletion mutagenesis and complementation analyses of *nifR3-ntrB-ntrC* have shown that *nifR3* is not essential for nitrogen fixation and that the reason for the Nif^- phenotype was polarity into *ntrB* and *ntrC* from the Tn5 and mini-*Mu*

insertions (Foster-Hartnett et al., 1993). Interestingly, *NifR3* is highly homologous to an ORF (called FIS ORF1) upstream of the DNA binding protein FIS, in an ORF 1-FIS operon. What is the function of *NifR3*? Typically, genes in operons encode proteins with functions in similar biological processes; such is the case for many *nif* genes (described here) and many of the photosynthetic and other genes described in this textbook. Does *NifR3* in some way modulate the activity of NtrB or NtrC under certain environmental conditions? Very recently, the *ntrB-ntrC* locus of the plant symbiont *Rhizobium leguminosarum* has been shown to possess an upstream *nifR3* gene (Patriaca et al., 1993). Thus, *nifR3* is probably not unique to photosynthetic bacteria but understanding its function requires further study.

C. Others

A question of considerable importance during the last 50 years has been the connection between photosynthesis and nitrogen fixation in anoxygenic photosynthetic bacteria. Approximately 15 years ago it was discovered that *Rb. capsulatus* can fix nitrogen both in the dark anaerobically and the light (Madigan et al., 1979). This result suggested that photosynthesis and nitrogen fixation were not obligatorily linked. Nevertheless, anaerobiosis alone is sufficient for both the induction of *nif* (under nitrogen limitation) and photosynthetic proteins. *Rb. capsulatus* mutants that are unable to grow photosynthetically but still able to express *nifH-lacZ* fusions seem to rule out direct biosynthetic linkage (Kranz and Foster-Hartnett, 1990). A class of *Rb. sphaeroides* mutants (called *drn*) that only express their genes for nitrogen fixation in the light but not in the dark have been described (Shestakov et al., 1988). These mutants are also derepressed for nitrogenase (i.e. $\text{Nif}^{\text{c:NH}_3}$). It was proposed that another level of control, above the proteins involved in the *nif* regulatory model for *Rb. capsulatus* (Fig. 2) was operating. However, very recently, these *drn* point mutations have been shown to be located in the *Rb. sphaeroides* *ntrC* gene (S. Shestakov, personal communication). How could *ntrC* mutants yield the *drn* phenotype described above? One possibility is that energy charge (or nucleotide triphosphate pools) differ in dark- and light-grown cells. The NtrC mutant protein, requiring high energy phosphate for both phosphorylation and ATPase/transcriptional activation would be sufficiently active in the light- but not dark-grown cells. Obviously,

other explanations are possible, including the unlikely prospect that light is sensed in some way by the NtrC protein. Nevertheless, there is presently no data suggesting that anoxygenic photosynthetic bacteria possess specific light-sensing mechanisms involved in *nif* gene regulation.

Another class of *Rb. capsulatus* and *Rb. sphaeroides* mutant that were originally thought to be *nif* regulatory mutants are the *adg* (ammonia-dependent growth) mutants (Zinchenko et al., 1990). These strains are unable to grow on nitrogen sources other than ammonia. Although the *Rb. capsulatus* defects were originally classified as *ntr* (nitrogen regulatory) mutants (Allibert et al., 1987), it is clear that these strains are able to express significant levels of nitrogenase (and a *nifH-lacZ* fusion). The latter point has been shown with the mutant PA3 that has the same phenotype (and gene that complements) as *adg* mutants (Kranz and Haselkorn, 1985; Avtges et al., 1985). The gene complementing these mutants has been cloned and sequenced and has in fact been isolated from a number of different bacteria. The *adg* sequence does not offer clues to its function but it appears to be a gene essential for growth since only *adg* point mutants (but not insertions) could be isolated. Very recently, Willison and Tissot (1994) have shown that *adg* encodes an ammonia-dependent NAD synthetase. A similar class of *Rb. capsulatus* mutant was isolated by Wall and colleagues many years ago (Wall et al., 1977).

V. The Alternative Nitrogen Fixing Systems: Aspects Concerning Gene Regulation

An alternative non-molybdenum nitrogenase in *Azotobacter* was initially proposed by Bishop and colleagues (see Joerger et al., 1989, and references therein). Recently, Schneider et al. (1991) discovered that an *Rb. capsulatus* strain deleted of its *nifHDK* genes could grow under nitrogen-free conditions if molybdenum was stringently scrubbed from the media. This alternative nitrogenase was determined to be free of a heterometal (e.g. Vanadium) and probably is an Fe-nitrogenase (Schneider et al., 1991). The *Rb. capsulatus* alternative nitrogenase, encoded by *anfHDGK*, is expressed only under Mo-free, anaerobic, nitrogen-limiting conditions. A regulatory gene called *anfA* is directly upstream of *anfHDGK*, and encodes a protein that is related to NifA

(Schuddlekopf et al., 1993). However, the *Rb. capsulatus* *AnfA* is not a member of the cysteine-containing, oxygen-sensitive NifA class. Thus, oxygen regulation of *anfHDGK* may be different than *nifHDK* in *Rb. capsulatus* (see VI). Further, it has been shown that the *Rb. capsulatus* *ntrB*, *ntrC* and *rpoN* but not *nifA1* and *nifA2* genes are required for *anfHDGK* expression (Schuddlekopf et al., 1993). Accordingly, one would predict that NtrC activates *anfA* in a nitrogen-dependent manner and *AnfA* and *RpoN*/RNAP subsequently activate other *anf* genes.

What represses the synthesis of *anf* genes when molybdenum is present? Wang et al. (1993) have characterized six genes (called *mol* and *mop*) linked to *nifHDKU2-rpoN-nifA2B2*, that are involved in the repression of *anf*. Four of these genes (*molPJDx*) may encode a typical ATP-dependent, membrane-bound importer, presumably of molybdenum. When these are inactivated, transport of molybdenum does not occur and the cell derepresses *anf* expression. Two other orfs, *MopA* and *MopB* are homologous to Mo-pterin-binding proteins. A *mopA mopB* double mutant is also derepressed for *anf* expression, suggesting that *MopA* and/or *MopB* is necessary for molybdenum-dependent repression of *anf* genes, possibly via *anfA* expression. The mechanism of repression (or involvement of *Mop* proteins) is unknown.

VI. Future Studies and Perspectives

Although many of the *trans* and *cis* acting factors that respond to nitrogen and oxygen in *Rb. capsulatus* have been discovered, the details of specific points of control still require further experimentation. Some of these fertile areas of research have already been discussed, including a possible nitrogen-sensitive NifA system, the direct involvement of IHF in transcription and the characterization of genes not yet discovered. The later includes a *glnD* analog and the sigma factor(s) involved in the NtrC-mediated activation systems described here. Development of *in vitro* systems to study these novel activation systems is of clear importance. Additionally, the regulatory cascades and proteins involved in *nif* genes from other anoxygenic phototrophs warrant future studies. Why does *Rb. sphaeroides* have two different *rpoN* genes? What about other phototrophs?

An interesting difference between the *Rb.*

capsulatus ntrC mutants and enteric *ntrC* mutants is phenotype. The *Rb. capsulatus ntrC* strains can grow on many different sources of fixed nitrogen. In contrast, the enteric *ntrC* mutants are more pleiotrophic because their *ntrC* is required for activation of genes involved in many nitrogen uptake or metabolic systems (eg. histidine, proline, arginine). How does *Rb. capsulatus* or other anoxygenic phototrophs regulate their distinct nitrogen uptake systems? In fact, although some studies have been carried out (e.g. Rapp et al., 1986), nitrogen metabolism and uptake in anoxygenic phototrophs has received little attention; are there differences in photosynthetically compared to aerobically grown cells?

Finally, an area of great interest concerns the exact mechanism(s) by which oxygen represses *nif* and *anf* transcription in anoxygenic photosynthetic bacteria. It should be noted that both the primary and secondary promoters of the *Rb. capsulatus rpoN* expression system are candidate points for oxygen-mediated repression; the NifA protein itself, as described earlier is an additional candidate. As defined for the *K. pneumoniae nifLA* promoter, could DNA supercoiling be involved in oxygen sensing? In this respect, an important lesson may be learned from the analysis of the regulation of *nif* genes in different diazotrophs: in many cases that have been investigated in detail, multiple mechanisms of oxygen control seem to exist in a single cascade. For example, *K. pneumoniae* is controlled at the level of the *nifLA* promoter by DNA supercoiling and by NifL inactivation of NifA in response to oxygen. *Rhizobium meliloti* is controlled at three different levels; FixL (via a heme group) in response to limiting oxygen phosphorylates FixJ that subsequently activates transcription of *nifA* (Monson et al., 1992); *nifA* expression is also repressed by FixK in response to oxygen (Waelkens et al., 1992); NifA is oxygen-sensitive and activates other *nif* genes (Huala and Ausubel, 1989).

When complex and energy-intensive processes (such as nitrogen fixation or photosynthesis) are necessarily controlled by oxygen, will multiple and overlapping regulatory mechanisms be the rule rather than the exception? Do multiple mechanisms evolve because of potential 'leakiness' or for 'fine-tuning' this regulation to respond to rapidly changing and/or distinct oxygen concentrations? Attempts to isolate Nif^c strains of *Rb. capsulatus*, that induce *nifH-lacZ* independent of oxygen, have failed (Kranz and

Haselkorn, 1986). This is true even when Nif^c:NH₄ strains were used for the selections. Possibly, overlapping controls in response to oxygen, mediated by completely independent mechanisms do exist. Because of their diverse metabolic capabilities, the anoxygenic photosynthetic bacteria will no doubt continue to be excellent systems to study gene regulation both from evolutionary perspectives and from the standpoint of understanding the molecular basis of transcriptional control mechanisms.

Acknowledgments

Due to publication deadlines, only a limited number of 1993/1994 manuscripts could be cited. The fields of *nif* and gene regulatory mechanisms are extensive with many contributions from many groups. We apologize for not citing many important contributors due to page limitations. These contributions can be found within the reviews (and primary literature) that are cited. R.G.K. is supported by NIH and the USDA.

Summary

Clusters of genes that encode pigment biosynthesis and pigment-binding proteins have been found in several species of anoxygenic photosynthetic bacteria. Transcripts in excess of ten kilobases in length have been found to encode what were previously thought to be separate operons with independent promoters in *Rhodobacter capsulatus*. This transcriptional organization of operons is called a superoperon, and is important for efficient transition in metabolism when cells are shifted from aerobic respiratory to anaerobic photosynthetic growth conditions. Since some key features of superoperons are present in other species of photosynthetic bacteria, the clustering of photosynthesis genes may have been evolutionarily conserved because of advantages accrued to cells that have linked transcription units into superoperons. The evidence for the types of transcription units in several species of anoxygenic photosynthetic bacteria is summarized and compared, with an emphasis on unifying patterns of transcript organization. Because much of the data are not conclusive, some of the conclusions are somewhat speculative in nature. Since more is known about transcripts of *Rb. capsulatus*, it is used as a model for the other species. The reader is advised to consult recent reviews of related areas (Wellington et al., 1992; Klug, 1993).

I. Introduction

A. Overview and History

One of the first discoveries of the organization of photosynthesis genes was that pigment biosynthesis genes in *Rhodobacter capsulatus* are clustered in a relatively small region of the chromosome (Yen and Marrs, 1976). This led Yen and Marrs (1976) to suggest that these genes might be clustered to obtain their coordinate transcription. In its most extreme form, this model would consist of a single transcript of all the genes located in the photosynthesis gene cluster, now known to be about 46 kb in length (see Chapter 50 by Alberti et al.). In the years that followed these pioneering experiments it became clear that, in addition to the pigment biosynthesis genes, the reaction center, light-harvesting I (LH-I or B870) and other genes were also present in this cluster (Taylor et al., 1983; Youvan et al., 1984; Zsebo et al., 1984). The initial studies of the regulation of transcription of the clustered photosynthesis genes indicated that there were separate transcripts of bacteriochlorophyll biosynthesis genes and genes that encode LH and reaction center (RC) proteins (Clark et al., 1984; Belasco et al., 1985; Zhu et al., 1986). Other data showed that transcription of some pigment biosynthesis genes was divergent, implying an organization of many transcription units (Giuliano

et al., 1988; Armstrong et al., 1989). A series of publications then appeared that showed read-through transcription from pigment biosynthesis genes, across promoter regions and into genes encoding LH and RC proteins (Wellington and Beatty, 1989; Young et al., 1989; Bauer et al., 1991; Wellington et al., 1991). More recently, the DNA sequence of a 46 kb contiguous region of the *Rb. capsulatus* photosynthesis gene cluster was generously deposited in GenBank by John Hearst (see Chapter 50 by Alberti et al.). This sequence is a valuable resource for prediction of possible transcripts, as well as for other purposes. It is now clear that, in *Rb. capsulatus*, the genuine organization of transcripts lies somewhere between the extremes of a single transcript and separate, independently regulated, transcription units of pigment biosynthesis and other photosynthesis genes.

As genetic research progressed in *Rb. capsulatus*, striking advances were made in the areas of the organization and regulation of expression of photosynthesis genes in other species, notably *Rhodobacter sphaeroides*. It now seems likely that many of the genes in photosynthetic bacteria that are homologous to those of the *Rb. capsulatus* photosynthesis gene cluster are organized and transcribed similarly to *Rb. capsulatus* (Wellington et al., 1992; Bauer et al., 1993; see below).

This chapter summarizes some of the current data and my speculations on the organization of photosynthesis genes into transcription units, and points out some unifying patterns of gene organization that seem likely to be related to transcript organization in a variety of species. The photosynthesis genes

Abbreviations: *Cf.* – *Chloroflexus*; *E. coli* – *Escherichia coli*; kb – kilobase(s); LH I – light-harvesting I complex; LH II – light-harvesting II complex; orf – open reading frame; *Rb.* – *Rhodobacter*; RC – reaction center; *Rp.* – *Rhodopseudomonas*; *Rs.* – *Rhodospirillum*

considered are those located within the *Rb. capsulatus* cluster, the LHII genes encoded by the *puc* operon, and their homologues in other species.

B. Methods Used for Analysis of Transcript Organization: Advantages and Drawbacks

DNA sequences of genes, coupled with genetic mapping, are powerful tools for obtaining the minimal number of transcription units within a cluster of genes. All of the techniques described here require cloned DNA fragments, and the ability to identify genes by complementation of mutations or by DNA sequence analysis. Unambiguous transcript analyses require the use of two or more of the methods described below.

1. Indirect Methods

The effects of polar mutations on phenotypes have been used to infer the directions of transcription and the existence of operons of two or more genes (Zsebo et al., 1984; Young et al., 1989, 1992). The omega cartridge (Prentki and Krisch, 1984) has proven to be a good polar mutagen, but its use requires the ability to return omega-disrupted fragments back into cells, preferably by homologous recombination into the chromosome. There must also be a way to distinguish between inactivation of one gene and inactivation of two or more genes.

Gene fusions have been widely used to identify the location of promoters and, therefore, the approximate location of RNA 5' ends resulting from transcription initiation. This is usually of fairly low resolution; however, see Adams et al. (1989), Lee and Kaplan (1992) and Ma et al., (1993) for the use of gene fusions to evaluate the consequences of site-directed promoter mutations. The presence of a promoter on a cloned DNA fragment does not mean that there is not another promoter further upstream, which functions in the chromosome but which may be absent from the DNA fragment.

2. Direct Methods

The crudest direct methods for analysis of transcripts are the original Southern blot method (radiolabelled RNA used to probe specific DNA fragments), or 'dot-blot' methods (Clark et al., 1984; Zhu and Hearst, 1986). Although these techniques can show that transcripts are derived from specific DNA

fragments, they do not differentiate between the existence of one or more transcripts. Unless the number and sizes of hybridizing transcripts are known, it is difficult to draw quantitative conclusions that relate the relative number of transcripts to the intensities of hybridization signals.

RNA (northern) blots give the number and sizes of transcripts, and their relative steady-state amounts, when corrections are applied for specific activities of probes and the lengths of transcripts. When a single-stranded probe is used, the direction of transcription can also be obtained. This procedure is less sensitive than end-mapping methods (see below) and, by itself, yields little information about transcription initiation and termination sites. Also, unless RNA is hydrolyzed by treatment with alkali or RNA is transferred from the gel to the membrane by electroblotting, large RNA molecules do not transfer as efficiently as small ones and may not be detected.

Mung bean or S1 nuclease end-mapping methods are probably the most sensitive techniques for detection of transcripts that are present in low amounts. These procedures can be quantitative, but require care in titration of the ratio of nuclease:nucleic acids, and the optimal temperature of hybridization must be determined with each probe. In conjunction with RNA blots, end mapping experiments are usually sufficient to define specific RNA molecules to the nucleotide level. When 'bipartite' probes (Wellington and Beatty, 1991) are used, end mapping methods can reveal the existence of read-through (superoperon) transcripts. However, differentiation of transcription initiation and termination sites from ends resulting from RNA cleavage requires additional techniques such as gene fusions (see above), pulse-chase analyses (Belasco et al., 1985), or 5' end-capping experiments (Zucconi and Beatty, 1988).

Primer extension mapping of a 5' end is technically easier to perform than nuclease end-mapping. However, DNA sequence information is necessary to design a oligonucleotide primer, and reverse transcriptase enzymes are not robust enough to extend very far.

II. Transcripts of *Rb. capsulatus* Photosynthesis Genes

A representation of the genes in the *Rb. capsulatus* photosynthesis gene cluster and the proposed primary transcripts is given in Fig. 1. The gene and orf

Figure 1. Representation of genes and transcripts of the *Rhodospirillum rubrum* photosynthesis gene cluster. Bacteriochlorophyll biosynthesis genes (*bch*) are designated by grey shading, carotenoid biosynthesis genes (*crt*) are shown by spots, light-harvesting and reaction center genes (*puf* and *puh*) are represented by diagonal lines, and open reading frames of uncertain function are shown as cross-hatched boxes. Proposed transcripts are designated by arrows, with possible read-through extensions shown as extensions beyond arrow heads.

designations are based on revisions (Bauer et al., 1993; Bollivar et al., 1994a,b) of those given in the Hearst laboratory's Genbank submission (accession number Z11165). Because experiments have not yet been done to directly identify some proposed transcripts, the location of many of the 5' and 3' ends in Fig. 1 is tentative. Processing products of primary transcripts are not shown.

A. The *crtEF*-*bchCXYZ*-*pufQBALMX* Superoperon

This region of the *Rb. capsulatus* photosynthesis gene cluster contains genes that give rise to the best-defined transcripts, at this time. The DNA sequence upstream of the *crtE* gene contains a motif with similarity to an *Escherichia coli*-like promoter (Armstrong et al., 1989). However, a low resolution 5' end mapping experiment indicated that there are two transcripts of *crtE* (one strongly oxygen-repressed) with 5' ends that map near the start of the *crtE* gene (Giuliano et al., 1988). Although it has been presumed that the *crtE* and *crtF* genes are co-transcribed, this supposition has not been tested. At least one of the *crtEF* primary transcripts extends into the *bchC* coding region, and transcription across the *bchC* promoter seems to stimulate transcription initiation at this promoter (Young et al., 1989; Wellington and Beatty, 1991; Wellington et al., 1991). Analogously, transcription that initiates at the *bchC* promoter continues through the *puf* operon promoter region, and seems to stimulate transcription initiation at the *puf* operon promoter (Wellington and Beatty, 1991; Wellington et al., 1991). Although it is probable that transcription which initiates at the *crtEF* promoters continues into the *puf* operon, this assumption has not been tested directly. Extensive post-transcriptional processing of the *crtEF*-*puf* transcripts occurs, best documented for the *puf* operon segments (described in the Chapter by Klug). Although two RNA 3' ends were mapped to two rho-independent terminator-like structures downstream of *pufX* (Chen et al., 1988), it is conceivable that there is read-through transcription from *pufX* into orf641 (and beyond).

B. The *crtD* and *crtC* Genes

These two genes are transcribed in the same direction and separated by only 70 base pairs (Armstrong et al., 1989), yet they seem to have separate promoters.

This is because polar omega cartridge insertions into the *crtD* gene did not eliminate expression of the *crtC* gene, and a low resolution S1 nuclease protection experiment showed the existence of a *crtC* RNA 5' end that mapped within the *crtD* gene (Giuliano et al., 1988). Thus, these two genes seem to form a superoperon, in the sense that a *crtC* promoter is located within the *crtD* gene. An *E. coli* promoter-like sequence upstream of *crtD* was described (Armstrong et al., 1989).

C. The *crtI*BK Genes

These genes are designated as a transcription unit because a polar mutation in *crtI* had a *crtB* phenotype (which would mask a *crtK* phenotype since *crtB* mutations cause a block earlier in the pathway), and because only about 75 base pairs separate *crtK* from *crtB* (Giuliano et al., 1988; Armstrong et al., 1989). A *crtI* RNA 5' end was mapped near the start of the *crtI* gene (Giuliano et al., 1988), and a possible promoter suggested from the DNA sequence (Armstrong et al., 1989).

D. The *crtA*-*bchI*D-*orf284* Genes

Experiments with omega interposon mutants of *crtA* indicated that a *crtA* transcript also encodes the *bchI* gene (Young et al., 1992). It is not clear if a single transcript encodes *bchD* and *orf284*, as well as *crtA* and *bchI*, although the DNA sequence is consistent with this likelihood (see Chapter 50 by Alberti et al.). The DNA sequence upstream of *crtA* contains an *E. coli* promoter-like sequence (Armstrong et al., 1989), and a low resolution S1 nuclease protection experiment demonstrated an RNA 5' end that mapped near the start of the *crtA* gene (Giuliano et al., 1988).

E. The *bchW*-*orf469*-*bchE*JG-*orf428*-*bchP*-*orf176* Genes

These sequences could be encoded by a single transcript, although this possibility has not been tested either indirectly or directly. Two transcripts are assigned in Fig. 1 because these proposed genes all have the same direction of transcription, are flanked by genes with opposite polarities of transcription, and a sequence with similarity to an *E. coli*-like promoter has been identified between *orf469* and *bchE* (see Chapter 50 by Alberti et al.).

F. The *bchF*BNHLM-*orf477*-*puhA*-*orf214*-*orf162b*... Superoperon

Transcripts of this region of the *Rb. capsulatus* photosynthesis gene cluster have been fairly well characterized, although several important questions remain to be answered. A long transcript initiated at the *bchF* promoter extends into the *puhA* gene, and seems to be degraded to a more stable *puhA*-encoding segment of 1.1 kb in length (Bauer et al., 1991). Although an *E. coli* promoter-like sequence exists upstream of the *bchF* gene (see Chapter 50 by Alberti et al.), it is not clear if this sequence functions as a promoter in *Rb. capsulatus*. A promoter within *orf477* (previously known as F 1696) yields a 0.95 kb *puhA*-encoding transcript (Bauer et al., 1991). Unpublished data (Wong and Beatty) indicate that expression of *orf214* and at least one additional gene beyond *orf214* are important for photosynthetic growth, and are dependent on read-through transcription from the *puhA* gene for normal expression. It is possible that a low-level promoter for *orf214* is located near the 3' end of the *puhA* gene, and that transcripts initiated at the *bchF* and *puhA* promoters extend into *orf214* and beyond.

G. The *pucBACDE* Operon

This operon maps to a region of the chromosome distant from the photosynthesis gene cluster (see Chapter 49 by Fonstein and Haselkorn). Two very abundant *ca.* 0.5 kb transcripts encode the *pucBA* genes (Zucconi and Beatty, 1988). Additional molecules of 2.4, 1.0, and 0.7 kb have been detected (LeBlanc and Beatty, 1993). The results of RNA blots, end-mapping and gene fusion experiments (Zucconi and Beatty, 1988; Tichy et al., 1989, 1991; Oberlé et al., 1990; LeBlanc and Beatty, 1993), taken together, are consistent with the synthesis of a *pucBACDE* primary transcript of about 2.4 kb in length, along with degradation of this transcript to yield molecules of 1.0 and 0.7 kb (encoding *pucDE*), and 0.5 kb (encoding *pucBA*). This model remains to be tested directly, as do the possibilities of transcription attenuation between *pucBA* and *pucC*, the existence of a weak *pucDE* promoter, and of transcripts extending into or out of the *pucBACDE* region.

III. Transcripts of *Rb. sphaeroides* Photosynthesis Genes

A. The *pufQBALMX Operon*

The stable transcripts of these genes are similar in size to the homologous *puf* messages of *Rb. capsulatus*, with similar endpoints (Zhu et al., 1986). The most likely origin of *Rb. sphaeroides* *puf*-specific transcripts is from a single promoter region upstream of *pufQ* and within a *bchZ* gene (Hunter et al., 1991; McGlynn and Hunter, 1993), although Kaplan and coworkers have argued for the existence of two promoters immediately preceding the *pufBA* genes (Kiley and Kaplan, 1988; Gong et al., 1994). Since the *puf* operon promoter identified by Hunter *et al.* (1991) lies within the *bchZ* gene, it is likely that *bchZ* transcripts continue through the *puf* operon, as part of a superoperon.

B. The *bchCXYZ Operon*

This region of the *Rb. sphaeroides* photosynthesis gene cluster is organized very similarly to, and with the same transcriptional polarity as the homologous region from *Rb. capsulatus*. Transcripts in excess of 9.5 kb in size that hybridized to *bchC*, *bchCX* and *bchYZ* probes were found in RNA blot experiments, and the DNA sequences of these genes showed overlaps of stop codons with start codons at the junctures of the *bchCX*, *bchYZ* and *bchZ-pufQ* genes (McGlynn and Hunter, 1993). A similar overlap was observed for the *bchYZ* juncture in *Rb. capsulatus* which has been implicated in promoting translational coupling of these genes (Burke et al., 1993). As noted above, a promoter necessary and sufficient for expression of *puf* operon genes was located within the *bchZ* gene (Hunter et al., 1991).

C. The *crtE* to *puhA* Region of the Photosynthesis Gene Cluster

Although only the *crtI* and *puhA* regions have been investigated in RNA and DNA sequence analyses, the overall similarity of the order of the *Rb. sphaeroides* *crt* and *bch* genes to the order of the homologues in *Rb. capsulatus* (Chapter 50 by Bauer; Bauer et al., 1993; Coomber et al., 1990) invites speculation that the polarities of transcription of these genes have also been conserved.

The *crtI* and *crtB* genes were sequenced and the proposed *crtI* stop and *crtB* start codons were found to overlap (Lang et al., 1994). Earlier studies indicated that transposon insertions in *crtI* reduced *crtB* expression (Coomber et al., 1990). However, Lang et al. (1994) found that *crtI* transposon mutants were partially complemented by a plasmid containing only the *crtI* gene. Furthermore, primer extension and RNA blot experiments on *crtI* messages showed the existence of a 5' RNA end 70 nt before the start of the 1.6 kb gene, and a *ca.* 1.6 kb *crtI* message. These results exemplify the difficulties in obtaining unambiguous data about labile transcripts of genes that are closely linked, yet possibly expressed from more than one promoter or from a promoter located within a 'polar' transposon insertion. It was concluded that a weak *crtB* promoter might be located within the 3' region of the *crtI* gene, although other possibilities were entertained (Lang et al., 1994).

The *puhA* gene is preceded by a sequence that appears to be part of a homologue of the *Rb. capsulatus* orf477 (Bauer et al., 1991; Donohue et al., 1986). RNA blot analysis of the *puhA* gene revealed two RNA messages of 1.4 and 1.1 kb in length (Donohue et al., 1986), analogs to two of the three molecules that code for the *Rb. capsulatus* *puhA* gene. If it is assumed that the 3' ends of these messages map near the 3' end of the *puhA* gene, their 5' ends would lie within the orf477 homologue. Although a large *bch-puhA* transcript was not found in *Rb. sphaeroides* (Donohue et al., 1986), this negative result does not prove the absence of such a transcript, so it is possible that *Rb. sphaeroides* and *Rb. capsulatus* have similar superoperons that yield similar primary and processed *puhA* transcripts.

D. The *pucBAC Operon*

The DNA sequence of this region of the *Rb. sphaeroides* genome showed that it differs from the analogous region in *Rb. capsulatus* because of the absence of *pucDE* genes (Gibson et al., 1992). RNA blot and 5' end-mapping experiments demonstrated the presence of a 2.3 kb molecule with the same 5' end as a more abundant 0.6 kb *pucBA* message (Lee et al., 1989). Therefore, by analogy with the *Rb. capsulatus* model, it may be that a large (2.3 kb) transcript is processed to yield a more stable, small (0.6 kb) molecule.

IV. Transcripts of *Rhodospirillum rubrum* Photosynthesis Genes

A. The *pufBALM* Operon

RNA blot and end-mapping experiments have shown that these genes are encoded by large (2.5 kb *pufBALM*) and small (*ca.* 0.6 kb *pufBA*) messages (Bélanger and Gingras, 1988). The *puf* operon promoter is located within a *bchZ* homologue (Lee and Collins, 1993), again inviting speculation that a superoperon exists, consisting of *bch* and *puf* genes.

B. The *puhA* Region

From the results of RNA blot, 5' and 3' end-mapping experiments (Bérard et al., 1989) it was concluded that the *puhA* gene is encoded by two primary transcripts (of approximately 1.2 and 1 kb in size) that originate at two adjacent promoters located within orfG115 (homologous to orf477 of *Rb. capsulatus* [Bérard et al., 1991]). Alternatively, Bauer et al. (1991) have suggested that one of these two molecules is the product of degradation of a larger transcript that originates upstream of orfG115. Although a large transcript encoding orfG115 and upstream sequences, and extending into the *puhA* gene, was not identified by Bérard et al. (1991), rigorous experiments to exclude this possibility have not been done. Additional experiments need to be done to directly test for read-through transcription into the *puhA* gene, and from *puhA* into orfs I2372 and I3087 (which encode amino acid sequences similar to the *Rb. capsulatus* orfs 214 and 162b). Because of the great similarities in gene sequences and organization between *Rb. capsulatus* and *Rs. rubrum*, the transcripts of these sequences may also be similar.

C. The Region between *puhA* and *puf* Genes

Several carotenoid and bacteriochlorophyll biosynthesis genes have been identified by mutation or DNA sequence analyses (Sägesser, 1992; Lee and Collins, 1993), and their locations relative to *Rb. capsulatus* and *Rb. sphaeroides* homologues indicate a conservation of gene order within these species (Bauer et al., 1993). However, the transcripts of these genes have not yet been studied in *Rs. rubrum* and their transcriptional polarities relative to the *puf* operon, apart from the *bchZ* gene, are not known.

V. Transcripts of *Rhodopseudomonas viridis* Photosynthesis Genes

A. The *pufBALMC* Operon

The *Rp. viridis puf* operon genes are encoded by two large (3.6 and 3.7 kb) *pufBALMC* and two small (0.6 and 0.8 kb) *pufBA* messages, as evidenced by the results of RNA blot, 5' and 3' end-mapping experiments (Wiessner et al., 1990). The 5' ends of the 3.7 and 0.8 kb molecules mapped within a sequence that encodes the carboxy terminus of a protein that is 50% identical to the corresponding end of the *Rb. capsulatus* BchZ amino acid sequence (Wiessner et al., 1990). Although 5' ends resulting from transcription initiation were not distinguished from 5' ends arising from cleavage of a precursor, the deduced overlap between *bchZ* and *puf* transcripts, once again, invites speculation that a labile *bch-puf* primary transcript is processed to contribute to more stable *puf* messages.

B. The Reaction Center H Gene Region

The distance between the *Rp. viridis* reaction center H gene and *puf* operon has been estimated to be in excess of 100 kb, which is a much greater distance than in *Rb. capsulatus* and *Rb. sphaeroides* (Lang and Oesterhelt, 1989). The gene encoding the *Rp. viridis* reaction center H subunit (homologous to the *puhA* gene of *Rb. capsulatus*; Michel et al., 1985) is located immediately downstream of an orfS, which exhibits 'strong homology' with orf477 of *Rb. capsulatus* (Wiessner, 1990). RNA blots showed the existence of 1.2 and 1.6 kb messages, and end-mapping experiments placed the 5' end of a H subunit transcript within orfS, analogous to the results obtained with *Rb. capsulatus*, *Rb. sphaeroides* and *Rs. rubrum* (see above). Thus, all of these species may contain superoperons that include *puhA* genes.

VI. Transcripts of *Rubrivivax gelatinosus* Photosynthesis Genes

A. The *pufBALMC* Operon

The *Ru. gelatinosus puf* operon genes are organized similarly to the *Rp. viridis puf* genes, except that an

orf1 was identified just upstream of *pufB* and an orf2 was found between *pufB* and *pufA* (Nagashima et al., 1994). This operon is encoded by 4 kp *pufBALMC* and 1 kb *pufBA* messages, as revealed by RNA blot, 5' and 3' end-mapping experiments (Nagashima et al., 1994). The 5' end of the 1.0 kb (and, presumably, the 4 kb) molecule mapped within a sequence that encodes the carboxy terminus of a protein that is similar to the corresponding end of the *Rb. capsulatus* BchZ amino acid sequence (Nagashima et al., 1994). Thus, the overlap between *bchZ* and *puf* transcripts is conserved in all species of purple photosynthetic bacteria that have been investigated.

VII. Transcripts of *Chloroflexus aurantiacus* Photosynthesis Genes

A. The *pufLM* Genes

A major transcript of approximately 2.1-2.3 kb, and minor species of 3.1, 1.7 and 1.5 kb in length were detected by hybridization of RNA blots with a *pufL* gene probe (Shiozawa et al., 1990; Chapter 54 by Shiozawa). Signals corresponding to molecules of 10 kb or more in length were seen, but were attributed to DNA contamination of the RNA preparations. Primer extension analysis showed a predominant 5' end that mapped about 130 bases upstream of the *pufL* gene start codon, near a sequence that was similar to an *E. coli* promoter consensus sequence (Shiozawa et al., 1990). Although the data are consistent with the existence of a single, ca. 2.3 kb *pufLM* primary transcript that is degraded to yield smaller quasi-stable segments, it is not clear if the *pufL* transcript 5' end that was mapped arises from transcription initiation or message processing, and if there are other promoters for *pufM* or far upstream of the *pufL* gene.

B. The Genes Encoding B806-866 LH α , LH β and Cytochrome *c*-554

These three genes are located adjacent to each other, in the order LH α , LH β and cytochrome *c*-554 (Watanabe et al., 1992). The distance from the *pufLM* genes is unknown. The results of RNA blot and primer extension experiments were interpreted as consistent with the existence of a 2.1 kb primary transcript encoding LH α /LH β /cytochrome *c*-554 genes that is degraded to yield a 0.5 kb LH α /LH β

segment, and a 1.5 kb segment encoding cytochrome *c*-554. It was proposed that another 1.5 kb message initiates about 80 base pairs downstream of the 5' end of the 1.5 kb proposed cleavage product of the 2.1 kb transcript (Watanabe et al., 1992). Although this interpretation is plausible, additional experiments need to be done to differentiate between 5' ends that arise from initiation of transcription and 5' ends that result from cleavage of a precursor molecule.

VIII. Prospects for the Future and Concluding Remarks

Although many of the details of photosynthesis gene transcripts have been elucidated in *Rb. capsulatus*, there are a number of outstanding questions that remain. For example, the distance that the *bchF-pufA* superoperon extends beyond orf214 (see Fig. 1) needs to be better defined, higher resolution transcript analyses need to be done of the *crtD* to *bchD* region, and the possibility that the *bchW*-orf176 genes are part of a (super-) operon should be tested.

A large amount of genetic mapping, DNA sequence and transcript analyses needs to be done with *Rb. sphaeroides*, *Rs. rubrum*, *Rp. viridis* and *Cf. aurantiacus* to extend the results summarized here. It would be of great interest to fill in the gaps in the genetic maps of these species and follow up the mapping with transcript analyses, to see if some of my speculations about the existence of superoperons are correct.

Relatively low resolution genetic mapping and complementation experiments resulted in a map of *Rhodospirillum centenum* photosynthesis genes (Yildiz et al., 1992). Although the conservation in gene order within this gene cluster, as compared to the *Rb. capsulatus* map (Bauer et al., 1993), suggests a similar organization of transcripts, no promoter mapping, DNA sequence or RNA analyses have been done on this species.

A DNA fragment containing *pufBALM* genes from an *Erythrobacter* species has been cloned and sequenced (Liebetanz et al., 1991). The *pufB* gene on this DNA fragment is preceded by a sequence with similarity to the 3' terminal region of *bchZ* genes, and the *pufM* gene is followed by a sequence with similarity to the 5' end of the *Rp. viridis pufC* gene. These results further underscore the existence of conserved patterns of photosynthesis gene organization, and raise additional questions about the how

these patterns relate to gene transcripts, the regulation of gene expression and the evolution of photosynthesis.

Finally, it would be extremely interesting to extend the genetic studies of anoxygenic photosynthetic bacteria to include purple sulfur bacteria. These species are likely to possess photosynthesis genes homologous to the genes identified in purple nonsulfur photosynthetic bacteria and *Cf. aurantiacus*, yet they are located within a separate, coherent group on the basis of 16S rRNA sequence analyses (Woese, 1987). Starts in this direction have been made with the cloning of reaction center genes of *Chlorobium limicola* (Buttner et al., 1992; Chapter 54 by Shiozawa), and the finding that *Chromatium* and *Thiocystis* species contain *puf* genes that are greatly homologous to the corresponding genes of purple non-sulfur bacteria. The benefits of widening the field of the genetics of photosynthetic bacteria include an improved understanding of genetic regulatory mechanisms and evolutionary processes.

Acknowledgments

I thank everyone who sent me reprints, preprints, theses and other information, and the members of my laboratory who gave helpful suggestions for modification of this chapter.

Summary

Regulation of photosynthesis gene expression has been a long studied area of research with anoxygenic phototrophic bacteria. This area of study predates the classical analysis by Cohen-Bazire et al., (1957) who performed a detailed measurement of the repressing effects of light and oxygen on synthesis of the purple bacterial photosystem. In their study they demonstrated that shifting photosynthetically growing cells from anaerobic to aerobic conditions resulted in the immediate cessation of photopigment biosynthesis. A similar effect was also observed when photosynthetically grown cells are shifted from low to high light intensity. We now know that the repressing effects of these environmental factors is a result, in part, to the regulation of photosynthesis gene expression. It is this topic, the repressing effects of light and oxygen on photosynthesis gene expression, that this review will be centered. This chapter covers our current understanding of *cis*- and *trans*-acting factors that controls transcription of the light harvesting and reaction center structural genes as well as genes involved in photopigment biosynthesis.

I. Introduction

Synthesis of the purple eubacterial photosystem has long been known to be influenced by such environmental factors as oxygen tension and light intensity. The first detailed analysis of the regulation of pigment biosynthesis is the oft cited study by Cohen-Bazire,

Sistrom and Stanier (1957). Their work clearly established that pigment biosynthesis in photosynthetically growing *Rhodobacter sphaeroides* cells is rapidly inhibited by the addition of molecular oxygen or by an increases in light intensity. Despite numerous physiological investigations that have been undertaken since then, the underlying molecular

mechanism(s) responsible for controlling photosynthesis are only now being unveiled.

Part of the difficulty in analyzing regulatory events responsible for controlling synthesis of the photosystem is the complexity of the 'regulatory circuits' that control photosynthesis gene expression. For example, light harvesting I (LHI) and reaction center (RC) gene expression are known to be regulated by such events as; (i) the control of transcription initiation, (ii) the linking of genes into 'superoperons' that contain overlapping transcripts, and (iii) the control of mRNA decay rate. This chapter will be centered on the first level of regulation, namely a discussion of *cis* and *trans*-acting regulatory factors responsible for controlling the initiation of photosynthesis gene expression in response to alterations in light intensity and oxygen tension. Related chapters in this volume which also overlap with this topic include Chapter 57 by Betty which covers the superoperonal organization of the photosynthesis gene transcripts, Chapter 59 by Klug which covers the mRNA decay events, Chapter 50 by Alberti et al. which covers the photosynthesis gene cluster sequence analysis, and Chapter 53 by Armstrong which covers carotenoid genes. There have also been several recent minireviews that cover this topic (Bauer et al., 1993; Klug, 1993).

II. The Photosynthesis Gene Cluster

A. Linkage Order of Photosynthesis Genes

Analysis of genes involved in bacterial photosynthesis was primarily advanced by the work of Marrs and coworkers who in the mid 1970's discovered and exploited the use of a generalized transducing agent (GTA) from *Rhodobacter capsulatus* (Marrs, 1974; Yen and Marrs, 1976). These studies established that carotenoid (*crt*) and bacteriochlorophyll (*bch*) biosynthesis genes are present in the chromosome in a tight linkage order (Yen and Marrs, 1976). The transduction mapping studies were followed by the isolation of an R' plasmid by Marrs (1981) that was shown by marker rescue/complementation analysis (Taylor et al., 1983), as well as by transposition

mapping techniques (Biel and Marrs, 1983; Zsebo and Hearst, 1984), to contain all of the essential genetic information needed by *Rb. capsulatus* to synthesize a 'core' bacterial photosystem composed of LHI and RC complexes. Structural and functional information regarding these loci has recently been refined to a high degree by the complete sequence analysis of the R' born 'photosynthesis gene cluster' by Hearst and coworkers, (discussed in detail in chapter 50 by Alberti et al.), as well as by the construction of a defined set of interposon mutations in each of the sequenced open reading frames (Giuliano, 1988; Young et al., 1989; Yang and Bauer, 1990; Bollivar et al., 1994a,b). Figure 1, summarizes the location of various open reading frames in the *Rb. capsulatus* photosynthesis gene cluster; as indicated, carotenoid genes (hatched boxes) and bacteriochlorophyll biosynthesis genes (shaded boxes) are clustered together in the central region of the photosynthesis gene cluster. The pigment biosynthesis genes are in turn flanked by the highly expressed LHI and RC structural genes that are coded by the *puf* and *puh* operons (highlighted as filled boxes in the expanded region). Unlinked to this region is the *puc* operon that codes for polypeptides involved in formation of the light harvesting II (LHII) complex (Youvan and Ismail, 1985). It is interesting that a similar clustering and linkage order of photosynthesis genes are known to occur in the closely related species *Rb. sphaeroides* (Coomber et al., 1990) as well as in more distantly related species such as *Rhodospirillum centenum* (Yildiz et al., 1992), *Rhodospirillum rubrum* (Sagesser, 1992) and possibly *Rhodospseudomonas viridis* (Wiessner et al., 1990) and *Rhodofera gelatinosus* (Nagashima et al., 1993). The conservation of the photosynthesis gene cluster among distantly related species has raised the possibility of acquisition of the photosynthesis gene cluster by horizontal gene transfer (Yildiz et al., 1992). This possibility has more recently been supported by phylogenetic analysis of RC genes which appear to diverge from that of phylogenetic trees derived from 16 S rRNA and cytochrome *c*₂ (Nagashima et al., 1993).

B. Photosynthesis Gene Transcripts

The first evidence that photosynthesis gene expression was regulated at the transcriptional level was a study by Biel and Marrs (1983) who constructed *lacZ* fusions of bacteriochlorophyll biosynthesis genes

Abbreviations: *bch* – bacteriochlorophyll biosynthesis genes; BChl *a* – bacteriochlorophyll *a*; *crt* – carotenoid biosynthesis genes; GTA – generalized transducing agent; LHI – light harvesting I; LHII – light harvesting II; *Rb.* – *Rhodobacter*; RC – reaction center; *Rp.* – *Rhodospseudomonas*; *Rs.* – *Rhodospirillum*

Fig. 1. Photosystem genes from *Rb. capsulatus*. Shaded boxes indicate bacteriochlorophyll biosynthesis genes (Bollivar et al., 1994a,b), hatched boxes indicate carotenoid biosynthesis genes (Armstrong et al., 1989), open boxes have indeterminate function and filled boxes code for LHI and RC structural polypeptides. The arrows denote proposed unprocessed transcripts.

with Mu d1 ($\text{Ap}^r \text{ lac}$). Their study indicated that bacteriochlorophyll gene expression was repressed approximately 2-fold when cells are grown under high oxygen (23% O_2) versus low oxygen tension (3% O_2). Subsequent RNA-DNA hybridization analyses performed in several laboratories confirmed this observation and, in addition, indicated that the LH and RC structural genes coded by the *puf*, *puf* and *puc* operons are expressed to a much higher level, and are more highly regulated (30 to 100x), than are the photopigment biosynthesis genes (Clark et al., 1984; Klug et al., 1984; Belasco et al., 1985; Zhu and Kaplan, 1985; Klug et al., 1985; Zhu and Hearst, 1986; Zhu et al., 1986a; Zhu et al., 1986b; Kiley and Kaplan, 1987; Donohue et al., 1986; Hunter et al., 1987). In good confirmation with the physiological studies of Cohen-Bazire et al., (1957), both oxygen and light were observed to repress transcription with oxygen exhibiting a more severe repressing effect than that of light.

Promoter mapping studies, the details of which are discussed below, also revealed that transcripts within the photosynthesis gene cluster are organized into large 'superoperons' containing overlapping transcripts. The overlapping nature of these transcripts is such that transcription of the weakly expressed and poorly regulated pigment biosynthesis genes extend into the more highly regulated *puf* and *puf* operons that code for the LHI and RC structural genes (Young et al., 1989; Bauer et al., 1991; Wellington and Beatty, 1991; Young et al., 1992). These overlapping transcripts appear to ensure that there is coupled

synthesis of enzymes involved in photopigment biosynthesis with that of polypeptides that ultimately bind the photopigments (Bauer et al., 1991; Wellington and Beatty, 1991). A more detailed description of the superoperonal organization of the photosynthesis gene cluster can be found in chapter 57 by Beatty and in a recent review by Wellington et al., (1992).

III. *cis*-Acting Regulatory Sites

Promoters that are responsible for expressing photosynthesis genes have been mapped using such techniques as S1 (or Mung bean) nuclease mapping, primer extension, 5' end capping and deletion analysis. Despite these efforts, there are relatively few sequenced regions for which there exists a consensus agreement among investigators that they actually contain a promoter region responsible for transcription of photosynthesis genes. Part of the historical difficulty in performing promoter mapping studies appears to reside in the difficulty in obtaining full length mRNA transcripts from photosynthetic bacteria. Many photosynthesis gene transcripts appear to undergo rapid processing events that affect the stability of the 5' end of the message (see chapter 59 by Klug; Klug, 1991a, 1993). Thus, published 5' ends of messages could either be the site of transcription initiation or produced by a processing event. Because of the problems that investigators have had in mapping the site of transcription initiation,

it is critical that primer extension or nuclease mapping procedures be corroborated by a functional deletion analysis of a putative promoter region. This has only been performed for a few photosynthesis gene promoter regions as discussed below.

A. *puf* and *puf* Promoters

The first photosynthesis gene promoter to be functionally mapped was the *puf* operon promoter from *Rb. capsulatus*. Deletion mapping (Bauer et al., 1988; Adams et al., 1989) indicated that regulated *puf* operon expression was dependent on a region of DNA that was located over 300 bp upstream from the previously mapped stable 5' end for the *puf* operon (Belasco et al., 1985). Subsequent analysis of the intergenic region indicated that there existed an additional gene upstream from *pufB*, termed *pufQ*, that was shown by mutational analysis to be required for synthesis of bacteriochlorophyll (Bauer et al., 1988; Bauer and Marrs, 1988; Klug and Cohen, 1988; Adams et al., 1989). It was also shown by mutational and sequence analysis that the *puf* promoter region was located within the *bchZ* (formerly called *bchA*; Burke et al., 1993) structural gene that codes for a subunit of an enzyme involved in bacteriochlorophyll biosynthesis (Bauer et al., 1988, Young et al., 1989). High resolution Mung bean and S1 nuclease mapping, as well as 5' mRNA capping experiments, confirmed deletion analysis by indicating that there was indeed a stable *puf* transcript 5' end located within the *bchZ* gene (Bauer et al., 1988; Adams et al., 1989). A similar 5' processing story appears to occur for the *puf* operon promoter region in *Rb. sphaeroides*. In this case, initial 5' mRNA mapping studies that utilized S1-nuclease mapping technique indicated the presence of two stable 5' ends within the *pufQ* region (Zhu et al., 1986). However, like that observed for *Rb. capsulatus*, subsequent deletion analysis indicated that the *Rb. sphaeroides puf* operon is also driven by a region that is located several hundred bp upstream from the S1 mapped stable 5' end, a region that is also within the *bchZ* open reading frame (Hunter et al., 1991). There has also been 5' mRNA analysis of the *Rs. rubrum* and *Rp. viridis puf* transcripts (Belanger and Gingras, 1988; Wiessner et al., 1990). However, deletion analysis of the putative promoter regions from these additional species has not yet been undertaken.

Less is known about the *puf* operon promoter region than that of the *puf* operon promoter. Using a

combination of deletion and Mung bean nuclease mapping techniques, Bauer et al., (1991) mapped the *Rb. capsulatus puf* promoter to a position 381 bp upstream from *pufA*. In an interesting analogy with the *puf* operon, the *puf* promoter is also located within an upstream open reading frame termed ORF1696. Mutational analysis indicates that ORF1696 may be involved in formation of a stable LHI complex (Bauer et al., 1991; Yang and Bauer, 1990). A stable 5' end for the *Rs. rubrum puf* message has also been mapped to be well within the upstream ORF 1696 coding region (Bérard et al., 1989). The *puf* promoter region of other species has not been mapped to high resolution, however, Northern blot analysis does indicate that the *Rb. sphaeroides pufA* transcript is initiated far upstream of the start of the *pufA* structural gene (Donohue et al., 1986).

Figure 2a shows an alignment of the putative *puf* and *puf* promoter regions from *Rb. capsulatus*, *Rb. sphaeroides*, *Rp. viridis* and *Rs. rubrum* each of which show some level of sequence conservation. [The putative *Rs. rubrum puf* promoter region shows no identifiable sequence similarity with that of other species and was therefore left out of the alignment. It is most likely that the S1 mapped *Rs. rubrum puf* transcript is a processing site since transposition mutagenesis 'functionally' places the *Rs. rubrum puf* promoter to within a region of the *bchZ* gene that is approximately 650 bp upstream of the mapped 5' end (Hessner et al., 1991)]. As shown in Fig. 2a, the *puf* promoter regions show a 'reasonable match' with the *puf* promoter sequences, especially when one considers that the *puf* and *puf* promoter sequences also code for polypeptides of differing function. Areas of noted similarity are the -12 and -24 regions from the start of transcription (Fig. 2a). The -12 and -24 regions share no similarity to known eubacterial promoter elements thereby indicating that they may be utilizing an alternative sigma factor for promoter recognition. Mutational and biochemical analysis for the existence for this putative sigma factor (sigma-P) is, however, still lacking. The *puf* and *puf* promoter regions also exhibit a 'pseudo' region of dyad symmetry at positions -30 to -57 relative to the start site of transcription (Bauer et al., 1988, Adams et al., 1989; Bauer et al., 1991). Deletion of this region results in loss of expression of the *puf* operon (Adams et al., 1989) indicating that this area is essential for expression. A point mutation in the region of dyad symmetry has also been shown to result in a 2-8 fold elevation of aerobic *puf* operon expression as well as

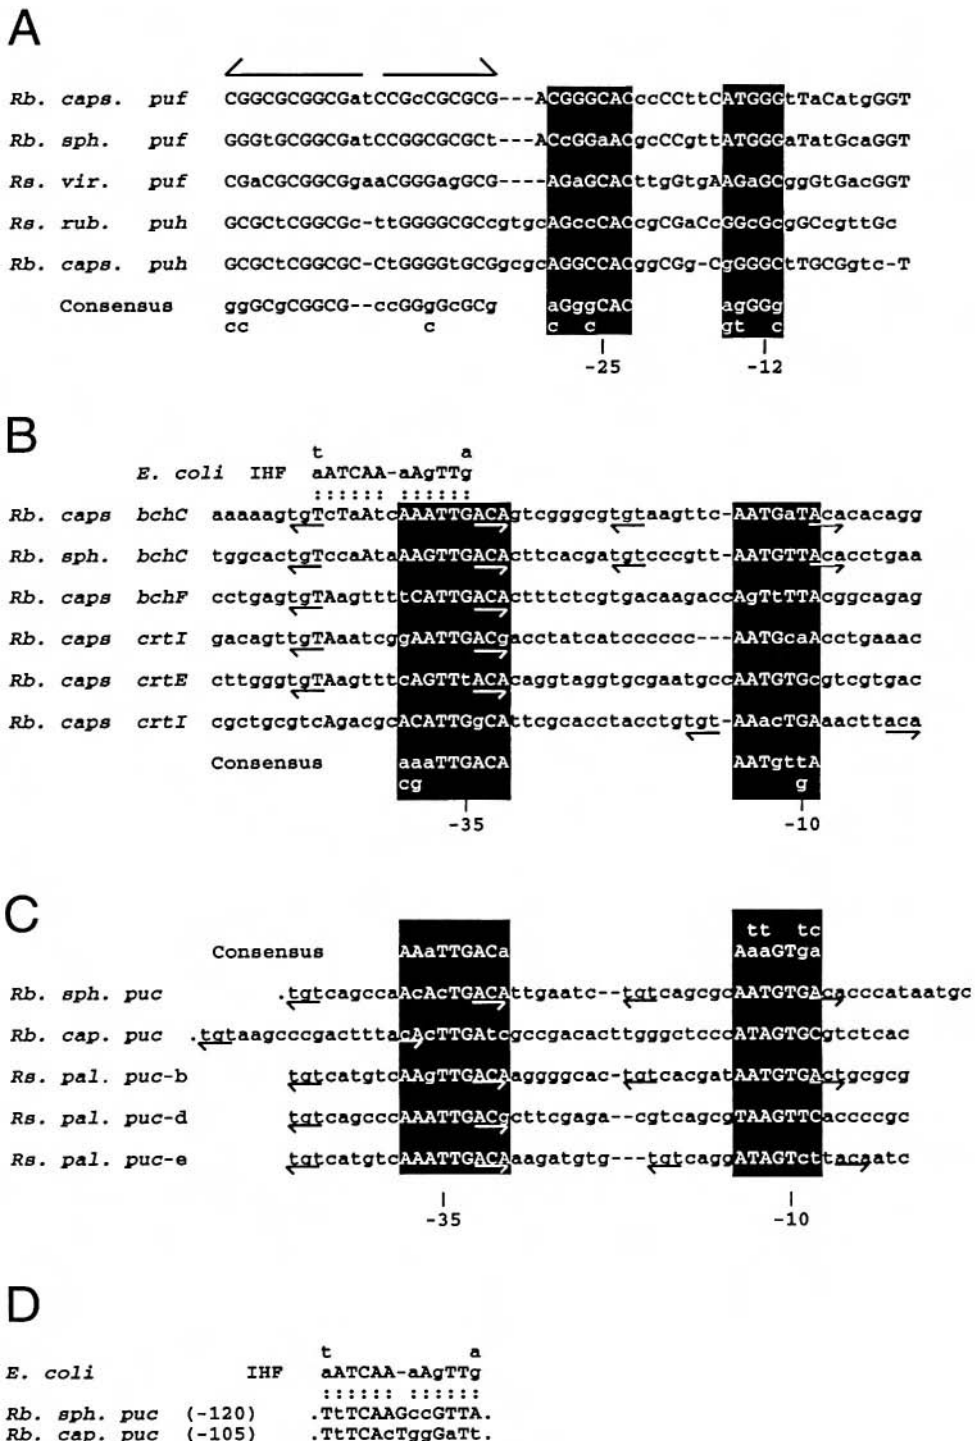

Fig. 2. Photosynthesis Gene Promoters. a) an alignment of putative *puf* and *puh* promoter sequences from *Rb. capsulatus* (Adams et al., 1989; Bauer et al., 1988; 1991), *Rb. sphaeroides* (Hunter et al., 1991) *Rs. rubrum* (Bérard et al., 1989) and *Rp. viridis* (Wiessner et al., 1990). b) an alignment of putative *bch* and *crt* photopigment promoters from *Rb. capsulatus* (Young et al., 1989; Wellington and Beatty, 1989; Ma et al., 1993; Alberti et al., chapter) and *Rb. sphaeroides* (McGlynn and Hunter, 1993). c) An alignment of putative *puc* operon promoters from *Rb. sphaeroides* (Lee et al., 1989) *Rb. capsulatus* (Zucconi and Beatty, 1988) and *Rp. palustris* (Tadros et al., 1993). d) Potential IHF binding domains (Hoover et al., 1990) in the *puc* promoter region of *Rb. sphaeroides* (Lee et al., 1993) and *Rb. capsulatus* (Nickens and Bauer, unpublished)

an effect on light mediated anaerobic expression (Narro et al., 1990; Klug, 1991b; Klug et al., 1991). Several groups have also provided evidence that the *puf* dyad region undergoes a gel mobility shift with cell free extracts in an oxygen and light dependent manner, the binding of which is affected by the phosphorylation state of protein extracts (Taremia and Marrs, 1990; Klug, 1991b; Shimada et al., 1993).

B. *bch/crt Promoters*

Perhaps one of the better characterized photosynthesis gene promoters is that of the *bchC* promoter of *Rb. capsulatus*. Deletion mapping of this promoter region was initially performed by Young et al., (1989). This was followed by high resolution primer extension 5' end mapping of the *bchC* transcript by Wellington and Beatty (1989). Unlike the *puf* and *puh* promoter sequences which exhibit a unique promoter sequence, Young et al., (1989) noted that the *bchC* promoter region contained a sequence that was similar to the canonical *E. coli* housekeeping sigma 70 promoter sequence (Fig. 2b). Recent mutational analysis of the *bchC* promoter region by Ma et al., (1993) has confirmed this observation by indicating that a sigma 70-like promoter sequence is indeed important for *bchC* promoter activity. Sequence gazing has also revealed the presence of 'sigma-70 like' promoter sequences upstream of other *Rb. capsulatus* photopigment biosynthesis genes such as *crtI*, *crtD*, *crtA*, *bchF* and *bchE* (Armstrong et al., 1989; Chapter 50 by Alberti et al.). There is also a similar sigma-70 like promoter sequence in the *Rb. sphaeroides bchC* region (Fig. 2b) that can be observed by sequence gazing of the intragenic region between *bchC* and *crtF* (McGlynn and Hunter, 1993). An more extensive discussion of these putative promoter sequences can be found in Chapter 50 by Alberti et al.

Also shown in Fig. 2b, and discussed in detail in Chapter 50 by Alberti et al., is the observation by Armstrong et al., (1989) that several of the putative *Rb. capsulatus* 'sigma-70 like' photopigment promoter regions also exhibit a nearby palindrome sequence (TGTGT -N₆₋₁₀- ACACA). Mutational analysis of the *bchC* palindromic sequence indicates that it may be involved in binding of a repressor to this region (Ma et al., 1993). Mutational analysis has also indicated that the palindromic region is not all that is needed to properly regulate *bchC* promoter activity as evidenced by the requirement for an additional upstream AT rich region for optimal activity

(Ma et al., 1993). As shown in the alignment in Fig. 2b, the AT rich region contains a sequence motif that is similar to an IHF binding site that actually overlaps with the *bchC* -35 promoter region. Also shown in Fig. 2b is evidence that there is an IHF-like sequence in the same region of the putative *bchF*, *bchC*, *bchE*, *crtI* and *crtA* promoter sequences. Regulated expression of photopigment promoters may therefore require two putative *trans*-acting factors, an IHF-like factor that binds near the -35 region as well as an additional factor that interacts with the palindromic sequence. It is also interesting to note that *puf* and *puh* promoter regions, which as discussed above exhibit a unique promoter motif, do not have an identifiable IHF or 'photopigment like' palindromic sequence. This would be consistent with mutational evidence that the *puf* and *puh* promoters are regulated independently of photopigment promoters (Sganga and Bauer, 1992; Mosley et al., 1994).

C. The *puc Promoter*

One of the more highly expressed photosystem promoters appears to be that of the *puc* operon which drives expression of the LHII structural polypeptides. Stable 5' ends have been mapped for the *puc* message from *Rb. sphaeroides* (Lee et al., 1989), *Rb. capsulatus* (Zuconni and Beatty, 1988) and more recently for the 'puc like' antenna cluster from *Rp. palustris* (Tadros et al., 1993). As indicated in Fig. 2c, the *puc* promoter regions exhibit a strong degree of sequence conservation among these differing species and genera. Surprisingly, the *puc* promoter alignments shows little similarity with that of the *puf* and *puh* promoters, and instead, exhibits a 'good fit' with the sigma-70 type *bch* and *crt* promoters (Fig. 2). Furthermore, as is the case with the *bch* and *crt* promoters, the *puc* promoter region also exhibit the TGTGT -N₆₋₁₀- ACACA palindromic motif. There is also a putative IHF binding sequence located 120 and 105 bp upstream of the *Rb. sphaeroides* and *Rb. capsulatus puc* stable 5' ends respectively (Fig. 2d). The putative IHF binding site has been shown by footprint analysis to interact with cell free extracts derived from *Rb. sphaeroides* (McGlynn and Hunter, 1992) as well with *E. coli* IHF (Lee et al., 1993). Deletion of the IHF binding site also shows a 5-fold reduction in anaerobic *puc* expression in vivo (Lee et al., 1993).

Despite sequence similarity of the *puc* promoters with that of the *bch* and *crt* promoters, there is no

strong evidence for coordinate regulation of these operons. Instead, there is evidence that the *puc* operon may utilize one or more *trans*-acting regulatory elements that interact with *puf* and *puh* promoters to which *puc* exhibits little sequence similarity. For example, gel retardation experiments indicates that the *puc* promoter region can compete for a protein which binds to the *puf* promoter region of dyad symmetry (Klug, 1991b). A mutation in the *puf* region of dyad symmetry which leads to increased expression of the *puf* operon has also been shown to cause instability of *Rb. capsulatus* strains that results in high frequency segregation of daughter cells that have reduced *puc* expression (Klug and Jock, 1991). There are also several *trans*-acting regulatory mutants that affect *puf*, *puh* as well as *puc* operon expression (Sganga and Bauer, 1992; Lee and Kaplan, 1992b; Eraso and Kaplan, 1994; Mosely et al., 1994) which provides strong evidence for the utilization of a similar set of *trans*-acting factors among these three operons.

Even though there appear to be a common set of *trans*-acting factors involved in *puf*, *puh* and *puc* operon expression, there is also several studies which indicate that *puc* expression is actually discoordinate from that of *puf* and *puh*. For example, kinetic studies involving growth shifts from aerobic to anaerobic conditions indicates that induction of *puc* operon expression lags that of *puf* and *puh* (Klug et al., 1985; Hunter et al., 1987; Kiley and Kaplan, 1987). Mutations that disrupt formation of the LHII complex, such as those which affect synthesis of carotenoids, bacteriochlorophyll or assembly of the LHII complex, also appear to reduce *puc* expression without significantly affecting *puf* expression (Klug et al., 1985; Lee et al., 1989; Tichy et al., 1991). *Puc* operon expression is also poorly regulated by the light responding *trans*-acting activator *hvrA* which coordinately regulates *puh* and *puf* operon expression in response to light intensity (Buggy et al., 1994b). Thus, a picture of discoordinate regulation of *puc* operon expression from that of other photosynthesis genes is emerging.

What then are the factors that allows discoordinate expression of the *puc* operon? One clue may be derived from promoter deletion analysis by Lee and Kaplan (1992a). In their study they concluded that expression of the *Rb. sphaeroides* *puc* operon involves a complex promoter region that extends up to 629 bp upstream from the point of transcription initiation. By deletion analysis they were able to separate the

puc promoter region into an upstream regulatory region (629 to -150) and a downstream regulatory region (-150 to -1). They concluded that the downstream regulatory region contained the *puc* promoter region (as mapped by deletion and primer extension analysis) whose maximal and proper expression required the upstream elements. Presumably the 'extended' length of the *puc* promoter region may be involved in the complex expression pattern of the *puc* operon. An additional conclusion of these studies, which was not directly addressed by Lee and Kaplan (1992a), is the possibility that the upstream region contains a second distinct promoter that is differentially regulated from a promoter that is present in the downstream region. If so, it could account for several of the above noted observations on *puc* operon expression.

IV. *trans*-Acting Regulatory Circuits

The first report of a regulatory mutant that affects synthesis of the eubacterial photosystem was a report by Lascelles and Wertlieb (1971) who described the isolation of *Rb. sphaeroides* strains that synthesized elevated levels of photopigments when grown under aerobic conditions. Unfortunately these strains were lost prior to the development of recombinant DNA technology so the genetic basis of their phenotype remains unknown. It wasn't until very recently that *trans*-acting regulatory genes that control photosynthesis gene expression were reported in the literature. The section below describes the current understanding of the *trans*-acting regulatory circuits that are emerging from these studies.

A. Regulating Transcription of Light harvesting and Reaction Center Genes

1. Oxygen Control Circuit

Sganga and Bauer (1992) initially performed mutational and molecular-genetic characterization of a *trans*-acting regulatory gene, termed *regA*, that appears to be responsible for coordinating expression of the *puf*, *puh* and *puc* operons in *Rb. capsulatus*. This study was followed by the isolation of a mutation in a similar locus in *Rb. sphaeroides* (Lee and Kaplan, 1992b) which was subsequently shown to code for a gene product that exhibits 92% sequence identity with that of *regA* (Eraso and Kaplan, 1994; Phillips

and Hunter, 1994). The *regA* gene product codes for a 184 amino acid protein that is homologous to the two component class of bacterial response regulators, specifically to the subclass of smaller response regulators such as CheY, SpoOF and CheB which do not interact with DNA but instead function as intermediates in a more complex multicomponent regulatory cascade (this class of prokaryotic regulatory cascades are reviewed by Parkinson and Kofoed, 1992). In a *regA* mutant background, cells fail to induce expression of *puf*, and *puf*, above basal levels, as well as for a significant (but not absent) reduction of *puc* expression (Sganga and Bauer, 1992; Eraso and Kaplan, 1994). RegA-mediated activation was initially thought to be specific only for LH and RC promoters, since RegA does not influence regulation of the nearby *bchC* or *bchH* promoters nor the expression of the oxygen regulated nitrogen fixation operon *nifHDK* (Sganga and Bauer, 1992; Mosley et al., 1994). However, Eraso and Kaplan (1994) recently reported that a disruption of the *Rb. sphaeroides regA* homolog also affects transcription of the cytochrome c_2 gene the product of which shuttles electrons between the cytochrome bc_1 complex and the RC. So it appears that RegA may also affect expression of electron transfer components of photosystem.

Based on homology to other prokaryotic two-component regulatory systems, RegA activity is thought to be modulated by a phosphorylation event in which a specific cognate sensor kinase acts to phosphorylate and possibly dephosphorylate RegA in response to environmental changes in oxygen tension (Fig. 3b). A RegA-specific sensor kinase has been shown to be the product of the linked *regB* gene (Fig. 3a) (Bauer et al., 1993; Mosley et al., 1994). Mutations in the *Rb. capsulatus regB* locus have a phenotype almost identical to that of a *regA* disruption; namely a dramatic decrease in RC and LH complexes as a result of a failure to activate *puf*, *puf*, and *puc* transcription under anaerobic conditions. DNA sequence analysis indicates that the RegB predicted amino acid sequence has a carboxyl terminal domain that is a member of the sensor kinase family of response regulatory proteins. Like that of many other sensor kinases, the amino terminal region of RegB also has three to four transmembrane domains. In vivo biochemical analysis of a truncated version of RegB which lacks the membrane spanning domains confirms that RegB has autophosphorylation activity and can rapidly transfer the phosphate to

Fig. 3. The *Rb. capsulatus* 'regulatory gene cluster' that code for components of the oxygen sensory transduction cascade. a) Open reading frames of the *Rb. capsulatus* regulatory gene cluster (Sganga and Bauer, 1992; Sganga et al., 1992; Buggy et al., 1994a,b; Mosley et al., 1994). Arrows denote direction of transcription. b) Component of the sensory transduction cascade that controls expression of the *puf*, *puh* and *puc* operons in response to alterations in oxygen tension. RegB is proposed to be a membrane spanning kinase as based in its amino acid sequence (Mosley et al., 1994). In vitro assays indicates that RegB exhibits rapid auto kinase activity and transfer of the phosphate to RegA (Inoue et al., 1995). This activity is inhibited by molecular oxygen (Inoue, Mosley and Bauer, unpublished). Based on the absence of any noticeable DNA binding sequence motif or DNA binding activity it is proposed that RegA then transfers its phosphate to a third component which then controls activity of the *puf*, *puh* and *puc* promoters.

RegA (Inoue et al., 1995). Surprisingly, the truncated RegB protein only has autophosphorylation activity under anaerobic conditions thereby indicating the redox sensing portion of RegB remains intact in the cytosolic domain of the polypeptide (Inoue, Mosley and Bauer, unpublished).

C

Fig. 4. Regulatory circuits that control synthesis of the *Rb. capsulatus* photosystem. a) Transcripts controlled by the RegB-RegA oxygen regulatory circuit (Sganga and Bauer, 1992; Mosley et al., 1994). b) Transcripts controlled by the hvrA mediated light regulatory circuit (Buggy et al., 1994b). c) Photopigment transcripts controlled by *crtJ* (Ponnampalam et al., 1995). The dotted lines denote proposed regulatory circuits whereas the solid lines denote those that are more firmly established.

Although RegB and RegA are the two primary *trans*-acting factors that are firmly established to be in the oxygen control circuit (as shown in Fig. 4a), there remains the possibility that the sensory transduction pathway is more complex than that of only two players. For example, inspection of the RegA primary amino acid sequence gives no indication of a DNA-binding motif. The apparent

absence of a DNA-binding motif is supported by the inability to observe consistent RegA-DNA interactions by gel mobility shift (unpublished results from the C. Bauer laboratory). It is therefore possible that RegA may only be an intermediary component of a more complex phosphorylation regulatory cascade that involves a downstream DNA binding protein. This latter possibility is supported by *in vitro*

observations that a protein that does not have a RegA amino terminal sequence interacts with the *puf* promoter region of dyad symmetry in a phosphorylation-dependent manner (Taremi and Marrs, 1990). There is also the possibility that there is more than one sensor kinase feeding into this signal transduction pathway. A candidate gene for additional input is *senC* which is a gene that is located immediately preceding *regA* (Fig. 3a). The polypeptide coded by *senC* has sensor kinase features although it is yet to be established that it indeed has kinase activity (Buggy and Bauer, unpublished).

2. Light Control Circuit

In addition to molecular oxygen, light also has a repressing effect on the synthesis of the purple eubacterial photosystem. The magnitude of the repressing effects of light (2-fold) is however, greatly overshadowed by the 30- to 100-fold repressing effects of oxygen. Thus, an analysis of light regulation has proven difficult, if not intractable, to classic genetic studies. Despite these difficulties there has been some recent advances in providing a molecular genetic understanding of light regulation of LH and RC gene expression. One advance was provided by the serendipitous linkage of the oxygen regulator *regA* to an open reading frame, termed *hvrA*, (Fig. 3a) that appears to be responsible for light-mediated regulation of the *puf* and *puh* operons (Buggy et al., 1994b). A mutation of *hvrA* results in the inability to *trans*-activate *puf* and *puh* expression in response to a reduction of light (Fig. 4b). Inspection of the *hvrA* sequence indicates that it exhibits a putative helix-turn-helix motif which would indicate that HvrA could interact with the *puf* and *puh* promoter regions. This is confirmed by footprint analysis which indicates the HvrA binds to a region 90–100 bp upstream of the base of *puh* and *puf* transcription initiation (Kouadio and Bauer, unpublished results).

The mechanism whereby light affects activity of HvrA is as yet unclear, however, Shimada et al., (1992) recently performed an action spectrum of the wavelengths of light that are responsible for controlling *Rb. sphaeroides puf* operon expression by light intensity. Their results suggest that blue light in the 450 nm region exhibits the most severe repressing effects. This would indicate that HvrA, or an upstream component in a light-mediated signal transduction cascade, may be a flavin binding protein. In plant systems, there are thought to be a number of blue

light photoreceptors that control plant development (Kaufman, 1993), one of which is also thought to be a flavin binding protein as based on sequence similarity to photolyase which is known to utilize flavin as a chromophore (Ahmad and Cashmore, 1993). HvrA does not exhibit any noticeable sequence similarity to other known flavin binding proteins, although as a class, they do not contain a universally conserved flavin binding sequence motif. Thus it remains unclear whether HvrA is itself a flavin binding protein or is instead a terminal component in a more complex light-mediated signal transduction cascade.

Light-mediated regulation of *puc* operon expression appears to be more complex than that of *puf* and *puh* as evidenced by some conflicting data in the literature. Several initial hybridization studies indicated that the steady state level of *puc* mRNA was reduced when photosynthetically grown cells are shifted from low to high light intensity (Zhu and Hearst, 1986; Kiley and Kaplan, 1987). However, when Zucconi and Beatty (1988) analyzed *puc* mRNA levels that were carefully normalized to rRNA levels, they observed that steady state *puc* mRNA levels were actually *higher* when the cells were grown under high light conditions than under low light conditions. This is despite the observation that the level of LHII polypeptide synthesis was inversely regulated (i.e. LHII polypeptides are present in higher amounts under low light growth conditions than under high light growth conditions). They therefore concluded that light regulation of *puc* expression involve an as yet unclear post-transcriptional control mechanism. A similar conclusion was recently obtained in a study of the 'puc-like' antenna gene cluster of *Rp. palustris* (Tadros et al., 1993).

B. Regulation of Pigment Biosynthesis Genes

Less is known about *trans*-acting factors involved in controlling bacteriochlorophyll and carotenoid gene expression in response to changes in light intensity and oxygen tension. As discussed above, gel mobility shifts by Ma et al., (1993) has indicated that there exists a protein which interacts with the palindrome sequence of putative promoters that control photopigment gene expression. The protein that interacts with the palindrome has not been purified or cloned so its identity is unclear. Penfold and Pemberton (1991, 1994) recently provided evidence that the *Rb. sphaeroides* photosynthesis gene cluster

codes for a repressor of carotenoid and *bchC* expression that they have termed *pps*. Sequence analysis indicates that *pps* is analogous to the *crtJ* open reading frame described by Zsebo and Hearst (1984). Mutational analysis of this open reading frame in *Rb. capsulatus* also indicates that it has a similar role in this species (Fig. 4c) (Bollivar et al., 1994; Ponnampalam et al., 1995). The polypeptide coded by the *pps/crtJ* open reading frame has a reasonable helix-turn-helix motif (Penfold and Pemberton, 1994) which would indicate that it may interact with the photopigment promoters. Purification and footprint analysis of this polypeptide has not been undertaken so it remains to be seen if PPS/CrtJ is the factor that interacts with the palindrome sequence that is present in these promoters. It is also unclear whether the *pps/crtJ* polypeptide responds to both light and oxygen or to only one of these signals.

V. Concluding remarks

Based on the repressing effects of light and oxygen on photopigment biosynthesis, Cohen-Bazire, Sistrom and Stanier (1957) proposed a model whereby synthesis of photopigments was regulated by a central redox responding 'regulator' that tempered synthesis of photopigments relative to changes in the redox state of the cells electron transport system. As we begin to identify regulatory factors that are responsible for controlling photosystem gene expression it is becoming increasingly evident that the mechanism of regulation is much more complex than could have initially been envisioned. There appears to exist independent and overlapping light and oxygen regulatory circuits that are responsible for controlling synthesis of photopigments relative to that of the pigment binding polypeptides. These circuits provide both coordinate and discoordinate regulation of the various components which comprise the purple eubacterial photosystem. Superimposed on the *trans*-acting circuits are layers of post-transcriptional control involving the formation of superoperons (see chapter 57 by Beatty), coupled with mRNA processing events (see chapter 59 by Klug). Although much progress has recently been made in identifying the existence of these various levels of regulation, there remains much to be learned about how they coordinately regulate proper synthesis of the photosystem in response changes in the environment.

Acknowledgments

I would like to thank members of the photosynthetic bacteria community for sending reprints and preprints of their work as well as members of my own laboratory for allowing communication of unpublished results. Research from the C. Bauer laboratory is supported by the National Institutes of Health and the National Science Foundation.

Summary

Oxygen tension and light intensity influence the formation of pigment protein complexes in facultatively photosynthetic bacteria. Multiple control mechanisms are required to regulate expression of photosynthesis genes in response to external factors and to guarantee the coordinated syntheses of components of the photosynthetic apparatus. Regulation of expression of photosynthesis genes is partly accomplished by variation of mRNA levels. Both the rate of synthesis and the rate of decay of mRNA are involved in determining these mRNA levels. Our current knowledge on the molecular mechanisms of stabilization and destabilization of mRNAs transcribed from photosynthesis genes will be summarized. Some experimental data suggest that photosynthesis genes are also regulated at later steps of gene expression. This chapter will address the 23S rRNA processing in *Rhodobacter* and its putative role in gene regulation. Other molecular mechanisms influencing the rate of translation or post-translational processes have not been investigated to date but evidence for their participation in regulation of photosynthesis genes is provided. Since regulation of bacterial photosynthesis genes has been studied most intensively in *Rhodobacter capsulatus* and *Rhodobacter sphaeroides*, this review will focus on the results obtained with these closely related bacterial species.

I. Introduction

Facultatively photosynthetic bacteria have the ability to use different modes of energy conversion and to adapt their cellular composition and membrane structure to environmental changes (reviewed in: Drews and Imhoff, 1991). Oxygen tension and light intensity are the two external factors known to regulate the formation of the photosynthetic apparatus. Regulation of gene expression in bacteria is often achieved by variation of transcriptional rates. Initiation of transcription is, however, not the only step in gene expression involved in the regulated formation of bacterial photosynthetic complexes. This chapter will summarize our current knowledge on the role of post-transcriptional processes that affect the expression of photosynthesis genes in *Rhodobacter*.

Under high oxygen tension facultatively photosynthetic bacteria perform aerobic respiration. When oxygen tension in the environment drops, these bacteria form photosynthetic complexes which are incorporated into intracytoplasmic membranes originating from invaginations of the cytoplasmic membrane. During phototrophic growth, light intensity affects the formation of the photosynthetic apparatus (reviewed in Drews (1992) and in Chapter 12 by Drews and Golecki). The interaction of pigments and proteins and their highly ordered structural organization is required for the formation of functional photosynthetic complexes.

All genes encoding pigment binding proteins and a large number of genes encoding the enzymes catalyzing pigment syntheses have been identified over the last years in the closely related species *Rhodobacter capsulatus* and *Rhodobacter sphaeroides* (Chapter 50 by Alberti et al.), and investigations on the regulation of the expression of these genes have been initiated (Chapter 58 by Bauer). A schematic overview on the molecular steps involved in the regulated expression of these photosynthesis genes is given in Fig. 1. The known cellular factors involved in transmitting the oxygen signal in the cell are described in Chapter 58 by Bauer, as is our knowledge on the effect of oxygen on the transcription of photosynthesis genes. Oxygen, however, also influences the rate of mRNA degradation, and some

observations suggest that later steps in gene expression may also be affected by oxygen. Post-transcriptional regulation of gene expression is also involved in the coordination of the syntheses of different components of the photosynthetic apparatus and in determining the relative levels of gene products.

II. Control of Photosynthesis Gene Expression on the Level of mRNA Stability

A. The Role of Segmental Differences in *puf* mRNA Stability in the Formation of the Photosynthetic Apparatus of *Rb. capsulatus*

The pigment-binding proteins of *Rb. capsulatus* are encoded by two polycistronic operons that are separated on the chromosome (Fonstein and Haselkorn, 1993). The *puf* operon (formerly *rxcA* operon, Belasco et al., 1985) (Fig. 2) encodes the proteins of the LHI complex (genes *pufB* and *pufA*) and of the RC complex (genes *pufL* and *pufM*) (Youvan et al., 1984). In addition it comprises the genes *pufQ* (Bauer et al., 1988) and *pufX* (Youvan et al., 1984) that are required for the formation of wild type levels of photosynthetic complexes (Bauer and Marrs, 1988; Klug and Cohen, 1988; Farchaus et al., 1992; Lilburn et al., 1992). All *puf* genes are under the control of an oxygen-regulated promoter positioned about 200 bp upstream of the first open reading frame (Bauer et al., 1988; Adams et al., 1989). This polycistronic organization allows the coordinated expression of all *puf* genes in response to oxygen.

Although the *puf* genes are part of the same transcriptional unit, the *puf* gene products are required in different amounts. 10-15 LHI complexes surround one RC complex in the membrane of *Rb. capsulatus* wild type cells (Kaufmann et al., 1982; Klug et al., 1987). The relative amounts of the *pufQ* and *pufX* gene products in the cells are not known, but there is evidence that PufQ is a regulatory protein (Bauer and Marrs, 1988) that is present in very low concentration. Synthesis of different amounts of the *puf* gene products is achieved by post-transcriptional regulation of gene expression. In *Rb. capsulatus* posttranscriptional regulation of gene expression occurs at least in part on the level of mRNA degradation.

Two *puf* specific mRNAs can be detected in *Rhodobacter* by Northern blot analysis (Belasco et

Abbreviations: bp – base pairs; *E.* – *Escherichia*; LH – light harvesting; *Rb.* – *Rhodobacter*; RC – reaction center; RNase – endoribonuclease

Fig. 1. Steps in gene expression involved in the formation of photosynthetic complexes. Sensing and transmission of the oxygen signal is described in Chapter 58. Oxygen affects the expression of photosynthesis gene by regulating their transcription and the stability of the corresponding mRNA. The effect of oxygen on later steps of gene expression has not been studied to date. Oxygen also affects pigment syntheses at multiple levels of gene expression (Chapter 58).

Fig. 2. Schematic genetic map of the polycistronic *puf* operon of *Rb. capsulatus*. Arrows represent mRNA species and half-lives as determined by Northern blot analysis (referring to Klug et al., 1987) are listed. The segmental differences in *puf* mRNA stability in part determine the relative amounts of the products of the individual *puf* genes in the cell. P: oxygen-regulated promoter, T: transcriptional terminators.

al., 1985; Zhu and Hearst, 1986). A 2.7 kb *pufBALMX* mRNA decaying with a half-life of about 8 min (Klug et al., 1987) and a 0.5 kb *pufBA* mRNA showing a half-life of about 30 min (Klug et al., 1987) share the same 5' end (Fig. 2). The *puf* mRNA segment comprising the untranslated 5' region and the *pufQ* gene is highly unstable. Due to its higher stability, the 0.5 kb *puf* mRNA encoding LHI proteins only, is present in a 10 fold molar excess over the 2.7 kb *puf* mRNA encoding LHI and RC proteins and PufX (Belasco et al., 1985). Pulse labeling experiments revealed that the 0.5 kb mRNA is a processing product of the 2.7 kb mRNA (Belasco et al., 1985). The 2.7 kb *puf* mRNA extends to either of two transcriptional terminators (Belasco et al., 1985). The 3' end of the 0.5 kb *puf* mRNA is formed by a highly stable secondary structure located in the intercistronic region between *pufA* and *pufL* (Belasco et al., 1985). This secondary structure is required for the higher stability of the 0.5 kb *pufBA* mRNA by protecting it against 3' to 5' exonucleases (Klug et al., 1987; Chen et al., 1988). Removal of this secondary structure results in continuous degradation of the 2.7 kb *pufBALMX* mRNA (Klug et al., 1987; Chen et al., 1988) and in altered stoichiometry of the *puf* gene products in the membrane. The ratio of LHI to RC complexes dropped from 15:1 in a wild type control to 7:1 in the absence of the intercistronic secondary structure (Klug et al., 1987). Although the chemotrophic and phototrophic growth rates of *Rb. capsulatus* cultures were not affected by this mutation in the presence of the LHII complex, cultures lacking the stable *pufBA* mRNA segment showed a prolonged lag phase when shifted from chemotrophic to phototrophic growth (Klug et al., 1987). Thus, segmental differences in the stability of *puf* mRNA segments are involved in regulating the relative amounts of *puf* gene products (Fig. 2), but are not the only molecular basis for the excess of LHI.

B. Oxygen Affects the Stability of mRNAs Encoding Pigment Binding Proteins

When the oxygen tension in aerobically growing cultures of *Rhodobacter* is reduced, the *puf* and *puc* mRNA levels increase 15–20 fold (Clark et al., 1984; Klug et al., 1985; Zhu and Kaplan, 1985; Zhu and Hearst, 1986). This increase is not only due to increased *puf* operon transcription (Bauer et al., 1988; Adams et al., 1989; Hunter et al., 1991; Lee and Kaplan, 1992; Chapter 58), but is in part the

result of altered *puf* mRNA stability (Klug, 1991). The 2.7 kb *pufBALMX* mRNA of *Rb. capsulatus* shows a half-life of about 3 min at high oxygen tension but of about 8 min at low oxygen tension, while the 0.5 kb *pufBA* mRNA decays with similar rate (half-life of about 33 min) at high and low oxygen tension. The decay of the 0.5 kb *pucBA* mRNA (encoding proteins of the LHII complex) is affected by oxygen to a lower extent (half-life 18 min under high oxygen, 29 min under low oxygen tension), whereas other mRNA species like *fbc* (cytochrome *fbc* complex), *puhA* (non-pigment binding subunit of the RC), and *cycA* (cytochrome *c₂*) decay independently of the aeration of the cultures (Klug, 1991). Hence, differences in mRNA stability not only influence the molar ratios of the *puf* gene products, but also contribute to the oxygen regulation of *puf* gene expression. The mechanisms by which oxygen can affect mRNA decay are not understood to date.

C. Stabilization and Destabilization of *puf* mRNA Segments

As pointed out above, and shown in Fig. 2, individual segments of the polycistronic *puf* mRNA exhibit extremely different half-lives. These differences in *puf* mRNA stability are involved in the oxygen dependent regulation of *puf* genes (A2) and in differential expression of LHI and RC genes (A1). In order to understand the regulated expression of *puf* genes, we therefore need to understand the molecular basis of mRNA degradation and stabilization.

The intercistronic secondary structure located between *pufA* and *pufL* is required for the stabilization of the 0.5 kb *pufBA* mRNA segment by protecting it against 3' to 5' exonucleases (Klug et al., 1987; Chen et al., 1988). In the same way, the structures that terminate *puf* transcription provide protection against exonucleolytic attack at the 3' end of the 2.7 kb *pufBALMX* mRNA (Klug and Cohen, 1988). The 5' end of the 2.7 kb and 0.5 kb *puf* mRNAs is also highly structured (Rothfuchs and Klug, unpublished). It was shown for the *E. coli ompA* mRNA that a secondary structure at the 5' end of this mRNA provides protection against endonucleolytic attack (Emory et al., 1992), and it is likely that the secondary structures at the 5' end of the stable *puf* mRNA species serve a similar function.

Decay of the 2.7 kb *pufBALMX* mRNA is initiated by endonucleolytic cleavages at multiple sites within

the *pufLM* coding region (Klug and Cohen, 1990; Chen and Belasco, 1990). One of the target sites for endonucleolytic cleavage was identified (Fritsch et al., 1995) and it shows remarkable similarity to *E. coli* RNA sequences that are recognized by the endoribonucleases (RNase) E (Ehretsmann et al., 1992) or K (Lundberg et al., 1990). When *Kb. capsulatus puf* mRNA is expressed in *E. coli*, the rate of decay of the 2.7 kb *puf* mRNA indeed depends on the activity of the RNase E enzyme, whereas the 0.5 kb *puf* mRNA decays with similar rates in presence or absence of RNase E activity (Klug et al., 1992). Remarkably, the putative recognition sequence for an endonuclease in *Rb. capsulatus* is part of the coding region for a structural protein of the reaction center. This mRNA sequence therefore has to fulfill two functions: i) encoding a functional RC protein, and ii) to serve as an endonuclease recognition site. Other *puf* mRNA sequences share homology with the endonucleolytic cleavage site within the *pufL* gene (Fig. 3) but their function has not been analyzed to date. Data on *puf* mRNA decay collected over the past few years resulted in a model that attributes the segmental differences in *puf* mRNA stability to the specific distribution of RNA decay promoting elements (recognition sites for endonucleases) or RNA decay impeding elements (secondary structures at the 3' or 5' end of stable mRNA species) (Klug, 1993) (Fig. 3).

D. Segmental Differences in Stability of Other mRNAs Encoding Photosynthesis Proteins

Differential decay of mRNA segments is most likely not restricted to the polycistronic *puf* operon of *Rhodobacter*. Bauer *et al.* (1991) detected 11 kb, 1.1 kb and 0.95 kb mRNA species that hybridized to the *puhA* gene (encoding the non pigment binding protein of the RC) (Fig. 4). The 11 kb mRNA also encodes the upstream *bchFNBHLM-F1696* operon, suggesting that the 1.1 kb mRNA is derived from the 11 kb precursor by processing. The 0.95 kb mRNA is initiated at the *puhA* promoter. The biological significance of the *bchFNBHLM-F1696-puhA* mRNA processing is not known.

The *puc* operon encodes the pigment-binding proteins of the LHII complex (genes *pucB* and *pucA*) and also comprises the *pucC* gene (Tichy *et al.*, 1991), which is required for high levels of *puc* expression, and the genes *pucD* and *pucE*, encoding gene products necessary for the assembly or

Fig. 3. Model for the degradation of the polycistronic *puf* mRNA. The segmental differences in mRNA stability are attributed to a specific distribution of endonuclease recognition sites (\square) and mRNA secondary structures that function as stabilizing elements (\circ). Degradation of the primary transcript is initiated by endonucleolytic cleavages (\uparrow) within the *pufQ* coding sequence (I). The 2.7 kb processing product is stabilized by several secondary structures at the 5' end (\circ) and by the two terminator structures at the 3' end that prevent 3' to 5' decay by exonucleases (\circ). Degradation of the 2.7 kb mRNA (II) is initiated by multiple cleavages within the RC coding region, (\uparrow) and the rate of cleavage is affected by the oxygen tension. Further degradation occurs by mechanisms that have not been identified (III) and results in the occurrence of the 0.5 kb mRNA that carries highly stable secondary structures at its 3' and 5' end and does not carry putative recognition sites for endonucleolytic cleavage. The mechanisms initiating the final degradation of the 0.5 kb *puf* mRNA segment (IV) have not been identified to date.

stabilization of LHII complexes (Tichy *et al.*, 1989; Lee *et al.*, 1989) (Fig. 4). mRNA secondary structures are predicted for the *pucA-pucC* intercistronic region (Zucconi and Beatty, 1988; Lee *et al.*, 1989; Tichy *et al.*, 1989) as for the *pufA-pufL* intercistronic region (Belasco *et al.*, 1985), and it was suggested that the

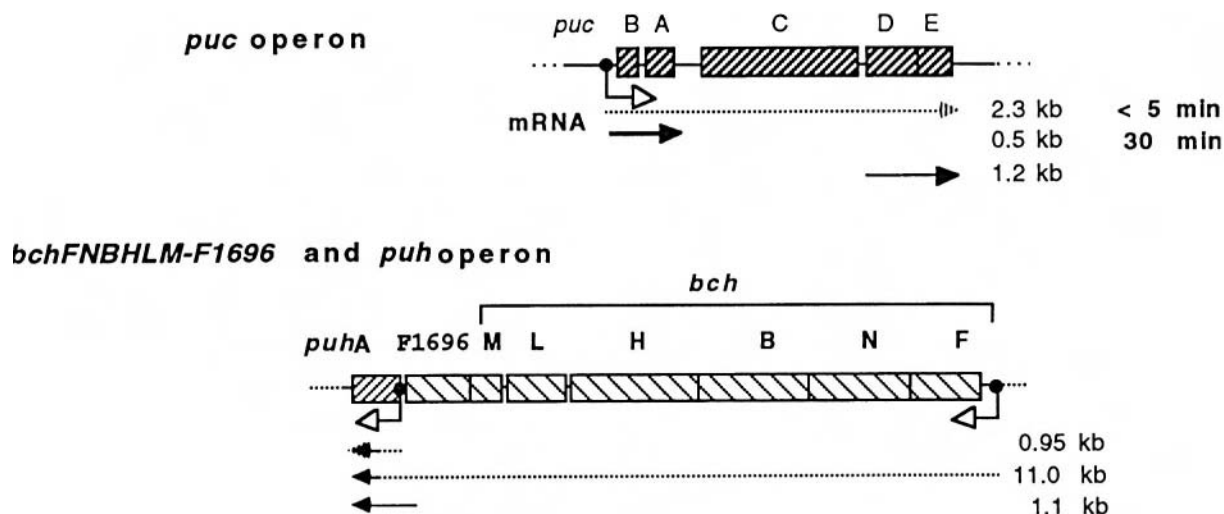

Fig. 4. Schematic maps of the *puc* operon and *puhA-bchFNBHLM* operon of *Rb. capsulatus*. mRNA species are represented by arrows and the mRNA half-lives are listed, if determined (Lee et al., 1989).

pucA-pucC intercistronic mRNA structure stabilizes the upstream mRNA rather than functioning as a transcriptional terminator (Tichy *et al.*, 1991). It was also reported that the *pucDE* mRNA segment is more stable than the *pucC* mRNA segment in *Rb. capsulatus* (Oberlé *et al.*, 1990) suggesting a similar role of mRNA processing in the regulation of *puc* gene expression as demonstrated earlier for the *puf* gene expression. No attempts have been undertaken to study the decay of *puc* mRNA, and therefore the mechanisms involved in this process remain to be solved.

III. 23S rRNA Processing in *Rhodobacter*

The bacterial 50S ribosomal subunit is generally composed of a 23S and a 5S rRNA molecule and ribosomal proteins. Some bacterial species, however, have ribosomes that do not contain an intact 23S rRNA species. In vivo fragmentation of 23S rRNA has been reported for some cyanobacteria (Doolittle, 1979), for *Agrobacterium tumefaciens* (Schuch and Loening, 1975), for *Bdellovibrio bacteriovorus* (Meier and Brownstein, 1976), for *Salmonella* (Burgin *et al.*, 1990) and for the closely related bacteria *Rb. sphaeroides* (Marrs and Kaplan, 1970), *Rb. capsulatus* (Lessie, 1965), and *Paracoccus denitrificans* (MacKay, 1979). The biological significance of 23S rRNA fragmentation is not understood.

In *Rhodobacter* 23S rRNA is processed to 16S and 14S rRNA species (Marrs and Kaplan, 1970). The *rrn* operons of *Rb. sphaeroides* and *Rb. capsulatus* (Dryden and Kaplan, 1990; Höpfl *et al.*, 1988) show strong homology. The organization of the *Rb. sphaeroides rrn* operons is identical to that found in *E. coli* with two tRNAs in the 16S-23S spacer region. An initiator methionine tRNA was identified immediately downstream of the 5S rRNA gene (Dryden and Kaplan, 1990). Comparison of the secondary structures of the 23S rRNA molecules from *E. coli* and *Rhodobacter* and the size of the cleavage products suggests that the cleavage of 23S rRNA occurs within an rRNA region forming a stem-loop structure that is present in *Rhodobacter* but absent from *E. coli* (Dryden and Kaplan, 1990; Fig. 5). The rRNA sequences forming these extra stem-loop structures postulated for *Rb. sphaeroides* or *Rb. capsulatus* differ significantly from each other. Hybridization experiments showed that the nucleotides forming this extra stem-loop in *Rb. capsulatus* are not part of the 16S nor the 14S rRNA of the wild type rRNA suggesting their loss during processing (Kordes *et al.*, 1994).

In *Anacystis nidulans* cleavage of 23S rRNA is induced by light indicating that it may be involved in gene regulation (Doolittle, 1973). Some early investigations reported differences in the ribosome composition of facultatively photosynthetic bacteria grown either chemotrophically or phototrophically (Mansour and Stachow, 1975; Chow, 1976). When

Fig. 5. Secondary structure of the *Rb. capsulatus* 23S rRNA (Gutell et al., 1990) in which processing to 16S and 14S rRNA takes place. The nucleotides forming the extra stem-loop structure have no corresponding sequence in the *E. coli* 23S rRNA sequence and differ significantly from the *Rb. sphaeroides* rRNA sequence, despite the strong overall homology of the *rrn* operons of *Rb. capsulatus* and *Rb. sphaeroides*.

Rb. capsulatus cells are shifted from high oxygen tension to low oxygen tension or from anaerobic phototrophic growth to chemotrophic growth, an increase of their rRNA content was observed (Klug et al., 1984; Drews et al., 1986). A relative higher content of unprocessed 23S rRNA was observed in aerobic cells, when compared to cells grown under low oxygen tension (Klug et al., 1984). Based on these observations, it was under discussion that the processing of 23S rRNA in *Rb. capsulatus* may be involved in the oxygen regulation of the formation of the photosynthetic apparatus.

The chemical mutant *Rb. capsulatus* Fm65 (Klug et al., 1984) was isolated due to its lack of bacteriochlorophyll, but it was reported recently that this strain also differs from the wild type strain 37b4 by containing an intact 23S rRNA (Kordes et al., 1994). The lack of 23S rRNA processing could be attributed to reduced levels of an RNase that is also

involved in processing of the primary rRNA transcript (Kordes et al., 1994). When the synthesis of bacteriochlorophyll of strain Fm65 was complemented by the transfer of wild type *bch* genes, the resulting strain formed photosynthetic complexes indistinguishable from the wild type photosynthetic apparatus but did not show processing of the 23S rRNA. When oxygen tension was reduced, photosynthetic complexes in the Fm65-derived strain and in wild type cells accumulated with the same kinetics and to the same levels (Klug et al., 1995). These data show that 23S rRNA processing is not involved in the oxygen-regulated formation of the photosynthetic apparatus in *Rhodobacter* and the biological relevance of 23S rRNA processing in this bacterial species remains obscure.

IV. Evidence for Translational or Post-Translational Regulation of Photosynthesis Gene Expression

The translation of bacterial photosynthesis genes has not been studied to date. We do not know whether individual *puf* or *puc* genes are translated with different rates and whether different rates of translation affect the rates of mRNA decay. Some data, however, provide evidence that translation or post-translational processes are involved in the regulation of photosynthesis gene expression. These regulatory processes seem to guarantee that some components of a photosynthetic complex do not accumulate in the absence of other components that are necessary to form functional photosynthetic complexes.

Many mutant strains that lack bacteriochlorophyll also lack significant amounts of pigment-binding proteins in their membrane, even under low oxygen tension. This is often due to an increased turn-over of pigment-binding proteins in the absence of bacteriochlorophyll (Dierstein, 1983; Klug et al., 1986). If bacteriochlorophyll synthesis was blocked at early steps by specific inhibitors, no RC and LHI proteins were detectable in the membrane or the soluble fraction even after pulse-labeling, although normal levels of *puf* and *puc* mRNA were detected, suggesting that an early block in bacteriochlorophyll synthesis may prevent the synthesis of pigment-binding proteins. Several strains with mutations in early steps of bacteriochlorophyll synthesis showed abnormal

oxygen regulation of the *puf* and *puc* operon (Klug et al., 1986; Neidle and Kaplan, 1993).

When oxygen tension is reduced, the accumulation of photosynthetic complexes occurs with kinetics that follow the increase of *puf* and *puc* mRNA levels in *Rb. capsulatus* (Klug et al., 1985). When light intensity was varied in phototrophic growing cultures, no direct correlation of the amount of LHII complexes and *puc* mRNA levels was observed (Zucconi and Beatty, 1988). Cells grown under low light intensity contained about four-fold less *puc* mRNA but about four times as much LHII complexes as cells grown under high light intensity, suggesting a regulation by light that occurs on post-transcriptional level of gene expression (Zucconi and Beatty, 1988).

As described above (II. A) the relative levels of the *puf* mRNA species influence the stoichiometry of LHI and RC complexes in the membrane. However, in cells with a continuous degradation of the 2.7 kb *pufBALMX* mRNA (LHI specific mRNA to RC specific mRNA is about 1:1) there is still a 7 fold excess of LHI complexes over RC complexes (Klug et al., 1987) indicating that later steps in gene expression affect the relative amounts of pigment protein complexes. Further investigations on the translation of *puf* and *puc* mRNA and on post-translational processes will be necessary to identify all steps of gene expression that are affected by external factors or are involved in the coordinated formation of the components of the photosynthetic apparatus.

V. Concluding Remarks

As demonstrated in Fig. 1, multiple steps of gene expression could be involved in the regulation of the formation of photosynthetic complexes. Oxygen affects the rates of transcription of photosynthesis genes and the rate of decay of some mRNA species. The formation of functional photosynthetic complexes also depends on translation, incorporation of the pigment binding proteins into the membrane and the correct assembly of the individual components. Despite some evidence that steps in gene expression following mRNA synthesis and decay may also be affected by oxygen and contribute to the coordination of the expression of the individual components, the regulatory mechanisms acting on these later steps in gene regulation have not been investigated to date. Our current knowledge on the mechanisms involved

in incorporation of pigment-binding proteins into the membrane and the assembly of photosynthetic complexes is summarized in the Chapter 12 by Drews and Golecki.

Summary

Poly- β -hydroxyalkanoates, TPHAs, are synthesized in bacteria and form unique intracellular inclusions. These inclusions can be found in a wide variety of anaerobic, aerobic and facultative chemotrophic and phototrophic bacteria, including cyanobacteria. Inclusions do not occur in the enteric bacteria of any known animal species. PHAs represent a family of aliphatic polyesters which are isotactic, biodegradable and biocompatible, thermoplastic elastomers. The organisms will utilize a wide variety of both hydrocarbons and fatty acid substrates of varying pendant chain lengths of three to twelve carbons to synthesize random copolymers of mixed-length, pendant carbon side chains. They will utilize functionalized substrates (phenyl, cyano, bromo, unsaturated and others) to synthesize chemically and biologically functional polyesters. Using the process of cometabolism, they will incorporate unnatural and even toxic substrates into polymer when co-fed a related natural substrate. Using the wide diversity of bacteria in nature, literally dozens of new and unusual biosynthetic PHAs have been produced. All PHA polyesters occur in bacterial cells as unique fluid inclusions surrounded by a single-layered, protein phospholipid coat. This coat is a monolayer and not a unit membrane. Both the metabolic pathways and the molecular genetics of the enzymes concerned with PHA synthesis, polymerization

and depolymerization (biodegradation) have been worked out in several microbial systems, including the phototrophic bacterium *Rhodospirillum rubrum*, an organism in which some of the first research on PHAs was done.

In order to cope with the overwhelming onslaught on the environment of plastic waste disposal into the next century, we must turn to biodegradable plastics. In order to compete with and supplant the petroleum-based polyester industry's production of non-biodegradable products, we must turn to large scale production from inexpensive resources. Using the results of the microbial studies on the synthesis, regulation, material science and molecular genetics of polyesters, we shall turn again to photosynthesis. Using genetic engineering technology from microorganisms, genes will be transferred into plant species such as sugar beet, potato and rape seed. New, unusual, practical and inexpensive polyesters can be made from CO₂ and the sun, completing three and a half billion years of the evolution of the production of biosynthetic and biodegradable thermoplastics.

I. Introduction

All organisms contain products of the polymerization of simple water-soluble or lipid-soluble monomeric molecules which, in one form or another, appear as repeating units in polynucleotides, polysaccharides, polypeptides, polyisoprenoids and a second class of hydrophobic biopolymers, the poly- β -hydroxyalkanoates, PHAs (Findlay and White, 1983, 1984). Most of these biopolymers have a relatively high molecular weight in the range of 100,000 to 1,500,000. PHAs exist in prokaryotic cells as inclusion bodies representing a family of aliphatic polyesters with the chemical structure shown below:

Polyesters from microbial inclusions show a wide variety of repeating units, have high molecular weights and, like all biological polymers, are isotactic. These properties cannot be reproduced from petroleum-based synthetic products. Because of the wide variety of repeating units and crystalline properties, these polyesters, unlike any other biopolymers, have the properties of thermoplastics and elastomers and, of course, are inherently (i.e. at least within the cell) biodegradable. Fig. 1A shows a thin section of cells of *Rhodospirillum rubrum* (x 200,000) and Fig. 1B and 1C show an optical image of Nile blue stained cells of *Bacillus cereus*.

Abbreviations: A. – *Alcaligenes*; B. – *Bacillus*; P. – *Pseudomonas*; PHA – Poly- β -hydroxyalkanoate; PHB – Poly- β -hydroxybutyrate; Rb. – *Rhodobacter*; Rs. – *Rhodospirillum*

II. PHAs as Prokaryotic Inclusions

PHAs, originally thought to be primarily poly- β -hydroxybutyrate, PHB, were first observed and characterized by Lemoigne at the Institute Pasteur in 1925 from *Bacillus megaterium* (Lemoigne, 1925). His characterization of the polymer and its potential functions was truly innovative and, from a chemical and biological point of view, way ahead of his time (Lemoigne, 1926). Chemically, polyester compounds had not yet been characterized in biological systems and the concept of these polymeric materials as energy storage products in cells had not been suggested.

Since that time, PHAs, as carbon and energy storage inclusions, have been described in a wide variety of prokaryotes. The most recent inventory has been compiled in a thorough review by Steinbüchel (1991), listing over 200 bacterial species known to contain PHA inclusions. Interestingly, in spite of the wide variety of microbial families of prokaryotes that contain PHA as storage inclusions, none of the Enterobacteriaceae or their relatives appear to contain them. However, PHB does occur in another polymeric form in the Enterobacteriaceae, in other bacterial families, and in many eukaryotic plant and animal cells (Reusch et al.; 1983, 1986, 1987, 1988, 1989). The role of this polymer, containing phosphorus and calcium and located in the cytoplasmic membrane, is not clear but may involve genetic competence. It is not a storage product in any event, and will not be discussed in this review. However, it should be noted for its ubiquitous occurrence and another important role that PHAs may play in nature.

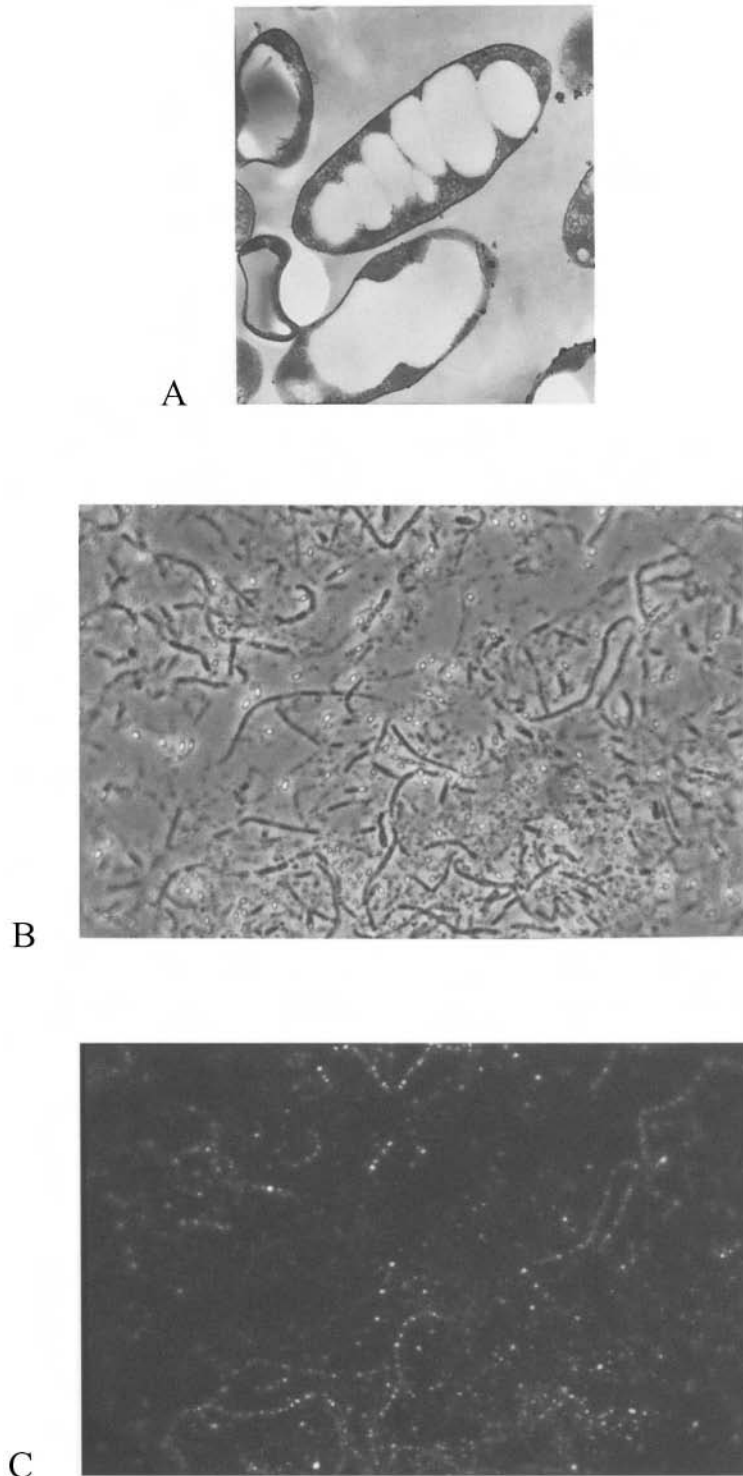

Fig. 1. (See also Color Plate 3.) A: A thin section of *Rs. rubrum* showing PHA occupying 70–90% of the cell, its ‘fluid nature’ and independence of intracytoplasmic membranes (chromatophores) and cytoplasmic membranes. B: Phase contrast optical microscope image of Nile Blue stained cells of *Bacillus cereus*. C: Same as B, but activated by 450 nm light showing specific fluorescence of PHA. Spores do not fluoresce and note that not all cells contain PHA. This is a very specific reaction and can give a quantitative measure of PHA from fluorescence intensity.

III. Occurrence of PHAs in Anoxygenic Phototrophic Bacteria

PHAs were first described in the phototrophic bacterium, *Rs. rubrum* in a series of papers by Doudoroff and Stanier (1959) and Merrick and Doudoroff (1961). Since that time, PHAs have been shown to be present in at least 14 facultative nonsulfur purple bacteria and 14 purple sulfur bacteria (see Tables 1 and 2).

A. Purple Bacteria

Tables 1 and 2 show the published and some unpublished references of the occurrence of PHAs in a variety of facultative nonsulfur purple bacteria and the obligately anaerobic purple sulfur bacteria. These data are reported by Liebergesell et al. (1991) and have been slightly modified and updated for this chapter. This list shows the wide distribution of PHAs in purple bacteria. However, it should be noted that of the organisms listed, 22 show a polymer content that is less than 5% of the cell mass. In addition, those with 5% polymer or less contain 100% of that polymer as PHB. This observation could mean that under the growth conditions used (acetate and succinate), the polymer measured could well be present only in the cytoplasmic membrane structures as described by Reusch in which *only* PHB, not a variety of PHAs, is observed.

In the case of two organisms, *Rs. rubrum* and *Rhodobacter sphaeroides*, large amounts of storage PHAs can be synthesized under controlled growth conditions on specific substrates. Brandl et al. (1991) have shown that *Rb. sphaeroides* when grown on acetate alone or acetate in combination with malate, pyruvate, glucose, crotonate, or propionate, can produce from 50–65% of its cell mass as PHA. In all cases, 98% of the polymer was PHB and the remainder consisted of a small amount of 3-hydroxyvalerate.

Table 2 (Liebergesell et al., 1991) summarizes the presence of PHAs in purple sulfur bacteria. In these organisms, the polymers consist of 100% butyrate repeating units when the cells are grown on acetate alone. Again, many contain less than 5% polymer and this may not be stored in inclusions as described above.

B. Green and Heliobacteria

At this point little is known about the presence of

storage PHAs in the green sulfur and nonsulfur bacteria. Several authors have reported PHA in *Chloroflexus aurantiacus* (Pierson and Castenholz, 1974; Sirevåg and Castenholz, 1979; Krasil'nikova et al., 1986). At the present time, it has not been demonstrated that the Chlorobiaceae accumulate PHA inclusions. Cells of *Heliobacillus mobilis* grown on acetate contained no detectable PHA as measured by gas chromatography (Madigan and Fuller, unpublished).

IV. Biosynthesis of PHAs in *Rhodospirillum rubrum*

The biosynthetic pathways of PHA synthesis in the various phototrophic bacteria are relatively unexplored. However, Moskowitz and Merrick (1969) undertook the study of the enzymes involved in the synthetic pathway of PHB synthesis in *Rs. rubrum* (Merrick and Yu, 1966 and Merrick et al., 1965). From this and comparative research on *Alcaligenes eutrophus* and *Pseudomonas oleovorans*, the overall biosynthetic pathway in *Rs. rubrum* can be represented as shown in Fig. 2.

The above pathway is the only well established synthetic route in any of the phototrophic bacteria. It is clear that in order to make PHAs other than PHB there must be a great deal of flexibility in at least two steps in the synthesis of PHA. The first is in the ability of the ketothiolase to form and condense the CoA derivatives of substrates from C-2 to C-7 monomers. The second, of course, is the polymerase reaction which, in the case of *Rs. rubrum*, can make a random co-polymer containing repeating units of 4, 5, or 6-chain monomers from both hexanoate and heptanoate (Brandl et al., 1989).

V. Regulation of PHA Metabolism

The enzymology of the biosynthetic polymerization and depolymerization reactions and the control mechanisms invoked in PHA synthesis have been thoroughly researched, primarily in the laboratories of Schlegel and Dawes using the system as it exists in *A. eutrophus*. This work has recently been reviewed and updated in an excellent review by Anderson and Dawes (1990) and will not be rereviewed here, but the same or similar control mechanisms are almost certainly applicable to the phototrophic bacteria in

Table 1. PHA content of nonsulfur purple bacteria and composition of the polyester

Fig. 2. *Rhodospirillum rubrum* PHA-biosynthetic pathway.

general, and to *Rs. rubrum* specifically (see Fig. 3). The same enzymes and cofactors seem to function in most organisms studied (Steinbüchel, 1991).

The *Rs. rubrum* (Merrick and Yu, 1966; and Moskowitz and Merrick, 1969), as well as *A. eutrophus* (Anderson and Dawes, 1990) and *P. oleovorans* (Huisman et al., 1991) PHA biosynthetic pathways include an NADH-dependent reductase that forms L(+)-3-hydroxybutyryl-CoA which is converted to the D(-)-3-hydroxybutyryl-CoA by two enoyl-CoA hydrolases. Parts of the pathway have been expressed in *Escherichia coli* (Fidler and Dennis, 1992). Balanced cell growth is dependent on NADH and the presence of acetyl-CoA. During balanced growth, cell synthesis and energy production is in competition with the PHA synthetic pathway for both NADH and acetyl-CoA. In addition, the accumulation of NAD⁺ represses enzymes of the Krebs Cycle and would favor the PHA synthetic pathway. Thus, there is probably an NADH ↔ NAD⁺ redox control system involved in the regulation of PHA synthesis during balanced or unbalanced growth conditions in these organisms.

PHAs are produced and degraded continuously in most microorganisms at low levels during cell growth. However, during periods of metabolic stress (e.g.,

low O₂ in an aerobe, or a shortage of nitrogen or sulfur in the environment, thus restricting protein synthesis) the cells convert any excess carbon present to PHA. This shift from the energy and growth-promoting Krebs Cycle to PHA synthesis is tightly regulated as shown in Fig. 4.

As diagrammed above, under conditions of balanced cell growth and ATP production (energy excess), NADH levels inhibit both the depolymerization of PHAs and the Krebs Cycle. The resulting reduced level of free CoA means that the acetyl-CoA thiokinase reaction can catalyze the condensation of acetyl-CoA to acetoacetyl CoA and free CoA and then polymer synthesis proceeds. When the control is reversed, depolymerization of polymers occurs.

VI. Polymer Production and Material Properties

At the time of the initial discovery and early characterization of PHAs in bacteria it appeared that the polymer consisted exclusively of four carbon β -hydroxy repeating units (PHB). It was first demonstrated by Findlay and White (1983) that *B. megaterium* had the ability to form random copolymers. In addition, both *P. oleovorans* and *A. eutrophus* (Brandl et al., 1988) form a wide variety of such copolymers (Anderson and Dawes, 1990). Bacteria can produce polyesters with pendant side chains of 8 carbons or higher. The physical and material properties of these copolymers such as stiffness, strength, melting point and brittleness, as well as degradability by extracellular lipases, vary widely depending on the monomer composition and the resulting degree of crystallinity. Whereas *P. oleovorans* will only make PHAs when grown on substrates containing six or more carbon atoms in the chain, both *A. eutrophus* and *Rs. rubrum* make shorter chain PHA copolymers. *A. eutrophus* makes a copolymer of PHB-PHV which is currently being commercially produced as 'Biopol.' *Rs. rubrum*, which can synthesize PHAs from substrates ranging from acetate to heptanoate, can make a number of copolymers including an interesting terpolymer consisting of C₄, C₅, and C₆ repeating units (Brandl et al., 1989). This variability and/or flexibility of the polymerase enzyme(s) to polymerize a wide variety of substrates yielding PHAs with differing material properties may prove very useful for the production

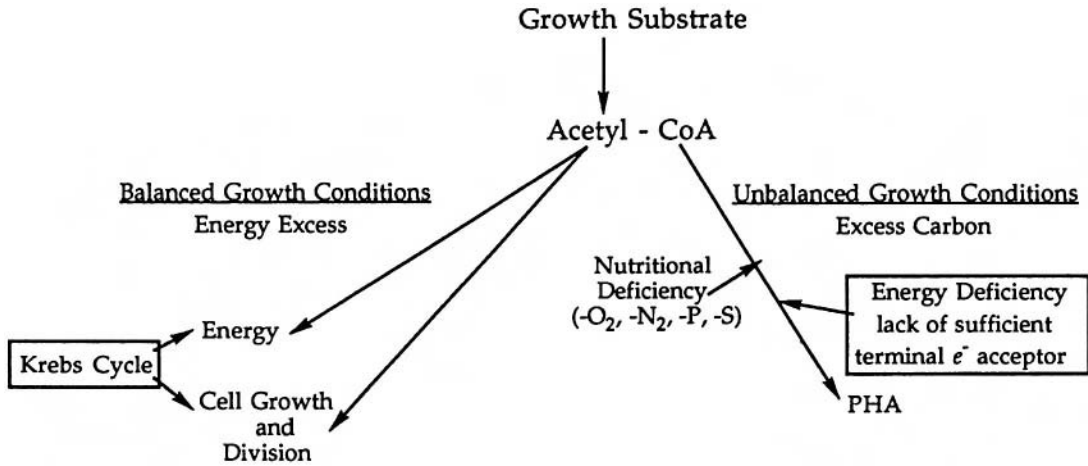

Fig. 3. The regulation and control of energy production, cell growth and PHA production in bacteria.

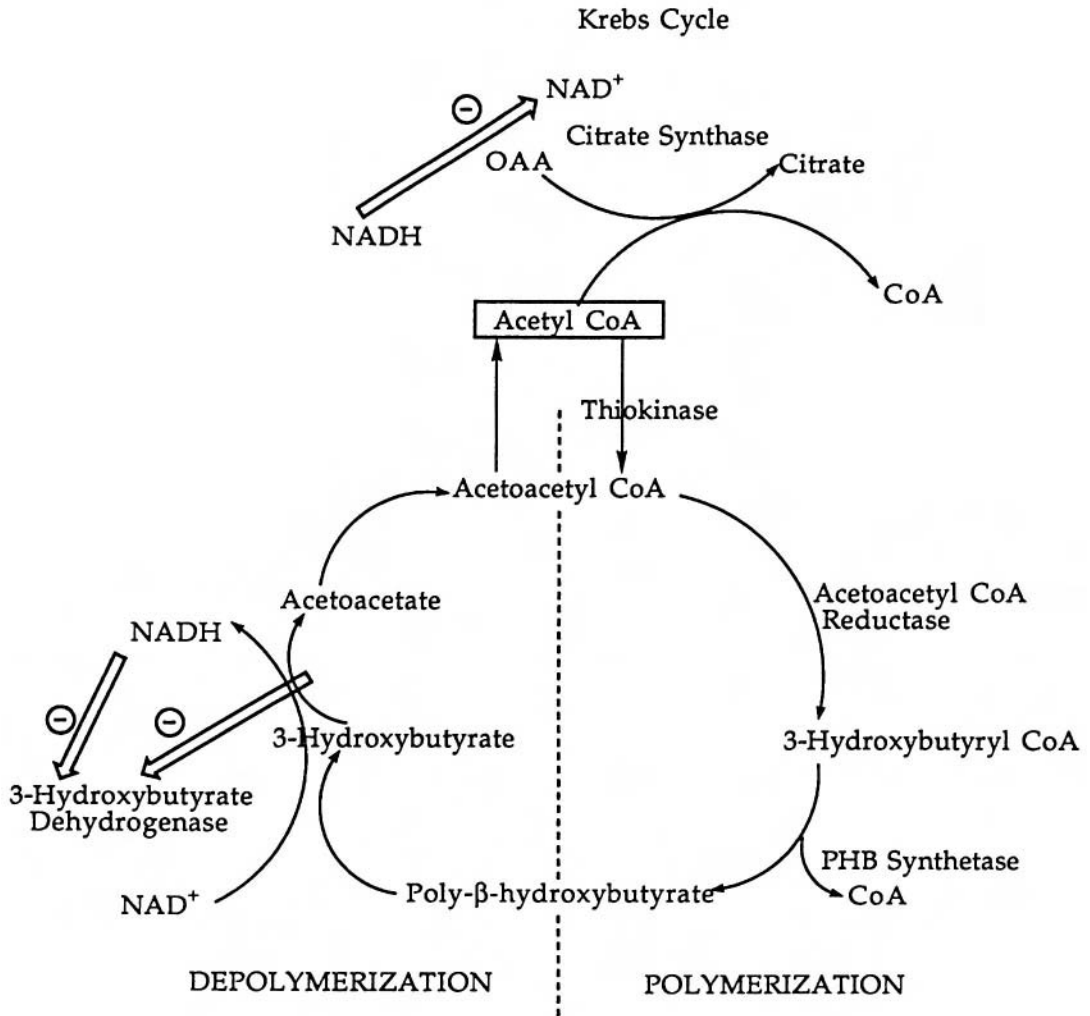

Fig. 4. Proposed regulatory mechanisms of PHA polymerization-depolymerization reactions (alkyl pendant group can be 0-8 or higher)

of thermoplastic polyesters of both commercial and medical value.

In addition to the polymerization of a wide variety of alkanolic acids, it has been shown that both *P. oleovorans* and *Rs. rubrum* are capable of producing unusual PHAs in which the substituent at the β -position is a structure other than an n-alkyl group (Lenz et al., 1992) and that contains functional or reactive groups. Since the pendant side chains are relatively inactive hydrocarbons, the addition of functional groups allows the production of polymers that can be further chemically modified. *Rs. rubrum* has been shown to be capable of polymerizing unsaturated compounds, thus positioning a reactive double bond in the resulting PHA. *P. oleovorans* shows a high degree of flexibility in incorporating functional groups into polymer. Methyl, cyano and phenyl groups, as well as substrates with varying degrees of unsaturation, can all be incorporated into the PHAs produced by this organism.

It has also been shown that when the compounds 5-methyloctanoic acid, 6-bromohexanoic acid and 11-cyanoundecanoic acid (none of which can be formed in polymers by themselves) are present in growing cultures with either octanoic or nonanoic acid as cometabolites, the previously unusable monomer is incorporated into polymer. This phenomenon of cometabolism (Leadbetter and Foster, 1960) was first described for the methanotrophic bacteria and no clear-cut mechanism for the process has been described. However, since cofeeding with a natural substrate can allow the incorporation of functional and even toxic groups into PHAs, this offers further flexibility in bacterial polyester synthesis. It is clear that at least *Rs. rubrum* and *P. oleovorans* have the ability to produce a wide variety of functional and unusual polyesters and, of course, contain the enzyme(s) for degradation of these polymers.

VII. Structure and Function of PHA Inclusions

A. State of PHA in Inclusion Bodies

Since the time of the initial identification of β -hydroxybutyrate in *B. megaterium* (Lemoigne, 1925), considerable interest has been focused on the physical and chemical state of the PHA inclusions and associated macromolecules in a wide variety of prokaryotes. That PHAs could occur in an amorphous

as well as a crystalline state was also first proposed in the initial research of Lemoigne, who suggested that during isolation of the inclusions, a lipid material was lost. Lundgren et al. (1965) also suggested that PHAs could occur in the crystallized state. However, recent work of Bernard and Sanders (1988, 1989) using ^{13}C NMR spectroscopy has indicated that PHAs are in a predominantly mobile state in the living cell and that this amorphous condition has water associated as an integral component of the inclusion. Bernard and Sanders stated that the 'enzyme(s) responsible for PHB biosynthesis and consumption operate only on mobile hydrated material, and that solid granules characteristic of dried cells are partially artifactual.' The studies of Alper et al. (1963), Merrick and Doudoroff (1964) and Lundgren et al. (1965) demonstrated the presence of proteins and enzyme activity associated with isolated inclusions. Ellar et al. (1968) has also described a role for proteins in, or at the surface of, the PHA inclusion. It is clear that PHA in the native state is not a solid nor a mobile liquid, nor is it in solution; rather it is present in cells as an amorphous elastomer (Horowitz et al., 1993). Whether complete enzymatic biodegradation can occur *only* in a hydrated state still is not clear and indeed a point of controversy that needs considerable clarification. How the amorphous state is maintained in native granules is not clear, nor are the association and distribution of enzymatic proteins on or within the granule fully understood or clearly defined.

B. Other Inclusion Components

Boatman (1964) described a limiting 'membrane' surrounding the inclusions in *Rs. rubrum* when observed in an electron microscopic thin section. Its composition was not determined. However, Griebel et al. (1968) and Griebel and Merrick (1971) purified PHB inclusions in density gradient systems and determined that PHB constituted 97–98% of the dry weight, the remainder being made up of protein (~2%) (Merrick et al., 1965) and lipid (~0.5%). It was assumed that these constituents were components of the outer shell of the inclusion.

1. Lipids

Although the evidence for the presence of lipids and/or phospholipids associated with the PHA was reported in 1968 (Griebel et al., 1968), further analyses were fragmentary. Kanaguchi and Doi (1990) have

used X-ray diffraction studies to evaluate the state of PHAs in whole cells and isolated inclusions from *A. eutrophus* and, like others, concluded that in both whole cells (wet) and in native isolated granules the polymer was still in a non-crystalline state. Treatment with hypochlorite, acetone or a lipase enzyme caused crystallization, leading to the conclusion that the removal of a lipid or lipids from the inclusion caused this change of state. Thin layer chromatographic analysis of acetone extracts of inclusions demonstrated the presence of at least two lipid components. Recently, de Koning and Lemstra (1992) have clearly shown phospholipid as a constitutive of PHA inclusions and have suggested their role in nucleation polymerization of PHAs during inclusion formation. These observations have been recently confirmed in our laboratory (E. S. Stuart, A. Tehrani and R. C. Fuller, unpublished).

2. Proteins

That enzymatic activity and proteins were associated with PHA inclusions was first demonstrated by Merrick and Doudoroff (1961, 1964). Both PHA synthetase and depolymerase activities were detected in cell-free systems prepared from *Rs. rubrum*. However, the clear separation and definitive cellular partition of the enzymes concerned in these preparations with the synthesis of the CoA substrate monomers and the actual polymerase reaction itself was not clearly established.

Using primarily a molecular genetic approach, Peoples and Sinskey (1989a and 1989b), Messner and Sleytr (1992) and Huisman et al. (1991) have established the enzymatic pathway of synthesis of PHAs in a number of chemotrophic organisms. They demonstrated that the polymerase enzyme (one or two depending on the organisms) and the depolymerase occurs along with a promoter as a single genetic operon. In all probability the polymerase-depolymerase system is associated with the PHA inclusions and the ketothiolase and NADH oxidation-reduction and hydratase enzymes are associated with the cytoplasmic membrane cell components.

Recent work using *P. oleovorans* grown on octanoic acid as a substrate has established protein association with the PHA inclusion. In this system, the PHA formed is a random co-polymer of C_6 , C_8 and C_{10} repeating units. When isolated, the inclusions maintained their amorphous hydrated state as a fluid elastomer. Both whole cells and highly purified

granules were examined in this native state using Nomarski computer-enhanced imaging light microscopy. This technique involves differential interference contrast using polarized light. Fig. 5a shows an image of unstained, unfixed living cells which show the internal PHA granules. Fig. 5b is an image of highly purified native granules from these cells (E. S. Stuart, R. W. Lenz and R. C. Fuller, unpublished).

The size of a typical PHA granule is around 0.5 μm . There is no sign in this, or many other such preparations, of significant contaminating membrane fragments. This is confirmed by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) peptide analysis after granule purification. This, of course, is an important consideration when assaying for inherent enzymatic activity of the proteins associated with granule preparations.

In addition to Nomarski computer-enhanced imaging and negative staining, freeze-fracture electron microscope examination of the surface structure of the granule was carried out. Again, the granules were maintained in their native state until they were rapidly frozen, fractured and either etched or stained with uranyl acetate. Examination of uranyl acetate-stained granules demonstrated a highly organized paracrystalline network located on the surface of the granule (not shown). Because of its staining properties, this network was clearly proteinaceous. A freeze etch of these same granule preparations is shown in Fig. 6 and dramatically emphasizes this surface network.

The image in Fig. 6 displays a network pattern with repeating units measuring 135 \AA in width which can be seen on the surface of the highly purified granules. The pattern resembles the regularly arranged outer membrane proteins (rOmp) of *P. acidovorans*. This kind of structure has never been observed in association with internal structures of prokaryotes. Purified inclusions were analyzed by SDS-PAGE and a characteristic pattern is shown in Fig. 7 lane 1. Fig. 7, lane 2 shows the granule fraction before final purification.

After granule purification, SDS-PAGE revealed four major polypeptides with molecular masses of 59 kDa, 55 kDa, 43 kDa, and 18 kDa (Fig. 7, lane 1). A minor protein band at 32 kDa was also consistently observed. Huisman et al. (1991) have used a recombinant strain of *Pseudomonas* to express the genes responsible for the two polymerases and found protein bands at 58 kDa and 56 kDa in the recombinant cells. In addition, the DNA sequence of esterase

Fig. 5. (A) Living *P. oleovorans* cells under computer-enhanced Nomarski light microscopy. (B) Isolated inclusions as in 5a.

Fig. 6. An electron micrograph of a single PHA granule ($\sim 0.5 \mu\text{m}$ diameter) showing an organized paracrystalline array of surface proteins that control structural, functional and probably material properties of the in vivo amorphous PHA.

suggests that the 32-kDa polypeptide could be the depolymerase system. These DNA sequence and derived molecular weights agree well with the above observations of native structural proteins on the purified granules of *P. oleovorans* (E. S. Stuart, R. W. Lenz and R. C. Fuller, unpublished).

These proteins could be removed from the granule using the NaOH extraction procedure developed by Merrick (1978). Thus it seems that in *P. oleovorans* the two polymerases from this organism, as well as the intracellular depolymerase, are associated with the PHA inclusion as in *Rs. rubrum* as was first suggested by Merrick.

However, the most abundant polypeptides on the inclusion are the 43-kDa and the 18-kDa bands. These molecular weights do not correspond to any of the biosynthetic or polymerase-depolymerase systems of either *P. oleovorans* or *A. eutrophus* (Peoples and Sinskey, 1989a and b and Huisman et al., 1991).

Since the protein surface of the inclusion shows a paracrystalline array much in the form of the S protein on the outer surface layer of most bacteria (Messner and Sleytr, 1992), it has been suggested that the 43-kDa polypeptide might play a similar structural as well as a developmental role for the

Fig. 7. S.D.S. Gel of purified inclusions from cells of *P. oleovorans*. See text for explanation.

PHA inclusion in *P. oleovorans*. However, the exact role of the 43-kDa and 18-kDa polypeptides remains to be determined. Liebergesell et al. (1992) have shown by gel electrophoresis that proteins isolated from PHA inclusions of *Chromatium* are also distinct from the polymerase systems from various chemotrophic organisms. An update of information on polymer inclusion proteins is presented in Stuart et al. (1995).

Acknowledgments

I wish to thank my colleagues, Dr. R. W. Lenz, Dr. Helmut Brandl, and Dr. Elizabeth Stuart, for their active collaborative work on the research of the phototrophic and chemotrophic polyester systems and the use of unpublished data. I also wish to thank Ms. Ann Brainerd for her thoughtful and thorough editorial contribution. The support of the National Science Foundation MRL Grant # DMR90-23848,

Professor Christopher Woodcock and the NSF-supported Microscopy and Imaging Center # NSF BBS 871-423335, NSF MCB-92022419, and the Johnson and Johnson Co. is gratefully acknowledged. I would also like to thank Dr. Alexander Steinbüchel and *FEMS Microbiol. Letters* and *FEMS Microbiol. Reviews* for use of previously published material.

Summary

The increasing sophistication of mutagenesis and screening technologies has led to the isolation of many biophysically important mutants of the photosynthetic reaction center and light harvesting antennae. Site-directed mutagenesis and structural motif rearrangements of these proteins have accelerated our understanding of the fundamental mechanisms of the light reactions of photosynthesis. Knowledge of structural requirements for pigment binding proteins has also been acquired through mutants. Combinatorial cassette mutagenesis promises to produce additional biophysically interesting mutants. Since protein structure and function can not yet be accurately predicted from protein sequence, this method has the ability to generate phenotypes that would not be found through point mutations or global rearrangements. Libraries generated through combinatorial cassette mutagenesis can be rapidly screened by digital imaging Spectroscopy, and mutants with interesting absorption spectra identified for further characterization. Currently, combinatorial cassette mutagenesis

* Author for correspondence.

experiments have focused on the reaction center and light harvesting II antennae. Specific amino acid residues in the reaction center were randomly substituted, and the library subjected to a photosynthetic selection prior to screening. Using such methodology, mutants can be isolated which occur with a frequency of approximately one-in-a-million. In the light harvesting system, strategies for more efficiently searching sequence space are being explored. Methods have been implemented which limit the amino acids coded for at each mutated position. These methods enhance for the desired phenotype over random mutagenesis. Goals for mutants generated via combinatorial methods include searching for reaction centers that perform wrong way electron transfer, and redesigning light harvesting antennae to perform charge separation.

I. Introduction

Light reactions of photosynthesis are mediated by membrane-bound pigment-protein complexes. Light is absorbed by the bacteriochlorophylls and carotenoids of light harvesting proteins which direct the energy to the photosynthetic reaction center (RC) where charge separation takes place. Extensive structural, spectroscopic, and genetic techniques exist for characterizing and manipulating the photosynthetic proteins of the purple nonsulfur bacteria, Rhodospirillaceae. The photosynthetic reaction center contains a bacteriochlorophyll (BChl) dimer, two BChl monomers, two bacteriopheophytin (Bphe) monomers, two quinones, and a ferrous non-heme iron atom attached to two quasi-symmetrically arranged protein subunits (L and M). The structure of the *Rhodospseudomonas viridis* RC has been determined through X-ray crystallography (Deisenhofer et al., 1985). Light harvesting I (LHI), the core antennae complex, is modeled to contain two transmembrane alpha helical polypeptides (α and β) which bind a BChl dimer. The peripheral antenna complex, light harvesting II (LHII) is also modeled to include two transmembrane alpha helical polypeptides (α and β) which bind a BChl dimer and a BChl monomer (Zuber, 1986). The bound pigments can be exploited as reporter groups; near infrared (NIR) and visible spectral information can be used to assay for protein assembly, structure, and function.

Molecular biological systems have been developed for the manipulation of both RC and LH proteins.

Abbreviations: BChl – Bacteriochlorophyll; Bphe – Bacteriopheophytin; CCD – charge coupled device; CCM – combinatorial cassette mutagenesis; DIS – digital imaging spectroscopy; EEM – exponential ensemble mutagenesis; LH I – light harvesting I; LH II – light harvesting II; NIR – near infrared; NIR – near infrared; PG – group probability; *Rb.* – *Rhodobacter*; RC – reaction center; REM – recursive ensemble mutagenesis; *Rp.* – *Rhodospseudomonas*; SDM – site-directed mutagenesis; SSD – sum-of-the-squares-of-the-differences; TSM – target set mutagenesis; WT – wild type

Screening technologies and mutagenesis techniques have undergone a dramatic increase in sophistication with the development of digital imaging spectroscopy and combinatorial cassette mutagenesis (Youvan, 1994; Youvan et al., 1994). Historically many biophysically important mutants have been isolated through advances in screening and mutagenesis, and the newest techniques promise to yield more interesting and informative phenotypes.

II. The Role of Mutagenesis in Photosynthesis Research

A. Spontaneous Mutations

Spontaneous mutants were used to isolate and/or confirm the identity of the genes for the photosynthetic apparatus. An R-factor with enhanced chromosomal mobilizing ability in *Rhodobacter capsulatus* was isolated and used to generate R-prime derivatives that carry a photosynthetic gene cluster (Marrs, 1981). R-prime plasmids carrying parts of the chromosome specifying the photosynthetic apparatus were confirmed by their ability to restore photosynthetic growth when mated to photosynthetically defective mutants. Mutants incapable of photosynthetic growth were isolated by subjecting them to a tetracycline suicide procedure. Mutants isolated from the tetracycline suicide were screened for enhanced fluorescence in the NIR; enhanced fluorescence mutants are typically defective in LHI or RC but have functional LHII (Youvan et al., 1983). An R-prime plasmid, pRPS404, complemented all the enhanced fluorescent mutants. The location of the genes for LHI and the RC were narrowed down further by complementation by pBR322 derivatives with smaller fragments of *Rb. capsulatus* DNA.

The LHII structural genes are not within the photosynthetic gene cluster, and were isolated using synthetic probes based on the amino-terminal

sequences of α and β LHII which were used in Southern hybridizations (Youvan and Ismail, 1985). A 6 kb *Eco* RI fragment that hybridized to the probes was subcloned into pBR322 (to form pRPSLH2). This construction was able to complement the strain MW422, which has a chromosomal mutation that inactivates LHII.

B. Site-Directed Mutagenesis

Introducing specific alterations in the protein sequence has allowed biophysicists to study some of the fundamental mechanisms of the light reactions of photosynthesis. In the mid 1980s, a series of genomic deletion backgrounds and plasmids (Youvan et al., 1985; Bylina et al., 1986) facilitated the use of site-directed mutagenesis (SDM) to modify the photosynthetic proteins of *Rb. capsulatus*. Sequence modifications have been made in the vicinity of all the prosthetic groups in the RC, and at a variety of non-symmetric amino acid residues in the RC (see Coleman and Youvan, 1990 and references therein). Many of these mutations lead to changes in spectral properties or differences in the rate of electron transfer. Both LHI and LHII antennae have been altered by SDM in attempts to correlate amino acid sequence with protein structure and function. A few examples of the SDM experiments that have been performed on both RCs and LH antennae are summarized below.

The heterodimer mutants are examples of SDM experiments which resulted in significant advances in our understanding of the molecular mechanisms of photosynthesis. Replacement of either His ligand to the BChls in the special pair (His^{L173}, His^{M200}) with an aliphatic amino acid residue (Leu) leads to a BChl/Bphe heterodimer (Bylina and Youvan, 1988, 1990). The M-side heterodimer mutant has been extensively characterized and resulted in a greater understanding of the very early steps involved in charge separation. The overall quantum yield is 50% (as opposed to 100% for wild type (WT)); the decrease in quantum yield is attributed to unproductive decay of the excited dimer to the ground state (Bylina et al., 1989). Picosecond transient absorption spectroscopy (Kirmaier et al., 1988, 1989), low temperature ground state and linear dichroism absorption spectra (Breton et al., 1989), electron paramagnetic resonance (Bylina et al., 1990), and Stark spectroscopy (DiMango et al., 1990) suggest the existence of an intradimer charge transfer state that mixes with the excited

singlet state. A charge transfer state has been postulated to exist in WT, but at a higher energy, making it harder to observe. The observation of the charge transfer state in the heterodimer mutant suggests that these states probably facilitate efficient charge separation in the RC.

In a similar type of pigment switching experiment, the Bphe acceptor was replaced with a BChl by substituting a Leu with a His which can act as a metal coordinating ligand for the Mg in BChl (Kirmaier et al., 1991). The resulting RCs from this Leu^{M214}→His mutant, undergoes charge separation from the special pair through the BChl intermediate acceptor to the quinone, but with a reduced quantum yield of 60%. The electron transfer from the acceptor to the quinone is responsible for the decrease in quantum yield, as charge recombination is much faster in the mutant and competes with electron transfer to the quinone. The heterodimer and Leu^{M214}→His mutants suggests that the WT RC achieves high quantum yield by avoiding situations where there is significant electronic coupling to the ground state, by limiting participation of states where charge is separated between strongly interacting chromophores (Kirmaier et al., 1991).

A strategy to determine which residues are responsible for the unidirectionality of electron transfer has been to symmetrize the RC by changing amino acid residues that differ between L and M. The first example of this type of experiment focused on Glu^{L104}, since this protonated amino acid is thought to hydrogen bond to the ring V C-9 keto group of the primary acceptor, which would be expected to lower the energy of the anion, thus facilitating unidirectionality. There is no analogous residue on the M side. The Glu^{L104}→Leu mutant resulted in only minor changes in the kinetics of electron transfer. The initial electron transfer step is less than two fold slower in the mutant and the second step is only marginally slower. However Glu^{L104} was found to be responsible for the spectroscopic red shift of the active branch Bphe relative to the inactive branch Bphe (Bylina et al., 1988b).

To study BChl-peptide interactions in LH antennae, mutations were made in the putative BChl binding sequence, Ala-X-X-X-His (Theiler and Zuber, 1984; Theiler et al., 1984), of the a subunit in LHI from *Rb. capsulatus*. No LHI assembly, as judged by absorption spectroscopy, was detected when the His is changed to any other amino acid residue, suggesting that in LH, no other residue can function in place of His as

a ligand to the Mg of the BChl. Mutagenesis of the Ala residue showed protein assembly occurred only when it is changed to an amino acid with a small molar volume (Gly, Ser, Cys) indicating that there are molar volume constraints for BChl binding at this position (Bylina et al., 1988).

In an investigation of residues at the N-terminus of the α and β subunits of LHI, charged amino acids were exchanged with those of opposite charge. It was believed that the positively charged α subunit N-terminal segment helped to direct the protein into the membrane and influenced its orientation, while the negative charges on the β subunit N-terminal were thought to help stabilize the complex by interacting with the α subunit. When four positively charged amino acid residues in the α subunit were exchanged with negatively charged amino acids no formation of the LH complex was observed. However, when four negative amino acids in the β subunit were changed to positive amino acids, LHI assembly was impaired but not completely blocked (Stiehle et al., 1990). This experiment shows that charged amino acids in α and β influence LHI formation in different ways, with β being much more tolerant of the mutations than the α subunit.

Extensive point mutations in LHI at amino acid positions which are highly conserved across species were performed to obtain information about their structural and functional role. Eighteen mutants with single amino acid substitutions were constructed. All the substitutions resulted in structural effects judged from characterization based on quantification of core complexes and the LHI spectral characteristics (Babst et al., 1991). For example, exchanges at $\alpha 8$ (Trp ^{$\alpha 8$} → Leu, Ala, Tyr) resulted in the absence of core complex, the absence of core antennae and a reduction in the carotenoid content of the complex respectively. While substitutions at $\alpha 43$ (Trp ^{$\alpha 43$} → Ala, Leu, Tyr) resulted in 8-11 nm blue shifts of the absorption peak.

SDM on charged and aromatic residues of LHII from *Rhodobacter sphaeroides* resulted in blue-shifts of the dimer band. A correlation was found between two Tyr residues in the α subunit of LHII and the dimer absorption band. By constructing the single (Tyr ^{$\alpha 44$} → Phe) and double (Tyr ^{$\alpha 44$} → Phe and Tyr ^{$\alpha 45$} → Leu) mutant, the band shifted 11 and 24 nm respectively (Fowler et al., 1992). This effect is interpreted as being due to interactions of the BChls with the aromatic amino acids. Changing :Lys ^{$\beta 23$} → Gln resulted in an 18 nm blue shift of the dimer band (Fowler et al., 1993). This amino acid is

near the putative BChl monomer binding site and is conserved in a number of LHII complexes. The monomer band was not affected in this mutant, and the interpretation given to the spectral shift of the dimer peak is that the relative orientation of the polypeptide backbone in the membrane might have been altered.

C. Structural Motif Rearrangements

Large scale rearrangement of RC sequences has been necessary to engineer phenotypes that could not be found by spontaneous or site-directed mutagenesis. Global changes have been made in both the RC and LH antennae.

Structurally important segments of the RC have been duplicated and exchanged between the L and M subunits. The D helices are good candidates for this type of manipulation as they have interactions with all the prosthetic groups. Mutants were constructed with two M subunit D helices (D_{MM}), two L subunit D helices (D_{LL}), and with the helices exchanged (D_{LM}) in the hope of identifying the asymmetric region responsible for the unidirectionality of electron transfer. The D_{MM} mutant resulted in a photosynthetically functional, but severely impaired RC. The D_{LL} mutant is photosynthetically inactive, and was found to be missing the primary electron acceptor. The D_{LL} RC has a total side chain molar volume greater than WT, which probably interferes with the Bphe binding pocket. Photosynthetically competent revertants of both D helix duplications have been isolated. All the D_{LL} revertants decrease the molar volume near the Bphe binding site, and all bind the Bphe. The positions at which reversions or secondary site compensatory mutations take place under photosynthetic selection point to what may be critical amino acid asymmetries (Robles et al., 1990a, 1990b). The extended lifetime of the excited dimer in the D_{LL} mutant allowed the observation of oscillations in the decay of this state which suggests that vibrational coherence may modulate electron transfer (Vos et al., 1991).

A second series of helix exchange and duplication experiments involved the amphipathic cd helices which provide the axial ligands to the accessory BChls and form part of the special pair binding pocket. None of the constructions resulted in photosynthetically competent mutants; however, functional revertants were obtained from both helix duplications. Compensatory mutations were found

in both the mutagenized and nonmutagenized subunits, and several pairs of symmetrical suppressors (compensatory mutations that occur at homologous positions in either subunit) were isolated (Robles et al., 1992). A speculative possibility is that the symmetrization of the RC caused the two chromophore branches to have the same potential for electron transfer, and that either branch could be activated by a secondary mutation. Further experiments will be needed to search for aberrant electron transfer in these mutants.

Structural motif mutagenesis has been used to investigate pigment binding and the criteria for proper helix formation in LHI antennae. Five amino acid residues in the α subunit of LHI (flanking the His thought to be the ligand to a BChl of the dimer) were changed to Leu. This resulted in a stretch of fourteen residues all of which are Leu except the Ala and the His in the Ala-X-X-X-His BChl binding motif. This 'poly Leu' mutant rapidly mutates to lose either carotenoid or LH expression (Arkin and Youvan, 1993). The α subunit of LHI seems to have only a limited tolerance to change in the vicinity of the BChl binding site.

III. Massively Parallel Screening of Mutants

A. Searching Protein Sequence Space

Combinatorial mutagenesis has a greater potential to generate novel phenotypes that can not be found using either SDM or structural motif mutagenesis, because of the inability to accurately predict the structure and function of proteins from their primary amino acid sequence. Combinatorial cassette mutagenesis (CCM) (Oliphant et al., 1986; Reidhar-Olson et al., 1991) allows the exploration of a large number of mutations in a protein. Multiple amino acid residues are simultaneously mutagenized in a random fashion resulting in a library of proteins, some of which may exhibit desired phenotypes. The complexity of these libraries grows exponentially with the number of sites mutagenized.

It is advantageous to reduce the total number of proteins in a combinatorial mutagenesis library to increase the efficiency of searching 'sequence space' for mutants with the desired phenotypes. Instead of using the codon NNN (i.e., N = 25% each A,T,G,C) at each mutagenized position, the nucleotide composition can be restricted. A simple example is

NN(G/C), which is an alternate way to randomize a sequence position using all 20 amino acids but only half as many codons. In more sophisticated doping schemes, criteria such as physicochemical parameters, expert rules, structural, and phylogenetic data can be used to construct 'target sets' of amino acids to be used at each mutagenized sequence position (Arkin and Youvan, 1992b). One of several algorithms can be used to convert these target sets into nucleotide mixtures amenable to DNA synthesis (Youvan et al., 1992).

Two equations for adjusting nucleotide dopes have been used experimentally: 1) Group Probability P_G :

$$P_G = \prod_i P_D[i] \quad (1)$$

where $P_D[i]$ is the probability of the i^{th} amino acid in a target set occurring based on a specific doping scheme; 2) Sum-of-the-Squares-of-the-Differences (SSD):

$$SSD = \sum_i (P_D[i] - P_T[i])^2 \quad (2)$$

where $P_T[i]$ is the fractional representation of the i^{th} amino acid in the target set. The best dope is found by either maximizing P_G or minimizing SSD. The P_G function forces every amino acid in the target set, regardless of the frequency at which they occur, to be encoded by the cassette. In contrast, the SSD algorithm takes into consideration how many times each amino acid is found in the target set and may drop infrequently used amino acids from the dope. Computer simulations show SSD generates a higher throughput of positive mutants than P_G (Youvan et al., 1992), but this is potentially at the expense of phenotypic diversity.

B. Digital Imaging Spectroscopy

Too many mutants are generated by combinatorial mutagenesis to screen individual isolates by conventional spectroscopy. Digital imaging spectroscopy (DIS) provides a method for the parallel screening of the ground state (visible and NIR) spectra from up to five hundred colonies directly on a Petri dish (Yang and Youvan, 1988; Arkin et al., 1990; Arkin and Youvan, 1994; Youvan et al., 1994; Youvan 1994). Spectra acquired from DIS are often superior to spectra recorded from purified chromophore membranes taken with a conventional

spectrophotometer because DIS is less sensitive to light scattering in these turbid samples.

1. Instrumentation

All current configurations of DIS use a charged coupled device (CCD) camera as a detector to image Petri dishes mounted on the exit port of an integrating sphere. The sphere provides uniform light across the Petri dish(es). In a second generation imager, up to 25 Petri dishes can be illuminated simultaneously. The light source uses Fabry-Perot interference filters or an 1/8 meter monochromator to illuminate the target at different wavelengths. Typically, spectra can be obtained at 5–10 nm resolution which can detect 2 nm band shifts. Images are transferred to a Silicon Graphics Personal Iris computer where they are stored, manipulated, and compiled into absorption spectra. Commercial imaging spectrophotometers have been recently reviewed (Youvan, 1994).

Fluorescence images and images taken at a single wavelength are useful for rapid pre-screening of colonies. Fluorescence images can be obtained by illuminating with broad band blue-green light, and placing an 830 nm long pass filter in front of the CCD camera. Screening at a single wavelength is a fast method to select mutants with strong absorption characteristics at an important wavelength. For example, a library of light harvesting antennae can be scanned by absorbance at 860 nm before acquiring the full DIS spectra.

2. Spectral Display

Spectra acquired by DIS can be displayed in either 'tile mode' or as 'color contour maps'. In tile mode, each spectrum is displayed as a conventional two dimensional absorption spectrum. However, after a few hundred colonies have been imaged, this type of display is not optimum for rapid inspection of the data. In the color contour mode, all the spectral data from a single Petri dish are presented as a two dimensional display. The vertical axis corresponds to different colonies and the spectra of each colony is represented by a horizontal row. Absorption is color-coded at each wavelength along the row (white = high absorption, black = zero absorption). Spectra can be sorted according to similarity or absorption at various wavelengths. This type of display makes it easier to identify and compare spectral classes. In either mode, the spectra can be scaled relative to the

lowest and highest absorption anywhere in the image, or each spectra can be scaled between its own minimum and maximum absorption (Arkin and Youvan, 1993; Youvan et al., 1994).

Images of Petri dishes screened by absorption at a single wavelength or by fluorescence can be displayed as either monochrome or pseudocolored images. Single wavelength images are divided by a blank image at the same wavelength to correct for uneven light intensity from the monochrome illumination. Gray scale values from the ratioed single wavelength absorption (or fluorescence) image are rescaled to enhance contrast. After establishing the low and high gray scale values, such monochrome images can be linearly mapped by pseudocoloring schemes to enhance differences between mutants.

IV. Combinatorial Cassette Mutants

A. Random Mutagenesis of the RC

Nine amino acid residues in the vicinity of the monomeric BChl on the active branch of the RC were randomly mutagenized using CCM. By manipulating the environment around the monomer BChl (and therefore its electronic states) it should be possible to affect the rate of electron transfer. Three libraries were constructed: one having five sites in the L subunit cd helix mutagenized (L146, L150, L153, L154, L157), another with four sites in the M subunit D helix mutagenized (M195, M201, M204, M205), and a third with all nine sites randomized simultaneously (Robles and Youvan, 1993). According to the X-ray structure of the *Rp. viridis* RC (Deisenhofer et al., 1985), all of these positions are in van der Waals contact with the active branch monomer BChl. Photosynthetically competent mutants were selected by growing the libraries under light: 1/3500 of the five site cd library, 1/15 of the four site D library and 1/50,000 of the nine site (combined) library were found to be functional. These frequencies show that criteria for functional residues mutagenized in the cd helix library are more stringent than in the D helix library. Plates having between 50 and 500 photosynthetically grown colonies were imaged for each library and representative colonies were chosen for sequencing. There is spectral diversity in the mutants constructed in this experiment; Fig. 1 shows the spectra from representative mutants from each library. In the most

Fig. 1. Digital imaging spectrophotometer data (tile mode) showing the spectral diversity of combinatorial mutants of the photosynthetic reaction center from *Rb. capsulatus*. Boxes labeled D and C correspond to mutants from the four site D helix and five site cd helix libraries, respectively. Boxes labeled B were obtained from the nine site library in which both helices were mutagenized simultaneously. The spectra of seven WT controls are labeled W. Spectra are shown from 700 to 930 nm from left to right. The spectra of a WT control and mutant B4 (with a blue shift of the dimer peak) are enlarged in the bottom panels.

striking spectral change, four unique mutants (out of four million selected and screened from the nine site library) have a well defined band at 825 nm that can be reversibly bleached with actinic light (Robles and Youvan, 1993).

B. Target Set Mutagenesis of LHIII

1. Using the P_c Algorithm

Phylogenetic data from 29 homologous LH antennae

(Zuber, 1990) were used as a database to construct target sets for seven amino acid positions on one face of a transmembrane alpha helix comprising a BChl binding site of the LHIII antennae. Amino acid residues in the β subunit of LHIII, one and two turns of the alpha helix away from the His modeled to be the ligand to a BChl of the dimer (positions -7, -4, -3, 0, 3, 4, 7 relative to the His) were mutagenized. Specific nucleotide mixtures were calculated by a computer program to maximize the probability of occurrence of amino acids in the target set according to the

equation for P_G . To compare throughput of BChl binding mutants from target set mutagenesis (TSM) and random libraries, CCM libraries were constructed with the seven amino acid positions randomized, and with six of the positions (-7, -4, -3, 3, 4, 7) randomized (Goldman and Youvan, 1992).

DIS was used to screen 10,000 TSM mutants directly on Petri dishes. Three phenotypes were observed: 1) pseudo LHII with absorbance at 800 nm and 860 nm, 2) pseudo LHI with reduced 800 nm absorbance and maximal absorption near 875 nm, and 3) null mutants with absorption characteristics of membranes with free pigments. Approximately 6% of the library assembled pigment-protein complexes as judged from absorption spectra (i.e., 4% pseudo LHII; 2% pseudo LHI). Representatives from each phenotype were sequenced. It appears that the molar volume of the -7 position residue is important in determining which of the two BChl binding phenotypes is expressed. When an amino acid with a small molar volume is in this position, the pseudo LHII phenotype is favored, while the pseudo LHI phenotype tends to be associated with amino acids of larger molar volume.

The TSM library showed a 100–600 fold improvement in throughput versus the random (NN(G/C)) library. In a comparison to conventional CCM, only 3 positives were observed out of 10,000 colonies screened in the seven site random library (see Color Plate 10A,B). A significant amount of the difference in gain is probably due to the fact that the phylogenetic data restricts the 0 position of the TSM library to His. The probability of finding positive mutants in a fully random CCM library is greatly diminished when a critical sequence position accepts only a few amino acid substitutions. Because of this, TSM throughput will be highest (versus conventional CCM) when sequence positions are stringent. A six site random library was constructed in which the His was not randomized. This yielded the expected result of a 1% throughput because His is a critical sequence position. As a first approximation, the stringency of an amino acid position can be estimated from phylogenetic data.

2. Using the SSD Algorithm

The SSD equation was used to construct a phylogenetically based cassette to mutagenize seventeen amino acid residues ($\beta 27$ – $\beta 43$) in the region of the binding site of the dimer BChl associated

with the β subunit of LHII. The amino acid complexity of the resulting library is 7×10^7 as opposed to 3×10^{13} if the P_G algorithm had been used to construct the cassette. Extrapolating from the results of the seven site phylogenetically based P_G experiment in this region, a dope which used the P_G algorithm on seventeen sites would generate a 0.03% throughput of positives. DIS was used to screen 5000 colonies; the library showed an extremely high throughput (5–10%) of mutants expressing LH, with good phenotypic diversity (see Color Plate 10C). Thus, while SSD reduced the total number of possible protein sequences in the library by orders of magnitudes, different classes of BChl binding mutants were still observed.

3. Comparing SSD and P_G

Seventeen amino acid positions in the β subunit in the vicinity of the BChl monomer binding site were mutagenized simultaneously. SSD was used with phylogenetically based target sets except at position $\beta 21$ where a dope was used that omitted the WT amino acid (Tyr) but still encoded the other two aromatic amino acids and other amino acids found in the core antenna phylogeny (Table 1). Ten thousand colonies were screened by DIS, and even with the inclusion of a non-WT position, 2% of the library was found to assemble LH antennae. Most of the 'positives' showed a WT like absorption spectrum in the NIR, albeit with lower optical density (see Color Plate 11). Sixteen of these pigment binding mutants were sequenced, and each one was found to have a unique sequence.

A second cassette was constructed (using the same seventeen sites) according to the equation for P_G . This library used a phylogenetically based target set at all of the mutagenized positions (Table 2). Out of 10,000 colonies screened no positive recombinants were found as judged by imaging spectroscopy. This result (in conjunction with the 2% throughput from the modified SSD library) indicates that SSD gives at least a 200 fold enhancement in the number of BChl binding proteins. When using TSM on a large number of sites (> seven), it is advantageous to use the SSD algorithm to construct cassettes because it increases the throughput of the library over P_G .

C. Recursive Ensemble Mutagenesis of LHII

Recursive ensemble mutagenesis (REM) (Arkin and

Table 1. SSD based nucleotide dopes for β monomer region

Nucleotide dopes used for the SSD based mutagenesis of the BChl monomer binding site of LHII. Amino acids listed in parenthesis are not in the target set, but are unavoidably coded for in the dope, because of the structure of the genetic code. The asterisks indicates that the WT amino acid had to be entered into the algorithm more often than it occurred in the phylogeny to ensure that it was encoded in the dope. Target sets were based on phylogeny except at position β 21 (in bold).

Youvan, 1992a; Youvan et al., 1992) uses sequence information acquired from random CCM to construct target sets for subsequent cassettes (Fig. 2). Six amino acid positions on the carboxyl-terminus of the β subunit of LHII were mutagenized using REM (Delagrave et al., 1993). Sites were randomized using NN(G/C) codons; mutants were pre-screened by fluorescence before evaluation by DIS. Only one out of 10,000 mutants screened had the desired fluorescence characteristics. Five positives recombinants were isolated and sequenced. This sequence data showed that the mutants were not merely trivial variations of the WT sequence. The sequences did not recapitulate the known phylogeny; one mutant showed an inversion in a completely conserved sequence motif that resulted in a 10 nm blue shift of the dimer peak. The next iteration of REM cassettes were designed using the P_G algorithm. REM returned a thirty-fold increase in the number of positive mutants over random CCM. Twelve mutants were sequenced and all were found to have unique peptide sequences that differed from both WT and the set of mutants used to generate the first target sets (Delagrave et al., 1993). This is a useful method when there is not an extensive phylogenetic data base. When mutagenizing larger stretches of amino

Nucleotide dopes used for the phylogenetic P_G based experiment in the vicinity of the BChl monomer binding site of LHII. This algorithm forces each amino acid in the target set to be coded for in the dope regardless of its frequency. Amino acid residues in parenthesis are not in the target set, but were unavoidably encoded because of the genetic code.

acids, short segments can be randomized independently and these sequences can then be combined. This defines exponential ensemble mutagenesis (EEM) (Delagrave and Youvan, 1993).

D. Exponential Ensemble Mutagenesis of LHII

An efficient method for generating combinatorial libraries with a high percentage of unique and functional mutants has been developed in recent studies. Exponential ensemble mutagenesis (EEM) should be advantageous in cases where many residues must be changed simultaneously to achieve a specific engineering (Delagrave and Youvan, 1993). With the enhanced functional mutant frequencies obtained by this method, entire proteins could be mutagenized combinatorially.

Combinatorial libraries have been successfully used in the past to express ensembles of mutant proteins in which all possible amino acids are encoded at a few positions in the sequence. However, as more positions are mutagenized the proportion of functional mutants is expected to decrease exponentially. Small groups of residues were randomized in parallel to identify, at each altered position, amino acids which lead to functional proteins. By using optimized nucleotide mixtures deduced from the sequences selected from the random libraries, we have

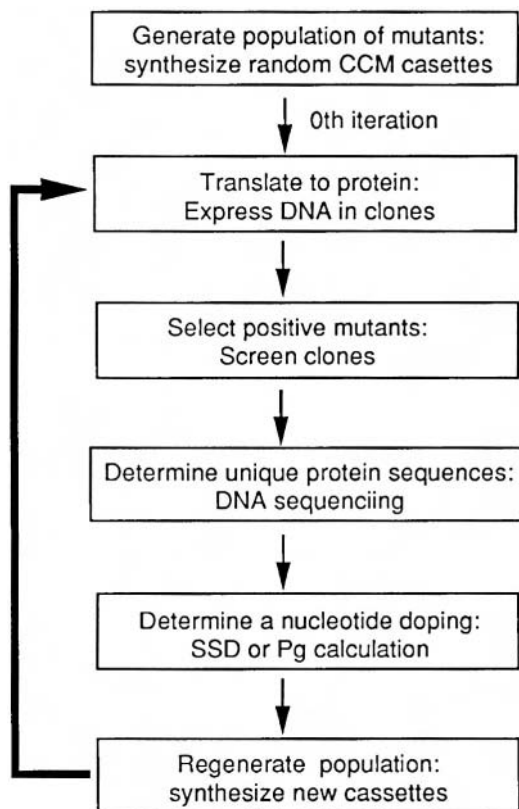

Fig. 2. Flowchart for the implementation of recursive ensemble mutagenesis. On the zeroth iteration, a random CCM library is expressed and screened. Two or more positives (clones that meet the phenotypic criteria) are selected and sequenced. The protein sequence of the positive mutants are used to define target sets for the construction of subsequent cassettes, and either the P_G or SSD algorithm can be used in the formulation of the nucleotide dopes.

simultaneously altered 16 sites in LHI; approximately one percent of the observed mutants were functional. Mathematical formalization and extrapolation of our experimental data suggests that a 10^7 -fold increase in the throughput of functional mutants has been obtained relative to the expected frequency from a random combinatorial library.

Recently, the comparison of two different combinatorial mutagenesis experiments on the LHII protein of *Rhodobacter capsulatus* indicates that heuristic rules relating sequence directly to phenotype are dependent on which sets, or groups, of residues are mutagenized simultaneously (Delagrave et al, 1995). Previously reported combinatorial mutagenesis of this chromogenic protein (based on both phylogenetic and structural models) showed that

substituting amino acids with large molar volumes at Gly^{β31} caused the mutagenized protein to have a spectrum characteristic of LHI (Goldman et al, 1994). The six residues that underwent combinatorial mutagenesis were modeled to lie on one side of a transmembrane α -helix that binds bacteriochlorophyll. In a second CCM experiment, a set of six contiguous residues was selected for combinatorial mutagenesis. In this latter experiment, the residue substituted at Gly^{β31} was not a determining factor in whether LHII or LHI spectra were obtained; therefore, we conclude that the heuristic rules for phenotype prediction are context dependent. While phenotype prediction is context dependent, the ability to identify elements of primary structure causing phenotype diversity appears not to be. This strengthens the argument for performing combinatorial mutagenesis with an arbitrary grouping of residues if structural models are unavailable.

V. Conclusions and Prospectus

We reviewed RC and LH mutants in *Rb. capsulatus* and *Rb. sphaeroides* that have been produced through increasingly sophisticated mutagenesis techniques. At present, combinatorial cassette mutagenesis of RC and LH antennae has only been accomplished in *Rb. capsulatus*. Although there is currently no crystal structure for the *Rb. capsulatus* RC, a chemoheterotrophic *Rp. viridis* genetic system is being developed in the Bylina laboratory (E. J. Bylina, personal communication). This could lead to a potentially useful combination of experiments in these two species: Sequence space can be screened by combinatorial mutagenesis in *Rb. capsulatus*, and when single interesting mutants are found they can be reconstructed in the *Rp. viridis* strain for crystallography.

Future goals include using cassette mutagenesis to engineer a RC mutant that performs wrong-way electron transfer. Instead of randomly mutagenizing sections of the RC, regions of the protein in contact with the pigments could be mutagenized using TSM. Phylogenetically based target sets are being constructed using the amino acid residues at homologous sites in both the L and M subunits, which are thought to be the product of a gene duplication (Youvan and Marrs, 1984).

A second goal is to alter LH antennae to perform charge separation. Combinatorial cassette muta-

genesis could be used to change the protein environment (i.e., the electronic environment) around the pigments. An antenna that was modified to perform charge separation would allow biophysicists to study electron transfer in a much simpler protein system than the RC.

LHII is an excellent model system in which to attempt to establish a correlation between sequence and phenotype. Computer programs can be used to correlate sequence data with phenotypic information to generate phenotypic estimators. This obliterates the need for a solution to the protein folding problem, and facilitates various engineering projects on pigment-protein complexes.

Mutant RC and LH complexes have helped biophysicists better understand the events in photosynthesis. In the future, increasingly complex mutagenesis techniques should contribute still more to our understanding of the molecular mechanisms of photosynthesis and more general problems in protein folding and design. Data already tabulated into this system are being used to train neural nets for 'phenotypic estimation'.

Acknowledgments

This work was supported in part by NIH GM42645, DOE DE-FG02-90ER20019, DOE DE-FG05-91ER79031, and by a grant from the Human Frontiers Science Program. ERG received an NIH Biotechnology Training Grant Award. We thank Dr. Mary Yang at KAIROS Scientific Inc. (Mountain View, CA) for her help with the imaging systems and for providing the computer programs to calculate nucleotide dopes, and Matthias Scholl for his assistance in the laboratory.

Summary

Based on ecological studies of anoxygenic phototrophic bacteria as to their presence and their role in the natural world, we have developed this knowledge to the level of an applied study connected with their practical utilization. After explaining these processes, Methods of biological treatment and applications related to bioremediation of various organic wastes are described.

I. Distribution and Interrelationship with Other Organisms

Anoxygenic phototrophic bacteria are widely distributed in aquatic and some terrestrial habitats in nature (Table I)(Kobayashi et al., 1967). Phototrophic bacteria grow favorably in polluted environments created from human activities (Fig. 1)(Kobayashi et al., 1978). Cultures of these bacteria are also used to feed animal plankton. In general,

phototrophic bacteria are, as shown in Fig. 1, capable of assimilating both carbon dioxide and molecular nitrogen (nitrogen fixation), using light as an energy source.

Cultures of phototrophic bacterial cells are used as feed for small organisms in water and soil, and the excretions of phototrophic bacteria are used by other organisms including heterotrophic bacteria and algae. For example, in paddy soils containing sulfur, as shown in Fig. 2, sulfate reducing bacteria grow

vigorously yielding hydrogen sulfide in the reproductive growth period of the rice plant (the young ear formation period: early in August); this leads to lowering the oxidation-reduction potential at the rhizosphere of the rice plant which can cause enormous damage to their roots. At the appropriate time, however, phototrophic bacteria grow and oxidize the toxic hydrogen sulfide, yielding favorable effects on the rice plant (see Fig. 3). Figure 4 shows the cycling of sulfur in the paddy field. It has been known that some useful substances excreted from phototrophic bacteria give favorable effects to the plants, including an increase in the number of grains per rice plant. Such useful substances were studied in detail, which resulted in our discovery of a substance accelerating formation of flower buds as well as the setting and thickening of fruits; these have been developed to the practical level, contributing much to improved agricultural productivity (Kobayashi et al., 1966) (high productivity of rice will be covered later, see Table 18).

II. Growth Acceleration by Symbiosis

A phenomenon was found that when *Rhodobacter capsulatus*, a nonsulfur purple bacterium, coexists with aerobic heterotrophs, the growth of both organisms is markedly accelerated (Okuda and Kobayashi 1961, 1963).

Figure 5 shows growth in co-culture of *Rb. capsulatus* and *Bacillus megaterium*. In an environment limited in combined nitrogen, coexistence of these bacteria accelerated their growth more than that in obtained in axenic culture. *Rb. capsulatus* cannot use glycerol although it is able to fix nitrogen, but nitrogen fixation is feasible by *Azotobacter* making use of glycerol. *Bacillus megaterium* and *B. subtilis*

are able to use glycerol, but are unable to fix nitrogen. However, in various mixed cultures of these organisms, nitrogen fixation and carbon

conditions for a month (25–30 °C), gas-bubbles are produced due to the abundant growth of heterotrophs accompanied by decomposition and foul odor. With the decrease of the substrate and accumulation of the decomposed products, the growth of the heterotrophs becomes poorer, and in such conditions the growth of phototrophic bacteria becomes rapid as shown in

Fig. 6. Microbial changes during the decomposing process of organic materials under submerged natural conditions.

- △-△- Heterotrophic microorganisms
- Phototrophic bacteria
- x-x- Algae

Fig. 6. In two or three weeks, phototrophic bacteria gradually stop growing and green algae appear. Examination of the change in the biochemical oxygen demand (BOD) during this process showed that the degree of putrefaction was high (greater than ten thousand ppm BOD) when the heterotrophs were growing but the BOD decreased to only several hundred ppm when phototrophic bacteria were growing. This indicates that purification of the medium progressed by the removal of soluble organic compounds, and with the appearance of green algae (and subsequent O_2 production), the purification could be accelerated even further (see Table 4) (Kobayashi and Haque 1971).

IV. Purification of Waste Water by Anoxygenic Phototrophic Bacteria

It was found that phototrophic bacteria play a major role in the natural purifying process of various kinds of waste water containing high organic concentrations (see Tables 5 and 6). Based on the theory of purification, various experiments and pilot plant tests were carried out. The commercialization was made about ten years ago (in Japan) and many purification treatment plants are being operated at present. A flow sheet (describing this process) is illustrated in Fig. 7, and some data on purification in Tables 7 and 8 (Kobayashi 1970, Kobayashi and Tchan 1973). The advantages of this system over the activated sludge

Table 4. Purification of polluted water, including organic materials (animal excrement), under natural biological processes^a

	Ammonia ppm	B.O.D. ppm
Heterotrophs growing stage	over 5,000	over 5,000

Various kinds of food industry wastes (canned food, bottled food, cakes, miso, tofu: bean cake, etc.)
Petroleum industry
Starch and woolen industry
Others: activated sludge, excrement, other organic materials

process are: a) dilution is not required so that a photosynthetic bacterial system can be used in areas where water is a scarce resource, b) unlike the activated sludge method which creates a secondary sludge disposal problem, this system produces phototrophic bacteria and green algae which are excellent and useful byproducts, c) because very little dilution is required, the space required for treatment facilities is much less in comparison with the activated sludge method.

V. The Use of Byproducts

A. Aquatic Feed

In outdoor experimental tanks, a rapid development of animal plankton was noted after increased growth of anoxygenic phototrophic bacteria; therefore, a series of detailed experiments using ¹⁴C-labelled phototrophic bacteria was carried out to study the feeding process. As a result, it was confirmed that animal plankton are direct predators of phototrophic bacteria and, upon addition of phototrophic bacteria, growth of zooplankton is stimulated much more than when green algae serve as food source (Fig. 8).

—○—○— Phototrophic bacteria

—△—△— Yeast

—×—×— Chlorella

In particular it was found that anoxygenic phototrophic bacteria are very useful for growth of brine shrimp, one of the most important salt water plankton, which is used as feed for fish and shellfish,

and for collection of their eggs. Thus, a favorable outlook for completely artificial fish culture, which thus far was considered infeasible, has now been formed. Further, the fact was also identified that fry of fishes (loach, goldfish, carp, ark shell, sweetfish, etc.) are direct predators of phototrophic bacteria soon after hatching, resulting in an increase in weight and survival rate of more than two fold within 2 to 4 weeks after hatching (nearly no death was noted in some experiments). Table 9 gives data for one of these experiments. It is shown that when live cells of phototrophic bacteria are added at 0.1 % to the formula feed given to the fry of crucian carp soon after hatching, the rate of survival highly increased and nearly no mortality was observed. Further, purple sulfur- and green sulfur-bacteria are phototrophic bacteria that use hydrogen sulfide, which is highly toxic, and the activities of these phototrophs convert H₂S into nonpoisonous sulfur compounds. Therefore, sulfur phototrophs are utilized for cleansing of waste waters high in sulfide or to clean the bottom environment containing high levels of sludge. For example, in the culture pond for eels, abnormal death was noted from the deteriorating water quality

Table 9. Effect of phototrophic bacteria on survival of young fry of crucian carp^a

	Survival numbers after one month	Survival ratio (%)
Control	2772	69.3
Treatment (with 0.1% PTB cells) ^b	3860	96.5

^a The experiment was carried out in a tank of 2 tons capacity with an initial number of 4000 fry.

^b The PTB cells were obtained from the waste treatment plant of a fish meat industry. The bacterial powder contained only 50 per cent of PTB cells; the other half contained heterotrophic bacteria (contaminants).

in winter, whereas treatment with phototrophic sulfur bacteria made the environment suitable for continued growth.

Special attention has been played to the use of phototrophic bacteria in the culture of prawn. As shown in Fig. 9, 50% of the prawn consumed in Japan is cultured in such large water tanks (prawns amounting to 20,000 million ¥en per month are consumed domestically), while another 50% depends on importation. Thus, prawns worth 100 million ¥en per annum are cultured in one of such water tanks (more than 100 tanks are operating in Japan). In the past prawns in such culture tanks were frequently

affected by gill disease causing great economic damage, however this has now been completely prevented by supplementing the tanks with anoxygenic phototrophic bacteria. In addition, such effects have also been displayed in suppression of virus diseases noted on others including swellfish (Okamoto et al. 1988, Hirotsani et al. 1991). Perhaps the presence of phototrophs creates unfavorable competitive effects for the pathogens, preventing establishment of the latter.

B. Livestock Feed

Since cells of *Rhodobacter capsulatus* contain much protein (showing a good balance of amino acids) vitamins and other effective substances, addition of cells at a rate of only a ten-thousandth increases the egg-laying rate of chickens by 15–20%. Tables 10–12 give data in this connection. Such effect to improve egg-laying is especially apparent in the sickly seasons (such as midwinter or midsummer). While testing the effect of phototrophic bacteria mixed in the feed, a favorable result was obtained in experiments with more than 2,000 hens that the egg-laying ratio was increased roughly ten percent by mixing fresh phototrophic bacteria into the formula feed at a rate of 1/10,000. The nutrient effect tests were carried out as follows. Phototrophic bacteria were given to chicks

one month after the beginning of egg-laying. The period of data collection was from October to March, including the winter season when the egg-laying rate decreases. The Haugh-Unit Coefficient (Table 15) is a coefficient representing the quantity of thick white and freshness of an egg.

As shown in Table 14, it was observed that the egg-laying rate tended to increase by increasing the amount of phototrophic bacterial cells added. The hens in the groups fed on phototrophic bacterial cells appeared to begin laying eggs a little earlier than the control, and the term until the egg-laying rate decreased was slightly prolonged. As shown in Table 15, in the groups with the added cells, both the yolk index and the Haugh-Unit Coefficient increased. Larger coefficients mean that the eggs maintain their freshness better in storage. Also, in the groups with the added photosynthetic bacterial cells, it was confirmed that the color of the yolk was improved and the carotene content was increased depending on the quantity of added bacterial cells. This suggests

that components from phototrophic bacterial cells can be well absorbed and transferred into yolk. In addition, the feed efficiency, the body weight of hens, and the weight of total eggs produced per hen during a 6 month period was found to increase much more than 10% by the addition of the phototrophic bacterial cells (Kobayashi and Kurata, 1978).

In addition, as phototrophic bacteria contain antiviral substances, they may effectively suppress Marek's virus diseases, which may stimulate the

weight gains and increase production rates of chickens observed in these experiments. If true, photosynthetic bacteria could be considered biocontrol agents of diseases in chickens.

C. Organic Fertilizer

As shown in Table 5, the kinds of liquid waste to which treatment with phototrophic bacteria is actually applicable, are noted in a fairly wide range. It is,

^b See text

however, likely that markedly contaminated water would certainly not be processed to obtain such byproducts to be used for livestock feed, but instead could be better utilized by returning it to the farming land to be used as an organic fertilizer, since this would serve as a natural fertilizer. Organic matter treated by phototrophic bacteria while passing through layers of the soil in the farmland could be used as the source of nutrition for the roots of higher plants, being useful for growth directly and indirectly. Further, being degraded and cleansed by other soil microorganisms, they stream again into the rivers, lakes and seas after passing through subsurface waters. Such technology of processing contaminated water is obviously an ideal resources- and energy-saving method, especially when it is noted that the energy to drive these conversions comes from sunlight.

As noted from the flow sheet in Fig. 7a, livestock liquid waste can be partially degraded in a first aeration tank, followed by secondary treatment by phototrophic bacteria grown in a second tank. This is an efficient way of processing wastes to return the bacterial suspension to the farmland. It is of special interest that when this material is added to soil previously damaged by continuous croppings of tomato, cucumber, eggplant and others, it is feasible to correct nutritional problems in the soil. This may

occur by stimulation of the growth of actinomycetes, which as antagonistic microorganisms, spontaneously suppresses growth of pathogenic fungi (Fig. 10).

Besides, as shown in Table 16, when the suspension of phototrophic bacteria is applied as an organic fertilizer to the persimmon tree, it not only improves the yield of fruit markedly, but also elevates the sugar level of the fruit and improves taste as well as color and gloss (Table 17).

At present in Okinawa (Japan), a plant is under operation wherein the electric power is developed from the energy of methane gas obtained from livestock barn liquid waste. After that, the waste water is processed making use of the phototrophic bacteria method, and is then returned to the farmland which helps to improve the yield of crops.

In addition, a technology has recently been established wherein dung and urine are not separated in the piggery but instead are mixed with running water into a strong aeration tank to be foamed under excessive aeration, where to highly activated phototrophic bacteria are added. Deodorizing and making it adsorbed into foams, the mixture is especially useful for treating fallen out hair from animal hides, undegradable soil and sand, etc., while denitrification and decarboxylation proceed nearly to completion. Such technology is suitable for cleansing small to moderate-sized piggeries with

prompt and economical advantages, and its utilization has been further enlarged.

As stated at the beginning of this chapter, photosynthetic bacteria technology has been applied to high-yielding culture of rice; as compared with the conventional method, referred to as the control, significant increases in yield can be expected (Table 18)(Yoshida et al. 1991). It can be seen in Fig. 3 that

roots of control plants show root rot due to the presence of hydrogen sulfide, while those treated with phototrophic sulfur bacteria show good root development and growth, which is closely connected with increase of the yield.

D. Removal of Offensive Odors

Offensive odors develop from livestock barns including poultry houses, as well as from garbage. Phototrophic bacteria are able to absorb, degrade and eliminate such substances responsible for these offensive odors (Lee and Kobayashi, 1992). For example, acetic acid, propionic acid, iso-butyric acid, iso-butyric acid, valeric acid and iso-valeric acid present in pig wastes were eliminated rapidly in the presence of phototrophic bacteria as shown in Fig. 11.

Putrescine and cadaverine, secondary amines with serious unpleasantness and high toxicity, and hydrogen sulfide, can also be eliminated, as shown in Table 19. Especially, those with the utmost unpleasantness (like mercaptans) are eliminated, too, as shown in Table 20. A higher removal can be obtained in the light, but even in the dark a certain

Treatment (added <i>Chromatium</i>)	3.8	0.8

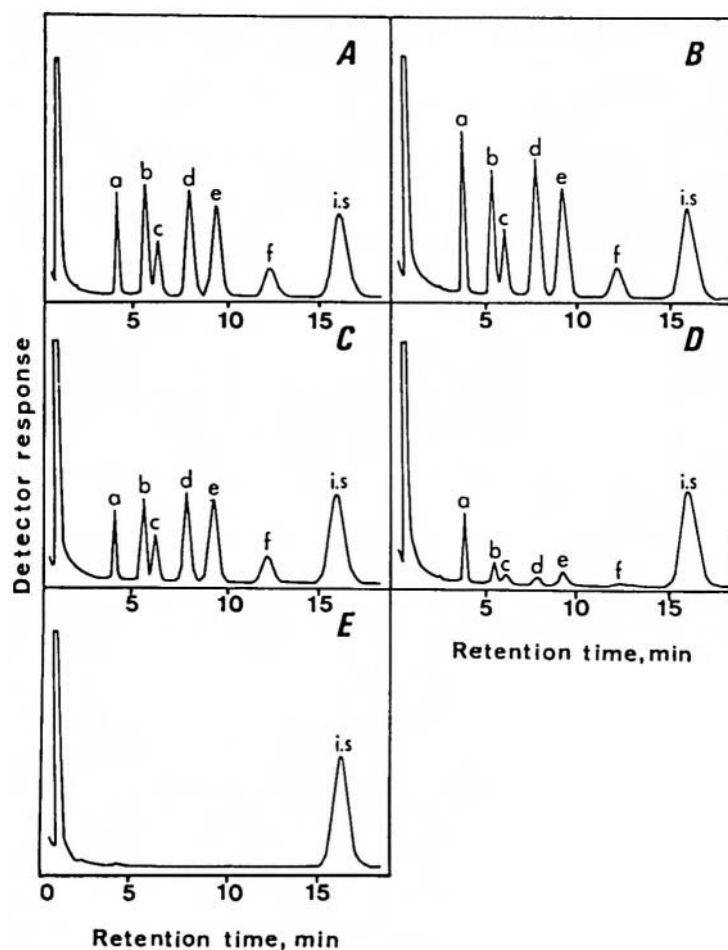

Fig. 11. Effect of incubation period on the amount of volatile fatty acids evolved from swine sewage. Swine sewage (50 g) was transferred to a 300 ml Erlenmeyer flask, and 10 ml of a *Rhodobacter capsulatus* suspension was added. (A) one day and, (B) 14 days without *Rb. capsulatus*. (C) one day, (D) 7 days, and (E) 14 days with *Rb. capsulatus*.

Peak identification: (a) acetic acid, (b) propionic acid, (c) isobutyric acid, (d) n-butyric acid, (e) isovaleric acid, (f) n-valeric acid. (i.s.) isocaproic acid as an internal standard.

level of elimination can be expected; therefore, photosynthetic bacteria are frequently used in livestock barns, being promoted as one of the solutions for offensive odor pollution, and thereby displaying its effect on sanitation and protection of the environment.

E. Utilization as Medicine, Food and Energy

Along with a clean discharge out of the foodstuff production plant, phototrophic bacterial cells yielded as a byproduct can be used for medicinal purposes and as a source of single cell protein. Since abundant ubiquinone, UQ_{10} , is contained in phototrophic bacteria, UQ_{10} extracted and purified from bacterial cells obtained from growth on liquid wastes has been placed on the market as a remedy for myocardial infarction, being very useful for saving human life.

Many other useful components have been extracted from phototrophic bacteria. They are nonpoisonous to normal cells and contain some antiviral substances; therefore, further development of their application is

very much anticipated. Especially in Brazil, where automobiles run with alcohol nowadays, the liquid waste of such alcohol fermentation can be considered not waste but an important resource for culture of phototrophic bacteria. From the standpoint of food protein and biomass production other than medicines, alcohol wastes can be a very hopeful processing technology. Further, as phototrophic bacteria can evolve hydrogen gas (via nitrogenase, see Chapter 43 by Ludden and Roberts), a technology of large-scale hydrogen gas development from such concentrated organic waste has successfully been established together with the hydrogen fueled engine technology. This technology is expected to be practically applied in the future as existing energy supplies from petroleum and other sources diminish.
